The use of direct microscopic count techniques for biomass estimation presents many challenges. Most bacteria live an attached lifestyle (11); therefore, in many systems microorganisms need to be quantitatively removed from surfaces, particles, host tissues, or each other before enumeration. Methods of sonication, homogenization, or dispersion are not uniformly effective for all populations (12–15). In some matrices, visualization of organisms may be obscured by detrital particles, sediment granules, or neighboring organisms (7,16,17). There are significant concerns associated with the choice of stain used in enumeration techniques. Although DAPI is considered to be more DNA specific than acridine orange, it binds poorly to DNA at high salt concentrations. In marine microbiology cells are often fixed with formaldehyde before enumeration. Recent evidence suggests that under these conditions DAPI stains reactive bacterial surfaces and is not specific to nucleoid containing cells (18). Therefore, total counts may overestimate bacterial abundance by 68 to 98% (18). Once microorganisms are collected and enumerated, there are uncertainties in using a per-cell carbon conversion factor for the determination of biomass (19–22). The range of dry weights for bacterial isolates from soil and litter varies between 1.66 and 67.5×10^{-13} g cell^{-1} (23). Assuming that 50% of cell mass is carbon, dry weight estimates for natural assemblages of aquatic bacterial cells are in the range of 0.4 to 0.5×10^{-13} g cell^{-1} (19). The use of inappropriate conversion factors will lead to corresponding errors in biomass estimates. Alternatively, many researchers have sought to measure biovolume and generate conversion factors for the determination of viable microbial biomass. Determination of size class distributions of microbial populations are achieved directly by using an eyepiece graticule or indirectly by taking photomicrographs or by using an image analysis system (7,8,19). Apparent size measurements are affected by sample preparation and sizing method (20,24–26) and artifactual errors can be significant (19,20).

There are several methods for calculating biomass from cell volume and their respective merits are still under debate (21). Studies indicate that for both bacteria and algae, smaller cells have more biomass per unit volume than large cells (27–30). For bacteria, the carbon to volume ratios can vary by a factor of 500 depending on the size classification (21). These variations are likely due to both real biotic variations (either in community composition or in physiological state) and cell dimension measurement errors (20).

Soil microbiologists have used chloroform fumigation incubation (CFI) and extraction (CFE) techniques for the indirect determination of biomass. The details of these techniques are described elsewhere (31). In each technique, soil samples are flooded with chloroform vapor to kill any living biomass. In the CFI technique, fumigated soils are reinoculated with a small amount of original soil. Mineralization of the freshly killed biomass is measured over a 10-day period and the resultant CO_2 and NH_4^+ are measured and used to calculate carbon and nitrogen biomass. The analysis of appropriate controls is essential and results should be calibrated by measuring carbon dioxide evolution derived from the addition of cells with known carbon and nitrogen contents (31,32). Some soils display background respiration from degradation of soil organic matter that is equal to the mineralization rates following fumigation, suggesting very low or even negative biomass (31). Although questions about these experimental problems are still being debated in the literature (33,34), investigators have continued to revise the equations for biomass calculation to account for the discrepancies (35). One of the major problems with this technique is that it requires the assumption that the respiratory activity of the reinoculated population is directly proportional to the quantity of newly killed biomass in the fumigated soil. These two parameters are frequently not correlated (36–39) and metabolic activity is often not a good predictor of biomass.

The CFE technique is not dependent on physiological measurements and requires no further incubation of soil samples. Killed biomass and other soil organic matter components are extracted from fumigated soils with 0.5 M K_2SO_4. Carbon content is determined from elemental analysis. Unfumigated soils are analyzed in the same way and used as background controls. These estimates have a high degree of uncertainty since biomass carbon extraction efficiencies can be variable depending on soil pH and soil type (40,41).

BIOCHEMICAL CONSTITUENTS

Technical problems and experimental biases associated with traditional biomass measures prompted microbial ecologists to use a biochemical approach for studying microorganisms in the environment. In 1981, Jenkinson and Ladd (42) put forth several useful criteria for the selection of a biochemical component that could be used for the indirect measurement of microbial biomass in soils. Through the years researchers have adapted these criteria (3,43–47) and facilitated the development of sensitive, quantitative, and unbiased methods that can be applied in any environment. The biochemical index molecule should (*1*) be common to all cells, (*2*) be present in a constant proportion in all microbial cells regardless of physiological state, (*3*) be present only in viable cells and be rapidly degraded on cell death, and (*4*) be present in sufficient quantity to be readily extracted from environmental samples. The quantity of this component should be easily related to biomass. Lastly, methods should be readily available for quantitative extraction and sensitive detection of the specific component within environmental samples. A number of different biochemical components have been used for the estimation of microbial biomass including cellular protein, ATP, phospholipid fatty acids, and nucleic acids. Cell constituents such as muramic acid, lipopolysaccharide, photosynthetic pigments, ergosterol, and glycerol ether lipids are phylogenetically restricted and are useful when a specific group is to be targeted. Each technique has certain advantages in the study of microbial communities, but none of these completely satisfy the described criteria as a perfect metric for total microbial biomass.

Cellular Protein and Adenine Nucleotides

Total protein can be easily quantified and is a useful measurement for characterizing bacterial populations in the laboratory. However, intracellular protein content varies with organism and growth conditions and, as a biomass measure, its use is limited. In addition, detrital protein pools are often high in environmental samples. For many years it was assumed that biomass production was proportional to ATP production. As this cell constituent is rapidly degraded on cell death and is present in all organisms, it is considered a reliable method for the indirect measurement of biomass. It is now well known that intracellular ATP concentrations change with growth rate, metabolic state, and nutrient limitation (48–51). Reported ATP contents per cell vary more than 1,000-fold (52). Total intracellular adenine nucleotide pools ($A_T = ATP + ADP + AMP$) are less sensitive to changes in specific growth rate (53–55), but are still somewhat variable with metabolic status (51,52). Much less is known about these relationships, and the utility of A_T as a surrogate for biomass is still not clear (52).

Phospholipid Analysis

All living cells contain polar lipids and in most microorganisms these are dominated by glycerophospholipids. Phospholipid content is relatively stable as a proportion of dry cell mass (56,57) although the actual fraction varies with different groups of microorganisms (47,58). In most environments, intact phospholipids are quickly hydrolyzed after cell death (within minutes to hours), releasing soluble phosphate (59). Consequently, phospholipid-bound phosphate and phospholipid fatty acids are unique to living organisms and meet many of the described criteria as appropriate cell constituents for indirect biomass estimation (46,59). These membrane components can be quantitatively recovered by organic solvent extraction, and sensitive detection methods are readily available. Balkwill and coworkers (16) compared these techniques to other biomass measures in a carefully designed experiment and found that these biochemical constituents were reliable measures of viable biomass, and under certain conditions, could be related to bacterial abundance. The following sections detail the experimental methods used for microbial phospholipid analysis and the subsequent determination of viable biomass.

Phospholipid fatty acid analysis has been effectively used for the determination of microbial biomass and community structure in almost every environment on Earth (60), including plant litter, ice cover, surface soils, aquatic sediments, biofilms, deep subsurface sediments and aquifers, planktonic communities, subterranean microbial mat communities, the Antarctic desert, hydrocarbon-contaminated sediments, filtered indoor air samples, sewage sludge, and rhizospheres. To obtain sufficient biomass for detection, sample concentration may be required in some environmental matrices (e.g., open water, indoor air, and industrial metalworking fluids). It is best to avoid using plastics either in sample preparation or as artificial substrates for growth when lipid analysis is to be applied. Lipid-soluble contaminants are often released from these materials during organic solvent extraction and can interfere with the detection of target molecules. Whenever possible, samples should be transferred directly to the solvent extraction mixture immediately after collection. This provides the best opportunity to obtain a snapshot of total viable biomass and community structure. If sample preservation is necessary, the best option is to immediately place the samples on dry ice and keep frozen at $-70\,^{\circ}C$ until lipid extraction can be performed. Up to 50% of the biomass may be lost if samples are allowed to thaw before lipid extraction (61). Storing samples at $4\,^{\circ}C$ can lead to biomass losses (61) and shifts in community composition (62). Laboratory-grown cultures should be centrifuged and rinsed with an appropriate buffer solution before extraction.

There are two general approaches to biomass estimation by means of phospholipid analysis (Fig. 2). The most convenient and inexpensive assay quantifies phospholipid-bound phosphate (PLP) as a principal component of living cells. The second approach is an extension of the first and involves the measurement of ester-linked phospholipid fatty acids (PLFA). The latter technique provides increased sensitivity and additional information on community composition (47,60,63). Unfortunately, PLFA techniques only allow the detection of bacteria and microeukaryotes and overlook the archaeal community

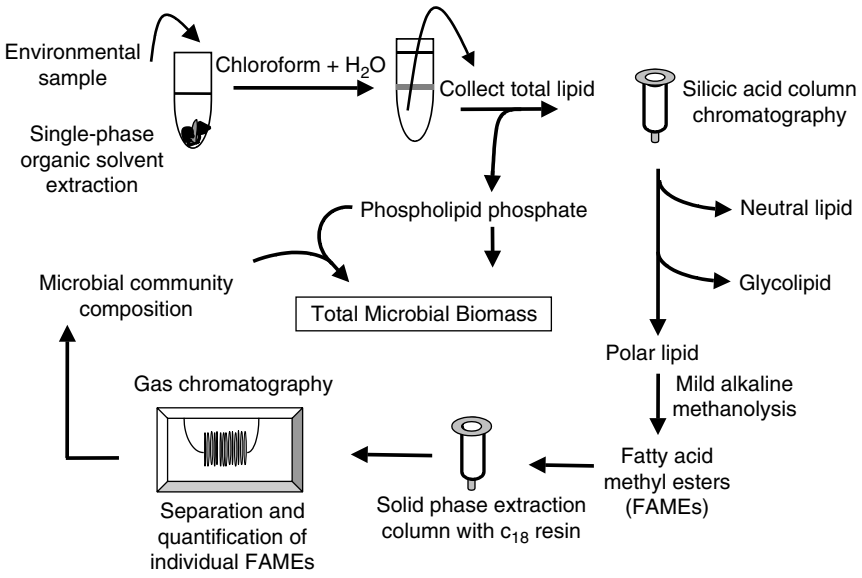

Figure 2. Experimental approaches for the determination of total microbial biomass using phospholipid analysis. Sub-samples of the total lipid extract may be removed for the determination of phospholipid phosphate and subsequent estimation of total microbial biomass. Alternatively, the determination of microbial community composition by quantification of PLFA may be used in conjunction with phospholipid phosphate data to estimate viable carbon biomass for individual groups (e.g., phototrophic microeukaryotes or prokaryotes).

component. The PLP technique allows detection of *Archaea* although few species have been characterized in this way, and conversion factors are not well established. Some researchers are using alternative biochemical approaches to better quantify this group of organisms and these methods are discussed in a separate section.

The general procedures for phospholipid analysis are outlined in the following segment but the reader should consult other references for more detailed protocol descriptions (47,56–60,63). When performing any type of quantitative lipid biochemistry, the researcher must take special precautions to minimize sample contamination. Procedural blanks should be processed in parallel with all sample sets to monitor contamination from reagents or solvents. Interfering compounds can originate from a multitude of other sources including dust, hair, fingers, plastics, soaps, adhesives, and oil lubricants. Laboratory glassware should be washed in hot soapy water (phosphate-free detergent is recommended) and vigorously rinsed at least 10 times with both tap water and deionized water. Once dry, all glassware should be baked for at least four hours at 450 °C to remove all organic contaminants. Use glass for sample and reagent handling whenever possible since organic solvents can dissolve interfering compounds from some plastics. High-purity organic solvents of gas chromatography/mass spectrometry (GC/MS) grade should be used when samples are destined for PLFA analysis. All screw caps for test tubes and reagent bottles should be teflon-lined.

The initial steps of the lipid extraction were adapted from Bligh and Dyer (64) and consist of a single-phase organic solvent extraction containing methanol, chloroform, and phosphate buffer (2 : 1 : 0.8) (56,59). Dichloromethane can be substituted for chloroform and gives equal recovery after an overnight extraction (47). Frostegard and coworkers showed greater extraction efficiency using citrate buffer in soils with high organic matter content (65). After a suitable period (typically 2–16 hours depending on the specific protocol), the single-phase extraction is split into aqueous and organic phases by addition of chloroform and water to obtain a final solvent ratio of 1 : 1 : 0.9 (methanol:chloroform:buffer/water). During the second step of the lipid extraction, samples are shaken vigorously and stored at 4 °C overnight in the dark to allow for phase separation. Lipid-soluble components are recovered from the lower organic phase. During recovery, the sample may be passed through a fluted Whatman 2V filter to remove residual water and extracted debris. When soils or sediments are used it may be difficult to collect the entire organic fraction, therefore it is best to measure the exact volume of chloroform recovered and normalize final biomass estimates accordingly. Samples are concentrated by nitrogen evaporation.

Total viable biomass is quantified by measuring PLP according to the procedures described by Findlay and coworkers (46). Briefly, replicate subsamples of the total lipid fraction are transferred to glass ampules and dried under nitrogen. The dried lipid is suspended in a potassium persulfate solution (made in saturated sulfuric acid, 0.36 N). Ampules are heat-sealed and the lipid-bound phosphate is liberated after overnight acid digestion at 95 °C. Orthophosphate is then detected using a colorimetric assay with ammonium molybdate and malachite green (46). A standard curve constructed using glycerol phosphate (ranging from 0 to 15 nmol per ampule) should be analyzed in parallel with all experimental samples.

The PLP method of biomass estimation is both quantitative and reproducible (coefficients of variation less than 5%) for environmental samples (46). When working in environments with high amounts of microbial biomass (e.g., surface soils, sediments, and some aquatic environments), the technique is convenient and inexpensive. Its use is limited when analyzing low-biomass samples. Lower limits of detection are around 0.1 nmol lipid-bound phosphate corresponding to approximately 3.4×10^6 cells per ampule (46). Therefore, if only PLP analysis is to be performed, the sample should contain at least 1×10^7 cells.

Microbial biomass and community structure can also be estimated from the quantification of individual PLFA. Extensive details of lipid biomarker analysis are described by Tunlid in LIPID BIOMARKERS IN ENVIRONMENTAL MICROBIOLOGY, this Encyclopedia. Briefly, the polar lipids are recovered from the total lipid extract by silicic acid column chromatography. Ester-linked PLFA are derivatized to form fatty acid methyl esters (FAMEs) by mild alkaline methanolysis (66). Resultant FAMEs can be purified on solid phase extraction columns packed with C_{18} resin (63), and separated and quantified by gas chromatography (GC) with flame ionization detection. Structural identification is verified by GC/MS. When using these techniques for biomass determinations, it is important to add a recovery standard such as phosphatidyl choline nonadecanoate (a 19 carbon PLFA present in very small amounts in natural samples) before lipid extraction. Phospholipid recovery from silicic acid columns can vary between laboratories and silica gel manufacturer; therefore, it is important to account for potential losses.

The quantification of individual PLFA provides greater sensitivity than the PLP method with detection limits at approximately 10^5 bacterial cells (67). Mass spectral characterization of membrane components has further been refined with the application of soft ionization techniques for the characterization of intact phospholipids (68). These molecules can be separated by liquid chromatography and subsequently quantified and characterized by electrospray ionization mass spectrometry (ESI/MS). These analyses increase the sensitivity of the assay by an order of magnitude and provide more specific information by discerning phospholipid classes as well as fatty acid profiles (68). This type of structural characterization has been performed with only a small number of bacteria, but expanding this database will undoubtedly improve our ability to detect and identify specific groups of microorganisms. Unfortunately, these techniques require sophisticated analytical equipment that are very expensive. Even routine PLFA analysis requires the use of high-purity reagents and specialized equipment such as gas chromatographs equipped with flame ionization and mass selective detectors.

The assay has been modified in a variety of ways to minimize extraction volume (46), enhance extraction efficiency (65,69), increase sample throughput (46,69), and enhance corecovery of other lipid biomarkers (70,71). For example, Macnaughton and coworkers developed a pressurized hot solvent extraction procedure that requires smaller extraction volumes and is complete in 35 to 40 minutes (69). When compared to the modified Bligh and Dyer procedure, the accelerated solvent extraction system gave similar yields for vegetative biomass and enhanced PLFA recovery for spores and airborne biomass. Other adaptations have been made to obtain other types of biological and physical information from a single sample. These include simultaneous extraction and purification of nucleic acids for molecular analyses (72), separation and specific derivitization of phoshpo-ether lipids for archaeal community structure determination (73), and simultaneous recovery of organic pollutants for additional chemical characterization (74).

Quantifying phospholipid content in environmental samples is relatively straightforward, but relating those values to a meaningful biomass estimate is much more difficult. If the experimental question is confined to determining differences among treatments for a single study or a few similar studies, it may be just as convenient to report biomass as nmol PLP per gram dry weight or volume of material. However, if interstudy comparisons are necessary, it might be useful to report biomass in units that are more easily interpreted.

Like cell size, cellular phospholipid content can vary with the physiological status of the cells. For instance, *Vibrio cholerae* cells had a 99.8% decrease in cellular phospholipid content after only seven days of starvation (75). Similarly, different groups of microorganisms have varying amounts of phospholipid in their cytoplasmic membranes (47). Consequently, phospholipid content cannot easily be related to cell abundance in natural microbial communities. In contrast, the relationship between phospholipid content and bacterial carbon appears to be less sensitive to changes in growth state and substrate concentration (76,77). Brinch-Iversen and King (76) determined conversion factors between phospholipid-bound phosphate and bacterial carbon for a variety of bacterial isolates and enrichment cultures. R. H. Findlay has summarized these results and comparable data for other types of microorganisms (47). The suggested conversion factors to calculate biomass in grams carbon for each group are 190 μmol P g^{-1} C for aerobic bacteria, 100 μmol P g^{-1} C for anaerobic bacteria, and 50 μmol P g^{-1} C for eukaryotes. To effectively apply these conversion factors, the researcher should have some information about the microbial community composition of the target environment. If the community is dominated by bacteria and the environmental conditions are well defined, then the choice of conversion factor is straightforward. When microeukaryotes or *Archaea* are prevalent, PLFA analysis can provide community structure information. For communities dominated by bacteria or microeukaryotes, the ratio of nmols PLFA to nmols PLP ranges between 1.7 and 2. Very low PLFA:PLP ratios (less than 0.8) may indicate a significant archaeal component. Similarly, the phospholipid biomarker analysis allows the researcher to quantify the relative dominance of prokaryotes versus microeukaryotes. Partitioning phospholipid biomass into prokaryote and microeukaryote components allows the more judicious application of conversion factors and more precise estimation of microbial carbon.

Nucleic Acid–Based Techniques

The development of nucleic acid–based techniques has drastically expanded our view of microbial diversity and has allowed the study of microbial community dynamics at the population level. Microbial ecologists have applied these tools through several different approaches that are thoroughly discussed elsewhere (78–82). If nucleic acid–based techniques are to be used as quantitative descriptors and to compare communities from diverse environments, at least two criteria must be met. Target nucleic acids should be extracted equally well from various environments and from various types of microorganisms (78).

These technical difficulties have not been fully resolved but investigators are making strides to quantify and account for relative extraction efficiencies of nucleic acids in various environmental matrices (78,83–85). There is also significant concern about biases associated with PCR amplification of community DNA and the generation of rDNA clones (86–88).

The use of rRNA for microbial community analysis is advantageous since it represents viable populations and can be used to discern community structure. In situ hybridization techniques that allow the identification of individual cells have proven to be extremely useful for studying population dynamics and physiological states of organisms in certain environments (89). Interpretation and extrapolation of these types of data is not clear-cut (90). Kerkhof and Kemp quantified per-cell rRNA content of nine strains of marine Proteobacteria during non-steady-state growth conditions (90). Cellular rRNA contents increased approximately 2- to 100-fold during the growth cycle, and there was a 2- to 15-fold difference in peak per-cell rRNA content between strains. Therefore, in a given environment, two populations may be equal in size and in a similar physiological state but still exhibit a 15-fold difference in total 16S rRNA content. In this situation, analysis of community RNA with phylogenetic probes would erroneously suggest that one population was numerically dominant. At present, nucleic acid–based techniques have utility as qualitative descriptors of microbial diversity and community structure but do not provide a quantitative description of microbial abundance or biomass. More research relating nucleic acid–based community assessment results to independent biomass or community structure measures (e.g., phospholipid fatty acid analysis) will help evaluate the influence of potential experimental bias imposed by some molecular techniques.

Bacterial Cell Wall Components

Muramic acid, lipopolysaccharide, and teichoic acid have all been proposed as biochemical index molecules for indirect biomass estimation. These cell wall components are only found in bacteria and can be recovered from the residual interface of a two-phase lipid extraction (45,91). Muramic acid is one of the amino sugars that constitute the peptidoglycan layer. Standard conversion factors have been put forth to relate muramic acid content to bacterial carbon for gram-positive bacteria, gram-negative bacteria, and cyanobacteria, but in reality this component can be highly variable for all groups. Lipopolysaccharide, a component of the outer membrane of gram-negative bacteria and cyanobacteria, has been used for both taxonomic characterization (92) and as a general biomass marker (93). Similarly, teichoic acids can be extracted and quantified from the cell walls of gram-positive bacteria (94). Because of their restricted distribution, they are of little use as biomass markers in most environments.

Photosynthetic Pigments

Satellite-derived measurements of ocean color can now be effectively used to calculate phytoplankton biomass in most areas of the open ocean (95–97). Primary production models incorporate a variety of parameters including chlorophyll concentrations derived from remote sensing, sea surface temperatures, incident solar irradiance, and knowledge of other physiological parameters that effect photosynthesis and pigment concentration. Model estimates indicate that oceanic phytoplankton biomass (approximately 1 Pg C) is turned over every week and is responsible for the global oceanic net primary productivity of 45 to 50 Pg C annually (95). Similarly, satellite observations have been used to revise estimates for terrestrial inputs to global primary production (98). On a slightly smaller scale, phytoplankton biomass and population structure can be determined by means of enumeration by flow cytometry and chlorophyllous pigment analysis with spectrofluorometry. Partensky and coworkers (99) combined these techniques to provide a detailed description of the vertical structure of picophytoplankton populations in the northeastern Atlantic Ocean. Similar to lipid analysis, photosynthetic pigments can be extracted from sediment or water samples with organic solvents such as acetone or methanol for the determination of phytoplankton biomass. Historically, these types of methods have been criticized because chlorophyll *a* contents (as a percentage of cell biomass) can vary significantly with light intensity and nutrient availability (96). In sediments, chlorophyll *a* concentrations are often overestimated because of the co-measurement of degraded pigments (100). Chromatographic methods for the quantification and identification of chloropigments and carotenoids (100) allows the investigator to account for the presence of pigment degradation products and can reveal important information about algal community structure.

FUNGAL BIOMASS

Fungi play an extremely important role as decomposers in both terrestrial and aquatic systems. These organisms often grow on or within opaque substrates such as rocks or plant surfaces. Traditional methods of community analysis (microscopy or culture-based techniques) are considered inadequate since in many environments hyphal structures are not clearly visible or easily separated from their associated substratum (101).

Ergosterol is a membrane component and with few exceptions is restricted to eumycotic fungi (101). As a constituent of intact membranes, its abundance should reflect the amount of living fungal biomass in an environment. This membrane component has been related to biomass by a number of investigators and the values range from 1.9 to 11.5 mg ergosterol g^{-1} mycelium (102). These conversion factors yield very high values for fungal biomass, and seem unrealistic (102) when compared with independent measures of bacterial biomass. It is likely that the ergosterol assay detects nonliving hyphae and these measures may overestimate viable fungal biomass.

Similarly, chitin is a dominant cell wall component in most fungi and has been proposed as a unique marker for total fungal biomass. Ekblad and coworkers (103) recently investigated the utility of these methods as indirect biomass measures. They monitored the variability of ergosterol and chitin content with respect to fungal species, growth conditions, and mycorrhizal age. Results

suggested that when the two are measured in combination they provide a reasonable estimate of total and living fungal biomass (103). Gessner and Newell offer a thorough discussion of the ergosterol assay and the various quantitative extraction techniques commonly employed for fungal biomass determinations (101). Standard techniques for lipid biomarker analysis may also reveal the presence of fungi through the detection of the polyenoic PLFA 18 : 2w6 and sterols in the neutral lipid fraction (Fig. 2; 60,102). There are uncertainties with conversion factors and relative extraction efficiencies. Therefore, these data should be applied only as relative measures of fungal biomass (102).

ARCHAEAL BIOMASS

Among the three domains of life, we know the least about the relative distribution and ecological role of the *Archaea*. Before the 1990s, it was assumed that they were only found in extreme physical environments (halophiles and thermophiles) or highly specialized niches (methanogens). Recent ecological surveys of bacterial phylotypes suggest that these organisms are more ubiquitous than previously thought (104–108). Most of these organisms are yet to be cultivated, but their molecular signatures are commonly found in a variety of aquatic and terrestrial habitats (104,109,110). We have very little quantitative information about their relative contribution to microbiota in most environments and better biomass estimates would be useful for determining their ecological roles.

Archaeal membranes are composed of phytanyl-based ether-linked lipids and thus the determination of ester-linked PLFA overlooks these organisms. It appears that most genera of this domain have glycerophospholipids (111). Although rarely applied to this group, the PLP method appears to be equally effective for the quantification of phosphorus-containing ether lipids of the archaea. For example, pure cultures of *Thermoplasma acidophilum* contain approximately 21 μmol PLP $g\,C^{-1}$ (112). This value is consistent with the report by Langworthy and coworkers (113) that phospholipids represent 1.75% of the cell's dry weight. Still, there is little information about archaeal phospholipid content as a proportion of cell mass and the application of general conversion factors for carbon biomass estimates is imprecise. Nevertheless, as a gross estimate, we may assume that lipids comprise 2.2–4% of the mass of an archaeal cell and 22–94% of these are polar lipids (111). With a few exceptions, these are dominated by phospholipids (111). Therefore, if we assume that the average molecular mass of archaeal phospholipids is 900 (including both diether and tetraether lipids) and 50% of a cell's dry mass is carbon, the projected phospholipid content ranges between 10 and 83 μmol P per gram bacterial carbon. These values are comparable to the range of values reported for microorganisms in the other two domains (14–520 $\mu mol\,P\,g\,C^{-1}$) (47). Ether lipid analysis has already been applied toward archaeal community structure determinations (73,104,109,110) and the further application of quantitative lipid biochemistry for archaeal biomass determinations would complement nucleic acid–based measurements that estimate archaeal diversity. Together these techniques will expand our understanding of microbial community dynamics in many environments.

CONCLUSION

During the last two decades there has been a rapid development of new techniques for in situ detection of microorganisms. Our increased ability to detect and identify these organisms has led to a new understanding of the vital role they play in the biosphere. The preceding discussion focused on evaluating the appropriateness of current detection methods for determining the quantitative importance of microorganisms in the environment. Several of the techniques described here may be useful for detecting organisms that are of quantitative significance. In turn, these methods may not be sensitive enough to detect certain organisms that are few in number but are functionally important. Each of the described methods has certain advantages and the researcher should carefully consider the experimental question and available resources while choosing the experimental technique. Similarly, results should be interpreted in the light of the inevitable shortcomings of each method.

Acknowledgments

I am grateful to R. H. Findlay, S. J. Macnaughton, D. C. White, J. C. Smoot, and editorial reviewers for suggestions and helpful discussions that improved this manuscript.

RADIOACTIVE WASTE DISPOSAL, GEOMICROBIOLOGY OF

JULIA M. WEST
British Geological Survey
Nottingham, United Kingdom

IAN G. MCKINLEY
NAGRA
Wettingen, Switzerland

Wastes containing significant quantities of radionuclides are produced not only by processes associated with nuclear power generation and the production of nuclear weapons but also by many other industrial, medical, and research activities. In common with other potentially hazardous wastes, the disposal of radioactive materials was somewhat haphazard in the past; either because their potential toxicity was not recognized or because of the pressures of bomb production during the Cold War period. However, over the last 20 years or so, a much more responsible approach to the disposal of such waste has evolved due both to generally increasing environmental awareness and to an increasing concern by the general public of all things nuclear. The growth of the new field of radioactive waste geomicrobiology has been paralleled by the development of rigorous methods to evaluate the performance and demonstrate the safety of special radioactive waste repositories.

Research and development (R&D) efforts in the 1970s focused on what was considered to be the more problematic waste — high-level waste (HLW) — which has such high concentrations of radioactivity that radiogenic heat output is significant. An example showing the diversity of radioactive waste is provided in Table 1. A consensus developed that deep disposal in stable geologic formations was the safest option for such waste. However, it was recognized that extensive investigations would be needed to demonstrate convincingly that no risk to the environment would arise over the very long timescales over which the contained radionuclides are potentially hazardous. This could be on the order of a million years. It was at this time that the evidence for the existence of microbial life in deep geologic formations was beginning to accumulate and some seminal studies of the potential influence of microorganisms on an HLW repository were carried out (2,3). Much to the surprise of many in the radioactive waste field, this early work showed clearly that microbial processes could be significant and led to nuclear waste management organizations being significant supporters of applied geomicrobiology.

Over the last 20 years, radioactive waste geomicrobiology has expanded to include analyses of disposal options for other types of waste. Projects have covered a wide range of areas including

- fundamental microbiology of deep geologic formations,
- microbial tolerance to extreme conditions,
- biodegradation of repository materials,
- interaction of microbes with radionuclides and their by-products, and
- microbial influences on the geochemistry of the repository environment.

The work involved has included field sampling, laboratory studies, and the development of mathematical models. All will be discussed from the viewpoint of those charged with developing concepts for nuclear waste disposal and assessing the long-term safety of existing and planned repositories.

FUNDAMENTALS OF RADIOACTIVE WASTE DISPOSAL

This article focuses on current concepts for the disposal of radioactive wastes in deep geologic formations. It does not directly include evaluation of "dilute and disperse" options for radioactive waste, which involves direct input of gaseous nuclides into the atmosphere or of liquid (occasionally solid) wastes into rivers, seas, or oceans. The role of microorganisms in the biogeochemical cycling of radionuclides after geologic disposal is, in principle, similar to that for other trace elements as considered elsewhere in this encyclopedia. There is also no direct consideration of near-surface disposal options; although many of the general principles discussed are equally applicable to surface repositories, in terms of microbiology, they tend to be more similar to disposal facilities for conventional (e.g., domestic) or chemotoxic wastes.

Deep geologic disposal (at least several tens if not hundreds of meters below surface) has been implemented, or is being planned, in many countries for many types of waste (e.g., 4). As yet, however, no repository for the most active HLW is operational, although significant steps in this direction have been taken in Finland and Sweden, and extensive site-characterization efforts are ongoing in the United States of America. Background principles of radioactive waste disposal can be found in a number of textbooks (5,6).

Table 1. An Extract from the Swiss National Inventory Providing Some Properties for HLW (WA-1) and Various Types of L/ILW–Average Values for Single Containers (1)

Waste Sort	Raw Waste	Material of Conditioning	α-Activity Bq/Container	β-γ Activity Bq/Container	Surface Dose Rate (Sv/h)	Heat Output (W)
			WA (Reprocessing Waste)			
WA-1	High-level vitrified residues	Glass	1.1×10^{14}	2.8×10^{16}	3.4×10^{3}	2.8×10^{3}
WA-2	Precipitates and sludges or $BaCO_3$ and MEB crud	Bitumen or cement	3.6×10^{8}–1.8×10^{10}	3.5×10^{11}–4.3×10^{12}	1.2×10^{-1}–5.2×10^{-1}	8.2×10^{-2}–4.5×10^{-1}
WA-4	Hulls and ends	Cement	1.4×10^{11}–2.8×10^{11}	1.4×10^{14}–8.2×10^{14}	2.4×10^{1}–3.9×10^{1}	2.0×10^{1}–1.2×10^{2}
WA-5	Technological low-level waste	Compacted	2.6×10^{6}–1.2×10^{8}	8.0×10^{7}–3.8×10^{9}	2.1×10^{-5}–1.0×10^{-4}	4.5×10^{-6}–2.1×10^{-4}
WA-6	α-emitting technological waste	Cement	7.4×10^{10}	7.3×10^{11}	7.0×10^{-3}	8.0×10^{-2}
WA-7	Centrifuge cake slurry	Cement	3.8×10^{11}	4.0×10^{13}	2.0	3.5
			MIF (Waste from medicine, industry, and research)			
MIF-1	β, γ-emitting waste	Cement	0.0	3.7×10^{10}	9.5×10^{-3}	3.1×10^{-3}
MIF-2	Tritium-bearing waste	Cement	0.0	1.2×10^{13}	3.0×10^{-5}	1.1×10^{-2}
MIF-3	"α" waste	Cement	1.2×10^{8}–1.3×10^{10}	0.0–1.1×10^{9}	3.0×10^{-9}–2.5×10^{-6}	1.0×10^{-4}–1.2×10^{-2}
MIF-4	Radium-bearing waste	Cement	2.1×10^{9}	0.0	5.4×10^{-6}	1.6×10^{-3}
MIF-5	"α, β, γ" waste	Cement	7.6×10^{8}–1.9×10^{9}	5.9×10^{10}–1.7×10^{11}	1.7×10^{-2}–3.2×10^{-2}	7.7×10^{-3}–1.5×10^{-2}

Note: Dose is dominated by γ-radiation; therefore absorbed dose (in Gray-Gy) is approximately equal to individual dose equivalent (in Sieverts–Sv).

Geologic repositories are based on the "multiple-barrier principle," in which long-term safety is assured by a series of engineered and natural barriers (Fig. 1). Waste is generally solidified in some kind of stable matrix, encapsulated in a container or some other type of package, and placed into underground tunnels, caverns, or silos. This packaged waste, along with any backfilling used to seal void spaces and other structural materials such as tunnel linings or plugs, is termed the *engineered barrier system* (EBS). Surrounding these engineered barriers is the rock itself, termed the *geosphere*. The "near-field" consists of the waste itself, the EBS, and disturbed rock surrounding the repository. The "far-field" comprises the undisturbed geosphere and extends into the biosphere.

Very many different combinations of engineered and geologic barriers have been designed to provide safe repository concepts for particular combinations of waste type(s) and geographic-geologic setting. Low- and intermediate-level waste (L/ILW) may be produced in a wide range of solidification matrices (e.g., cement, bitumen, resins, and metals), but is usually contained in steel drums or concrete packages with disposal caverns backfilled with cement-based grout (Fig. 2). Although such waste is very heterogeneous, the large amounts of cement and concrete used in construction tend to dominate the "near-field" in and around the EBS.

HLW usually consists of spent fuel — if this is considered as a waste for "direct disposal" or the solidified, high-activity wastes from the reprocessing of such fuel. In the latter case, the solidification matrix is usually a borosilicate glass or some kind of ceramic [e.g., "SYNROC" (7)]. A range of corrosion-resistant canisters has been developed for HLW, using steel, copper (Cu), titanium (Ti), or special alloys. The backfill used is either purified clay (e.g., bentonite) or clay–sand mixtures in many concepts (Fig. 3).

The simplified picture outlined holds for most national programs in which waste is disposed of in crystalline or sedimentary rocks below the water table. In these cases, the EBS plays a powerful role of delaying the access of liquid water to the waste and reducing the rate of subsequent release of radionuclides to surrounding groundwater. In many analyses, it is calculated that most nuclides decay to complete insignificance within the EBS.

The situation may be somewhat different in the case of "dry" evaporitic rocks such as salt. In such a case, the main barrier is the impermeable rock. Here, concern in the design of the EBS may focus on processes with the potential to perturb this function (e.g., production of gas). Crushed rock salt may be the ideal backfill in this case. Similarly, for deep repositories in desert areas, which are above the water table, low water availability is a key factor contributing to safety. In this case the EBS may be designed to take maximum credit for this factor (e.g., by ensuring temperatures stay above 100 °C for very long periods of time). Either no backfill at all or simple crushed rock for mechanical stability have been suggested for this case.

Despite the great diversity in the details of individual repository systems, a common concern is the quantification of their behavior over very long periods of time. The formalized procedures used to carry out such a

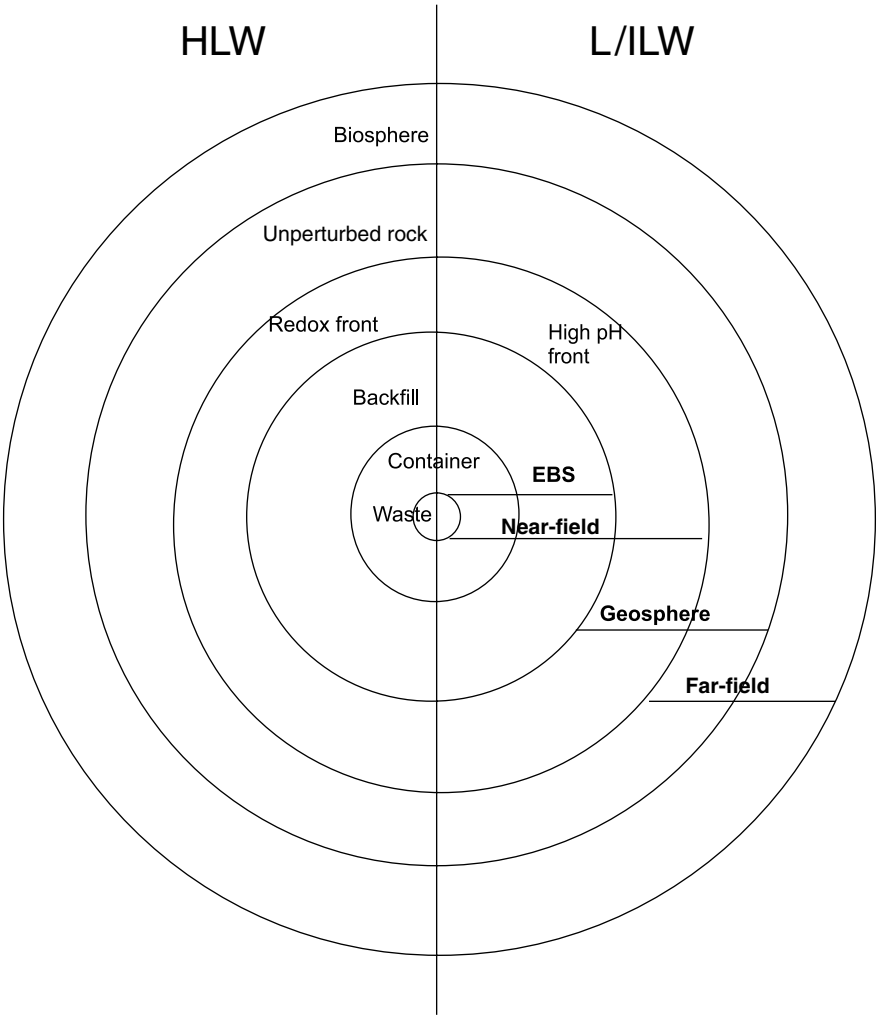

Figure 1. Radioactive waste–disposal concepts. EBS = engineered barrier system.

"performance assessment" (PA) utilize a database of the characteristics of the waste, the EBS, the surrounding geologic barrier, and the surface "biosphere." This provides input and boundary conditions for a series of models to represent slow EBS degradation, the release of radionuclides, and their transport through the geosphere to the accessible environment. Because it is not possible to predict the future, such analyses are carried out for a range of possible futures, termed scenarios. Given the requirements for PA it is important to consider the effects of microbial activity in this context. The following sections consider, in turn, the presence of microorganisms within the repository system, their possible influence on the performance of the engineered and natural barriers and, finally, the more challenging questions of how such influences can be quantified, especially in view of the enormously long timespans involved.

MICROBIOLOGY OF RELEVANT GEOLOGIC FORMATIONS

Following initial literature searches, an early part of several national geomicrobiology programs was to establish the presence of microbes in geologic formations being considered as host rocks for repositories; the rationale being that if no indigenous populations are present then microbes may not be viable in the environment selected and hence not be a problem. Studies have taken place in granites in Canada (8), Japan (9), Sweden (10–12), Switzerland (13), and the United Kingdom (14,15). Analyses have also been performed in sedimentary rocks in Belgium, Germany (10), the United Kingdom (15), Italy (16), and Japan. Evaporites (gypsum and salt) were sampled in Switzerland and Germany (17,18). In the United States, work has been undertaken on volcanic tuff (19,20). General reviews of microbial populations in a range of potentially relevant formations have also been presented (21,22). Analyses have mostly concentrated on groundwaters, although solid materials have been investigated for microbial content (14,15). In addition, studies on biofilms found on fracture surface in granitic environments have also been performed (23). All these studies have confirmed the presence of microbes in every sampled environment. Numbers vary from 10^2 colony-forming units (CFU) per milliliter to 10^5 CFU per milliliter in some groundwaters. A single exception is the salt site at Asse in Germany. Here quantification was impossible, although there were indications of the presence of small populations of extremely oligotrophic organisms

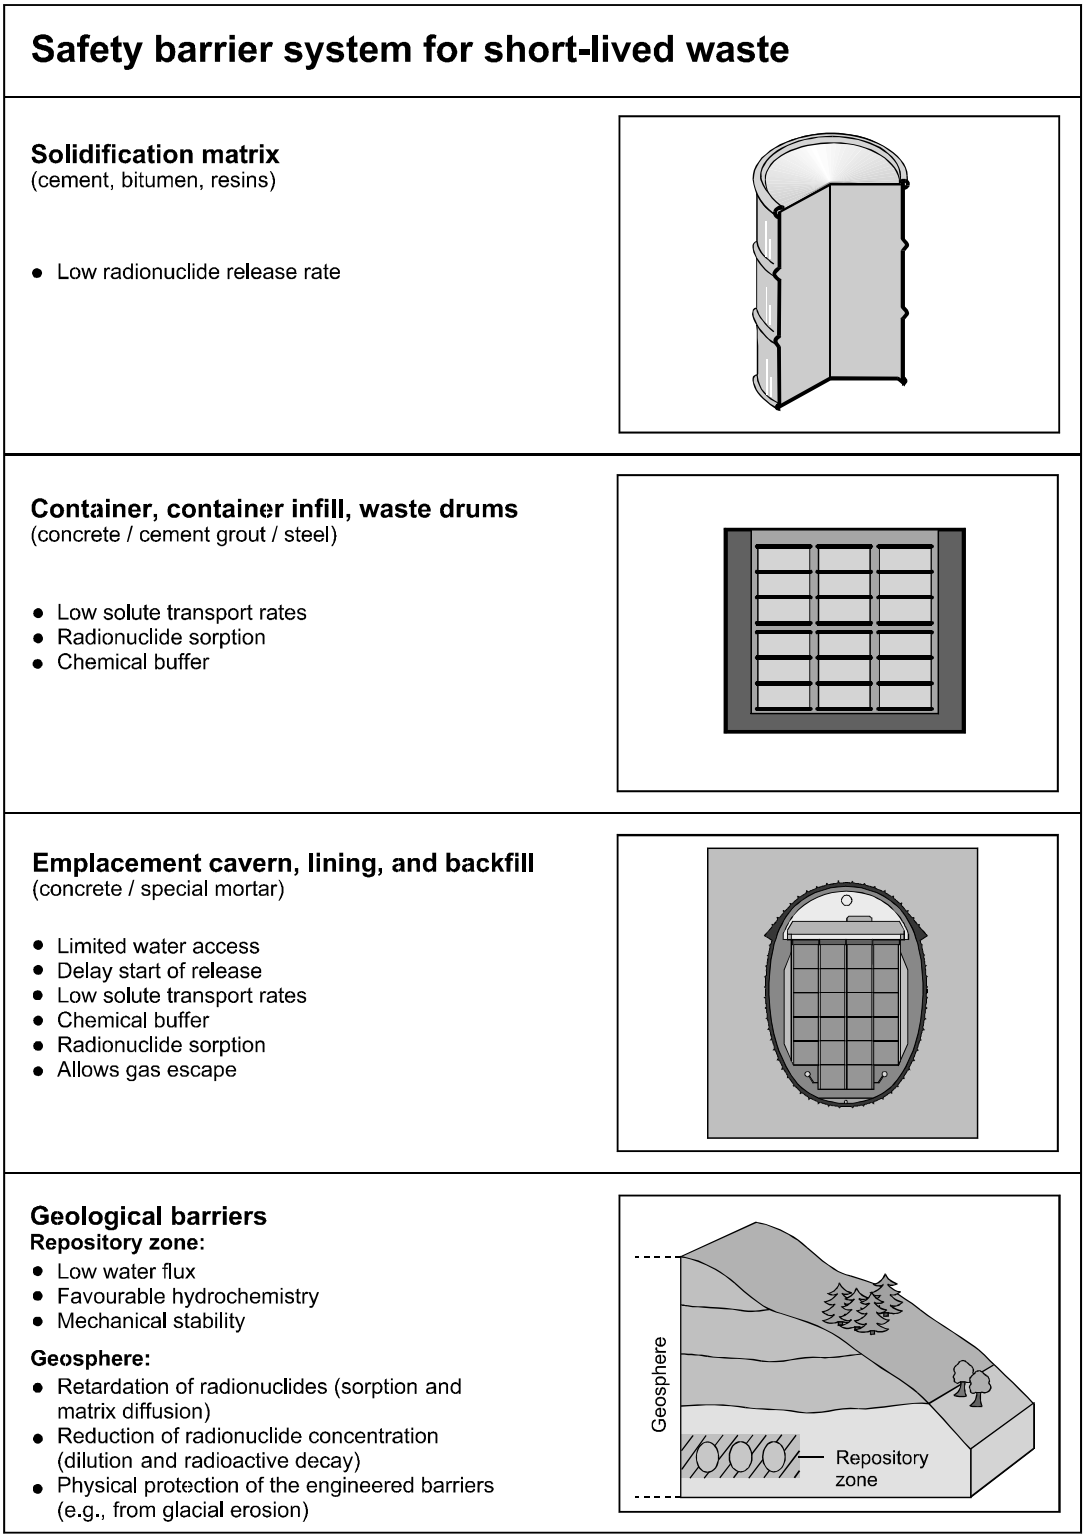

Figure 2. Example of a sequence of engineered barriers for L/ILW.

adapted to hypersaline conditions. A summary of findings at selected sites is given in Table 2.

The composition of microbial populations varies with site (24). It is, however, increasingly recognized that the analysis of ambient microbial populations is part of site characterization (25) and may be more critical to understanding the hydrogeochemistry of the site than to assessing the role of microbes on repository performance. For example, the oxidizing-reducing (redox) conditions of a site are critically important in assessing

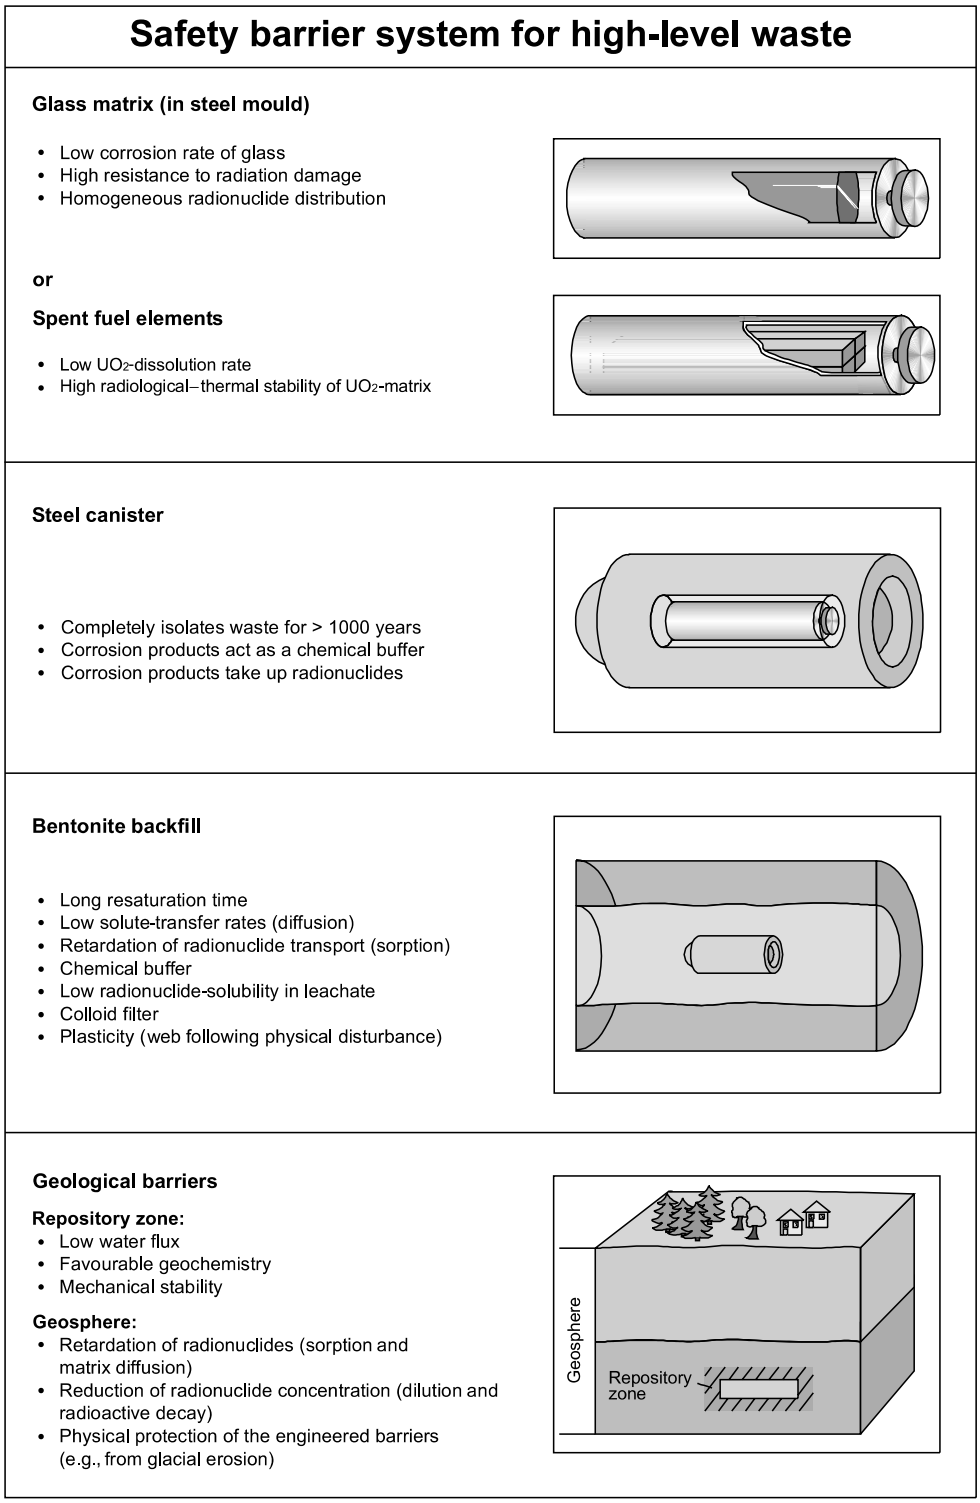

Figure 3. Example of a sequence of engineered barriers for and high-level waste/spent fuel.

site suitability. However, many of the redox complexes used to characterize "Eh" are multielectron transfers of sulfur (S), nitrogen (N), and carbon (C) species, which are kinetically slow at relevant temperatures and will proceed only with microbial catalysis (26). In experiments with rock and groundwater from a granitic environment, sulfate and iron-reducing bacteria appeared to catalyze secondary smectite formation (27). It is important, therefore, to focus on the activity levels of relevant microbial groups, such as sulfate-reducing bacteria (SRB), sulfur oxidizers, and methanogens, rather than counting numbers of cells or "stamp collecting" microbial families or species.

Table 2. Bacterial Populations in Deep Groundwater Environments (24)

Location	Geology	Depth (mbgl)	Bacterial Count
Canada	Granite	350–400	Total counts 10^3–10^5 cells ml^{-1}
Japan	Granite	Approx. 400–790	Total counts 10^2–10^7 bacteria ml^{-1}
Stripa, Sweden	Granite	799–1,240	Total counts 2.0×10^1–1.3×10^5 cells ml^{-1}
Aspo, Sweden	Granite	129–1,078	Total counts 1.5×10^4–1.8×10^6 cells ml^{-1}
Grimsel, Switzerland	Granite	Approx. 350 m	9.5×10^1–9.0×10^4 CFU ml^{-1}*
Altnabreac, U.K.	Granite	10–281	9.4×10^5 CFU ml^{-1}*
Mol, Belgium	Boom clay	190–223	1.2×10^3 CFU ml^{-1}*
Harwell, U.K.	Oxford clay	165–331	8.6×10^3–3.5×10^5 CFU ml^{-1}*
Asse, Germany	Salt	750	ND
Yucca	Volcanic	60	10^2–10^3 bacteria g^{-1}dry weight
Mountain, U.S.A.	Tuff		NB Above water table

*= aerobic heterotrophs.
ND = Not detected.

THE NEAR-FIELD

A range of microbes, potential energy, and nutrient sources are added to the subsurface environment during repository excavation, construction, and waste emplacement. These changes may convert the environment from a low nutrient system to one that, at least temporarily, could support substantial microbial growth and metabolic activity. Work on the disposal of spent fuel in granitic environments, for example, has shown that a significant amount of nutrients may be introduced from explosive residues associated with excavated rock, which is reused in backfill material. Also organic matter in backfill clays has been shown to increase microbial viability when treated with heat and radiation (23). For assessing microbial effects on the EBS, measurements on microbial populations in emplaced materials are probably more relevant than studies of the host rock. Alternatively, studies of natural alkaline environments could be relevant in which cement and concrete are of interest in the waste-disposal concept (28,29).

Tolerances to Repository Conditions

Conditions in a repository vary with waste type and with materials used in its construction (Table 1). For HLW, conditions are very radioactive (hundreds to thousands of Sieverts at the surface of the waste) and hot (in most cases ~50–100 °C). In the early phases of some concepts for the Yucca Mountain proposed site in Nevada, United States of America, the temperatures could be up to 300–400 °C. There is also be considerable pressure generated from the overlying water column and rock burden (up to ~10 and 25 MPa, respectively) and, for some concepts, high salinity up to concentrated brines. Heat and radiation are much less in an L/ILW repository, although the concretes used generate a hyperalkaline environment.

Such extreme conditions were initially thought to preclude life and hence most early analyses considered that a repository would be a completely sterile environment. However, this encyclopedia is full of examples of individual microbial species tolerating specific extreme environments. Some of those relevant to a repository are given in Table 3. However, it is difficult to find reported work on environments where all the conditions generated by a repository are produced (30).

Table 3. Tolerance of Microbes to Extreme Environments (24)

Condition	Example of Organism	Limit of Growth
High temperature	"Black smoker" bacteria	Reported to 113 °C.
Low temperature	*Sporotrichum carnis*	−20 °C
High pH	Nitrifying bacteria	12
Low pH	*Thiobacillus ferrooxidans*	0
High salinity	*Halobacterium halobium*	50% salt by weight
Low salinity	*Salmonella oranienburg*	70 ppb dissolved salts
High pressure	*Desulfovibrio desulfuricans*	180 MPa
Radiation	*Deinococcus radiodurans*	Single dose 5,000 Gy
Chemical toxins, e.g., $PbCl_2$	*Aspergillus niger*	67 mg ml^{-1}

The ability of microbes to simultaneously tolerate high-radiation doses and high temperatures is of particular interest to HLW programs. Studies in Canada suggest that radiation and desiccation effects could create a zone of depleted or reduced microbial activity extending a few tens of centimeter into a buffer material (23). Work on indigenous microbes from the Yucca Mountain, Nevada Test Site demonstrate that they are capable of surviving gamma radiation up to 10^4 Gy (at 1.63 Gy min^{-1}) in a viable but nonculturable form and can be resuscitated to a culturable form (20,31). Other radiation work with sulfate-reducing bacteria found a joint tolerance up to 80 °C and 310 bars and a separate tolerance of up to 10^3 Gy over 40 hours (24). Observations of the reactor core at Three Mile Island showed that microbes were present and were receiving doses of 10 Gy hr^{-1} despite the hydrogen peroxide used regularly as a biocide (32). All these figures are compatible with dose estimates of HLW disposal.

The effects of moisture content on microbial presence were investigated further in an in situ experiment with a

full-scale nuclear fuel waste disposal container in which a heater (simulating a nuclear fuel waste container) was surrounded by sand and bentonite backfill material (33). Microbes could only be isolated and were viable from the backfill material in which the moisture content was above 15%. This suggests that buffer material is populated by viable microorganisms only where the moisture content is above a value where free water is available for active life. The effects of temperature on microbe survival and migration were studied for the Yucca Mountain project. Here a block of tuff was heated to a maximum temperature of 142 °C. Two test isolates were found to tolerate the conditions and to migrate through the tuff itself to a distance of 1.5 m from their injection point (34).

Tolerance to alkaline conditions has been shown in a study of alkaline groundwaters in Jordan in which a range of microbes tolerated pH 12 and above (29). Work in France has shown also that fungi, likely to be important in LLW, grow when in contact with cement and reduces the water's pH (35). In experiments in which sulfate-reducing bacteria have been grown over a range of pH and Eh, activity at pH 8–10 was found to be enhanced by decreasing Eh (36).

In summary, microbial tolerance to a whole range of extreme environmental conditions demonstrate that a repository, even for HLW or for a repository backfilled with cement, cannot be assumed to be sterile for its entire lifetime. Given this fact, it then becomes clear that an assessment must be made of the likely impacts of microbial activity on the waste itself and on the containment materials.

Biodegradation of Repository Materials

Considerable work has been performed on the biodegradation of a number of repository structural materials and on materials used for encapsulation and wasteforms. These include bitumen, ion-exchange resins, organic components of L/ILW (e.g., cellulose), concretes, backfill material, and metals.

Much work has been undertaken on bitumen degradation because it is extensively used in nuclear waste solidification, for example, for encapsulation of ion-exchange resins. Laboratory studies have confirmed that biodegradation can be expected of both the bitumen and the resins themselves under aerobic and anaerobic conditions (37,38). In an operational repository, biodegradation is likely to be more rapid because consortia of microbes are present that work together to degrade such materials more efficiently than under experimental conditions. However, recalcitrant organic fractions are likely to remain (39), which are unavailable for microbial use. Much work has been performed on cellulose degradation because this is a major component of some LLW (40). A variety of organic acids are produced, iso-saccharinic acid being particularly significant. The impact of this acid production in relation to an alkaline repository is being intensively studied and modeling approaches have been developed (41).

Degradation of cements and concretes is commonly observed under aerobic conditions (42) and could occur in the early phase of a repository. Sulfur-oxidizing bacteria such as *Thiobacillus* sp. oxidize sulfur, sulfides, and thiosulfates producing sulfuric acid under aerobic conditions. Nitrifying organisms use ammonia and produce nitric acid in the same conditions. These acids can then attack the concrete matrix by dissolving calcium silicate hydrates (CSH) gel and $Ca(OH)_2$. Direct anaerobic corrosion of concretes is not known, although organic acids produced from microbial attack on organic materials could be a significant factor (35). Biofilms can also develop on concrete surfaces (40,43) although the organisms may be utilizing the organic plasticizers added to concrete to increase their workability. The local alkaline conditions produced by the concretes seem unlikely to preclude potential growth.

Microbially influenced corrosion (MIC) may affect the integrity of metals and alloys, such as steel, Cu, and Ti, which may be used as encapsulation materials (8,44–46). In addition, gas may be generated by such corrosion and this could exert pressure on containment materials, again affecting integrity. MIC can be either direct, microbes using the metals as energy sources, or indirect where microbes change the local conditions to enhance chemical corrosion to take place. In both cases the corrosion effects will be controlled by the amounts of nutrients and energy sources available to the organisms. In laboratory experiments simulating an L/ILW disposal regime, sulfate-reducing bacteria enhanced carbon steel corrosion by three times the rate of a control (42). Other experiments in realistic conditions have also shown potentially more important localized and deep pitting of steels, which was directly attributable to microbial action (44).

Ti and Cu alloys are candidate encapsulation materials in several HLW-disposal concepts. The use of such expensive material is justified by their corrosion resistance over very long periods of time and hence the possible role of microbes has been a significant area of study. There are no reports on MIC of Ti (45).

Within an HLW repository, the environmental conditions will change with time. Upon emplacement of the waste, the conditions will be warm and oxidizing. As the radionuclides contained in the waste decay and the initially trapped O_2 is consumed (by corrosion of the container and microbial activity), conditions will change to be cool and anoxic. Consequently, the nature of the chemical-corrosion reactions will also change with time. In general, localized corrosion and fast uniform corrosion are only expected to occur in the oxidizing phase when sufficient oxidant is present (8). For HLW such a timescale would correspond when conditions are most hostile and in which lack of moisture might inhibit microbial activity (33). However, later repopulation is possible — although this will depend on whether organisms can move through the pore space in the backfill material. Experiments to investigate buffer material repopulation with viable *Pseudomonas stutzeri* after a "sterilization" period suggested that movement could not take place within a compacted bentonite matrix (23). However, movement was shown to occur at interfaces between the backfill and other experimental materials. This suggests that fractures or discontinuities within the EBS may be a preferred pathway for microbial migration, for example, cracks in the backfill resulting

from desiccation. Resealing will occur as groundwater resaturates the buffer, but resealing may be slower than microbial movement. This remains to be investigated. If a zone of depleted microbial activity is created during the high-heat and desiccation period and repopulation is limited by the pore size of the buffer material then microbial activity would be limited to regions outside this depleted zone. Only anaerobic corrosion, probably involving sulfate-reducing bacteria, could occur because the repository would no longer be in the oxidizing phase. In this case, the only microbial impact on the encapsulation materials will result from the diffusion of microbially reduced S species to the container surface. Modeling studies have predicted the extent of sulfate reduction in such a situation and the consequent effects on copper corrosion are likely to be minimal (46). Biogenic organic acid production is likely to be very limited in an HLW environment (33).

Influence on Radionuclide Release

In addition to degrading the materials used to immobilize radionuclides, as considered earlier, microbial activity can influence the release of radionuclides in a number of ways (47):

- Alteration of bulk pore water chemistry (especially pH and redox),
- production of organic complexant by-products, and
- direct uptake onto or into cells.

The alteration of bulk chemistry predominantly occurs due to microbial catalysis of reactions, which produce or consume either protons or oxidants. A good example would be pyrite oxidation (consuming oxidants and producing protons), which may directly lead to acid conditions under which many radionuclides are much more soluble than in a more neutral environment. Even if the initial acid production is buffered by, for example, calcite dissolution, the resultant increase in carbonate concentration in solution could well increase the solubility of many key radionuclides (e.g., actinides).

The catalysis of redox reactions is not, however, necessarily detrimental to near-field performance. Radiolysis of water can give rise to production of equal quantities of oxidants (e.g., H_2O_2) and reductants [e.g., hydrogen (H_2)]. Because H_2 is kinetically inert, this gives an effectively oxidizing environment that tends to increase the solubility of many key nuclides. The presence of microbes that can obtain energy from the recombination of H_2 and H_2O_2 would, however, minimize the potential for this "oxidizing" front or "redox front" to form (Fig. 1).

The catalysis of redox reactions may directly involve radionuclides. Elements such as selenium (Se) may be present in water in an oxidized form (SeO_3^{2-} or SeO_4^{2-}, in this case) that, although thermodynamically unstable in reducing repository conditions, is kinetically hindered from undergoing reduction. It is known that common groups of microbes often "carry" such trace nuclide in their catalysis of reactions of major elements [e.g., sulfate-reducing bacteria producing selleno-sulfides (29)].

The production of organic by-products that can mobilize trace elements is well known for a wide range of relevant organisms. The most extreme examples are organic molecules that are directly utilized for this purpose (e.g., siderophores), which can complex strongly (effectively irreversibly) with a range of relevant elements, notably actinides (48). Nevertheless, a very wide range of by-products ranging from simple organics (e.g., formate, acetate, and oxalate), larger biodegradation products (e.g., iso-saccharinic acid from the breakdown of cellulose), and large macromolecules (fulvic and humic acids) can be of importance. This has been reviewed in detail elsewhere (48).

The third key process considered is radionuclide sorption onto or uptake into microorganisms (49). The net effect of such sorption depends on the extent of its reversibility and the mobility of the organisms involved. Irreversible uptake is of most significance but its net effect is negative only if the organisms are mobile. Uptake into microorganisms may, superficially, be difficult to distinguish from sorption onto outer membranes. The difference becomes particularly significant for the cases in which internal mineralization occurs — which is well known for many microbial groups (50). In the extreme case, this can result in the immobilization of radionuclides in mineral forms, as can occur in the formation of ores of elements such as uranium (U). The same process can be detrimental, however, if the microbes containing the concentrated radionuclide can migrate through the engineered or natural barriers or if the mineralized form is released as a mobile colloid.

A general conclusion from these observations is that, if microbial activities are significant, there are a number of processes that could influence the rate (and form) of release of radionuclides from the EBS. The processes may, however, be either positive or negative in terms of their effect on the containment of radionuclides. In performance assessment of repositories, the worst case is normally assumed but, as seen from observations of natural concentration of radionuclides in areas of reasonably intense microbial activity (1,52a,b), this may be overly pessimistic.

Gas Production

Gas production is of considerable concern in repositories where the waste has a high organic content or contains large quantities of metals. This is because of both the potential for gas pressurization and the inherent properties of gas (radio or chemotoxicity, flammability, and chemical reactivity). Gases can be formed by microbial activity in three ways:

- Direct biodegradation of organic materials, which act as a nutrient source for biogenic gas formation,
- direct catalysis of anaerobic corrosion of metals, and
- indirectly, by producing chemical environments, which cause production of gases, for example, acid conditions that enhance corrosion of metals.

Microbes can also act as consumers of gases (53). For example, carbon dioxide (CO_2) is utilized as an electron

acceptor for methanogens and acetogens, whereas H_2 can be used as an electron donor.

Under the aerobic conditions encountered in a repository soon after waste emplacement carbon dioxide is likely to be the main gas produced by direct microbial action. As the redox conditions change, a range of other gases are produced. Sulfate-reducing bacteria generate sulfide that may form toxic hydrogen sulfide gas and, under very reducing conditions, methane and H_2 may be formed by methanogens. The net effect of microbial activity is difficult to quantify because gas may also be produced by inorganic mechanisms. Studies on degradation of cellulosic waste under alkaline conditions have showed that carbon dioxide is the major gas produced[1] but once the redox potential dropped, methane is also generated and becomes the principal component of the produced gas (40). Little net H_2 was produced — probably being used as a substrate by some species. For HLW, biogenic gas production is not expected to be very significant because the amount of organic material is generally much lower. Studies of gas production from laboratory systems containing backfill and granitic groundwater have shown that the backfill may have a suppressing effect on methane production, which may be attributable to competing sulfate-reduction processes (23).

THE FAR-FIELD

The main aim of a repository is to contain radionuclides and thus any process causing their transport is of concern. In deep geologic systems, advective groundwater flow is the main process mediating such transport. Some engineered barrier materials, such as bentonite and good quality concrete, have such low hydraulic conductivities that advective transport is minimal. Hence diffusion may dominate solute transport. Host rocks with similar properties would be very desirable because it can be shown that diffusive transport is extremely slow for distances of even tens, if not hundreds, of meters. In natural systems such rocks normally contain discontinuities (fractures, faults, etc.), which can serve as potential advective pathways. Repository construction may also produce possible advective short circuits.

The key questions are thus whether microbial processes could influence the rate of transport of radionuclides in the undisturbed geosphere and if the presence of the repository could influence the geosphere-barrier role.

Radionuclide Migration in Undisturbed Systems

The radionuclide transport properties of any medium depend on both the processes moving solute in solution (advection, diffusion, and dispersion) and those transferring solute from dissolved to a solid phase (sorption and precipitation).

The physical processes of advection, diffusion, and dispersion can be influenced by microbes only if they can increase (because of dissolution of solid phase) or close (clogging and formation of biofilms) fluid-filled pore space. If very intense microbial activity occurred in an EBS in which porosity was very small, an influence might well be expected. Significant effects for macroporous EBS systems or for the geosphere would require either very high concentrations of biomass or biofilms/secondary-alteration products. Laboratory experiments have, rather unexpectedly, observed blocking of flow cells within two days owing to intense microbial growth–alteration of crushed rock (27), but the extent to which this is relevant to real systems is not known. Another exception to this generalization would be in cases in which advective flow occurs in fractures with diffusion into nonflowing porosity of the surrounding rock. Biofilms on fracture surfaces could certainly limit access to the matrix and thus greatly reduce the retardation of many key radionuclides.

Sorption is a bulk term for a range of processes causing uptake of solute onto surfaces. Such sorption is generally assessed in laboratory-uptake experiments and, in cases in which microbiology is considered at all, it is assumed that the experimental systems already include microbial effects because no attempts are made to limit microbial growth. In some cases, the agreement between the predicted rate of retardation based on laboratory-sorption measurements with that observed in in situ tracer tests argues that this assumption is justifiable. Experiments suggesting that microbial activity plays a role (54) do, however, suggest that care must be taken when attempting to develop mechanistic sorption models based entirely on physicochemical mechanisms.

The effects of microbes on radionuclide migration can be positive (if sorbed onto attached organisms or onto biofilms) or negative (if sorbed onto mobile or motile organisms). Biofilms have been observed forming on surfaces in deep subsurface environments (55). In many low nutrient environments, microbes are starved; becoming small and mobile and capable of penetrating deeply into geologic formations (56). Experiments in which microbes are in solution suggest that they have varying effects in conventional radionuclide-sorption experiments. For example, in experiments with ^{137}Cs, microbes appear to compete for sites on rock materials with the radionuclide (54). Indeed at the Yucca Mountain repository site there is a potential risk of the subsurface microbial population promoting plutonium transport, based on the high potential for biogenic chelation and carbon dioxide production to accelerate transport (49).

Perturbations Caused by the Repository

Physical damage to the host rock caused by construction processes will not be considered further here, although it is noted that microbial processes can contribute to such perturbation effects [e.g., oxidation of pyrite in the "excavation-damaged zone" (57)].

Two major chemical perturbations that can result from the presence of the repository have been introduced previously in the "near-field" section — the oxidizing redox front resulting from radiolysis caused by HLW (especially important for directly disposed spent fuel) and the high pH plume resulting from hyperalkaline leachates from repositories. The extent to which these reaction fronts can be locations of enhanced microbial activity and the

[1] under alkaline conditions this will be quickly consumed by carbonation reactions

consequences of such activity have been reviewed (58). It was concluded that microbial processes probably play a critical role in the development and movement of redox fronts as commonly observed in nature (e.g., roll-front ore deposits). A microbial role in the high pH front was shown to be theoretically possible, but was identified as an area in which relevant experimental data and field observations were lacking.

EVALUATING THE RISK OF MICROBIOLOGICAL EFFECTS

The greatest challenge in nuclear waste management is demonstrating the safety of repositories over the period for which the radionuclides remain harmful; up to hundreds of thousands or millions of years. Although it is clearly impossible to predict repository evolution in detail over such long periods, the deep geologic environment has the great advantage of very low fluxes of energy or materials that makes simple, scoping assessments feasible. Procedures for quantifying very slow physical (e.g., water flow and rock deformation), chemical (e.g., corrosion and radionuclide sorption), and geologic (e.g., uplift/erosion and fault movement) processes have been established. Quantifying the influences of the microbial processes discussed in the previous sections is less well developed.

Model Development

The clear aim of microbiological studies in the nuclear waste field is to provide information for the safety assessment of repositories. Two main modeling approaches have been examined to date. The first is based on models that use energy and nutrient inventories to calculate maximum microbial biomass and thus quantify perturbing effects in a particular scenario. The second uses models that describe microbial communities and their interactions in organic degradation processes in a more explicit manner.

The nutrient and energy inventory calculations approach was first examined in work performed for the Swiss HLW repository (59) and has subsequently been used for their L/ILW concept (60).

The fundamental assumption is that the maximum possible biomass for the extremely oligotrophic environments found deep underground will be set either by the flux of utilizable energy or by the supply rates of essential elements such as C, N, S, or phosphorus (P) (Fig. 4). Of course, both these constraints are difficult to quantify rigorously and require discussion of questions such as the following:

- What exoenergetic reactions can be used by the chemolithotrophic organisms supporting any microbial communities present, what is their efficiency of utilization of such reactions, and what are the energy requirements to maintain very slowly growing biomass?
- What inorganic sources of essential trace elements can be utilized, what is the rule of utilization of these sources, and what are the energy requirements involved?

Such questions are fundamental to quantitative geomicrobiology and although they cannot yet be answered in a rigorous manner, bounding values can be set, which should represent a worst case (which maximizes possible consequences; "conservative" in the performance-assessment jargon). Such calculations have shown that microbial influences in a Swiss HLW repository are not so great as to perturb the anticipated "sterile" worst case.

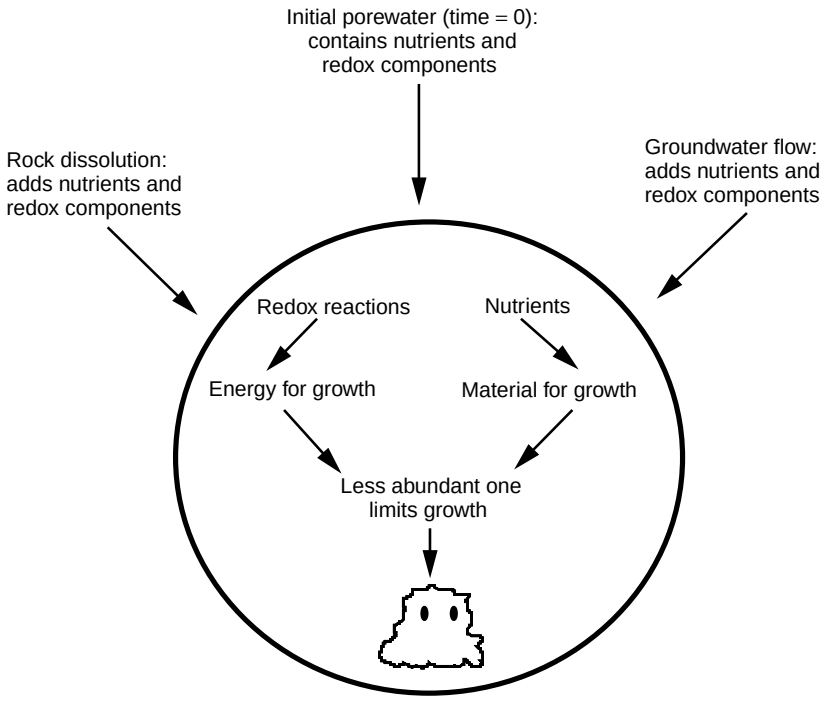

Figure 4. Diagrammatic representation of nutrient/energy computer models.

They also identified the low energy flux, set by the limited availability of electron acceptors (oxidants) as the main constraint on microbial growth. A similar approach was taken for a reference British HLW case (61) that came to the same conclusions, as did the Canadians (62). In the L/ILW situation, by contrast, energy supply was less critical and phosphorus was predicted to be the limiting nutrient. This modeling approach, which determines maximum available energy from a list of all potential redox half-reactions, has been formalized in the generic computer code BGSE (63), which can be used for a wide variety of waste types or subsurface environments.

The alternative approach has been developed that views the LLW repository as a complex system of microbially catalyzed organic-breakdown reactions (64). A generalized kinetic model of organic breakdown to generate biomass (active and inactive), soluble metabolic products, chemical intermediates, and gases has been developed (40). The rate of appearance and disappearance of these products can be modeled over the lifetime of a repository by solving the set of coupled kinetic equations subject to the boundary conditions defined by materials inventories and fluxes in the repository. Microbial activity in a British LLW repository has been modeled over the first 400 years of the repository lifetime, although the model does not yet take into account evolution of some key environmental variables such as pH and temperature.

The models described focus on looking at the "near-field" of various types of repository and quantifying the maximum extent of some potentially perturbing processes (e.g., gas production, metal corrosion, and production of organic by-products). Efforts to quantify effects in the far-field have been more limited. However, it has been demonstrated that the energy/nutrient-constraint approach can be applied to the particularly relevant question of the extent to which chemical perturbation from the EBS can penetrate the geosphere (58).

Verification and Validation

The microbiology models were all developed based on a range of observations and data from laboratory and natural system studies. The key questions to be addressed thereafter are the following:

- Do the models correctly solve the equations describing the system (verification)?
- Do the models adequately represent reality (validation)?

The former question is the easier and can be addressed either by comparison of computer code results and direct analytical solutions for simple test cases or by intercomparison between different models. Validation is much more challenging and requires testing model predictions against observations of systems with appropriate levels of complexity and that operate over appropriate timescales.

To address processes occurring over timescales of thousands or millions of years, conventional laboratory studies are inappropriate and hence similar geologic or archaeological systems must be sought; the "natural analog" approach (51,52a,b).

Natural analogs can be used to first confirm that long-term microbial influences are significant in particular environments. These have included U movement in sites in the United Kingdom (65), at the Poços de Caldas uranium mine in Brazil (66), and at hyperalkaline sites in Oman and Jordan (29). These studies have shown that microbes are ubiquitous in environments resembling those found in a repository and that they play a role in U-mobilization and deposition. For example, at Poços de Caldas, the microbes found around redox fronts, where the U was being mobilized and then reconcentrated, were supported by nutrients and energy supplied by the rock-alteration processes. It was suggested that the complex S-cycling around the redox front was microbially catalyzed. Moreover, this would explain the formation of nodular pitchblende concretions associated with secondary pyrite at the redox front (66).

The energy/nutrient-limit modeling approach has been tested by comparing predictions with observations from both laboratory and natural analog studies. In experiments examining the effects of microbial activity on a suite of repository materials (44), populations of $\sim 10^6$ CFU per cubic centimeter were found, which were much lower than that predicted by modeling. At Maqarin natural analog site in Jordan the modeling approach suggested a population of up to 100 million organisms per cubic centimeter. The observed populations are factors of between 1,000 and 10,000 smaller than this (29). These differences between observed and predicted populations are not unexpected because plate counts always underestimate actual populations. However, at Poços de Caldas uranium mine, the maximum annual production of 0.01–0.1 gram biomass (dry)/m^2 at the redox front was in good agreement with observed standing populations (66). Taking all these results together it appears that microbes may not be able to use all the available nutrients in a repository environment but the modeling approach appears to be conservative in all cases (possibly overly pessimistic).

Analogs may also be used to check models of individual processes, such as cement degradation, bitumen leaching, metal corrosion,.and so forth, but, to date, attempts to quantify the role of microbes in such processes has been very limited. Studies at existing repositories (for radioactive and/or toxic wastes; usually shallow sites with a poorly defined composition) can also be used, to some extent, as analogs of deep disposal sites. Results must be treated with caution because, in such sites, water movement is usually rapid and pH varies from neutral to acid (67). General trends can, however, be clearly observed. For example, leachates rich in organics are produced whose concentrations are reduced by microbial activity; recalcitrants such as the chelating agent EDTA do, nevertheless, remain.

Treatment in Formal Performance Assessments

Until the late 1970s, microbial processes were not even mentioned in safety assessments of potential deep repositories for radioactive waste. Even in the mid 1980s, when the potential for microbial perturbations was acknowledged, microbes (together with organics and colloids) were usually considered simply as "problem

areas" or "open questions" (e.g., 68). For wastes containing large quantities of organic materials, the potential was assessed quantitatively, even if only by very simple scoping calculations.

At the turn of the century, the position is improved with attempts made to quantify microbial processes in most performance assessments, even if under the heading of a "perturbation scenario" rather than in the main "expected evolution" or reference case. As more projects move toward site-specific studies and implementation, the pressure to carry out a more rigorous quantitative assessment of all "open questions" will increase and this can be expected as a key development over the next decade.

INTO THE FUTURE

Although the basic concepts of nuclear waste management remain constant, several recent trends are apparent, which are influencing the development of disposal options. For example, there are increasing pressures to delay final disposal, monitoring waste at special surface storage facilities or in deep repositories that are kept open for periods of up to 100 years or more. If any problems are detected during this period (in terms of containment), then the waste can be easily retrieved and problems rectified before final disposal. There is also time to reevaluate the choice of final disposal of the waste, if future improved technological solutions present themselves. Such extended storage has, however, implications for microbiological processes. Extended storage, whether at the surface or at depth, will ensure prolonged exposure of the waste to both aerobic conditions and to microbial contamination. As a result, the rates of biodegradation of materials, gas production and so forth will increase, with consequences that have not been assessed as yet. Increasingly, as national programs move toward implementation, countries are seeking to optimize somewhat simple initial designs by taking into account decades of experience in R&D and the actual practicalities of waste disposal. These optimized designs seek to reduce long-term uncertainties by strengthening the EBS while also easing the practicality of construction/quality assurance and reducing costs (69). As yet, none of the published studies includes a determination of the significance of microbiological effects for these changing repository designs but this will clearly be another focus for future work.

Public confidence in the safe disposal of radioactive waste has been identified as one of the most important factors to be addressed before a repository can be implemented. All possible perturbing effects must be shown to have been examined based on knowledge that is state of the art. It is therefore essential that, as advances are made in relevant areas of microbiology, they are assessed in the context of waste disposal. For example, the recent discovery of nanoorganisms (70) in extreme environments could well have implications for radionuclide migration. Such organisms may well be more mobile than other larger microbes and could transport nuclides more rapidly away from the repository.

Conversely, the simple models developed for assessing microbiological effects in a repository, which were described earlier could be modified for use in other environments. Such an application could be enhancing the bioremediation of contaminated land, by identifying and controlling the rate-limiting microbial process, or examining the potential for microbial life on other planets using geochemical data only. As such models are utilized more widely, they will tend to improve and the resultant second-generation models can then be reapplied to repository studies. The potential for cross-fertilization of ideas beyond radioactive waste disposal is immense and movements in this direction represent one of the few predictions of the future, which can be made with confidence.

RAINWATER ROOF CATCHMENT SYSTEMS, MICROBIAL QUALITY OF

ROGER S. FUJIOKA
University of Hawaii
Honolulu, Hawaii

Clean and safe water piped to homes by a reliable supplier (water utility) and available at the turn of a tap is taken for granted by most people in developed countries. However, in developing countries, large populations of people are not supplied with clean water piped into their homes. Even in developed countries, many houses do not receive piped water from a public water utility because of practical or economical conditions related to houses being too far away from a public water utility, houses being located at too high an elevation, or because the houses in rural areas are too few and too scattered. Under these conditions, homeowners will rely on the most feasible source of water for their household needs, such as surface waters (rivers, streams, lakes) or groundwater sources (boreholes, wells). However, under some conditions these sources of water are not readily available, and harvesting (collecting and storing) rainwater may be the most feasible way to obtain water for household use. In its simplest form, open tanks can serve the dual purpose of collecting and storing rainwater. However, this method is applicable only to few places where rainfall is frequent and the volume of water required is low. In most situations, a designated surface area or catchment is required to collect sufficient volumes of rainwater. Pipes or channels are then required to transport this water to a storage tank or cistern for future use. In some situations, the ground (cemented area, lined cliff-side, roads, airport runways) is used as a rainwater catchment area. Ground catchment systems will be excluded from discussion in this paper because they are generally designed for community use and are vulnerable to many sources of contamination, and will generally require some treatment, depending on the expected sources of contamination. Also excluded are catchment systems, which utilize large surfaces of public buildings such as stadiums because these systems are generally highly sophisticated and the water collected is not for household use. The objective of this review is to assess the microbial and hygienic quality of rainwater collected from roof catchment systems from private homes and stored in cisterns or tanks for household use. This class of systems will henceforth be called rainwater roof catchment systems (RRCS).

USE AND STATUS OF RAINWATER ROOF CATCHMENT SYSTEMS

Historically, RRCS are most commonly used in developing countries and in rural areas of developed countries where water is not provided by a public or a private purveyor. For these homeowners, the primary motivation to build RRCS is to obtain sufficient quantity of water for household use at the least cost. Homeowners have long assumed that the quality of water collected by RRCS is good because rainwater is a known source of purified water. However, during the process of collecting and storing rainwater, all RRCS contribute to contaminating the collected rainwater. Multiple factors, such as the design, materials used, maintenance of the RRCS, surrounding environmental conditions, and the practices of the homeowner, contribute to the degradation of the quality of collected rainwater. These factors are in turn controlled by practical considerations such as the wealth and education of the homeowner, as well as the availability of power supply, building materials, and technical support in that area. In most cases, homeowners will follow the recommendations of people, agencies, or local construction companies in the immediate area to build RRCS and will choose the most economical system. This has led to great variations in the construction materials used and in the design of RRCS used in different areas of the world.

The status of RRCS is that each system is considered a private source of water because it serves only a limited number of people (<25). This status of RRCS has led to several consequences. First, the quality of water from RRCS has never been regulated, and as a result the quality of water from RRCS has generally not been determined. Second, since government agencies are not responsible for the quality of water collected by RRCS, no government agency has been identified or tasked to support the needs of homeowners who utilize RRCS. Third, construction and design of RRCS have not been optimized based on water quality. Fourth, even in developed countries where building codes are required for the construction of RRCS, the codes focus on structural stability rather than water quality. Fifth, research publications that discuss problems and solutions for RRCS are not readily available to homeowners or those who build RRCS throughout the world.

TYPES OF RRCS USED THROUGHOUT THE WORLD

Although there are many different designs of RRCS used in different parts of the world, the quality of water collected by RRCS is primarily affected by the design of the RRCS, the materials used, the sanitary conditions of the country, and the resources (wealth, education, supplies, technical support) available to the homeowner.

Minimally Designed RRCS

Figure 1 illustrates the design of a minimally designed RRCS. This type of RRCS is characteristically found only

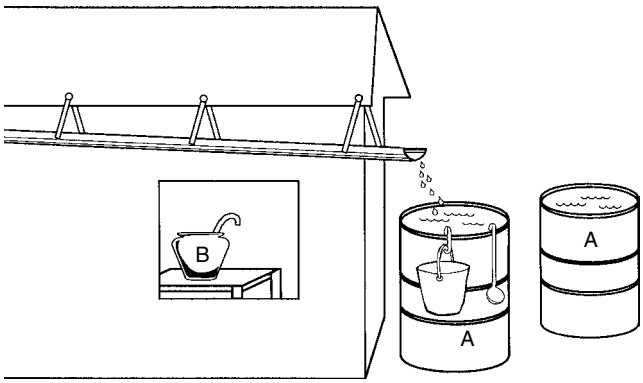

Figure 1. Example of a minimally designed RRCS showing oildrums with open tops A, used as cisterns, with ladles and buckets to collect water from the cistern and a household container B of water.

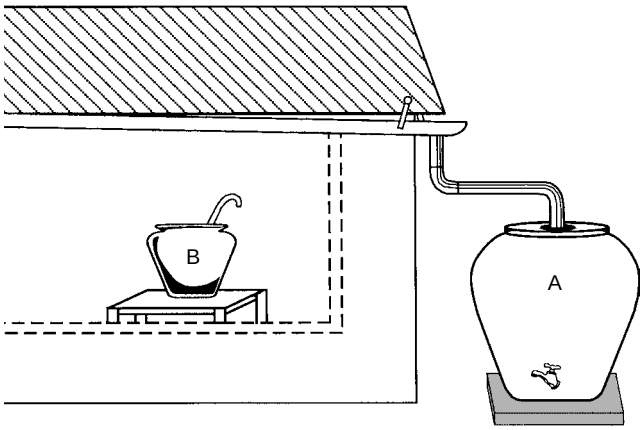

Figure 2. Example of practically designed RRCS showing closed Thai jar cistern A) with water collecting spigot and a household container B) of water.

in remote areas of developing countries where homeowners have minimal resources such as building materials and where technical support from agencies is not available. Therefore, homeowners use material available in the area to design RRCS to simply collect rainwater. Under these conditions, the roof of the house may be plant material (thatched roof), lumber, or corrugated iron. A split bamboo suspended at the ends of the rooflines is often used as gutters. The rainwater is collected into any available and sturdy tank, which is generally small enough to be carried or moved by the homeowner. Empty, used, and uncovered oildrums (200-l capacity) are often used because this kind of tank is available even in remote areas throughout the world. The top of these oildrums is often uncovered and therefore, this source of collected water is highly vulnerable to contamination by all the elements including dust as well as by animals that will seek this source of water. Moreover, the homeowners themselves will contaminate this source of water by using unclean buckets, ladles, or hands to obtain water from this source. Because minimally designed RRCS are used primarily in isolated areas and are not designed to maintain good water quality, this kind of RRCS will be excluded from further discussion.

Practically Designed RRCS

Figure 2 illustrates the popular Thai jar model used extensively in Thailand as an example of a practically designed RRCS. Practically designed RRCS generally result from previous experience. They are characterized as systems, which can be economically built on site, using materials readily available in that area and using a relatively simple construction technique. As most practically designed RRCS are used in developing countries where water is collected primarily for essential needs (drinking, cooking, washing), the water usage rate is low (5–20 liters/person/day) and the size of the cistern is relatively small. For example, the most popular Thai jar model has a volume capacity of 2,000–3,000 l and water programs in that country have promoted its use, its construction using ferro-cement, and design features to maintain water quality (1). For example, the tops of the jars are covered to prevent external contamination and a spigot is installed near the bottom of the cistern so water can be collected without contaminating the water in the cistern (see Fig. 2). The advantages of small-sized cisterns include their ease of construction, the ease by which they can be visually checked to determine when the jar is contaminated, and the ease by which these cisterns can be washed. The main disadvantage of these small tanks is that not enough water can be stored to maintain hygienic conditions in the home. Some households use multiple tanks to store larger volumes of water. Larger sized cisterns (10,000 l) are constructed in other parts of Thailand and in other parts of the world, but they increase the complexity in the construction techniques and increase cost. In summary, these practically designed RRCS represent the majority of the RRCS used throughout the world, especially in developing countries but also in developed countries as well.

Homeowners that use practically designed RRCS often lack many modern resources, such as electricity, to pump the water from the tank back to the house. Thus, the water must be collected from the storage tank outside of the house and brought back into the house where a household container of water is stored for household use (see Fig. 2). Because the total volume of stored water is of limited supply, all household utensils and hands of homeowners cannot be adequately washed. As a result, the container used to collect the water from the reservoir tank (cistern) is usually contaminated and will further contaminate the water before it is brought into the house. Within the house, use of unclean ladles, spoon, cups, and hands are some of the common ways by which post contamination of the water collected by RRCS occurs (2). This secondary contamination of water collected by RRCS is a common and serious problem but is not specifically related to the collection of rainwater by RRCS. This problem persists in all households that must transport water to their homes from an external source (rivers, wells), and then store water in the house for domestic uses.

Commercially Designed RRCS

Figure 3 illustrates a commercially designed RRCS that can be built on site or prefabricated by a private company.

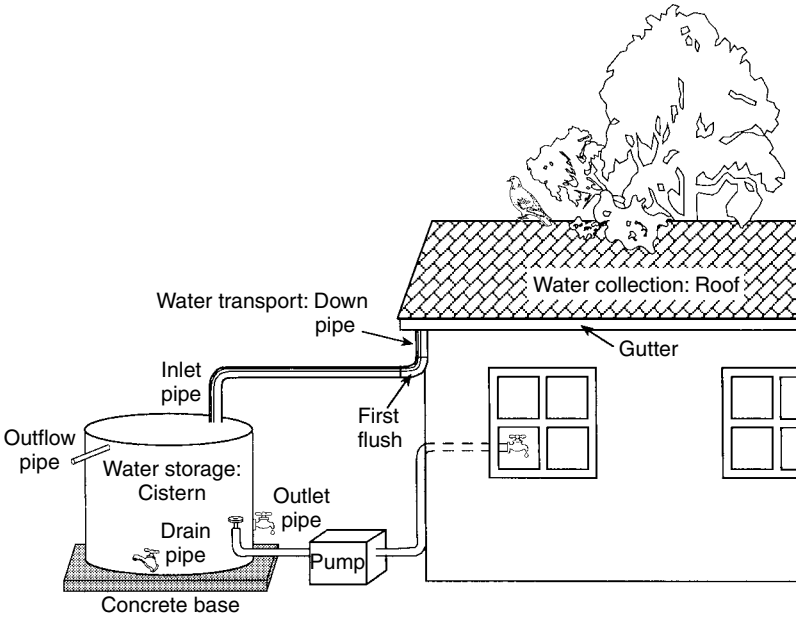

Figure 3. Example of commercially designed RRCS, showing the three major components (water collection, water transport, water storage) of RRCS, and subcomponents, including a pump to transport the water from the cistern back into the house via pipes and faucets.

These companies can manufacture RRCS using traditional and newer building materials (fiberglass). Because the services, materials, and transportation for commercially designed RRCS are expensive, these systems are primarily used by relatively wealthy homeowners. Even in developed countries, homeowners who use RRCS are generally not wealthy and will choose materials and design based on minimal costs. There are several advantages for homeowners in developed countries. The first advantage is the availability of commercially designed RRCS, which are built with good quality control and can be sized for the needs of the homeowner. In this regard, homeowners in developed countries are accustomed to using more water per capita (>200 liters/day/person) and therefore, they generally need to build homes with larger roofs to collect more rainwater and larger cisterns to store more water (e.g., 38,000 to 114,000 l). Some homeowners choose to have more than one cistern to store more water for household use and as a source to put out fire. The second advantage is that when cisterns run dry, private water purveyors are available to transport water to fill cisterns, although this is usually a costly option. The third and very important advantage is the availability of power supply and pumps so water collected in the cistern can be pumped back into the house via piping similar to houses receiving piped water (see Fig. 3). This option eliminates the serious problem of secondary contamination of the collected rainwater. Moreover, it enables homeowners to use many of the available technology such as in-line filters, point of use, and point of entry devices (3) that have been developed to improve the quality of water for homeowners with piped water. In summary, commercially designed RRCS have the potential of providing homeowners with a reliable source of relatively clean household water. However, the rainwater collection system of these commercially built RRCS is still susceptible to contamination by many of the same factors that contaminate rainwater collected by practically designed RRCS.

COMMON COMPONENTS OF RRCS AND THEIR IMPACT ON WATER QUALITY

All RRCS comprise common components and the design, the materials used, the maintenance, and the practices of the homeowners can affect the quality of the collected rainwater. The functional roles of each RRCS component and its susceptibility to contamination, especially with fecal matter, is discussed. The commercialized RRCS as shown in Figure 3 will be used as the model to illustrate each of the components.

The Water Collection Area: The Roof

For individual homes, the roof is the catchment or surface area, which is large enough and strategically located to collect rainwater (Fig. 3). However, because the roof is exposed, it tends to accumulate contaminants such as dirt, leaves, and fecal droppings of animals, especially birds. Trees, which overhang the roof, create additional problems because they are constant sources of leaves and branches, they provide a habitat for birds and insects, and they also provide a means for other animals (rodents) and insects to gain access to the roof. These animals often contaminate roofs with their urine, their fecal droppings, and occasionally their dead bodies. Deteriorating roof material and lead in paint are other known sources of contaminants from the roof. Thus, when it rains, all of the contaminants on the roof will pollute the collected rainwater. Of these contaminants, waterborne microbial pathogens are especially significant because they may be present in animal fecal droppings on the roof, they contaminate and survive well in water, and they may cause disease when ingested. Roofing materials made of smooth and nonwater absorbing materials (tiles, galvanized iron) reduce the accumulation of contaminants, whereas roofing materials made of rough and water-absorbing materials (wood, shingles, gravel) tend to trap more contaminants. Periodic washing of the roof can wash

away the contaminants but is usually not feasible because of insufficient supply of water and the difficulty of washing the entire roof.

The Water Transport System: Gutters and Downpipes

Gutters and downpipes serve to transport the rainwater collected from the roof to a storage tank (Fig. 3). Light-weight, smooth, nonporous, and nondegrading materials (plastics, aluminum, galvanized iron) are suitable. A particular problem with gutters is that all the contaminants on the roof are washed into the gutters and because gutters have only a slight slope, heavy debris such as dirt and leaves tend to accumulate in the gutters. This results in a habitat, which is conducive to the growth of insects, microorganisms, plants and favors the survival of fecal-borne pathogens. Thus, gutters often serve as the site for the concentration of contaminants. However, gutters are accessible to homeowners and periodic cleaning can greatly reduce the transport of contaminants to the cistern. Another means to reduce large-sized contaminants such as leaves from entering the cistern is to install filters, screens, or diverters on the downpipes. However, the actual use of these screens and filters is limited because they must be cleaned regularly to be effective and they can reduce the volume of water to be collected.

Recognizing that the initial volume of rainwater falling on the roof will be the most contaminated, a first-flush mechanism has been developed to collect and void the initial volume of the most contaminated rainwater before directing the subsequent volumes of cleaner water to the cistern. There are many designs of this first-flush mechanism and they are usually installed as part of the downpipe design (see Fig. 3). Mechanical, first-flush mechanisms are simple to operate but homeowners must be there during the first rainfall to void the collected water and to direct the subsequent flow of water into the cistern. There are two practical limitations to this device. First, homeowners cannot be relied on to be present to operate this first-flush device during the initial rainfall. Second, if this device is set to void, there is a danger that it will void most of water. Automated first-flush devices are more feasible because they are not dependent on timely operation by the homeowners. Although the use of first-flush systems is highly recommended, Gould and Nissen-Petersen (1) have reported that their actual use is limited.

The Water Storage Tank: Cistern

Because rainfall is not continuous, a water storage tank or cistern is required to store sufficient rainwater for future household use, especially during the long, dry periods. These cisterns must be large enough to store sufficient volumes of water based on expected household needs and frequency of rainfall to replenish the supply in the tank. Cisterns are usually built as a separate structure next to and below the roofline of the house. Although cisterns can be placed below ground level, most cisterns are built above ground as shown in Figure 3. To maintain the quality of the collected water, the top of the cistern must be sealed from external contamination. It should be noted, however, that many cisterns do not have a tightly sealed cover and many are covered with only a wire mesh material. These kinds of cisterns are highly susceptible to external contamination.

An example of an above-the-ground cistern with a sealed top and the four basic subcomponents is shown in Figure 3. The first component is the water inlet line, which is generally located at the top of the tank and serves as the port where the collected water enters the tank. To prevent external contamination at this point, this water inlet line should be sealed to allow only water to enter. However, in many cisterns, this intake line is not well sealed and any opening allows insects, animals, dust, microorganisms, and sunlight to enter the tank at this site. If significant sunlight penetrates this tank, it will induce the multiplication of cyanobacteria and algae, which can affect the esthetic qualities (discoloration, bad taste, bad odor) of the stored water. The second component is the overflow pipe that is placed near the top of the tank. This pipe is required to allow excess water to flow out of the tank and therefore this pipe is usually left open to the environment. However, this opening serves as an opening for insects, animals, and dust to enter the tank. Fine meshed screen can be made to cover this pipe opening, to allow water to pass, but prevent the entrance of insects and animals. The third component is the drainpipe that is placed near the bottom of the tank for the purpose of draining out the sediments. This pipe is usually closed and is only opened when the cistern is cleaned. The fourth component is the water outlet pipe that is usually closed but is opened to collect water for household use. This outlet pipe is located several centimeters above the drainpipe to prevent sediments in the cistern from being drained out with the water used by the homeowner. However, two conditions have been identified to cause sediment in the tank to become resuspended and to impair the quality of the water drawn from the cistern. First, when the volume of the water in the tank drops to such a low level that turbulence is caused by suction of water out of the tank and this causes resuspension of the sediment in the cistern. Second, when sediment accumulation in the tank reaches a level that is so close to the outlet pipe that the sediment is resuspended as water is drawn from the tank.

Water entering the cistern is already contaminated with particulate materials and microorganisms. Besides serving to store water, cisterns serve as settling tanks and self-purifying systems. Thus, most of the particulate contaminants that enter the tank will eventually settle to the bottom of the tank to form a layer of sediment. This process will clarify the stored water, which is used by the homeowner. Microbial contaminants such as fecal-borne pathogens are so small that it takes time for them to settle into the sediment and they often remain suspended in the water for long periods of time. If the homeowner ingests water contaminated with sewage-borne pathogens, there is a chance that the homeowner will become infected and diseased. However, most of the microbial pathogens are incapable of growing in the water stored in the cistern, and with time the pathogens will die due to physical, chemical and biological activities within the cistern. Thus, with time, the cistern serves as a self-purifying system.

In houses where power supply is not available, water is collected into buckets from the outlet pipe and carried into the house. This creates the problem of secondary contamination, which was discussed earlier. In houses where power supply is available, extension pipes are attached to this outlet pipe, and electrical pumps are used to pump the water from the outlet pipe to a piping system throughout the house (see Fig. 3). As stated earlier, piping the water back into the house avoids the serious problem of secondary contamination and enables homeowners to use many of the point of use and point of entry devices that have been developed to purify water for piped systems (3).

PROFESSIONAL ORGANIZATIONS AND GUIDELINES FOR RRCS

The International Rainwater Catchment Systems Association (IRCSA) is the professional organization that has been officially addressing all problems related to harvesting rainwater throughout the world (4). This professional organization held its first international conference in Honolulu in 1982 and has continued to hold biannual international conferences and to cosponsor other regional conferences on this subject. The most recent, the 9th International Rainwater Catchment System Conference, was held in Brazil in 1999. Proceedings from all of these conferences have been published and contain a wealth of information. More recently, another professional organization called GARNET (Global Applied Research Network) has initiated worldwide email conferences on specific problems associated with rainwater harvesting (5).

Anyone involved in harvesting rainwater should seek the assistance of IRCSA and GARNET. It is recommended that homeowners obtain examples of relevant research articles (2–8), booklets (9,10) and books (1,11) that specifically address how construction, design and maintenance of RRCS affect the quality of the collected water. Unfortunately, these publications are often too theoretical, too specific or too academic to be useful for most homeowners. The recent (1999) publication of a book entitled "Rainwater Catchment Systems for Domestic Supply" by John Gould and Erik Nissen-Petersen (1) is suitable for homeowners, builders of RRCS, and researchers because it is comprehensive, up-to-date and highly descriptive. Some of the recommended construction guidelines to improve the quality of the cistern waters are summarized as follows:

- Use nondeteriorating material characterized by smooth, nontoxic surfaces to construct roof, gutter, pipe, and storage tank. Rough surfaces will trap contaminants, and degradation of building material will contribute to water contamination. Aluminum, galvanized iron, clay, and other smooth, nonwater absorbing materials are recommended for roof material. Aluminum, galvanized iron, plastics, and copper are some of the materials recommended for gutters and pipes. Stronger and more durable materials, such as steel, concrete, ferro-cement, polyethylene and fiberglass, are recommended to build the storage tank or cistern. To prevent leaching of building materials and to retard biofilm growth, the inner walls of some tanks may be lined with vinyl or plastic material.
- Use lead-free construction materials (paint, nail, solder) because lead in drinking water is a definite health hazard, and water collected by RRCS is highly susceptible to lead contamination.
- Establish routine cleaning and maintenance of roof, gutters, and inlets to cisterns because these areas can be expected to become contaminated with dust, leaves from trees and droppings from birds, insects, geckos, and occasionally, the entire bodies of dead animals (birds, cats, rats).
- Use a first-flush mechanism near the downspout area to divert and void the initial volume of rain that contains most of the contaminants washed from the roof and gutters.
- Install screens, diverters, or coarse filters in the downpipes or at the inlet pipe to remove large debris, such as leaves, from being transported into the cistern. Be sure the cistern is covered and does not contain openings as ports for contamination. A wire mesh is recommended to cover the overflow pipe because this pipe is usually left open and this opening allows insects and small animals to enter the tank.
- Install filters to remove particulates and suspended matter from water drawn from the cistern because contaminants (heavy metals, pathogens, nutrients) are concentrated on particulate matter. By removing these particulates and suspended solids from the cistern water, the health risk to homeowners will be reduced. Moreover, this procedure will optimize the water for any subsequent disinfection procedures. In developing countries, a simple sand and gravel filter can be used to filter the water drawn from the outlet pipe. In developed countries, a ceramic filter can be placed within pipes leading from the tank back to the house. However, since these kinds of filters must allow free flow of water, their porosity will not remove all of the contaminating microorganisms, metals, and organic matter in the collected water.
- Because RRCS are vulnerable to contamination with microorganisms, disinfection is the only reliable means to consistently produce water that is microbiologically safe for household use. It should be noted that the obvious method of chlorinating water stored in a cistern has not been widely used and accepted because the homeowner must determine the dose of chlorine to add, which is dependent on both the quantity and quality of water in the tank. Moreover, the simple addition of chlorine to the tank does not ensure effective disinfection because mixing the chlorine in the water is a prerequisite for effective chlorination and this is not practical in a large cistern tank. If the water in the tank is mixed well, it will resuspend the sediment, which will decrease the quality of the water and react with the chlorine. Another problem is the input of additional contaminated water that can only be effectively disinfected by another treatment with chlorine. Homeowners generally feel that these requirements are too demanding. Moreover, the

strong taste of chlorine in chlorinated cistern water becomes unacceptable to most homeowners. Thus, many homeowners do not disinfect water stored in a cistern. There is a need for a more feasible means to disinfect water.

VULNERABILITY OF RRCS FOR MICROBIAL CONTAMINATION

A reasonable assessment can be made regarding the vulnerability of RRCS to microbial contamination of water stored in cisterns. Although rainwater is generally considered of excellent quality and suitable for drinking, anthropogenic practices related to agricultural, industrial, and urban activities have been shown to be responsible for air pollution in the form of particulates, sulfur dioxide, carbon monoxide, nitrogen oxides, hydrocarbons including pesticides, and lead (12,13). Thus rain falling in these areas of activities may also become contaminated with these atmospheric pollutants before it reaches the roof. Of these air pollutants, formation of acid rain is a serious problem. Acid rain is often produced by coal-fired electric plants (12), and is caused by the chemical reaction of rainwater and sulfur dioxide. However, some atmospheric pollution is due to natural causes. For example, the emissions from Kilauea Volcano on the island of Hawaii, state of Hawaii, has increased its venting of sulfur dioxide from approximately 80,000 m tons annually during periods of low activity to approximately 370,000 m tons of sulfur dioxide annually during high activity, which has covered the period from 1983 to the present (14,15). This increased level of atmospheric sulfur dioxide has exacerbated the problem of acid rain on the island of Hawaii. Acid rain causes lead to leach from building materials (paint, nail, solder) used in the construction of many of the 7,000 RRCS located on that island. This has resulted in increased levels of lead in cistern waters impacted by acid rain, and has raised concerns that the most susceptible population (children) who drink cistern water may be at risk. Under nonacid rain conditions, the leaching of heavy metals from roof materials is generally below health levels in the cistern waters, but remains a potential problem (16,17).

In contrast to chemicals, there is little evidence to show that microbial pollution of the atmosphere is a significant factor. Microbial contamination occurs during the process of collecting and storing water. Wind carries dirt and leaves onto the roof. Some animals (birds, gecko, rats, cats, insects) can gain access to the roof and will leave fecal droppings that are potential sources of pathogens to infect humans. Occasionally, these animals die on the roof and their bodies deteriorate on the roof or in the gutters. These materials, which accumulate on the roof and gutters, are resuspended by rain and transported to the cistern. If the cistern tanks are not completely sealed they become vulnerable to contamination, even during dry days. In summary, there does not appear to be any practical means to prevent the contamination of rainwater collected by the RRCS. Therefore, water collected by RRCS will be contaminated with microorganisms and nutrients. The degree of contamination will vary with each RRCS and will depend on multiple factors related to the design, the material used, the surrounding environment and the maintenance and treatment procedures used for each system.

Microbial contamination of cistern waters can have two detrimental effects. The first detrimental effect is to alter the esthetic quality of the water such as adding color, turbidity, taste, or odor. Although these changes may not be related to health effects, homeowners can easily detect this type of change in their water quality and will usually initiate action to address this problem. The microorganisms responsible for these changes in water quality are primarily those that grow under ambient temperature conditions such as in soil, water, plants, insects, reptiles, and worms. Microorganisms that can grow in these habitats represent numerous species and are generally nonpathogenic to humans. Many of these microorganisms can be cultured using general microbiological growth media and they are called heterotrophic bacteria. The concentrations of heterotrophic bacteria in cistern water can be used to estimate the overall quality of that water source. The second detrimental effect is when pathogenic microorganisms contaminate cistern water and affect its hygienic quality. Cistern waters contaminated by pathogens can transmit diseases to humans. Fecal-borne pathogens are the most likely to be transmitted by cistern waters because they represent a large and heterogeneous group (protozoa, bacteria, virus), survive for extended periods in cistern water, and infect humans as a result of drinking contaminated water. However, there are other kinds of potential pathogens, which can be transmitted by cistern waters via other means. For example, legionella bacteria are transmitted by aerosolized contaminated water, whereas acanthamoeba protozoa, adenovirus, and staphylococcus bacteria can cause infections of eyes and skin by direct contact with water, and leptospira bacteria in water infect humans by actively burrowing into broken skin or mucous membranes. Homeowners usually cannot detect that their cistern waters are contaminated with pathogens and will continue to use this water for most household and consumptive uses. There are numerous microorganisms that are pathogenic to humans, but only a few are likely to contaminate cistern waters at a given time. Moreover, they will not be able to multiply in the cistern water environment and will tend to die with time. Because many of these pathogens may survive for weeks in cistern waters, cistern waters contaminated with pathogens represent a definite health risk to homeowners.

AN ASSESSMENT OF THE MICROBIAL AND HYGIENIC QUALITY OF CISTERN WATERS

Because RRCS have been classified as private sources of water, no agency is responsible for the quality of cistern waters used for household purposes. As a result, most of the available data on the quality of cistern waters are based on studies conducted by research organizations such as those at universities rather than agencies associated with federal, state or county regulatory agencies. The available microbial monitoring studies for cistern waters

can be characterized as being conducted on a sporadic basis from many different countries, mostly from developing countries, because RRCS are used more extensively in developing countries. The reported studies from developing countries often represent studies conducted under very particular conditions, such as the surrounding environment, the building materials used, the design of RRCS, and the economical and hygienic status of the cistern owners. For studies assessing the microbial or hygienic quality of cistern waters, cistern water samples have primarily been analyzed for total coliform and/or fecal coliform bacteria because United States Environmental Protection Agency (U.S. EPA) (18) and WHO (19) have adopted hygienic standards for drinking water based on 0 total coliform per 100 ml and 0 fecal coliform per 100 ml. The microbial monitoring data show that although some cistern water samples can actually meet the coliform standard (20,21), most cistern water samples cannot meet the total coliform standard (17–25) and often contain very high concentrations of total coliform, fecal coliform and *Escherichia coli*. In addition to the coliform standard, U.S. EPA and WHO have recommended that drinking water should not contain more than 500 per ml of the total heterotrophic bacteria because higher levels of total heterotrophic bacteria can interfere with the enumeration of total coliform bacteria. In addition, concentrations of heterotrophic bacteria in drinking water reflect the nutrient level in that source of water and are used as an independent measurement of the overall quality of that water source. The available monitoring data show that concentrations of total heterotrophic bacteria in cistern waters often exceed 500 per ml (17–25) and provide additional data that cistern waters are susceptible to contamination, and that the quality of cistern waters does not meet the expectation of a good drinking water source.

Gould (26) recently reviewed the available monitoring and epidemiological data for cistern users and reported that although most cistern waters cannot meet the coliform drinking water standards, these results do not necessarily mean that this source of water is unsafe to drink. Gould points out that millions of people in rural areas around the world depend on rainwater for household use and the number of reported cases of serious health problems related to drinking cistern waters is very few. Gould (26) reports that the best documented study is the report by Koplan and associates, (27) of a salmonellosis outbreak at camp in rural Trinidad, West Indies, where 63 of 83 people developed gastrointestinal illness. In that study, epidemiological and monitoring evidence indicated that the collected rainwater was heavily contaminated by dried and fresh feces of birds that had accumulated on the roof of that house. The feces from these birds were concluded to be the most likely source of the salmonella causing the outbreak. However, this was not a typical RRCS used by a homeowner. Rather it was a system used only occasionally for a camp facility. It is unlikely that homeowners would allow the roof of their homes to become fully contaminated with feces of birds or to allow overhanging trees as a roosting place for birds. Thus, the results of this study do not apply to most RRCS used by homeowners. Less convincing evidence was reported to link drinking cistern waters with infections with other pathogens such as salmonella, campylobacter, giardia, and cryptosporidium (28).

Although the epidemiological method is the traditional approach to show that water is the cause of an outbreak, this approach is effective when large numbers of people are exposed to a common source. It is less effective in determining the risk of using cistern waters because the users represent a small number of people who are exposed to different sources of cistern waters, and these sources of water cannot be assumed to be of the same quality. Moreover, incidences of individual cases of illness among a small number of people are not reported to officials. Finally, cistern users often live away from urban centers, and medical services are not easily accessible. Moreover, many cistern users are susceptible to other sources of infections such as contaminated food. In the absence of good epidemiological data, Simmons and Heyworth (28) proposed that the microbial risk assessment (MRA) method be applied to predict the microbial health risks to people who consume cistern waters. This method estimates risk based on expected concentrations of pathogens, the likelihood of exposure to these pathogens in cistern waters, the vulnerability of the population exposed, and characteristics of the specific pathogen such as infectious dose and disease outcome. The rationale for this approach has been reports that several pathogens have been recovered from cistern water samples obtained from different countries. For example, salmonella bacteria and *Clostridium perfringens* have been recovered from cistern waters in Hawaii, (29), *Cryptosporidium* and *Giardia* from Virgin Islands (30) *Legionella* from Puerto Rico (31) and Kentucky (32), and *Leptospira* from Hawaii (33).

Using the microbial risk-assessment approach, Sasaki and associates (34) reported an association between the use of cistern water for household use and infections with leptospirosis in Hawaii. Using a similar approach, Eberhart-Phillips and associates (35) reported an association with using rainwater as a source of household water and incidence of campylobacter infections in New Zealand. These risk assessments studies are effective in linking drinking cistern waters with the likelihood of contracting specific diseases. The results of these kinds of studies are useful in establishing management decisions in the absence of other kinds of data. However, these kinds of data fail to address specific questions related to microbial water quality in specific RRCS and whether outbreaks of diseases occurred among users of this source of water.

RECOMMENDATIONS FOR MICROBIAL CONTAMINATION IN RRCS

Historically, the number of studies that have measured the microbial quality of cistern water samples have been limited and represent sporadic studies from various parts of the world. The results of these specific studies cannot be easily applied to predict water quality of RRCS used at other parts of the world because many of the conditions at a given study site differ significantly from other study sites. The cumulative results of all these studies show that RRCS

throughout the world are vulnerable to contamination with microorganisms and the water collected in cisterns cannot be expected to consistently meet the drinking water standards based on absence of coliform bacteria. Moreover, pathogens have also been recovered from cistern waters. However, there is little supporting evidence for serious disease transmission to people who consume cistern water, and most cistern owners generally consider their source of water to be of satisfactory quality for household and consumptive uses.

In summary, the problem of the quality of water collected by RRCS can be defined by the three most common questions. First, is the quality of most cistern waters safe for drinking and therefore, acceptable as a potable source of water? Second, if cistern waters cannot meet the established drinking water standard based on concentrations of coliform bacteria, should this source of water be declared as unsuitable for potable use? Third, is there a reliable, feasible, and inexpensive method to treat and disinfect all cistern waters to meet the coliform standard? Fourth, should a less stringent or alternative water quality standard be applied to assess the hygienic quality of cistern waters?

The results of most of the previously conducted studies could not adequately address the above questions because the studies collected only minimal monitoring data, and the studies evaluated RRCS from various sites around the world. Moreover, in many of these studies, questions regarding personal hygiene and secondary contamination of cistern water could not be adequately resolved. To adequately address these questions, researchers at the University of Hawaii have completed a series of comprehensive studies to assess the microbial quality of cistern waters in a community that offered several advantages. The first advantage is that the location of the study is in a country (State of Hawaii, U.S.) with high hygienic standards and effective environmental and health regulations to maintain a sanitary environment. Thus, many of the problems related to unhygienic conditions and contamination of food will play a minor role in assessing the microbial quality of cistern waters in this study. The second advantage is that the community is characterized as comprising relatively wealthy residents with large, expensive homes. The houses are provided with all modern conveniences except piped water from a public utility. Thus, most of the houses use commercialized RRCS with covered cisterns to obtain household water. Moreover, the water from the cisterns is piped into the house using pumps so water can be drawn from faucets in the houses, similar to houses that received piped water from a water utility. This eliminates the problem of secondary contamination. The third advantage is that this population of cistern users (approximately 110 houses) is stable, highly educated, and belongs to an active community association in which common problems are discussed. As a result, communication between the residents and with the researchers is good. The fourth advantage is that there was sufficient variety in the building materials used, the design used and the maintenance and treatment of the RRCS. The fifth advantage is that the quality of water from the cisterns of this community has been studied for more than 16 years. The sixth advantage is that the community is located only four to six kilometers from the University of Hawaii and therefore sampling and analysis of the samples could be completed expediently. The seventh advantage is that the microbial monitoring studies were comprehensive in that several different microorganisms were always measured along with other relevant parameters. Thus, the hygienic quality of cistern water was better defined than in most other studies. In summary, the conditions at this community were optimized for RRCS to collect high-quality rainwater. Using cistern waters from this community, experiments were designed to address the problems related to the hygienic quality of cistern users in both developing and developed countries throughout the world. The major conclusions and recommendations from these studies are summarized below.

Appropriate Microbial Water Quality for RRCS

The worldwide microbial drinking water standard for potable water provided by a water utility is 0 total coliform per 100 ml and 0 fecal coliform per 100 ml. This is a very stringent standard developed specifically for water utilities that have the resources and supporting regulations to use the most protected water source and the best technology to provide this drinking water product. These standards were not established for rainwater catchment systems and other private sources of water. Because water to be used for drinking should be safe, it is reasonable to expect that the same hygienic water quality standard should be applied to all sources of drinking water. However, there are large populations of people that are not provided piped water, and they must obtain water for their household use from alternative sources (wells, streams, rivers, lakes, rainwater). These populations are generally not provided funds, incentives and technical support to properly treat their water source. Recognizing that these populations must obtain water from an alternative source and that these sources of water will not be used by large populations, the WHO classified this alternative source of drinking water as a nonpiped source, and recommended a more practical bacterial water quality standard of not more than 10 total coliform per 100 ml (19).

Technically, RRCS are grouped with other nonpiped and generally unprotected sources of water. However, the vulnerability of RRCS to contamination by fecal matter differs significantly from that of surface (streams, rivers, lakes, wells) and groundwater sources that are highly susceptible to contamination by human feces (sewage) and animal waste. Historically, epidemics of waterborne diseases have been documented from contaminated surface and groundwater sources. In contrast, it is unlikely that the roof of houses will become contaminated with human feces and with the feces of most large land-dwelling animals. It should be noted that contamination of water by human feces results in the highest risk to transmit more diseases to humans because this source of feces may contain all fecal-borne pathogens, including human enteric viruses, enteric bacteria, and enteric protozoa. The contamination of water by feces with the larger, land-dwelling animals (cattle, pigs, sheep) results in moderate risk to transmit diseases to humans because these animals

produce large volumes of waste and may contain most of the fecal-borne bacterial and protozoan pathogens but not the human enteric viruses as these viruses infect only humans. In reality, relatively few kinds of animals (birds, rodents, insects) can gain access to the roof of houses and will contaminate this area with their feces. The feces of these animals will not contain human enteric viruses, but will contain fewer kinds of human pathogenic bacteria and protozoa. Moreover, these animals will generally produce relatively small volumes of fecal matter. Finally, soil and dust are common contaminants of roofs. In this regard, coliform bacteria, including *E. coli*, have been reported to multiply in the soil environment of tropical areas, and these coliform bacteria have a very low association with fecal-borne pathogens (36).

Based on the assessment of fecal contamination of RRCS, it can be reasonably assumed that the source of the coliform bacteria recovered from RRCS will not be from feces of human (high risk) or large ground dwelling animals (moderate risk), but from the limited number of animals (low risk) that can gain access to the roof or soil (very low risk). These assessments were supported by monitoring data from RRCS that showed elevated levels of total and fecal coliform bacteria from cistern water samples, but the general absence of two other fecal indicators (*Clostridium perfringens*, FRNA coliphages), which are always found with fecal coliform bacteria in sewage (37). Since concentrations of total heterotrophic bacteria are elevated in cistern waters, the assay for total coliform bacteria may be interfered with, whereas the assay for fecal coliform will not. On the basis of specific assessment for RRCS, Fujioka (38) proposed a more appropriate potable drinking water standard for RRCS based on 10-fecal coliform per 100 ml. This proposed standard takes into consideration the actual risk associated with concentrations of coliform bacteria in cistern waters and the need for homeowners with RRCS to have a reasonable chance of implementing improvements and disinfection procedure so rainwater can be used as a source of drinking water.

A Practical Approach to Disinfect Cistern Water for Household use

Recognizing that all RRCS are vulnerable to contamination with fecal bacteria, Fujioka (38) recommended that this source of water should be disinfected before it is used for drinking. Boiling the water is an acceptable method to disinfect the water, but this approach has been recognized as being too energy demanding. Thus, there is a need to find a practical, economical and reliable method to disinfect sufficient volumes of cistern water to meet the daily household needs. To address this need, Rijal and Fujioka (39) determined that the highest risk for disease transmission is related to consumptive use of cistern waters, such as drinking, and in the preparation of food. In comparison, there is a low risk associated with using cistern water for other household uses, such as bathing, toilet flushing, general cleaning purposes, watering of plants, and even washing of dishes if they are dried before use. In this regard, the volume of water used for consumptive use represents a minor fraction of the total daily needs.

A practical approach is to selectively disinfect the water to be used for consumptive purposes. In this regard, point of use devices such as small UV units can be placed under the sink to disinfect water flowing from the kitchen faucet. These under-the-sink UV units are readily available, are economical in cost, and can be easily installed. The advantage of UV is that overdosing results in better disinfection without affecting the taste and chemical properties of water. Moreover, UV treatment requires a short contact period and UV-treated water can be obtained directly from the kitchen tap. However, to overcome the electrical and maintenance cost of UV, one can selectively treat a set volume of water to be stored in bottles for daily use. Using this approach, the UV unit need only be used for an hour or less per day to treat the volume of water required for consumptive uses such as drinking, brushing teeth, and preparing food. This will greatly reduce the energy and maintenance cost and will extend the life of the UV system. Two of these, under-the-sink and UV units, were installed in two homes, and the cistern waters before and after UV treatment were assayed for various bacteria (total coliform, fecal coliform, *E. coli*, fecal streptococci, total heterotrophic bacteria). The results showed that these UV units were able to disinfect at least 99.9% of the fecal indicator bacteria in cistern waters. After UV treatment, total coliform and fecal coliform bacteria were no longer detected and therefore the treated cistern water was able to meet current drinking water standards (39).

Use of Solar Power to Disinfect Cistern Water

In developing countries, large populations of people live in places where electricity and piped water are not available. Under these conditions, RRCS are often used to obtain water. These communities require a reliable and economical source of renewable energy source. Fortunately, ample sunlight is generally available in places where people use RRCS. Sunlight is a readily available and renewable energy source. Several technologies have been used to harness this energy source for use by rural communities. Sunlight or solar energy can be used to disinfect water using three technologies. The first and simplest technology is to use the rays of sunlight to disinfect cistern water designated for drinking. If the cistern water is turbid, it should be clarified by settling or by filtration to remove the large particles. The water is then added to transparent bottles and the bottles are exposed to sunlight for several hours or an entire day. Several studies (29,40) have shown that this method effectively inactivates most pathogens, especially bacteria such as salmonella and fecal indicator bacteria (fecal coliform, *E. coli*, fecal streptococci).

The second technology is to use sunlight to heat the water to approximately 60 °C to attain pasteurization conditions. There are many economical solar-pasteurization units designed for rural use, and when properly used, solar-pasteurized water will effectively inactivate most pathogens and microorganisms. Fujioka and Rijal (41) evaluated the effectiveness of an inexpensive (approximately $20) solar pasteurization unit that is not dependent

on electricity and was constructed of durable material to treat 19 liters (5 gallons) of cistern water, stream water and stream water contaminated with sewage. Under sunny conditions in Hawaii, the water in this solar-pasteurizing unit reached pasteurizing temperature within three to five hours of exposure to sunlight and effectively disinfected the fecal indicator in all three types of water. Although practical and easy to use, the major disadvantage of solar-pasteurization units is the small volume of water that they can disinfect per day.

The third technology is to utilize solar energy to charge a battery that can then be used to power a UV system to disinfect water. The advantage of this system is that it can treat large volumes of water without the need for pumps or external sources of electricity. The disadvantage of this system is that its component parts are expensive and sophisticated and moreover, the system is fragile. However, the operation and maintenance of this system is relatively simple, and a trained person can maintain this system for a long period of time. A likely scenario is to train members of the family who live next to the well, from which the entire village obtains its household water, to operate and maintain this solar UV unit. Villagers will obtain water from this well and will be instructed by this family on whether the water needs to be prefiltered before it is poured into a vessel established at a predetermined height so the water will flow by gravity through the UV unit at a specified rate to be sufficiently dosed with UV. As time for disinfection is very short, the villagers can promptly take home their disinfected water, which should be suitable for consumptive uses. A small prototype of this solar-powered UV system that was able to process 1.5 l of water per minute was assembled at the top of a building at the University of Hawaii. Natural cistern water samples were then allowed to flow by gravity through the UV unit. Analysis of the water before and after this treatment with UV showed that 99.9% of fecal indicator bacteria (fecal coliform, *E. coli*, enterococci) and up to 99.999% of total heterotrophic bacteria (37) were inactivated. Thus, the treated cistern water was able to meet the current coliform drinking water standard. In summary, where electricity is not available, these solar power technologies can be used to disinfect cistern water.

A Homeowner's Test to Measure the Hygienic Quality of Cistern Waters

The hygienic quality of water is based on determining the concentrations of fecal indicator bacteria. All approved tests for fecal indicator bacteria require specialized laboratory equipment and trained laboratory personnel. Thus, the only way to determine whether the homeowner's cistern water meets drinking water standards is to send samples of this water to a certified water quality laboratory. This option is not possible for many owners of RRCS. Thus, there is a need for a simple test that homeowners can use to determine the hygienic quality of their water and the degree to which the water is contaminated with fecal bacteria. The test should be reliable in showing that treatment has disinfected the bacteria in the cistern water sample and rendered the water safe to drink. Of all the available methods, the presence or absence test for hydrogen sulfide–producing bacteria is the only simple and reliable test that can be conducted by the homeowner because this test does not require any special equipment such as a laboratory incubator. Moreover, the concentrations of hydrogen sulfide producing bacteria were shown to correlate with concentrations of total coliform bacteria before and after treatment of the water (37,41,42). The test can be carried out at a wide temperature range (20–35 °C) under ambient conditions.

To conduct this test, the homeowner will be provided with sterile and capped vessels containing filter papers with dried bacterial growth medium. These test vessels can be stored at room temperature for a year. To initiate this test, the homeowner opens the caps to two vessels and fills one vessel with 10 ml of cistern water and another vessel with 100 ml of that same water. Each of these vessels will have an etched mark to easily determine the level of sample to be added. The vessels are then capped and held at room temperature and read after 24–48 hours. The test is positive for hydrogen sulfide–producing bacteria when the filter paper and water turn black, an end point that is easy to read. When the 10 and 100 ml samples of water are determined to be negative, the quality of the water is assumed to meet the U.S. EPA drinking water standard of 0 coliform per 100 ml and the proposed RRCS water standard of 10 fecal coliform per 100 ml. When both 10 ml and 100 ml samples are positive, the quality of the water is assumed to exceed the two standards. However, if the 100 ml sample is positive but the 10 ml sample is negative, the water is assumed to exceed the current EPA drinking water standard of 0 total coliform per 100 ml but to meet the proposed cistern water quality standard of <10 fecal coliform per 100 ml. This test is recommended for homeowners because it will empower them to determine when the quality of their water is satisfactory and when it is not and how their own actions and treatment methods can affect the quality of their water. The feasibility of this test for homeowners and the reliability of this hydrogen sulfide test as a surrogate for coliform test have been previously determined (37,39,41,42).

CONCLUSION

Rainwater is a naturally clean source of water. However, much of it falls onto the ground, becomes contaminated, and flows out to sea without being used as a source of drinking water. As the supply of available freshwater for potable use becomes limited, the use of more rainwater for potable use should be encouraged. For many years, homeowners who live in remote areas where water is not provided by water utilities, have determined that collection of rainwater is the most feasible way to obtain water for household use. For some, no other reliable source of water is available. For others, alternative sources of surface and groundwaters are so polluted that the health risk of drinking these sources of water is extremely high. Although water collected by RRCS often contains elevated concentrations of coliform bacteria, this source of water is much safer than alternative sources of surface or groundwater sources in the area with equivalent

concentrations of coliform bacteria. This source of water has historically been used for all household uses, including drinking, and most homeowners accept this source of water as satisfactory and safe.

Government agencies have not addressed the water needs of homeowners who use RRCS because this source of water has been determined to be private and therefore outside the regulations and responsibilities of any government agency. When questions are raised regarding the quality of water collected by RRCS, the approach has always been to apply the same assumptions on water quality and the same expectation that this source of water should also meet the same microbial standard of zero coliform per 100 ml as has been established for drinking water provided by a water utility. This approach has discouraged the use of RRCS and the development of technology to improve the quality of water collected by RRCS. However, a realistic assessment of rainwater collected by roof catchment systems shows that the expected ratio of coliform bacteria to potential sewage-borne pathogens is low because only a limited number of animals can contaminate the roof with their feces and it is highly unlikely that sewage will contaminate the roof of houses. Thus, the potential of disease transmission in water collected by RRCS differs from that from surface or groundwater sources, which are susceptible to contamination by sewage and feces of man and many animals. A more realistic water quality standard for water collected by RRCS should be developed to encourage the use of this source of water. It is time for the government to implement a policy to encourage more effective use of all sources of water, including rainwater, and to ensure that all populations within a country obtain sufficient water of good quality. One of the steps to implement this goal is to designate a government agency to provide more education and assistance to homeowners who use RRCS and to encourage the development of better technology to improve the quality of rainwater collected by homeowners.

RED TIDES AND OTHER HARMFUL ALGAL BLOOMS

KAREN A. STEIDINGER
Florida Marine Research Institute
St. Petersburg, Florida

Harmful algal blooms occur around the world from New Zealand to Norway and from China to Europe in almost all seas, coastal waters, bays, and freshwater. In the marine environment, they have been known as red tides, although they are not always red or visible to the human eye, and not always associated with tides. So the term "red tide" has been a misnomer and its replacement "harmful algal blooms" (HABs) is more descriptive of the events that occur (1). The word "harmful" means that during toxic events, animals and humans can become sick or even die. In nontoxic events, there still can be impacts that affect community structure or even cause mortalities due to other factors, such as hypoxia. The second word "algal" means that algae, typically microscopic algae including phytoplankton, cause the harmful effect(s). The last word "bloom" means that the microalgae are at high enough concentrations in seawater to cause an impact, whether it is a fish or bird kill, toxic shellfish, sick marine mammals, or altered habitat and community structure. This concentration may be high enough to discolor the seawater red, brown, green, yellow, white, or other colors. In 1993, Sournia (2) estimated that there were 60 to 78 toxic species, or about 2% of the world's phytoplankton. Of the 100 or so toxic microalgae known today, over 70% dinoflagellates. The economic impacts from HABs are often difficult to determine, but a recent report (3) estimated that between 1987 and 1992, the average loss of revenue for a HAB in the United States was 49 million dollars (using Yr 2000 dollars). This is a conservative estimate. A breakdown of costs revealed that 45% was for public health impacts, and about 37% for commercial fisheries, 13% for tourism, and 4% for monitoring/management.

THE CAUSATIVE ORGANISMS (ALGAE)

Most harmful microalgal species range from several micrometers to 120 μm or so, and although many can be identified with a light microscope, some require the magnification of a scanning electron microscope or special processing in order to visualize specific characters. HAB species occur in the following botanical classes: Dinophyceae (dinoflagellates), Diatomophyceae (diatoms), Rhapidophyceae (flagellate), Prymnesiophyceae (flagellate), and others (4,5). There are several classification schemes available, and the use of one over the other is a matter of choice by the specialist.

Sample Preparation and Identification

Fixation and preservation techniques can be critical because some of the species are fragile and distort easily, for example, flagellates and some dinoflagellates (Fig. 1). Typically, field samples are collected and either handled live back at a central facility or fixed and preserved in 5 to 10% acidic or nonacidic Lugol's solution of iodine and potassium iodate or fixed and preserved in buffered 2% glutaraldehyde (GTA) (6–9). Nonacidified Lugols can keep many dinoflagellates in good shape for several years if the sample is refrigerated. If left to stand at ambient room temperature, the sample will only last several months and much of the material will clump. Once the solution loses its color and is clear, the sample is no longer preserved and will deteriorate rapidly. This can also happen if sodium thiosulfate is added to the sample to destain specimens in order to use other stains or see certain characters. Again, it is best to add Lugol's to the sample in order to preserve it, or, to preserve it in buffered formalin. Buffered GTA is a good fix for some flagellates and dinoflagellates, but there can be distortion and samples have to be refrigerated. For scanning electron microscopy, Lugol's fixed material can be post fixed with paraformaldehyde and processed following standard techniques (Paula Scott, FMRI, personal communication). This technique has been applied to both dinoflagellates and diatoms. For toxic pennate diatoms, it is best to clean the frustules for light microscopy or SEM (10). The best techniques allow the processing of live material, for example, for unarmored dinoflagellates such as *Karenia*, the best fixation protocol is a combined GTA-OsO4 fix in the cold at 4 C, but the sample has to be adjusted for osmolality (9). This cannot be done in the field, so live samples are collected

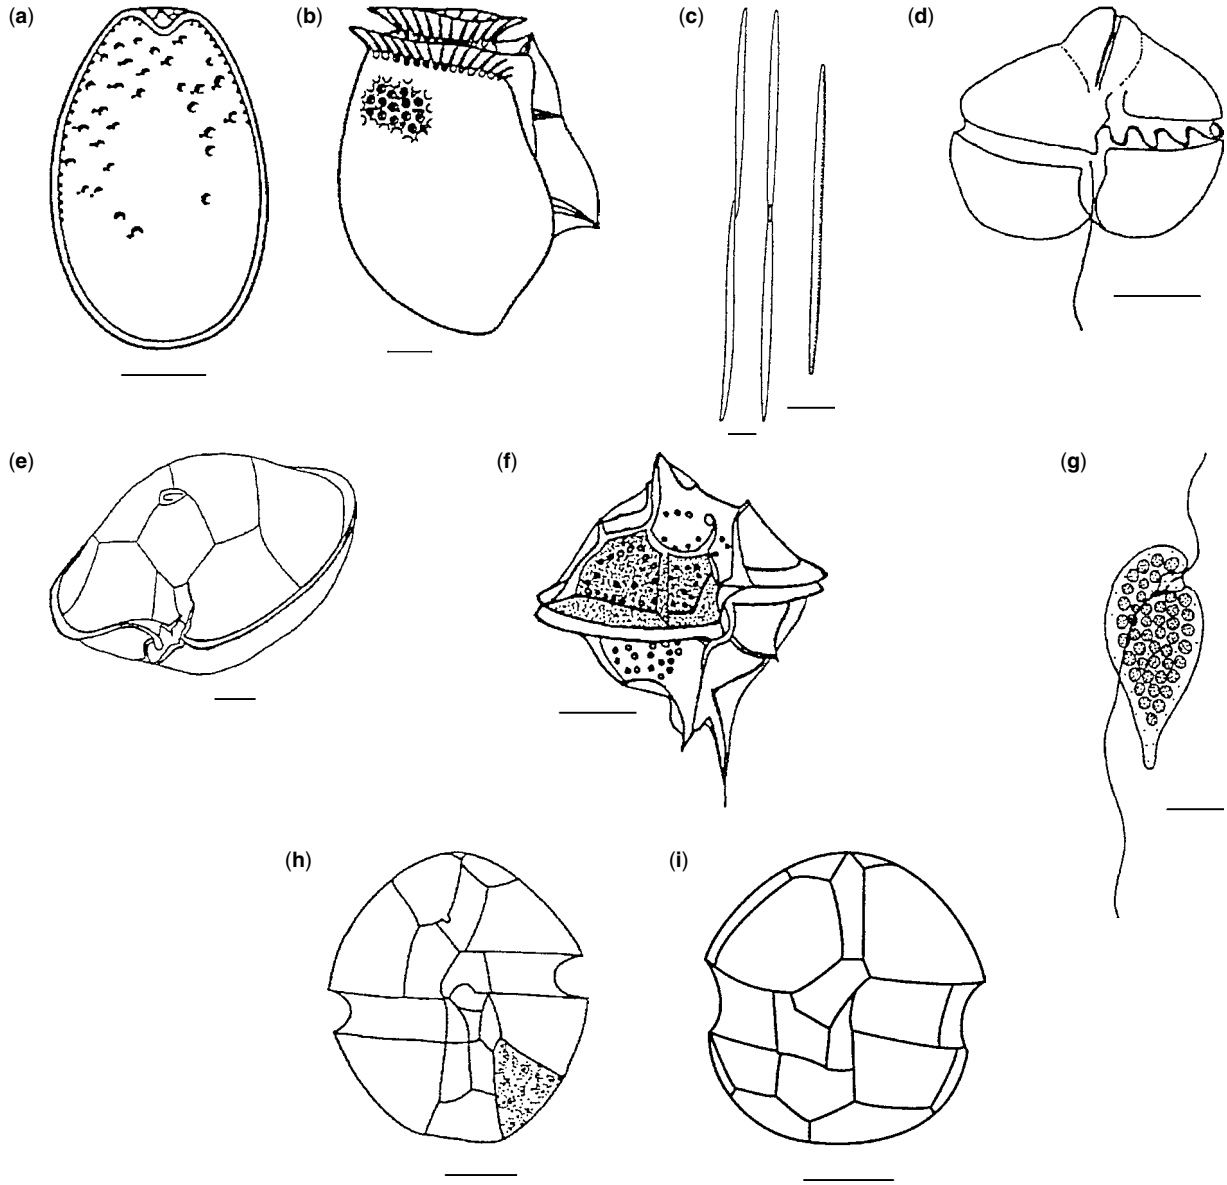

Figure 1. All scale markers = 10 m. Figures after K. A. Steidinger and K. Tangen, *Identifying Marine Phytoplankton*, Academic Press, San Diego, Calif., **1997**, pp. 387–584. in containers, which are wrapped in wet paper to keep them at ambient temperature. If samples are shipped by overnight express, HAB species are usually alive and well and ready for fixation. The added advantage to live samples is that the investigator can see cytological, and often some morphological features clearly, for example, color, nucleus, and shape, as well as swimming behavior of a flagellate or dinoflagellate. These can be critical observations.

Knowing the identity of the organism can often (*Gymnodinium breve*) pinpoint what toxins are involved. For example, *K. brevis* and *K. brevisulcata*, both produce brevetoxins as do other to be named *Karenia* species and these toxins have been found in edible bivalves. Another (*Karenia* species) produces gymnodimine, a nonpolyether toxin. Several rhapidophytes in the genus *Chattonella* also produce brevetoxins. In Florida, the *Karenia* are typically neritic species, while *Chattonella* are typically estuarine (11); however, their distribution can be wider. Toxic *Chattonella* occur in high numbers where there are edible shellfish; however, no human illness has been associated with these blooms to date. Other rhapidophytes such as *Fibrocapsa* and *Heterosigma* reportedly produce brevetoxins as well. In addition, there can be toxic and nontoxic isolates of *C. subsalsa* and probably other *Chattonella*. To date, there have been no

nontoxic isolates of *K. brevis*, but that is not true for other dinoflagellates. *Gambierdiscus toxicus* has toxic and nontoxic strains as does *Alexandrium tamarense*, both armored dinoflagellates. In the case of *G. toxicus*, which was a monospecific genus until recently (12), differences in toxicity can be found in the same geographic locale.

Pfiesteria piscicida, a thinly armored dinoflagellate that is a heterotroph capable of phagocytozing other plankton and even attaching to fish, has been associated with fish kills in the mid-Atlantic states (13–15, see also *Pfiesteria*: The Toxic Pfiesteria Complex, this Encyclopedia). It produces a water-soluble ichythotoxin that is as yet uncharacterized (16). There are several other non-*Pfiesteria* lookalikes, which can easily be confused with the fish-killing *P. piscicida* at the light microscope level, but they can be differentiated at the SEM level (17). This becomes important if cell counts of undifferentiated *Pfiesteria* species and *Pfiesteria*-like species, commonly called PLO counts, are being used as a screen for processing and treating with further protocol. In addition, there are molecular probes that can identify and quantify *P. piscicida*'s presence in water or sediment samples, even preserved samples (18–19). To produce toxins, *P. piscicida* needs exposure to fish as a stimulant; however, not all isolates become toxic. So again, there are toxic and nontoxic strains (20). The age of the culture is also important. Burkholder and Glasgow have found that isolates can lose their toxicity after six months to a year. So, although specific toxins or toxin activity has been associated with known species of dinoflagellates, flagellates, and diatoms, the presence of a specific species does not automatically mean it is toxic, rather it means there is the potential for toxicity and harmful effects to living resources and even to humans. All surveillance programs should have the capability of isolating HAB species, testing them for toxins or toxin activity, and looking at any variability in toxin production and potency, geographically, providing the toxins are characterized.

Molecular Techniques for Identification

As more HABs occur, as more surveillance programs are implemented in shelf and bay waters, and as fewer taxonomists emerge to face this challenge, the efficacy of rapid assays or probes is being realized. This can be inferred by available protocols, kits, and the increased number of DNA gene sequences for HAB species on GenBank (*www.ncbi.nim.nih.gov/web/Genbank*). New molecular technology in the form of nucleic acid or other biochemical probes is making identification of HAB species less complicated and less time consuming. Microscopic examination is typically lengthy and can require an expert for the final species identification, while a DNA probe designed for that specific species can accurately detect very low quantities of a specific species, or even a specific strain. The potential for the new probes is tremendous; not only can they be used in the laboratory, but also they can be adapted and configured for automated instrument packages at sea (21). Some probes have been shown to cross react with other species within a group and are less specific, but often this can be resolved. The most promising aspects of this new technology are accuracy without an "expert," rapid results, and *in situ* results from a buoy at sea or a platform in an estuary. The different probes use different approaches, such as antibody-antigen reactions and different ways to visualize the results, for example, chemiluminescence or epifluorescence. The technology is advancing on a daily basis using a variety of nucleic acid methods, for example, polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP), and sandwich hybridization for detecting specific nucleic acid sequences from cell homogenates (22,23). In addition, cell surface recognition enzyme-linked probes targeted for proteins such as lectins, have worked with whole cells where there can be a colorimetric or chemiluminescent reaction.

EFFECTS AND IMPACTS (HARMFUL)

Many HABs are associated with the shellfish poisoning of humans (24–26). If shellfish, such as oysters and clams, are exposed to a HAB, they can filter out the microalgal cells/particles with toxins and become toxic to humans that consume them. The most noted shellfish poisoning is Paralytic Shellfish Poisoning, and it occurs worldwide with a historic human mortality rate of about 20% of those affected. Today, with good surveillance and control programs, shellfish poisoning incidents are lower, except where they are new events, and resource and public health managers are not prepared. The United States Food and Drug Administration requires that states that ship shellfish interstate have a biotoxin control program that involves surveillance and testing protocol that would monitor shellfish growing areas for HABs and their toxins (27, see also Cyanobacteria-Toxins in Drinking Water, this Encyclopedia). Paralytic Shellfish Poisoning (PSP) has specific causative organisms, most of which are dinoflagellates, which produce the toxins saxitoxin, neosaxitoxin, and/or gonyautoxins. Cyanobacteria or blue-green algae are also known to have saxitoxin, as are nonpigmented bacteria. PSP occurs in the waters of the United States, Canada, Mexico, Central America, South America, Africa, Europe, Scandinavia, the Mediterranean, and the Pacific, Malaysia, Philippines, Japan, China, India, and elsewhere (25,28). Of all the HABs known, PSP is associated with the most human mortalities and is the most widely distributed. However, it is not alone. There are other shellfish poisonings such as Neurotoxic Shellfish Poisoning (NSP) caused by brevetoxins produced by gymnodinioid dinoflagellates such as *Karenia* (fish kills, bird kills, marine mammal mortalities, airborne respiratory irritant, and human illness, but not human mortalities) (29,30). Another type of poisoning is diarrheic shellfish poisoning (DSP) which is also caused by dinoflagellates, for example, some species of *Prorocentrum* and *Dinophysis* (Fig. 1a and 1b). The toxins associated with these dinoflagellates are also thought to work in synergy with viruses or other agents to promote tumors in vertebrates and mammals. A fourth type of shellfish poisoning is known as Amnesic Shellfish Poisoning (ASP) and is caused by another microalgal group known as diatoms; the most notable species are in the genus *Pseudo-nitzschia* (Fig. 1c). This type of poisoning has caused

severe effects in humans, such as permanent or short-term memory loss and death. The most famous cases occurred at Prince Edward Island in 1987 and represented the first recognized Amnesic Shellfish-Poisoning event. Although this poisoning has had its most notoriety by causing human amnesia, the toxin domoic acid has been associated with marine mammal and bird kills in California (31,32), again produced by the diatom *Pseudo-nitzschia*.

Toxins associated with shellfish toxicity, such as saxitoxin, brevetoxins, domoic acid, and okadaic acid, have also been implicated in living aquatic resource impacts. The death of pelicans and seals off California due to domoic acid are just two examples which illustrate one path of intoxication. Typically, illness and death are due to the transfer of toxins through the food chain. In the case of the pelican deaths, pelicans ate anchovy, which had eaten and accumulated the toxins from *Pseudo-nitzschia*. Toxins such as saxitoxin, which is best known for bioaccumulation in shellfish (and consequently impacting humans), can accumulate in zooplankton and ultimately affect larval fishes and larger animals (33). If in any of the "who eats who" scenarios there are toxic microalgae, there is the likelihood of bioaccumulation and effects further up the food chain. There are other effects less well known but certainly experienced by beachgoers when there is a Florida red tide caused by *K. brevis* (Fig. 1d). With blooms of this organism and some other gymnodinioids, the toxin adsorbed to particles can become airborne in sea spray (34) and create respiratory irritation. Beachgoers can be affected for the time of exposure; however, the symptoms of coughing and tearing usually disappear when people are no longer exposed to the irritation. Occasionally, some people will experience contact dermatitis from being in the water. The question being asked today is whether there are any long-term chronic effects of exposure, and this is being investigated by an interdisciplinary team headed by D. Baden of the University of North Carolina at Wilmington (personal communication). Very few epidemiological studies have been done on people exposed to HAB toxins over long periods, and therefore little is known about chronic effects over a lifetime.

Ciguatera, known as tropical fish poisoning, occurs in tropical and subtropical areas of the world (25), and is caused by dinoflagellates such as *Gambierdiscus* sp., notably *G. toxicus* (Fig. 1e). There are several aspects of ciguatera, which make it different from the other types of poisoning. Although ciguatoxin is a polyether compound related to brevetoxins, the ciguatoxin does not kill fish (that we know of), rather it accumulates in the muscle tissue as well as organs. In most of the other cases of bioaccumulation, for example, saxitoxin, brevetoxins, and domoic acid, the toxin is found in the digestive tract and organs like the liver or kidneys but not in the muscle or flesh of fish. That is why there are few effects on humans from eating fish exposed to the other toxins. In many parts of the world, fishermen fillet their catch and discard the entrails. In countries where fish are eaten whole and there are events like PSP, (for example, southeast Asia) (35) there have been human mortalities associated with eating whole fish exposed to toxic *P. bahamense var. compressum* (Fig. 1f). But with ciguatera, the toxin ciguatoxin and other toxins accumulate in the muscle tissue so that filleting the catch is not a protective procedure. There are more than 175 reported human symptoms (36,37) associated with ciguatera around the world. It is thought that this is an indication that more than one toxin is involved (38) and there has been speculation on okadaic acid, palyotoxins, prorocentriles, histamines, and other types of bioactive compounds contributing to the symptomology. The confounding aspect of ciguatera is that victims can have a recurrence of the illness years after the first insult, and the illness can be very debilitating. Of course ASP also has long-term effects. Typically with PSP, NSP, and DSP, the effects are over within several days to a week.

Toxins and Their Detection

Phycotoxins or biotoxins can be neurotoxic, cytotoxic, hemolytic, or cause immunosuppression (25). With many of the neurotoxins, activity is at the sodium or calcium channel of nerve and muscle membranes (39). These toxins can close or open channels and cause an imbalance that interferes with nerve transmission or muscle relaxation/contraction. There are specific sites in the channels where the toxin molecule binds, and this known activity has been used in designing analytical tests for the biological activity of the toxin. For example, with brevetoxins that cause marine animal mortalities, a receptor-binding assay with a tritiated toxin analog is used. The natural toxin actively competes with the analog for a specific site on sodium channels in rat synaptosomes (40–42). There are a variety of toxin assays, like an ELISA, (enzyme-linked immuno sorbent assay), which can detect the toxin itself (not its activity) in the nanogram range, and quantify the concentration with a color reaction that is read on a plate reader that interprets colorimetric density. Other detection methods utilize high performance liquid chromatography (HPLC) and variations of HPLC to enhance its capabilities as well as LC- mass spectrometry. More recently, a very sensitive test (micellar electrokinetic capillary electrophoresis with laser-induced fluorescence) with detection limits of picograms has been developed and used in looking at the transfer of toxins through the food web (43).

Most toxins are considered secondary metabolites (44) that may have had or still have a function. For example, toxins could protect their host from UV light, or actually be an intracellular nutrient store. Or, they could inhibit other species by being toxic to predators, or being alleopathic to competitors. More recently, their role as a siderophore is being reevaluated. Domoic acid in toxic *Pseudo-nitzschia* species has recently been shown to act as a siderphore and bind trace metals such as iron and copper. Through binding, it can make trace metals available for cell metabolism, or remove trace metals which may be toxic (45). Toxin production in HAB species can vary depending on environmental cues, such as stress, including phosphorus limitation (46), light and salinity (47), or cell cycle stage and differences in genetic strains.

A recent review, "Seafood and Freshwater Toxins", (39) gives an excellent description of toxins produced by

harmful algae. HAB toxins typically have gastrointestinal (diarrhea, nausea, vomiting), neurological (lethargy, disorientation, paralysis, loss of short-term memory), and/or hemolytic effects on animals. The most potent of the marine nitrogen-containing toxins (there are also non-nitrogen-containing low molecular weight toxins) is palyotoxin, produced by the dinoflagellate *Ostreopsis siamensis*, with an LD50 (μg/kg) of 0.5 compared to gymnodimine, produced by *Karenia* species, which has an LD50 of 450 μg/kg. Many HAB species produce multiple toxins, such as the dinoflagellate *K. brevis* that has nine brevetoxins. Brevetoxin B has an LD50 of 60 μg/kg, compared to brevetoxin B2 which has an LD50 of 300 μg/kg. Brevetoxin B blocks neuromuscular transmission, and when this happens in the diaphragm muscle of an animal, the animal can die from respiratory failure. *Karenia brevis* and related brevetoxin-producing dinoflagellates are not the only HAB organisms that produce brevetoxins, *Chattonella* (Fig. 1g), *Fibrocapsa*, and *Heterosigma* species do as well (6,11). Not only do different toxins produced by the same species have varying potencies but also different isolates of the same species can have different proportions of toxins and different potencies. One recent finding that has a public health implication is that shellfish, and other animals that take up HAB species and their toxins, can actually metabolize the toxin(s) and alter the toxin structure and activity, which can make detection difficult depending on the method (48). The mouse bioassay method is the accepted "gold" standard for public health issues (6,27), but there are a variety of methods for chemical detection which involve very sensitive methods. Kits for several toxins are now available that can be used in screening protocol (6). Scientists are seeking a rapid, effective alternative to the mouse bioassay for certain toxins. These alternative methods will have to be compared against the mouse bioassay results to insure adequacy in protecting public health.

In some cases, it is debated as to whether the HAB species itself or endo- or exocellular bacteria produce the toxins (49,50). Bacteria within residual or accumulation bodies, such as in some mixotrophic *Alexandrium* (Fig. 1h), may represent a symbiotic association, whereby the intermediate products in bacterial metabolism might produce the precursors for saxitoxins. However, dinoflagellates have been shown to have toxin genes and are able to produce toxins on their own without bacteria.

BLOOMS

Although this review deals specifically with microalgal blooms, there are macroalgal blooms of *Codium*, *Gracilaria*, *Ulva*, and other green, red, and brown algae that can be nuisance blooms (1). They may impact living resources through creating turbidity, high organic loads and low dissolved oxygen, stranding organisms in wrack lines, and altering food webs; however, they have not been associated with public health risks or known illnesses. Most of these large biomass events occur in bays or lagoons, but can occur in open shelf areas, like the seasonal accummulation of "June Grass," on the northwest Florida shelf. Other nuisance blooms can be ascribed to microalgae as well, where the species does not produce a toxin but its abundance can cause the same effects of the macroalgal blooms, for example, turbidity, altering food webs, and even affecting reproductive success in marine animals. One such bloom is known as "brown tide." In Texas, the causative organism is *Aureoumbra lagunenis* while in the northeast United States, it is a related species known as *Aureococcus anophagefferens*. Both are pelagophytes, which have adapted to changing environments of reduced flushing, elevated salinities, and are efficient at nutrient uptake (51–55). For these blooms to continue as they do, there has to be reduced grazing pressure.

Microalgal Bloom Detection

Microalgal blooms can occur in two marine realms, the pelagic and benthic realms. Pelagic covers most of the vertical water column, whereas, benthic means the bottom, whether it be a hard bottom such as reefs or outcroppings, or a soft bottom such as sand. These organisms can be free in the water or attached by mucilaginous strands or sheaths to a substrate such as a macroalgal frond or seagrass blade. In the pelagic realm, the microalgae are typically known as phytoplankton because they contain photosynthetic pigments and are planktonic. The blooms can often be visualized when cell concentrations are high because of the chlorophyll and accessory pigments. For Florida red tides caused by *K. brevis*, cell concentrations in the millions can be detected by surface discoloration, whereas a satellite over 400 miles above earth can detect concentrations at 10^5 cells per liter of seawater. In this case, the color sensors aboard the satellite are more sensitive than the human eye (56). Detection of bloom concentrations is a forewarning of potential harmful effects. There are several methods of detection currently available. Sentinel stations provide a monitoring program with the ability to monitor the water as well as resources for HAB species or their toxins. States impacted by HABs typically have monitoring programs which test shellfish meats for toxins, and then those growing areas are regulated based on a threshold level of toxin in meats. Or, monitoring programs test the water using microscopic or molecular probe techniques. These programs, if sampling is frequent enough, provide adequate warning. As was discussed earlier, sensors aboard satellites can detect chlorophyll concentrations at certain levels. Usually, this means that a pelagic bloom, in order to be detected, is already established in surface waters. With this technology, the bloom can be tracked and, in concert with other parameters like wind direction and intensity, its movement may be predicted. Satellites also have sensors that can detect sea surface height, sea temperature, and other physical variables that can be used in predicting the physical and meteorologic setup of bloom initiation and initial growth (57–60). Blooms of benthic species are typically not obvious without collecting substrate such as macroalgae and determining the abundance of the attached microflora. Occasionally, benthic species can become pelagic with disturbance of the bottom sediments, dislodging and floating of substrate, transport of cells by gas bubbles from the bottom, or just migration into the

water column. This happens with *G. toxicus* and *P. lima*, two well known benthic species. With many HAB species, there is coupling between the pelagic and benthic realms beyond the species habitat preference discussed earlier. In this scenario, a pelagic dinoflagellate or other HAB species can produce a benthic resting stage known as a cyst or zygote. These resting stages can lay dormant for months or years and still be viable, unless they are buried too deep in the sediment by sedimentation or reworking.

Sequential Bloom Development Phases

Steidinger (61,62) introduced the concept of sequential bloom development stages: initiation, growth, maintenance, and termination. Although this applies to the sea, it is mimicked in the laboratory with the culturing of microalgae. In an artificial culture, populations of species are studied in an enriched artificial growth medium. First, there is the inoculation of cells into the medium. This is followed by a lag stage in which the population adjusts to its new environment and can even condition the water for its growth. After the lag phase comes a log phase, where there is exponential growth until the population peaks. This plateau can be maintained for some time until the culture goes into senescence. This initiation phase (63) in nature requires that there be an inoculum of the HAB species. This could be from benthic resting stages where cells excyst and come out of this stage and become planktonic in the pelagic realm. Or, the inoculum of cells can come from another area, in essence be introduced. This can happen via water mass movement such as oceanic intrusions, eddies, even ballast water and sediment discharge. Once there is an inoculum, then the ambient conditions have to be such to support growth of the initial population and this will require a certain level of major and minor nutrients, including organics. The growth phase (63) of a bloom involves competition with other species and outcompeting them, particularly if the bloom is near monospecific, for example, 80 to 98% of the microalgal population being dominated by one species (64). In this phase, population growth has to exceed loss factors such as advection, cell death, predation, et cetera. Once the gains exceed the losses, there is a developing bloom. When the bloom reaches high concentrations, for example, Florida red tides in the millions of cells per liter of seawater, then the maintenance phase (63) supports high biomass through physical concentration by winds and currents, as well as adequate available nutrients to support the higher biomass volume. During the initiation to growth to maintenance transitions, the *K. brevis* blooms are often being moved across the shelf from the mid-to-inner regions. Recently, it has been speculated that, at least for Florida red tides, there is a chemical-biological-physical coupling, which promotes large events. Walsh and colleagues (65,66) have shown by an analysis of historical data that wet deposition of Saharan dust precedes cyanophyte blooms of *Trichodesmium erythraeum* on the west Florida shelf. It is known that *Trichodesmium* (a N_2 fixer) precedes and co-occurs with *K. brevis* blooms, and there was speculation that this cyanophyte conditioned the water for such dinoflagellate blooms (67,68). Now it is a matter of establishing whether the dissolved organics released by this nitrogen fixer support growth of *K. brevis* directly or indirectly. It has been established that inorganic nitrogen is not at a supporting level on the midshelf, but that organic nitrogen is high enough to support bloom concentrations during blooms (69,70). Vargo and colleagues speculated that phosphorus, caused by the abundance of nitrogen, was the limiting nutrient inshore where blooms have their most significant harmful effects. *Trichodesmium* blooms in the open sea can be larger than *K. brevis* coastal blooms and over 50% of the nitrogen fixed daily by this cyanophyte is excreted as dissolved organic nitrogen (71,72). Such a large amount of new nitrogen can be used by the associated heterotrophic community as well as by successional species (73). The last phase, termination phase (63) has also been known as the dispersal phase and is really not well understood. Why do blooms disappear? Where do they go? Are they advected out of an area by currents, winds, or other physical means? Do they just form resting stages and settle out of the water column? Do marine viruses or bacteria attack and kill them? Different HABs may have different termination mechanisms, for example, some of the *Alexandrium* species that cause PSP have vegetative cells, which undergo sexual reproduction and produce zygotes that settle out of the water column into the sediments. These zygotes excyst sometime later when conditions (light, temperature, D.O.) are suitable (74,75). In many cases, cyst dormancy is entrained, and to have encystment out of seasonal cycles means that the entrainment has to be broken.

CONCLUSION

Harmful algal blooms occur worldwide and are principally caused by microalgae, which produce bioactive compounds such as neuro- or cytolytic toxins that can cause illness and death in animals and humans. The intent of this review is to give the reader an introduction to these events, so they can seek further information if they desire. Today, because of Internet access, information on HABs is readily available and updated. In some cases, abstracts, papers, and even manuals can be downloaded from web sites. Key words would be red tide, brown tide, harmful algal blooms, ciguatera, paralytic shellfish poisoning, diarrhetic shellfish poisoning, amnesic shellfish poisoning, neurotoxic shellfish poisoning, fish kills, mass mortalities, phycotoxins, biotoxins, *Gymnodinium*, *Karenia*, *Alexandrium*, *Pyrodinium*, *Gambierdiscus*, *Dinophysis*, *Prorocentrum*, *Pfiesteria*, *Psuedo-nitzschia*, *Heterosigma*, *Chattonella*, *Prymnesium*, *Aureococcus*, and *Aureoumbra* as a start. For web sites, two are listed that have many links to other HAB sites, *http://www.floridamarine.org* and *http://www.whoi.edu/redtide*. One of the questions that will appear on these sites is whether harmful algal blooms are increasing in frequency. The answer is not as straightforward as might be expected. It is a split verdict—yes and no. Yes, new areas are being affected, it seems, every year. In 1972, a Canadian *Alexandrium* bloom was transported down to the northeast states and advected inshore where it established resident populations through cysts on the bottom. Was this species there before this inoculation? Probably, but it did not bloom

and did not cause obvious shellfish poisoning, maybe because of low cyst density. In the 1970s, the Pacific experienced *P. bahamense* var. *compressum* blooms that spread from Papua New Guinea to other areas such as Malaysia and the Philippines (35). Did currents and winds and upwelling/downwelling events cause this? What was the origin of the Central America *P. bahamense var. compressum* blooms in the Pacific? This armored species, as well as unarmored gymnodinioids found in New Zealand, and new benthic armored species associated with ciguatera endemic areas, account for many of the new areas affected by planktonic HAB species. Most of these species were "discovered" as new, although they probably existed there before, and were never studied and differentiated. *Pseudo-nitzschia* blooms in the Pacific and Atlantic are now causing concern, where several years ago no one knew they were toxic. There are established species that were not known to be toxic, and there are "new species" that were not known to be toxic and cause risk to natural resources and public health. Smayda (76) referred to the "new species," (which had not caused problems) as the hidden flora meaning that they were there all the time, just not stimulated to reach bloom concentrations and cause an impact. Today in some areas actual frequency of blooms is lessening or in the down cycle, but clearly in other areas HABs are increasing in frequency, as in New Zealand. Or in some areas, one HAB species may not be blooming whereas another has taken its place. It would appear that each geographic area needs to be considered separately in relation to the historical record, if there is one, and in relation to transport and inoculation mechanisms. Earlier, ballast water was mentioned as a mechanism. It is documented that ballast water (and sediment) can transport resting cysts of *Alexandrium*, and that Australian and Japanese populations of *Alexandrium catenella* and *A. minutum* are the same genetically (6,22,77–79) The inference being that toxic microalgae, in a resting stage, can be transported via ships and if receiving waters are suitable, they can survive and grow. Introductions of exotic species, and in some cases pathogens, show that if receiving waters are suitable, a toxic or nuisance alga can become established and cause resource, economic, and public health risks.

The introduction of harmful algal bloom species whether by natural processes, for example, currents and winds, or human related events, such as ballast water, shellfish stock transplanting or aquaculture product movement, is a concern. There are surveillance programs that can be expanded, integrated, and enhanced to accomplish detection and quantification of HAB species or their toxins. In time, hopefully, autonomous instruments that can measure environmental variables and HAB species will be aboard buoys, platforms, ships of opportunity, autonomous submersible vehicles and gliders. Near real-time reception of telemetered data is a reality and data can even be displayed on web sites. All of this makes forecasting a possibility in the near future. With forecasting comes the question of mitigation and control (80). In one example, clays are being either used in Asian countries (8) or tested for use in North America (81) as flocculants and adsorbents for HAB species and their toxins at aquaculture sites or in small contained areas. Certainly forecasting and prediction using coupled biological-physical models are part of mitigation and one further step toward management (82). Often, harmful algal blooms are looked at as imbalances in nature, but some HABs could be natural perturbations, which actually build stability and resistance into a system, and if control were applied, it might lessen productivity (62).

REGULATION OF THE COMMERCIAL USES OF MICROORGANISMS

DAVID J. GLASS
D. Glass Associates, Inc.
Needham, Massachusetts

A large variety of microorganisms, including many genetically engineered microorganisms (GEMs), are used commercially because of advances in modern biology. However, many of these commercial applications, particularly those intended for use in the environment, are subject to government health and safety regulations. These regulations have largely been established in response to the scientific debate that followed the first proposals to use engineered microorganisms in open environment field–testing. Although these regulations are not as stringent as they were when first introduced, they may potentially affect both research and commercial uses of certain microorganisms, with the need to gain regulatory approvals adding time and expense to certain projects or programs.

COMMERCIAL USES OF MICROORGANISMS

Microorganisms have been used for the benefit of mankind for centuries and have had significant commercial utility for most of the twentieth century. Processes like wine and beer fermentation, now known to be microbiological in nature, have been used for centuries and were in many cases known to our early ancestors. In recent decades, mankind has discovered and learned how to harness responsible microbial agents, and a number of naturally occurring microorganisms have been used in fermentation throughout the twentieth century for production of commercial products such as antibiotics, food-processing and other industrial enzymes, and other food additives. Natural characteristics of microorganisms have been used in agriculture for more than 100 years — the first commercial products incorporating nitrogen-fixing rhizobia to promote growth of legumes were introduced in 1898, and the first microbial pest control agents were approved for commercial sale in the 1940s. Microbial cultures are also used in wastewater treatment, hazardous waste bioremediation, enhanced oil recovery, and many other industrial processes (1,2).

HISTORY OF BIOTECHNOLOGY REGULATION

Early Years: The Recombinant DNA Debates

Microorganisms, as natural products with a long history of safe use, are considered by many to represent safe and beneficial products when used correctly for agricultural purposes in the environment or for the manufacture of commercial products through fermentation. In fact, microbial products such as *Bacillus thuringiensis* and nitrogen-fixing rhizobia have long been favored by the organic farming community and are often considered an important part of sustainable programs such as integrated pest management.

Microorganisms (as well as plants and animals) have been genetically manipulated for many years using classical techniques, and the strains resulting from such manipulations and their wild-type parents were subject to little or no government regulation for much of the last century. However, this situation changed due to the advent of the powerful new technologies of modern molecular biology. When the techniques of recombinant DNA (rDNA) were invented in 1973, public and media reaction to this discovery led to an unprecedented public debate over the safety and ethical implications of recombining genes from different sources, and leading scientists in the field convened an international symposium to review the available scientific evidence about the technology's possible risks (3). This conference ultimately led, in 1976, to the promulgation, by the U.S. National Institutes of Health (NIH), of guidelines for the safe conduct of rDNA experiments. These guidelines assigned, to many possible rDNA experiments, physical and biological

controls appropriate for the perceived levels of risk to ensure as much as possible that recombinant organisms would be contained within laboratories. The guidelines originally prohibited the deliberate outdoor release of any recombinant organism. Although the guidelines were binding only on institutions receiving federal funds, they have served as a safety standard for industry and academic researchers alike.

At first, the major safety concern involved potential public health hazards that might occur if altered organisms were to accidentally leave the laboratory, but this lessened over time. As the NIH Guidelines were progressively relaxed, deliberate releases of engineered organisms into the environment became possible on a case-by-case basis with the express permission of the NIH and its outside scientific advisory committee, the Recombinant DNA Advisory Committee (RAC). NIH's 1983 approvals of the first field tests of recombinant microorganisms shifted the attention of the public and the scientific community to the possible adverse environmental effects of the use of engineered plants and microorganisms outside the laboratory. The resulting public controversy and litigation delayed these early field tests and ultimately led to the adoption of a comprehensive federal regulatory framework that ensured review of all early field test proposals (described in a following section).

The NIH Guidelines remain in effect to this day, with the most recent version effective June 24, 1994 (59 Federal Register 34496). The Guidelines were progressively relaxed as more experience was gained with rDNA techniques and as specific risk assessment experiments showed initial concerns to be largely unfounded. Today very few classes of experiments require any kind of prior approval and most rDNA experiments are conducted at safety level one or lower. In fact it was estimated that by the early 1980s, 80–90% of the rDNA experiments conducted across the country were exempt from the Guidelines (4). The NIH Guidelines have not adversely affected the conduct of microbiology research in the United States, due to their widespread acceptance and their ongoing modification to accommodate evolving concepts of risk.

The Federal Coordinated Regulatory Framework and its History

In the early years of the biotechnology era, the NIH Guidelines were the only federal government oversight over this technology; however, they did not have the power of actual government regulation, which concerned many observers. Congress briefly considered passing legislation to make compliance mandatory, but ultimately took no action (3). This led to the passage, beginning in the late 1970s, of several local and state laws that required compliance within that jurisdiction. The most famous of these was adopted in Cambridge, Massachusetts, in 1977, after a frenzied series of City Council debates. These first ordinances did little more than mandate compliance with the Guidelines, but, beginning in 1981, a number of communities began adopting ordinances requiring institutions to obtain permits for rDNA research and large-scale manufacturing. These laws were designed to give local governments better control over biotechnology research in the industrial laboratories that were by then beginning to appear. Cambridge was again the first to pass such a law and several other towns and cities, all in Massachusetts, followed suit throughout the 1980s (3). By the late 1980s, about 20 communities and four states had adopted such laws (5).

The combination of voluntary research guidelines and local ordinances served as the only regulation directed specifically at biotechnology for some time. Commercial firms using biotechnology to develop new drugs and diagnostics were approaching the U.S. Food and Drug Administration (FDA) about the regulations for such products. Aside from requesting information about the genetic changes introduced into the production organism, FDA created no new requirements for rDNA products or genetically modified organisms used in drug production. However, beginning in 1983, academic and commercial biotechnology research programs began to progress from the laboratory into the environment. This development triggered a concern over possible environmental effects of biotechnology and over the adequacy of voluntary guidelines to regulate the diverse areas where biotechnology would be used commercially.

Concerns first arose in the area of agricultural applications of rDNA technology. Agricultural organisms developed by any technology and tested in laboratories or greenhouses must also be tested in the field under conditions approximating actual farming use before they can be accepted and purchased by farmers. The first proposals in 1982 to 1983 for field tests of engineered organisms triggered new discussions and debates within the scientific community over the possible environmental risks of GEMs released into the environment and the ability to predict or monitor such environmental behavior. These discussions also showed that guidelines adopted to cover indoor biomedical laboratory research were not well-suited to apply to outdoor agricultural experimentation.

The first few of these proposals all arose from academic laboratories, which were subject to the NIH Guidelines. So-called "deliberate releases to the environment" were among those experiments originally prohibited under the Guidelines, but which were later put into a class where they could be allowed on approval by both the RAC and the Director of the NIH. In 1982 and 1983, three experiments involving genetically engineered plants were approved by NIH, and in 1983, NIH issued an approval for the first field test of an engineered microorganism (6,7). This was a proposed field test by Stephen Lindow and colleagues at the University of California, Berkeley, of an organism later dubbed the "Ice-Minus" bacterium (another test of a similar microbe was later proposed and carried out by a commercial firm, Advanced Genetic Sciences). This microorganism was a variant of a strain of *Pseudomonas syringae* that plays a crucial role in ice nucleation on plant leaves; the wild-type microorganism contains a protein that promotes ice crystal formation, and the engineered variant had the gene encoding this protein deleted. Lindow and his colleagues wanted to field-test the variant, to test its ability to provide potato plants with the ability

to withstand freezing temperatures up to a few degrees lower than normally possible.

The NIH approved this experiment in June 1983, following a review by the RAC over the course of several months. Shortly before the experiment was to begin, it was stopped by a lawsuit filed by a coalition of activist groups led by author Jeremy Rifkin, alleging that such tests posed unacceptable environmental risks and that the NIH had not followed proper federal procedures for assessing such risks in approving the experiment. Rifkin alleged that NIH should have prepared an environmental assessment under the terms of the National Environmental Policy Act and made that assessment available for public comment before issuing a final approval. Rifkin eventually won the suit (although a final decision took several years), and NIH was forced to prepare environmental assessments for any deliberate release experiments it intended to approve (6).

Although the court case took so long to resolve, its impact on commercial biotechnology was more immediate because it exposed the unsuitability of the NIH Guidelines as commercial regulation. Commercial companies could not live with the possibility that proposed field tests could be continually delayed by the time-consuming NIH review process, the need for public comment periods, and the threat of litigation by activists opposed to the technology.

At the same time, the federal government was beginning to realize that it needed a regulatory process more stringent than the NIH Guidelines to oversee the growing biotechnology industry, and agencies other than FDA began contemplating how they might use their existing statutes and regulations to apply to biotechnology. The most prominent of these was the U.S. Environmental Protection Agency (EPA), which, in the summer of 1983, announced that it was considering regulations under the Toxic Substances Control Act (TSCA) that could have potentially covered most, if not all, aspects of commercial biotechnology, even those that were already regulated elsewhere in the federal government. The political reaction to this announcement and the aftermath of the Rifkin lawsuits were among the factors that led to the Reagan Administration's decision to take a more comprehensive approach to biotechnology regulation.

In April 1984, the Administration convened an interagency working group to develop a unified approach to the regulation of commercial biotechnology. The group included representatives from seventeen federal agencies and cabinet departments and published the results of its work in a Federal Register notice on December 31, 1984 (49 Federal Register 50856). This notice, entitled "Proposal for a Coordinated Framework for Regulation of Biotechnology," had three components: (*1*) a "matrix" of existing laws and regulations applicable to biotechnology products; (*2*) policy statements by the FDA, EPA, and the U.S. Department of Agriculture (USDA) describing their approaches to regulate biotechnology products; (*3*) a proposal for the oversight of biotechnology regulation by two interagency committees: one to oversee scientific issues and one to cover policy issues. A public comment period on this notice followed.

The regulatory matrix established what would become a cornerstone of federal regulatory policy: that existing laws and regulations would suffice for the regulation of biotechnology products. The agency policy statements were in all cases preliminary; FDA and USDA made no new proposals beyond their existing regulations, whereas EPA put forward an initial proposal to apply TSCA and the pesticide law FIFRA (Federal Insecticide, Fungicide and Rodenticide Act) to regulate biotechnology products. The EPA statement was controversial, primarily because EPA proposed a "process-based" approach, choosing to regulate only those organisms produced by recombinant DNA and related techniques rather than a "risk-based" approach focusing on the inherent traits of the final microorganism, regardless of how it was constructed.

This Federal Register notice generated a great number of comments from the public, and the working group then changed many of its basic assumptions. Its next public pronouncement came in November 1985, when the Biotechnology Science Coordinating Committee (BSCC) was created as the new interagency committee. Established under the provisions of the Federal Coordinating Council for Science, Engineering and Technology, the BSCC consisted of senior policy officials from those agencies primarily involved in oversight of biotechnology research and commercialization.

The BSCC assumed responsibility for continuing development of the Coordinated Framework and published an updated version on June 26, 1986 (51 Federal Register 23302). This notice largely had the same thrust as the 1984 version, although both USDA's and EPA's proposed regulatory approaches were modified somewhat. The 1986 Coordinated Framework provided the basis for the first round of biotechnology rulemaking, which began taking place in 1987, with the adoption of regulations for transgenic plant field–testing by the USDA. The BSCC is no longer in existence, having been displaced by other working groups more closely controlled by the White House. Although aspects of this framework have been relaxed over the years, for the most part it remains in effect as of this writing.

The Coordinated Framework and Its Philosophy

The philosophy behind federal regulation under the Coordinated Framework is that biotechnology products can be regulated on a product-by-product basis under existing statutory authority. This is sensible because biotechnology is a tool being applied to many industries, resulting in products of many different types. It might have been difficult to abandon the product-specific regulatory structure that had existed for decades to create a new system for a small class of dissimilar products whose only similarity is their method of manufacture.

Hence, biotechnology products are regulated under a scheme that follows from the product categories traditionally regulated by three federal agencies: FDA, EPA, and USDA. The FDA, with existing authority over human drugs and biologics, animal drugs, medical devices, and human and animal foods, food additives, and their manufacturing processes, regulates the lion's share of biotechnology products, all under preexisting statutory and regulatory authority. Many uses of microorganisms in commercial fermentation are regulated by the FDA under

these statutes. EPA uses existing authority to regulate new chemicals produced by biotechnology (under TSCA) and pesticides derived from or containing microorganisms (under FIFRA). Products regulated under traditional USDA authority are primarily animal biologics (e.g., vaccines) and certain microbes derived from plant or animal pathogens.

The Coordinated Framework primarily relied on existing laws and regulations and spawned new rules only for a small number of biotechnology products: primarily, engineered organisms intended for use in the environment. Thus, USDA began using the Plant Pest Act to regulate environmental introductions of transgenic plants and certain agricultural microorganisms. EPA is using TSCA to oversee certain commercial uses and "deliberate releases" of microorganisms not regulated elsewhere in the federal government. Outdoor rDNA experiments conducted by academic or government laboratories are to be regulated by the agency supervising or funding the work, such as the NIH, the USDA, or the National Science Foundation.

In the early years, under the framework, every proposed field test of an engineered microorganism or plant was subjected to a thorough risk assessment, focusing on the potential environmental effects of the introduced microorganism. Such assessments examined generally applicable questions such as the toxicity, infectivity, persistence, competitiveness, and possible dispersal of GEM (see a following section). Early field tests were often required to include extensive testing to monitor the persistence of GEM in the environment and to detect its possible transfer beyond the experimental field. In later years, agency rulemaking relaxed the standards so that fewer plants and microorganisms were subject to such thorough scrutiny.

The Scope Policy and the Finalization of the Framework

The intent of the Coordinated Framework has always been to provide a risk-based (and science-based) approach to biotechnology regulation. Politically this has not always been possible because genetically engineered (i.e., recombinant) organisms were singled out by public interest groups as allegedly posing unique risks, and in the early years of regulation, this led to federal oversight of any proposed outdoor use of an engineered plant or microbe, regardless of the size or scale of the use and even if used for research purposes. However, beginning in the late 1980s, the risk-based approach became the focus of a federal interagency committee, whose formal task it was to define a presumably narrow class of microorganisms judged to be risky enough to warrant regulatory oversight even for small-scale field testing. This committee published its initial recommendations known as the Scope Policy in July 1990 (55 Federal Register 31118–31121). The Scope Policy gave individual agencies guidance to define categories of those "organisms deliberately modified in hereditary traits" that could be excluded from oversight at the level of small-scale R&D by creating several categories of exclusion based on the method used in their creation.

However, over time, the federal government reopened the Scope negotiations, partially because the categories of exclusion were seen as process-based (i.e., they were defined by the types of modifications imparted to the organism in question). The interagency group eventually abandoned the July 1990 document in favor of a revised Scope Policy that was published in February 1992 in the Federal Register (57 Federal Register 6753–6762). This final statement on scope read as follows:

> Within the scope of authority provided by statute, federal agencies shall exercise oversight of planned introductions of biotechnology products into the environment only upon evidence that the risk posed by the introduction is unreasonable.

The policy also stated that "where oversight is warranted, the extent and type of oversight measure(s) must be commensurate with the gravity and type of risk being addressed. . ." The Federal Register notice stressed that the new Scope Policy was a risk-based approach: that is, it is totally blind to "process" (i.e., how an organism is created) and is solely based on the inherent risks of the organism and the environment into which it will be placed. The thrust of the policy was to ensure that genetically altered organisms received no greater oversight than would be warranted by similar nonaltered organisms. Furthermore, the 1992 policy recognized that the risk-based scope principles could only be interpreted in the context of the different statutes administered by the agencies.

The publication of this policy opened the door to new biotechnology rules substantially less rigid than those that were adopted earlier: the FDA's 1992 food biotechnology policy (allowing transgenic plants to be used in food without labeling or special testing) and the USDA's 1993 revised regulations for agricultural field tests (further revised in 1997 to provide greater deregulation, see below). The Scope Policy also allowed EPA to continue its rulemaking efforts under both FIFRA and TSCA, which had been stalled by the six-plus years of interagency wrangling. The history and status of rules relevant to genetically engineered microorganisms are discussed in the following section.

Current Status of U.S. Regulation of Commercial and Environmental Uses of Microorganisms

Under the Coordinated Framework, microorganisms used in commerce might be regulated as shown in Table 1 and as summarized below. The regulatory programs relevant to environmental uses of microbes are explained in more detail in the following sections.

Microorganisms, including GEMs, used in commercial manufacturing would be regulated by the agency having jurisdiction over the end product. For example, FDA would regulate microorganisms used to produce drugs, biologicals, or food additives. Many microbes used to manufacture products not regulated by FDA would generally be regulated by EPA under TSCA;

- Microorganisms, including GEMs, designed to act as pesticides or that are deemed to act through killing or displacing an agricultural pest would be regulated as pesticides by EPA under FIFRA;

Table 1. Major U.S. Laws and Regulations Affecting Genetically Engineered Microorganisms

Law	Agency	Legislative Citation	Biotechnology Regulations	Microbial Products Covered
Federal Food, Drug and Cosmetic Act	Food and Drug Administration	21 USC 301	Many parts of 21 CFR	Microorganisms used to manufacture drugs, biologicals, foods or food additives, animal feed or feed additives.
Federal Insecticide, Fungicide and Rodenticide Act	Environmental Protection Agency	7 USC 136	40 CFR 152–186, especially Parts 158 and 172	Microbial pesticides.
Toxic Substance Control Act	Environmental Protection Agency	15 USC 2601	40 CFR 725	Microorganisms for industrial bioprocesses, nonpesticidal agricultural uses, bioremediation
Federal Plant Pest Act	Department of Agriculture	7 USC 150aa	7 CFR 340	Engineered microorganisms for agriculture that may be plant pests.

- Modified microorganisms intended for environmental use other than as a pesticide may be subject to EPA regulation under TSCA. Certain plant growth — promoting bacteria (e.g., for nitrogen fixation), microorganisms for bioremediation, enhanced oil recovery, and similar uses, are included in this category;
- Microorganisms that are, or are derived from, a plant pest, may be subject to regulation by the U.S. Department of Agriculture (although USDA would generally defer to EPA authority for any organisms in this category that also fall into one of the previous two categories).

THE POTENTIAL ENVIRONMENTAL IMPACTS OF INTRODUCING ENGINEERED MICROORGANISMS INTO THE ENVIRONMENT

The regulatory framework described in the preceding section was largely driven by scientific debate over the possible risks of introducing microorganisms, particularly genetically modified microbes, into the environment. Although magnified and possibly distorted by the concerns of the general public and environmental activists, several legitimate scientific issues underlie this concern. There are numerous historical instances where exotic or nonindigenous plants or microbial species dramatically outcompeted native flora or fauna after intentional or accidental introductions into a new environment, with resulting adverse effects. Although not an ideal model for the introduction of microorganisms possessing only a few genetic differences from wild type, this paradigm shaped the early debate. Accordingly, among the issues identified as important to assess in proposed uses of GEMs in the environment were (*1*) the toxicity, infectivity, or other risks inherent to the GEM itself; (*2*) the ability of the GEM to persist or become established in the environment; (*3*) the ability of the GEM to compete with or displace natural microflora at the release site; (*4*) the possibility that the GEM could spread or be dispersed from the release site; and (*5*) the possibility that genes introduced into the GEM could themselves spread through horizontal gene transfer to be taken up by and expressed in different microbial species (1).

This scientific debate continued for much of the 1980s and a detailed discussion thereof is beyond the scope of this article. Although many scientific issues remain for investigation, for the purposes of the development of regulations, much of the debate was settled in the late 1980s by the appearance of peer-reviewed reports (8,9) that generally concluded that the behavior of GEMs in the environment would be similar to that of nonengineered strains introduced into new environments and that such behavior could be predicted and monitored using appropriate risk assessment tools. The results of many of the earliest GEM field tests and the monitoring programs that accompanied them have generally borne out the predictability and low risks of many uses of GEMs in agriculture (1).

EPA REGULATION OF MICROBIAL PESTICIDES UNDER THE FEDERAL INSECTICIDE, FUNGICIDE AND RODENTICIDE ACT

Background

Most of the genetically engineered microorganisms that are used in the environment are pesticides that are regulated by EPA, using existing regulations under the pesticide law FIFRA (7 U.S. Code 136). A number of naturally occurring microorganisms have been used for decades as pesticides because their natural properties give such strains the ability to selectively kill or inhibit growth of certain agricultural pests. More recently, genetically modified or engineered microorganisms have also been used or proposed as pesticides.

All pesticide products (e.g., insecticides, herbicides, and fungicides) must be registered by the EPA before they can be sold commercially, and microbial pesticide products are generally subject to the same registration requirements as

are chemical pesticides (described in a following section). It is necessary to conduct several years of field tests first to identify commercially viable pesticides and to gather the data on efficacy and safety that are needed to support EPA registration. EPA allows most pesticide products to be field-tested at any level up to 10 terrestrial acres without agency oversight, in recognition of the limited risks posed by such small-scale experimental uses. However, to conduct field tests of greater acreage, companies must first obtain an experimental use permit (EUP), which requires the applicant to conduct much of the testing that would later be required for product registration, including product characterization, short-term toxicological testing, and a certain amount of environmental effects testing, including effects on nontarget organisms.

Under EPA's biotechnology regulations, however, the ten-acre exemption has been removed for certain genetically altered microbial pesticides, including ones of recombinant origin. For such products, applicants must first notify EPA of any proposed field test, regardless of size, and possibly obtain an EUP to conduct the test. To obtain EUPs for microbial products, applicants must carry out standard safety testing along with testing to assess the potential environmental effects of the product, often relying on results of monitoring studies conducted during small-scale tests. The scope of this oversight was narrowed in the final biotechnology rules that took effect in September 1994, but many biotechnology-derived microbial pesticides are subject to this extra level of regulation.

History

The first microbial pesticide, *Bacillus popilliae*, was registered for agricultural use in 1948, and since then interest in microbial pesticides has grown. Beginning in 1974, EPA began to investigate the scientific basis for risk assessment of microorganisms used as pest control agents, and in 1983 the agency issued testing guidelines for microbial pesticides and biochemical pesticides (pesticides based on natural chemicals that act through biochemical pathways rather than through sheer toxicity) as Subpart M of the Pesticide Assessment Guidelines. Using these guidelines and existing regulations, EPA registered about a dozen naturally occurring microorganisms for use as pesticides in the years before the biotechnology era.

In 1984, even before the earliest proposal for the Coordinated Framework, EPA established an interim policy for regulation of genetically modified microbial pesticides ("Microbial Pesticides: Interim Policy on Small-Scale Field Testing," October 17, 1984, 49 Federal Register 40659). This main feature of this policy was that the ten-acre (terrestrial) exemption under the then-existing EUP regulations (40 CFR 172.3) would not automatically apply to tests using genetically altered and nonindigenous microbial pesticide products and that EPA should be notified before initiation of any such testing. Since that time, the Agency has used this notification scheme to evaluate small-scale tests, involving genetically altered and nonindigenous microbial pesticides, for possible risk to human health or the environment and to determine whether EUPs would be required before the tests could be initiated.

EPA's final statement of policy, incorporating this interim policy, was published with the Coordinated Framework on June 26, 1986, and the Agency stated its intention to codify the major elements of the notification procedure in the revised EUP regulations. EPA published its first formal proposal to amend its EUP regulations on January 22, 1993 (58 Federal Register 5878) and this Proposed Rule relied heavily on public comments on the 1986 policy statement and the Scope Policy described in the preceding section. After consideration of public comment on the Proposed Rule, EPA issued a Final Rule entitled "Microbial Pesticides; Experimental Use Permits and Notifications" on September 1, 1994 (59 Federal Register 45600), which took effect on October 31, 1994, and which is described below.

Microbial Pesticide Regulations

Using principles established for the earliest (nonengineered) microbial pest control agents, microbial pesticides are regulated by EPA under the same regulations used for chemical pesticides. Some of the required testing data is different for living biological agents, but for genetically modified biopesticides the key issue became the identification of those modified microorganisms that required additional oversight at the level of small-scale field–testing.

Large-scale tests under 40 CFR Part 172 are defined as any terrestrial application on a cumulative total of more than 10 acres of land or any aquatic application on more than one surface acre of water. Although EPA has generally presumed that testing on up to 10 acres of land or one surface acre of water would not require EUPs, the Agency decided that small-scale tests in the environment with some microbial pesticides may pose sufficiently different risk considerations from conventional chemical pesticides to require a closer evaluation at the small-scale testing stage. Therefore 40 CFR Part 172 was amended to require agency notification before initiation of small-scale testing in the environment of certain microbial pesticides so that EPA may determine whether these tests should be conducted under an EUP.

Under the 1984 interim policy, all genetically modified microbial pesticides and all microorganisms not indigenous to the United States required EPA notification before field-testing at any level, and many of these products were judged to require an EUP before tests could be carried out. The 1994 microbial pesticide regulations relaxed this requirement through three important provisions. First, the notification requirement was lifted for many genetically modified microbial pesticides: the only organisms now requiring notification are those where the pesticidal property is imparted or enhanced by the genetic manipulation, and notifications are specifically not required for genetic modifications that are solely deletions or rearrangements of a single genome. Second, notifications are no longer required for nonindigenous microbial pesticides, except in the rare cases where such organisms would not be covered by the USDA's importation regulations (described in a following section). Finally, the regulation gave EPA the authority to exempt specific classes of microorganisms

from the need for notifications at small-scale testing. This has allowed EPA to exempt categories such as many genetically modified *B. thuringiensis* strains from the need for notification at the early stages of R&D.

The rule proposed in 1993 had requested comment on two options for defining which microbial pesticides would be subject to the notification requirement. A third option was also discussed but only for illustrative and comparative purposes. In the proposed rule, EPA indicated its preference for Option 1, under which notification would be required before small-scale testing of microbial pesticides "whose pesticidal properties have been enhanced or imparted by the introduction of genetic material that has been deliberately modified." This option was selected in the final rule as the one that best addresses potential risks presented by certain categories of microbial pesticides by focusing the notification requirement on tests involving microbial pesticides with the potential for presenting new and different hazards or exposures to humans or the environment on the basis of simple and directly addressable criteria.

In the proposed rule, EPA no longer required notifications for any naturally occurring nonindigenous microbial pesticides, based on its experience since 1984 with the assessment of numerous nonindigenous microbial pesticide products for which notifications were submitted under the interim policy. This provision was included in the final rule but, in response to public comment, the rule retained a provision that EPA requires notifications at the small-scale testing stage for nonindigenous microbial pesticides that have not been reviewed by USDA.

The final regulations added a Subpart C, "Notification for Certain Genetically Modified Microbial Pesticides," to the existing EUP regulations and specified the data that is required to accompany notifications. EPA's review of a notification must be completed within 90 days and at the conclusion of the review, the Agency could either approve the test without requiring an EUP; approve the test without requiring an EUP if certain modifications in the proposed test plan are incorporated; require additional information; require an EUP for the test; or disapprove the test because of the potential for unreasonable adverse effects.

The final rule also provides that testing conducted within a facility with adequate containment and inactivation controls would not be subject to the notification requirement. Responsibility for selection and use of adequate containment and inactivation controls would lie with the researcher or institution conducting the test.

Data Requirements

Registration of biopesticides follows existing EPA regulatory procedures for all pesticides, with specific data requirements enumerated in Subparagraph M of 40 CFR Part 172. These requirements include

- product analysis to identify the active ingredient and any inert substances added thereto;
- toxicology testing, including short-term tests to evaluate the potential for toxicity, infectivity, or pathogenicity (Tier I), as well as more specific and sensitive tests in Tiers II and III;
- residue data to quantitate the amount of the pest control agent or its toxins that might appear on food or feed crops, although this is only required if toxicology testing leads to human health concerns;
- ecological effects and environmental expression testing, also grouped in tiers, to assess possible effects of the agent on nontarget organisms (Tier I), with further testing to address more specific concerns in Tiers II, III, and IV.

EPA has stated that most microbial pesticides will not require testing beyond Tier I, but some genetically engineered products might be judged to need some Tier II tests. In addition to safety testing, pesticide registration applications must also include proof of the product's efficacy, generally obtained in field tests.

EPA is also responsible under the Food, Drug and Cosmetic Act to establish tolerances (maximum allowable concentrations) of pesticides in food products. Applicants, to register pesticides for use on specific crops, must petition the Agency, with the necessary data to establish a tolerance level or to obtain an exemption from tolerance, based on a lack of human toxicity of the product. Many biological products are toxic only to the target pest (*B. thuringiensis* being a good example) and many have had little trouble obtaining exemptions from tolerance.

Products Approved Under FIFRA

Table 2 shows the microbial pesticide products that EPA has approved to date under FIFRA and the interim and final biotechnology regulations. This table groups these products according to taxonomic criteria (e.g., bacteria, fungi, viruses), but the products can also be grouped according to their end use. Most of the approved products are insecticides, with the bulk of these being wild type or mutant strains of *B. thuringiensis*, an organism producing a delta-endotoxin that is toxic to specific orders of insects but that is generally nontoxic to nontarget species. More recently, GEMs expressing *B. thuringiensis* endotoxins in other host species have also come onto the market. Other bacteria and fungi are used for insect control, as are a large number of natural and modified insect viruses. In all cases, the biological agent has high selectivity for the targeted insect pest.

Another class of product is fungicides, where a number of bacterial and fungal strains are used as agents against specific fungal diseases of plants, roots, or stored grain. *Trichoderma* species have been the most frequently investigated and registered in this category. There are also biological herbicides, generally fungal strains that can selectively kill weedy plants without harming crop species. Smaller classes of products include nematicides and bactericides.

EPA BIOTECHNOLOGY REGULATION UNDER THE TOXIC SUBSTANCES CONTROL ACT

Background

EPA is using TSCA to regulate the microbial production of certain chemicals or enzymes not regulated elsewhere in

Table 2. EPA-Approved Microbial Pesticides under FIFRA

Microbial Pesticide	Type of Pesticide: Target Pest
Bacteria	
Agrobacterium radiobacter K84	Bactericide: Crown Gall Disease
Agrobacterium radiobacter K1026	Bactericide: Crown Gall Disease
Bacillus cereus Strain BP01	Microbial plant growth regulator
Bacillus popilliae & Bacillus lentimorbus	Insecticide: Japanese beetle larvae
Bacillus sphaericus	Insecticide: Mosquito larvae
Bacillus sphaericus Serotype H5a5b strain 2362	Insecticide: Mosquito larvae
Bacillus subtilis GBO3	Fungicide: Rhizoctonia, Fusarium, other diseases
Bacillus subtilis MBI 600	Fungicide: Rhizoctonia, Fusarium, other diseases
Bacillus subtilis var. *amyloliquefaciens* strain FZB24	Fungicide: fungal diseases in greenhouse, indoor plants
Bacillus thuringiensis Berliner	Insecticide
Bacillus thuringiensis CryIA(c) & Cry I(c) delta-endotoxin in killed *Pseudomonas fluorescens*	Insecticide: larvae of many moth species
Bacillus thuringiensis subsp. *aizawai*	Insecticide: Wax moth larvae
Bacillus thuringiensis subsp. *aizawai* GC-91	Insecticide: Wax moth larvae
Bacillus thuringiensis subsp. *israelensis*	Insecticide: Mosquito larvae
Bacillus thuringiensis subsp. *israelensis* EG2215	Insecticide: Mosquito larvae
Bacillus thuringiensis subsp. *kurstaki*	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* BMP123	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* EG2348	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* EG2371	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* EG2424	Insecticide: Lepidopteran and Coleopteran larvae
Bacillus thuringiensis subsp. *kurstaki* EG7673 Coleoptera	Insecticide: Coleopteran larvae
Toxin	
Bacillus thuringiensis subsp. *kurstaki* EG7673	Insecticide: Lepidopteran larvae
Lepidoptera Toxin	
Bacillus thuringiensis subsp. *kurstaki* EG7826	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* EG7841	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *kurstaki* M200	Insecticide: Lepidopteran larvae
Bacillus thuringiensis subsp. *tenebrionis*	Insecticide: Coleopteran larvae (Colorado potato beetle)
Burkkholderia cepacia type Wisconsin IsoJ82	Fungicide/Nematicide
Burkkholderia cepacia type Wisconsin M36	Fungicide/Nematicide
Pseudomonas aureofaciens strain Tx-1	Fungicide: Turf grass diseases
Pseudomonas fluorescens 1629RS	Bactericide: Frost-forming bacteria
Pseudomonas fluorescens A506	Bactericide: Frost-forming bacteria
Pseudomonas syringae 742RS	Bactericide: Frost-forming bacteria
Pseudomonas syringae ESC 10	Fungicide: Postharvest decay on fruits
Pseudomonas syringae ESC 11	Fungicide: Postharvest decay on fruits
Streptomyces griseoviridis K61	Fungicide: Seed rot, root and stem rot, damping-off disease
Fungi	
Ampelomyces quisqualis M10	Fungicide: Powdery mildew on grapes, tomatoes, strawberries, ornamentals
Beauveria bassiana ATCC 74040	Insecticide: Whitefly, grasshoppers, locusts, crickets
Beauveria bassiana GHA	Insecticide: Whitefly, grasshoppers, locusts, crickets
Candida oleophila isolate I-182	Fungicide: Rot disease on fruits and vegetables
Colletotrichum gloeosporioides f.sp. *aeschynomene* ATCC 20358	Herbicide: Northern joint vetch
Gliocladium catenulatum Strain J1446	Fungicide: Pythium, Rhizoctonia
Gliocladium virens G-21	Fungicide: Pythium, Rhizoctonia
Lagenidium giganteum	Insecticide: Mosquito Larvae
Metarhizium anisopliae ESF1	Insecticide: Cockroaches, flies
Paecilomyces fumorsoroseus Apopka strain 97	Insecticide: Whitefly, thirps, aphids, spider mites
Puccinia canaliculate (Schweinitz) Langerheim ATCC 40199	Herbicide: Nutsedge weeds
Trichoderma harzianum ATCC 20476	Fungicide: Damping-off diseases
Trichoderma harzianum Rifai T-22 (KRL-AG2)	Fungicide: Pythium, Rhizoctonia
Trichoderma harzianum Rifai T-39	Fungicide: Gray mold
Trichoderma polysporum ATCC 20475	Fungicide: Wood rot microorganisms
Viruses	
Anagrapha falcifera Nucleopolyhedrosis Virus (NPV)	Insecticide: Lepidopterans
Autographa californica NPV	Insecticide: Alfalfa looper
Cydia pomonella Granulosis virus	Insecticide: Codling moth
Douglas fir tussock moth NPV	Insecticide: Douglas fir tossack moth
Gypsy moth NPV	Insecticide: Gypsy Moth
Helicoverpa zea NPV	Insecticide: Corn Earworm

(*continued overleaf*)

Table 2. (*Continued*)

Microbial Pesticide	Type of Pesticide: Target Pest
Mamestra configurata NPV	Insecticide: Bertha Army Worm (approval pending)
Spodoptera exigua NPV	Insecticide: Beet Army Worm
Miscellaneous Microbials	
Nosema locustae	Insecticide: Grasshoppers
Nonviable Microbials	
Bacillus thuringiensis CryIA(c) & Cry I(c) delta-endotoxin in killed *Pseudomonas fluorescens*	Insecticide: Larvae of many moth species
Bacillus thuringiensis K CryIC in killed *Pseudomonas*	Insecticide
Bacillus thuringiensis subsp *kurstaki* delta-endotoxin in killed *Pseudomonas fluorescens*	Insecticide: Caterpillars
Bacillus thuringiensis subsp San Diego delta-endotoxin in killed *Pseudomonas fluorescens*	Insecticide: Colorado potato beetle
Myrothecium verrucaria, Dried fermentation solids & solubles of	Nematicide: Parasitic Nematodes

the government, and planned introductions of microorganisms into the environment that are not regulated under other federal statutes. TSCA (15 U.S. Code 2601) is a law requiring manufacturers to notify EPA at least 90 days before commencing manufacture of any "new" chemical, that is, one that is not already in commerce for purposes not subject to regulation as a pesticide or under the food and drug laws. In the Coordinated Framework, EPA decided to use TSCA in this same "gap-filling" way to capture those microorganisms that were not regulated by other federal agencies. The primary areas that therefore became subject to the TSCA biotechnology regulations were (*1*) microorganisms used for production of non-food-additive industrial enzymes, other specialty chemicals, and in other bioprocesses; (*2*) microorganisms used as, or considered to be, pesticide intermediates; (*3*) microorganisms used for nonpesticidal agricultural purposes; and (*4*) microorganisms used for other purposes in the environment, such as bioremediation.

The key to the historical development of this regulation was the definition of organisms that are "new," and which therefore are subject to reporting requirements under TSCA. Another feature of the regulations is a two-tiered review structure, under which all commercial uses of new microorganisms (within the scope of TSCA's applicability) would require agency review, and research uses of new microorganisms in the open environment ("uncontained uses") would also require some agency oversight, regardless of scale (although most indoor research is exempted). The regulations adopted in final form in 1997 instituted reporting requirements specific for microorganisms (but which paralleled the commercial notifications used for traditional chemicals), while also creating new requirements to provide suitable oversight over outdoor uses of genetically modified microorganisms.

Procedures under the TSCA biotechnology regulations are similar to existing practice for new chemical compounds. Manufacturers of chemicals new to commerce must file premanufacture notices (PMNs) with EPA at least 90 days prior to the first intended commercial sale, use, or importation. Manufacturers must submit all relevant health and safety data in their possession, and although EPA has published guidance documents, specifying the types of data that it wants to see in PMN submissions, there are no formal data or testing requirements under TSCA. As applied to new chemical entities, TSCA is a "screening" statute: the 90-day review period is sufficient only to allow EPA to identify chemicals that might pose an environmental or public health risk, and in such case it can take any of several actions to extend the time period and keep the product off the market until suitable data is submitted to show its safety. The large majority of PMNs are approved within the 90-day period after only brief agency review.

History

TSCA biotechnology policy originated in EPA's 1986 Coordinated Framework statement that the agency intended to use this law to regulate certain commercial uses of "new" microorganisms (it was in this 1986 statement that the policy was first restricted to microorganisms and excluded plants and animals). This statement introduced the concept that EPA would consider any "intergeneric" organism (i.e., one containing deliberate combinations of genetic material from more than one taxonomic genus) as "new" under TSCA. The rationale for this definition (that the agency acknowledged was somewhat arbitrary) was that *intra*generic organisms were likely to occur naturally via normal mechanisms of genetic exchange but that organisms in different genera were unlikely to exchange DNA via natural mechanisms. Intergeneric microorganisms not regulated by other federal agencies were proposed to be subject to mandatory PMN reporting if they were to be used for commercial purposes and voluntary PMN reporting if used for research outside of contained facilities, in the latter case because of the potential for microorganisms to multiply and disperse beyond the site of application.

Effective with the June 26, 1986 publication of the Coordinated Framework, EPA established this scheme as an interim policy. This required intergeneric microorganisms used in indoor manufacturing (i.e., fermentation) to be subject to premanufacture notification 90 days or more before commercial use. The interim policy also subjected all outdoor research uses of "intergeneric" organisms to agency review under "voluntarily submitted" PMNs. With this 1986 publication, EPA also began the process of drafting and adopting formal regulations under TSCA for certain commercial uses of microorganisms.

In late 1988, EPA informally circulated for public comment a controversial advance draft of a proposed regulation, that would have subjected many naturally occurring microorganisms to EPA oversight, in addition to broadly capturing most engineered microbes. These draft

rules were withdrawn and never formally proposed, in part because of the negative public and industry reaction and in part because the process was superseded by the Scope Policy discussions discussed in the preceding sections.

In June 1991, EPA formally announced the availability for public comment of draft proposed regulations for biotechnology products under TSCA. The draft-proposed rule and its governing definitions were based on guidance from the first federal Scope Policy. For example, in this proposal, EPA abandoned the definition of "new" organisms as "intergeneric" and instead used a definition arising from the first Scope Policy: "organisms with deliberately modified hereditary traits," except for those falling under certain exclusion categories. EPA solicited public comments on this draft and intended to use the comments to produce actual proposed regulations within one year.

However, the publication of the revised Scope Policy in February 1992 rendered obsolete many of EPA's 1991 assumptions and definitions, so the agency had to revise its rulemaking efforts. EPA was finally able to publish proposed regulations in September 1994. These proposed rules returned to the definition of "new organism" as an "intergeneric organism" and were otherwise in conformance with the second Scope Policy. After a public comment period and much internal discussion and revision, the rules were finalized in April 1997 and took effect 60 days later in June 1997.

Overview of EPA TSCA Biotechnology Regulation

EPA's final TSCA biotechnology rule was published in the Federal Register on April 11, 1997 (62 Federal Register 17910–17958). These rules amended the existing TSCA PMN regulations by creating a new 40 CFR Part 725, that specifies the procedures for EPA oversight over commercial use and research activities involving microorganisms subject to TSCA. The rule also amends other existing parts of the TSCA regulations, where necessary, to be consistent with the new microbial sections.

The final rule defines a "new organism" as an "intergeneric organism" as instituted in the Coordinated Framework and used continuously since then in the interim policy. Organisms that are not new, including naturally occurring and classically mutated or selected microbes, are exempt from reporting requirements under TSCA.

New microorganisms used for commercial purposes not regulated under any of several other specific federal statutes require premanufacture reporting 90 days in advance of the commercial activity, using a new procedure called a Microbial Commercial Activity Notification (MCAN) that is analogous to the previous biotechnology PMN procedures under the interim policies and to long-existing PMN practice for chemical entities. However, several exemptions from MCAN reporting are possible for specific organisms that qualify. The most important exemption categories involve the use, as the recipient organism, of certain of the microbial species having the longest history of safe commercial use in fermentations, including *Acetobacter aceti*, *Aspergillus niger*, *Aspergillus oryzae*, *Bacillus licheniformis*, *Bacillus subtilis*, *Clostridium acetobutylicum*, *Escherichia. coli* K12, *Penicillium roqueforti*, *Saccharomyces cerevisiae*, and *Saccharomyces uvarum*. A procedure was also put into place for EPA to create new exemption categories based on appropriate scientific evidence.

Generally speaking, research activities involving new microbes are exempt from reporting if used only in "contained structures." The rule specifically contemplates that this exemption would apply broadly to many types of structures, including greenhouses, fermenters, and process stream bioreactors. Outdoor experimentation remains potentially subject to some sort of reporting, although the preexisting requirements were eased in several ways: certain exemption categories are created, although at this writing these exemption categories apply only to certain strains of *Rhizobium* and *Bradyrhizobium* engineered in specific ways. Field tests that do not qualify for an exemption can be conducted under a reduced-reporting requirement known as TSCA Environmental Release Application (TERA). The TERA process replaced the previous (voluntary) policy under which all outdoor uses of intergeneric microorganisms were reviewed under PMN reporting, regardless of the scale or potential risks of the field experiment. The regulations specify that TERAs would be reviewed by EPA within 60 days, although the agency could extend the review period by an additional 60 days. In approving TERAs, EPA has the authority to impose conditions or restrictions on the proposed outdoor use of GEMs.

Interestingly, because TSCA is a statute covering "commercial" introductions of new chemicals (i.e., into commerce), EPA in the final rule decided that noncommercial research would be exempt from TSCA, meaning that many academic research activities, unless clearly supported by or done for the benefit of a for-profit entity, would be exempt from TSCA reporting.

Data Requirements

The technical information that is required for each MCAN submission includes the following:

- Description of the recipient ("host") microorganism and the new microorganism resulting from the engineering.
- Genetic construction of the new microorganism.
- Phenotypic and ecological characteristics of the microorganism.
- By-products of the production process.
- Total production volume.
- Worker exposure and environmental release.
- Health effects information.

For submissions of TERAs, the following technical information is needed beyond that listed in the preceding section for MCANs:

- Phenotypic and ecological characteristics of the subject microorganism as they relate to the conditions of the proposed research and development activity (e.g., habitat, geographical distribution, and source of the recipient).

- Survival, dissemination, and detection of the subject microorganism.
- Anticipated adverse ecological effects.
- A detailed description of the proposed research and development activity.
- Methods of application or release.
- Characteristics of the test site.
- Information on monitoring, confinement, mitigation, and emergency termination procedures.

These data requirements are described in more detail in a document entitled "Points to Consider in the Preparation of TSCA Biotechnology Submissions for Microorganisms" (available at *www.epa.gov/opptintr/biotech/biorule.htm*), but the agency has a fair amount of leeway in determining which data are needed for each GEM based on its characteristics and intended use.

Microorganisms Approved Under TSCA

EPA has been receiving PMNs and other notifications of biotechnology products under TSCA since 1987. As listed in Table 3, most of the notifications received were for contained applications: uses of intergeneric microorganisms for manufacturing products for commercial purposes not regulated by other federal agencies. The bulk of these have been for manufacture of industrial enzymes but several others have been for manufacture of pesticide intermediates (which, under the statutes, are covered by TSCA,

Table 3. Submissions to EPA for Microorganisms Under TSCA

Host Microorganism	Modification
	PMNs for contained applications of microorganisms
Escherichia coli	Containing human gene for insulin-like growth hormone
Bacillus subtilis	Engineered for protease production
Bacillus licheniformis	Engineered for enhanced hydrolase production
Bacillus, (alcalophilic strain)	Engineered for enhanced production of protease
Aspergillus oryzae	Engineered for enhanced lipase production
Bacillus subtilis	Engineered for enhanced alpha amylase production
Bacillus licheniformis	Self-cloned for enhanced alpha amylase production
Bacillus subtilis (asporogenic strain)	Containing *S. aureus* antibiotic resistance gene and lipase gene
Bacillus licheniformis	Modified to contain *B. stearothermophilus* alpha-amylase gene and antibiotic resistance genes
Bacillus (sporulation deficient)	Containing genes enhancing subtilisin production
Aspergillus oryzae	Containing cellulase gene
Bacillus licheniformis	Containing xylanase gene
Bacillus licheniformis	Containing pullulanase gene
Escherichia coli K12	Containing gene for indigo production pathway
Escherichia coli K12	Containing *P. putida* naphthalene dioxygenase gene cluster
	Test marketing exemptions for microorganisms
Pseudomonas fluorescens	Containing delta endotoxin gene from *B. thuringiensis*
	MCANs for contained applications of microorganisms
Bacillus amyloliquefaciens	Engineered for commercial biosynthesis of an alpha-amylase enzyme
Bacillus lentus	Engineered for commercial biosynthesis of subtilisin
Pseudomonas fluorescens	Engineered for commercial biosynthesis of an enzyme for secondary oil recovery
	PMNs for environmental applications of microorganisms (all are research uses unless specified)
Rhizobium meliloti	Engineered for yield enhancement in alfalfa
Pseudomonas aureofaciens	Engineered to contain genes from *E. coli*
Rhizobium meliloti	Engineered to contain antibiotic resistance genes
Bradyrhizobium japonicum	Engineered to contain antibiotic resistance genes
Rhizobium meliloti	Engineered to contain antibiotic resistance genes and genes to enhance nitrogen-fixing ability (certain strains also allowed for commercial sale)
Bradyrhizobium japonicum	Engineered to contain antibiotic resistance genes and genes to enhance nitrogen-fixing ability
Psuedomonas fluorescens HK44	Containing naphthalene degradation gene and bioluminescent reporter gene
	TERAs for environmental applications of microorganisms (all are research uses)
Bradyrhizobium japonicum	Engineered to enhance competitiveness and nitrogen-fixation abilities in soybean plants
Pseuodomonas putida	Modified to emit detectable light in presence of TNT

Source: U.S. Environmental Protection Agency (*www.epa.gov/opptintr/biotech/biorule.htm*).

not FIFRA). Since the adoption of the final rules in 1997, several MCANs have been received for such products.

There have also been numerous PMNs (and more recently, TERAs) received for environmental introductions of altered microorganisms. Most of these have been for genetically altered nitrogen-fixing bacteria (*Rhizobium* or *Bradyrhizobium*), and in fact several strains of engineered *Rhizobium meliloti* for improved nitrogen fixation are the only recombinant microorganisms used in the open environment approved for commercial sale under TSCA. In addition to these agricultural tests, there have been two notifications relating to bioremediation, both for R&D projects, involving bacteria modified to contain marker genes to facilitate environmental monitoring of introduced strains. There have been no PMNs or MCANs submitted to EPA for uses of microorganisms in bioremediation or industrial processes other than production of enzymes.

U.S. DEPARTMENT OF AGRICULTURE BIOTECHNOLOGY REGULATIONS

Background

The third major regulatory program that might affect microorganisms, including GEMs, used in research and in the environment are the plant pest regulations of the USDA. Historically, USDA has maintained regulations under the Federal Plant Pest Act (7 U.S. Code 150 aa) that are intended to prevent the entry of plant pathogens and pests into the United States or to regulate the movement within the United States of plant pests that have been introduced for research or other legitimate purposes. The goal of these regulations is to prevent American agriculture from infestation from pest species not native to North America, and under these regulations, permits are needed for the importation or interstate shipment of certain listed plant pest species.

In 1987, USDA promulgated regulations under the Plant Pest Act to allow the agency to regulate certain uses of genetically engineered plants and microorganisms that were derived from, or contained genetic material from, plant pests. These regulations became the major U.S. government oversight over the field–testing of transgenic plants (because most transgenic plants are constructed using sequences derived from *Agrobacterium tumefaciens* or other microorganisms subject to this regulation) but this rule has also been used to regulate importation, interstate transport, and field-testing of certain GEMs derived from species having plant pest characteristics.

History and Regulatory Requirements

USDA has regulated the movement of plant pests since the passage of the Plant Pest Act in 1957. Plant pests are defined as "any living stage of any insects, mites, nematodes, slugs, snails, protozoa, or other invertebrate animals, bacteria, fungi, other parasitic plants or reproductive parts thereof, viruses, or any organisms similar to or allied with any of the foregoing, or any infectious substances that can directly or indirectly injure or cause disease or damage in any plants or parts thereof, or any processed, manufactured, or other products of plants." Under regulations in 7 CFR Part 330, it is necessary to obtain a permit in advance for the importation or interstate shipment of any organism meeting this definition.

In the Coordinated Framework, USDA through its Animal and Plant Health Inspection Service (APHIS) proposed new regulations, 7 CFR Part 340, under the Plant Pest Act that would allow it to review in advance proposed environmental uses or interstate shipments of genetically engineered plants or agricultural microorganisms. The title of the rule, "Introduction of Organisms or Products Altered or Produced through Genetic Engineering which are Plant Pests or which there is Reason to Believe are Plant Pests" states the philosophy behind the regulation: to cast a broad net to regulate many categories of engineered organism by defining a long list of genera, families, and orders that "are or contain plant pests." A genus or family was included on the list if even one species therein was known or believed to be a plant pest, with the result that many organisms not necessarily having plant pest characteristics would fall under these regulations. Anyone proposing to "introduce" (import, move interstate, or release into the environment) an organism derived by genetic engineering from a species on the list, needed to first obtain a permit from USDA APHIS. This permit scheme parallels the permits that have long been needed for movement of known plant pests under 7 CFR Part 330.

These regulations were finalized with some revisions in June 1987 (52 Federal Register 22892–22915). Among the more important revisions were the imposition of time frames for USDA review of 120 days for an environmental release permit and 60 days for a movement permit, the addition of a petition procedure to request additions or deletions in the list of potential plant pests, and a provision for notification of the state in which a field test was proposed to take place. Under the final regulations, a person or institution wishing to conduct a field test of a regulated organism needed to consult APHIS and possibly apply for a permit to conduct the test. For permit applications involving field tests, the submission was to include a description of the modifications made to the organism, data characterizing the stability of these changes, a description of the proposed field test, and the procedures to be used to "contain" the organisms in the test plot. Submitters needed also to assess potential environmental effects.

APHIS review of permit applications was straightforward and was generally completed well within the 120 days allowed by the regulations. From 1986 to 1990, APHIS approved about 100 field tests of transgenic plants under these regulations and the program was largely considered successful by government and industry alike. Because of the experience gained in its review of transgenic plant field tests, APHIS issued a revised final rule on March 31, 1993 (58 Federal Register 17044–17059), establishing a less-stringent scheme, whereby most transgenic varieties of six specific crop species (the ones most frequently tested up to that date) could be field tested merely on advance notification to APHIS (i.e., without a permit), and also establishing procedures for specific

varieties to be delisted so that permits for use of such plants would no longer be required. In a further relaxation, on May 2, 1997 (62 Federal Register 23945–23958), the notification scheme was extended even further so that virtually all transgenic plants could be field tested merely upon agency notification without need for a permit, except certain plants derived from species known to be noxious weeds. Genetically engineered microorganisms, however, were not affected by these revisions and for the GEMs covered by these regulations, most proposed uses in the environment still require a permit rather than qualifying for the notification procedure.

Although primarily used to regulate field-testing of transgenic plants, the Part 340 regulations have been used to regulate introductions of a relatively small group of GEMs, as shown in Table 4. Many of these are engineered versions of organisms having pesticidal or other agriculturally useful properties, and although some of these permits were issued to persons or institutions that were also subject to EPA regulation (e.g., under FIFRA), several of these were for research uses that were not regulated by other federal agencies.

Table 4. Genetically Modified Microorganisms Approved by USDA for Environmental Use Under the Plant Pest Act

Microorganism	End Use or Application
Aspergillus flavus	Not available
Cephalosporium gramineum	Not available
Clavibacter xyli	Endophyte of corn, engineered to express *B. thuringiensis* endotoxin.
Cryphonectria parasitica	Virulence-attenuated pathogen (chestnut blight)
Fusarium graminearum	Virulence-attenuated pathogen (wheat head scab disease), also reduced mycotoxin production
Fusarium moniliforme	Virulence-attenuated pathogen (corn ear rot), also reduced mycotoxin production
Fusarium sporotrichioides	Not available
Heterorhabditis bacteriophora Pseudomonas	Not available
Pseudomonas putida	Engineered to express luciferase gene as marker.
Pseudomonas syringae	Virulence-attenuated pathogen (bacterial speck disease)
Pseudomonas syringae	Reduced epiphytic survival
Rhizobium etli	Nitrogen fixation
Rhizobium fredii	Nitrogen fixation
Rhizobium leguminosarum	Nitrogen fixation
Rhizobium meliloti	Nitrogen fixation
Xanthomonas campestris	Virulence-attenuated pathogen (bacterial spot disease)
Xanthomonas campestris	Crucifer black rot pathogen, engineered to express luciferase gene as marker.

Note: The microbial species mentioned, genetically modified in various ways, have received permits or have otherwise been allowed to be field-tested or imported into the United States by the U.S. Department of Agriculture.

Data Requirements

Among the data required to be submitted to USDA to support an application for a permit under Part 340, is the following scientific information:

- All scientific, common, and trade names, and all designations necessary to identify the donor organism(s), recipient organism(s), vector or vector agent(s).
- A description of the anticipated or actual expression of the altered genetic material in the regulated article and how that expression differs from the expression in the nonmodified parental organism.
- A detailed description of the molecular biology of the system (e.g., donor-recipient-vector) used to produce the regulated article.
- A detailed description of the purpose for the introduction of the regulated article, including a detailed description of the proposed experimental and production design.
- A detailed description of the processes, procedures, and safeguards that have been used to prevent contamination, release, and dissemination in the production of the donor organism, recipient organism, vector or vector agent.
- A detailed description of the proposed procedures, processes, and safeguards that will be used to prevent escape and dissemination of the regulated article at each of the intended destinations.
- A detailed description of the proposed method of final disposition of the regulated article.

OTHER U.S. BIOTECHNOLOGY REGULATION

Uses of microorganisms in commerce or in the environment are potentially subject to other regulations as well. Two types of regulation where rules specific to microbiology exist are federal export controls and state regulation of biotechnology activities.

The U.S. Commerce Department's Bureau of Export Administration regulates exports of all commodities, requiring that permits be obtained in advance for export of commodities to certain politically sensitive countries. The Department maintains regulations specific for biological materials based on concern over spread of biological weapons. Regulations that took effect in early 1989 created a situation where almost all exports of recombinant organisms would require an advance permit from the Commerce Department. In response to public comments that these regulations were overly broad, in March 1990 the Department published revised rules, requiring permits only for exports of potentially pathogenic organisms (15 CFR 742.2; 55 Federal Register 11361–11362), thus limiting the impact of these regulations.

In the late 1980s, there was a flurry of activity in state legislatures to enact biotechnology laws. Many of these covered possible field tests of GEMs or transgenic plants and by the time this activity peaked in 1991, there were approximately nine state laws that would impact planned environmental introductions of GEMs. Some of these laws required separate state permits for planned environmental uses of GEMs or transgenic plants, whereas others were simply notification schemes to ensure that the relevant state government agency was informed of proposed field tests (5,10). USDA's decision to require formal notification of the states in which field tests were proposed helped in part to stem the need for further state regulation, however, it is possible that environmental uses of GEMs in certain states would trigger additional regulatory requirements.

BIOTECHNOLOGY REGULATION OUTSIDE THE UNITED STATES

Several nations or jurisdictions outside the United States have adopted biotechnology regulations. Two of these regulatory schemes are briefly described in the following section, as they relate to the possible environmental use of genetically engineered microorganisms.

Canada

Canada's regulatory approach resembles that of the United States, in that existing laws and regulations are used to regulate biotechnology in a product-specific way. Therefore many products of biotechnology would be regulated in Canada under federal laws, such as the Pest Control Products Act (pesticides), the Seeds Act (plants), and the Fertilizers Act (nitrogen-fixing microbes and inorganic fertilizers). In November 1997, after several years of deliberation, Environment Canada issued biotechnology regulations under the Canadian Environmental Protection Act (CEPA) that are similar in scope and approach to the U.S.EPA's TSCA regulations. Environment Canada will use CEPA to conduct risk assessments of certain biotechnology products that are new to commerce in Canada and are not regulated by other federal agencies. Among products that would fall within the scope of this law would be microbial cultures used for bioremediation.

Environment Canada considers microorganisms as being potentially subject to these "New Substance Notification" (NSN) regulations if they meet the definition of "new substance." Unlike the U.S. EPA, however, Environment Canada did not create a specific definition of "new microorganism" based on scientific criteria but instead is relying on the definition in the law that a "new substance" is one intended for introduction into commerce that is not on the domestic substance list as having been used in commerce between January 1, 1984 and December 31, 1986. Thus, if a microorganism was used in commerce in this time period in a way such that "its entry into the environment was unrestricted," it is exempt from reporting; but all other microorganisms, regardless of make-up, are subject to reporting. In this way the Canadian CEPA regulations are broader than those of the U.S. EPA, in subjecting a larger class of microorganisms to regulation, including naturally occurring or classically mutated strains.

Under the NSN regulations, any person who manufactures or imports substances subject to notification must provide a notification package to Environment Canada, which contains certain information specified in the regulations. Environment Canada uses this information to conduct a risk assessment prior to entry into commerce. These requirements are generally similar to those used by the U.S. EPA. Information on the Canadian biotechnology rule is available at *www.ec.gc.ca/cceb1/eng/biohome.html* and the regulations themselves can be found at *www.ec.gc.ca/cceb1/eng/nsnregejan1597a.html*. A Guidelines document that is similar to the EPA "Points to Consider document" can be accessed at *www.ec.gc.ca/cceb1/eng/97gle2.html*.

European Union

Many countries now in the European Union have adopted biotechnology regulatory policies following the same historical pattern as that seen in the United States: early concerns over public health issues, leading to controls over contained uses, followed by commercial regulation triggered largely by environmental concerns. For example, many European countries have adopted laboratory and manufacturing guidelines similar to the U.S. NIH Guidelines. Most of these laws were initially aimed at laboratory research but some covered commercial activities as well.

Within the European Union these individual country laws have been subsumed by two Union-wide biotechnology directives adopted by the European Commission's (EC's) Environmental Directorate, DGXI, in April 1990 (EC directives are not themselves laws or regulations but require each EU member state to adopt its own implementing laws to achieve the result specified in the directive). The first is a directive, covering contained uses of genetically modified organisms. This directive is similar to the NIH Guidelines in establishing appropriate procedures, both at small-scale and large-scale, for the use of engineered organisms in contained systems. Regulatory authorities in the member states must be notified or must actually approve certain biotechnology activities.

The other directive DGXI adopted was aimed at outdoor uses of genetically manipulated organisms. This directive required each member state to appoint a regulatory agency with the authority to review and approve environmental introductions within its jurisdiction. Proposals for R&D field tests must address similar environmental issues as are considered in the United States. Member states have sole authority to approve R&D uses within their jurisdiction, after EC notification and a 90-day review period. Commercial use proposals are to be made to a single member state. The competent authority would review the application and forward its recommendation to the Commission within 90 days. For products recommended for approval, other EC member states then have 60 days to lodge objections and if none are raised, the manufacturer could sell the product throughout the Union. Any state, however, may prohibit sale of a product if it had

reason to believe that the product presented unreasonable risks.

The approach adopted by the EU for implementation by its member states differs from the product-specific approach adopted by the United States and Canada, by creating a single biotechnology law to govern all field releases of engineered organisms regardless of end use. In some countries this has created the situation where a GEM might be subject to dual regulation, under the biotechnology law and the product-specific law applying to the use for which the GEM is intended (e.g., a pesticide law). This was among the early criticisms levied against the DGXI directive by industry spokespersons.

However, during the years this directive has been in effect it has worked reasonably well to allow for research field tests of genetically modified plants and microorganisms, although certain countries within the EU have been less than hospitable to outdoor uses of GEMs. More recently, however, this directive has allowed individual nations to ban commercial use or shipment of transgenic plants intended for food use, leading to significant uncertainties and consumer concerns throughout Europe about engineered plants in foods. These concerns seem not to be directed to environmental uses of GEMs or plants for the most part.

REMOVAL OF PATHOGENIC MICROBES BY GRANULAR HIGH-RATE FILTRATION

KWOK-KEUNG AU
Greeley and Hansen, LLP
Chicago, Illinois

MARK W. LECHEVALLIER
American Water Works Service Company
Voorhees, New Jersey

With proper design and operation, filtration can act as a consistent and effective barrier for microbial pathogens. The most commonly used filtration processes in potable water treatment and the pore size of filter medium are listed in Figure 1. The sizes of different microbial particles are also included. These size spectra provide insight into understanding the removal mechanisms and efficiencies and into developing strategies to remove microbes by different filtration processes.

Granular filtration is the most widely used filtration process in drinking water treatment. A comprehensive review of granular filtration process is available (1). High-rate granular filtration is the focus of this chapter. Slow sand filtration, which is operated under a very low filtration rate (less than 0.4 m/h), is described in another chapter. Note that the design/operating criteria and mechanisms to remove microbes by slow sand filtration are considerably different from high-rate granular filtration processes. Membrane filtration, another effective barrier for microbial pathogens, is also covered in another chapter.

PROCESS DESCRIPTION

In granular filtration, water passes through a filter consisting of a packed bed of granular materials. Removal of microbes is achieved when microbes or microbe-associated particles deposit on the filter medium. This removal is within the granular medium (depth filtration) rather than on the top layer of the filter medium only (cake filtration). After a period of operation, the head loss through the filter increases or the effluent quality deteriorates to an unacceptable level; the filter has to be cleaned by backwashing. Initially, after backwashing, filters exhibit a poor performance followed by a period with improvement in filtrate quality until they reach a stable level of performance. Passage of microbial pathogens during this so-called ripening period can be formidable. Different methods are used to minimize this impact, such as filter-to-waste (wasting the initially filtered water) or slow start (limiting initially filtration rate until the filtrate quality is acceptable).

Granular filters can be constructed as monomedium (typically with silica sand), dual media (usually with anthracite coal and sand), and trimedia (commonly with coal, sand, and garnet). A schematic representation of these configurations is shown in Figure 2. Granular-activated carbon is used when both filtration of particles and adsorption of organic compounds are considered. Depending on raw water quality, granular filtration can be operated in three different modes: conventional, direct,

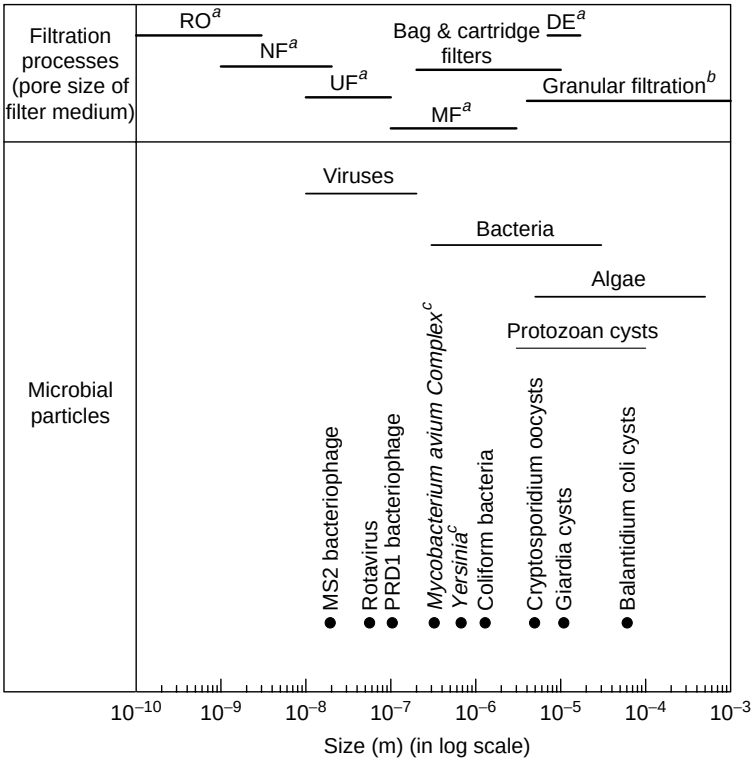

Figure 1. Pore size of filter medium and size of microbial particles.

[b]Including slow sand filtration. Slow sand filter has a lower pore size than rapid-rate filter.
[c]These bacteria are rod-shape. The sizes shown represent the smallest dimension.

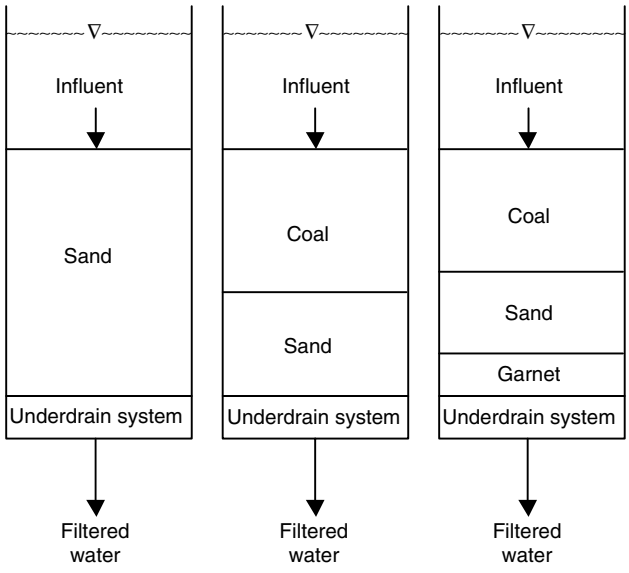

Figure 2. Schematic representation of filter configurations.

and in-line filtrations. The operation of conventional treatment includes addition of coagulants (rapid mixing), flocculation (slow mixing), sedimentation, and filtration. When sedimentation is omitted, the process is termed *direct filtration*. If both flocculation and sedimentation tanks are omitted, it is termed *in-line filtration*. Conventional treatment is appropriate for raw waters with a variety of water quality. Direct and/or in-line filtrations are used for raw water with good quality (low turbidity and color).

Removal of microbial pathogens by granular filtration is not a purely physical process. By comparing the pore size of granular filters with the size of most microbes shown in Figure 1, one can interpret that effective removal of microbes by granular filtration cannot rely on physical straining, at least at the initial stage of a filter run. The removal of particles by granular filtration is considered to involve two sequential steps: transport of particles from suspension to filter medium followed by the attachment of particles to the medium (2). Transport step is determined by the physical hydrodynamic properties of the system. Important transport mechanisms include diffusion, interception, and sedimentation (see below). Process variables such as the size and density of microbes, size and depth of filter medium, and filtration rate affect transport efficiency. For transport of motile microorganisms, an additional mechanism is the active movement of the cell (3). Attachment is determined by the surface and solution chemistry of the system (4). Unfavorable interaction among particles and filter medium must be avoided so that particles can attach to the filter medium. Proper chemical pretreatment is used to achieve this purpose and is the single most important factor in determining filtration efficiency. Without proper chemical pretreatment, rapid rate filtration probably works as a simple strainer and cannot be an effective barrier to microbial pathogens. Traditionally, chemical coagulation before filtration is used to destabilize particles and thus promote their adherence to the filter medium. Recently, mechanistic study has been performed and showed that applying oxidants such as chlorine and/or ozone prior to filters can also change the surface properties of particles and, in particular, destabilize particles (5). This result has been used

to explain the positive effects of preoxidation on filtration performance.

FILTER PERFORMANCE

The importance of chemical coagulation pretreatment on removal of microbes by granular filtration has been emphasized by numerous studies. Al-Ani and coworkers (6) conducted a pilot-scale filtration study for low-turbidity waters (less than 1 ntu). Without chemical pretreatment, poor filtration performance was observed. The removal by filtration averaged 69% (0.51 logs) for *Giardia* and 28% (0.14 logs) for turbidity. When optimum coagulation conditions were achieved by adding alum and polymeric filter aids, the removal efficiency increased to exceed 95% (1.30 logs) for *Giardia*, 99% (2 logs) for total coliform bacteria, and 70% (0.52 logs) for turbidity. Other process variables such as filtration mode (direct and in-line filtrations), filter media (monomedia with sand and dual media with sand and anthracite), and temperature (5 °C and 18 °C) did not exhibit significant effects on filtered water quality in this particular study. Varying filtration rate from 5 to about 20 m/h showed little effect on the removal of *Giardia*, total coliform bacteria, and standard plate-count bacteria but increased turbidity in filtered water.

Robeck and coworkers (7) reported that when alum was used as coagulant, the removal of poliovirus type 1 by a pilot-scale dual-media filter was more than 98% (1.70 logs). Ongerth (8) conducted pilot studies for conventional and in-line filtrations. Without chemical pretreatment, removal of Giarida cysts averaged 75% (0.60 logs) for conventional treatment and 64% (0.44 logs) for in-line filtration. With optimum chemical pretreatment by alum and polyelectrolytic filter aid, the removal increased to 98% (1.70 logs) for conventional treatment and 93.6% (1.19 logs) for in-line filtration.

Nieminski and Ongerth (9) performed a two-year evaluation of the removal of Cryptosporidium oocysts and Giardia cysts at pilot-scale and full-scale filtration plants, both operated under direct filtration and conventional treatment modes. Dual-media filters with anthracite and sand were used. The results indicated that maintaining optimum coagulation conditions to produce low turbidity (0.1 to 0.2 ntu) filtered water provided effective removal of *Giardia* and *Cryptosporidium*. Under optimum coagulation conditions by polymers together with either alum or polyaluminum chloride, the average removal of *Giardia* was 3.3 logs or better and the average removal of *Cryptosporidium* was 2.3 logs or better in both pilot-scale and full-scale plants, regardless of the treatment modes (direct filtration or conventional treatment). Correlation between the removal of cysts and of surrogate parameters were also investigated. A high correlation was found between removal of cysts and of the respective size particles (4–7 μm and 7–11 μm), with an R^2 value of 0.79 or higher. A low correlation was established between the removal of *Giardia* and *Cryptosporidium* and the removal of turbidity (R^2 value 0.64 or lower). This indicated that particle counting could serve as a better indicator of cyst and oocyst removal than turbidity, at least for this particular study. No correlation was found between log removal of seeded cysts and log removal of heterotrophic plate counts (R^2 value 0.08 or lower), meaning that heterotrophic plate counts were probably not a good surrogate in the evaluation of cyst removal.

Swertfeger and coworkers (10) evaluated the effects of filter media design on cyst and oocyst removal. Pilot-scale filters with three different media designs were used. These included monomedia (sand with a depth of 750 mm), fine dual media (anthracite and sand with a depth of 900 mm and 300 mm, respectively), and deep dual media (anthracite and sand with a depth of 1,500 mm and 300 mm, respectively). The feed water to the pilot systems was taken from the effluent of a sedimentation unit in a full-scale water treatment plant and was in optimum coagulation condition. They reported that there was no statistically significant difference in the filtration performance for the different media. Removal of *Giardia* was 4.4 logs or better, with greater removal efficiency in the summer than in the winter. Removal of *Cryptosporidium* during the summer was similar to that in winter and averaged 2.7 logs or better.

Payment and coworkers (11) reported the water quality monitoring results for a full-scale conventional water treatment plant using dual media filters. Coagulation was provided using alum and activated silica. Prechlorination was applied at a dosage of 1 mg/L. The results confirmed that a properly operated conventional treatment plant provided a substantial barrier to microbial pathogens. Giardia cysts were detected in only 1 of the 32 filtered water samples, with a mean removal of 3.6 logs after filtration (including removal by coagulation and sedimentation). Removal of Cryptosporidium oocysts was lower than that for *Giardia*. Oocysts were detected in 7 of the 32 filtered water samples with a mean removal of two logs. *Clostridium perfringens* were detected in 9 of the 33 filtered water samples with a mean removal of 4.4 logs. No human enteric virus was detected in 32 filtered water samples with a mean removal of 3.1 logs (assuming that the concentration of human enteric virus in filtered water was equal to the detection limit). *Somatic coliphages* were detected in 24 of the 32 filtered water samples with a mean removal of 3.5 logs.

FILTRATION MODEL

In this section, a mechanistic performance model for removal of particles by granular filtration is used to predict the impact of process variables on removal of microbial pathogens. This model was first developed and applied in water filtration by O'Melia and coworkers (2,12). Substantial modifications have been made by Fitzpatrick and Spielman (13), Rajagopalan and Tien (14), and others. An extensive review of these theoretical models is available (15). The version by Rajagopalan and Tien is used in this report. Model equations used in these calculations are shown in Table 1.

In this model, particle removal by granular filters is considered to involve two steps: transport and attachment. Particles are transported from suspension to the close distance of a media grain. The transport step is

Table 1. Equations Used in Model Calculations for Figure 4

(1)	$\frac{C}{C_0} = \exp\left(-\frac{3}{2}\frac{(1-f)\alpha\eta_0 L}{d_c}\right)$	C: influent concentration; C_0: effluent concentration; f: porosity of the packed bed; α: attachment efficiency; η_0: overall single collector efficiency; L: bed depth; d_c: diameter of the filter media (collector)
(2)	$\eta_0 = \eta_D + \eta_I + \eta_G$	η_D: single collector efficiency due to diffusion; η_I: single collector efficiency due to interception; η_G: single collector efficiency due to gravity
(3)	$\eta_D = 4.0A_s^{1/3}\left(\frac{D}{Ud_c}\right)^{2/3}$	A_s: flow parameter to account for the effects of neighboring collectors (see equation (6)); D: diffusion coefficient of particles (see equation (8)); U: filtration rate
(4)	$\eta_I = A_s N_{LO}^{1/8} R^{15/8}$	N_{LO}: van der Waals number (see equation (9)); R: size ratio (see equation (11))
(5)	$\eta_G = 3.38 \times 10^{-3} A_s N_G^{1.2} R^{-0.4}$	N_G: gravitational force number (see equation (10))
(6)	$A_s = \frac{2(1-\rho^5)}{2-3\rho+3\rho^5-2\rho^6}$	k: Boltzmann constant; T: water temperature; d_p: diameter of particle; μ: water viscosity; A: Hamaker constant; ρ_p: mass density of particle; ρ: mass density of water; g: acceleration due to gravity
(7)	$\rho = (1-f)^{1/3}$	
(8)	$D = \frac{kT}{3\pi d_p \mu}$	
(9)	$N_{LO} = \frac{4A}{9\pi\mu d_p^2 U}$	
(10)	$N_G = \frac{(\rho_p - \rho) g d_p^2}{18\mu U}$	
(11)	$R = \frac{d_p}{d_c}$	

Note: Equation (1) is the master equation used to calculate the removal efficiency of a clean bed.

physical hydrodynamic in nature. Three transport mechanisms are important for water filtration: interception, sedimentation, and diffusion. Interception refers to the mechanism by which particles following the streamline of fluid flow come into contact with a media grain by their own sizes. Sedimentation refers to the mechanism by which particles with density greater than that of water deviate from the streamline of fluid flow by gravity and come into contact with a media grain. Diffusion refers to the mechanism by which particles subjected to random motion by their thermal energy come into contact with a media grain. A schematic representation of these transport mechanisms is illustrated in Figure 3. Single collector efficiencies have been well developed to describe these transport mechanisms.

Once particles come into contact with a media grain, removal is achieved only if the particles attach to the media. The attachment step is dominated by various physicochemical interactions between particles and media grain at a short distance. Because of these interactions, it is not necessary that all the contacts between particles and media lead to attachment. An attachment efficiency (α) is used to represent the fraction of successful contact. The value of α varies from 1.0 (all contact result in attachment) to 0.0 (no contact results in attachment). In drinking water treatment, α is promoted by chemical coagulation pretreatment, with a higher value of α provided by a better coagulation condition. A combination of the single collector efficiency, attachment efficiency, and the total number of media grains in a filter results in a predictive equation for removal efficiency.

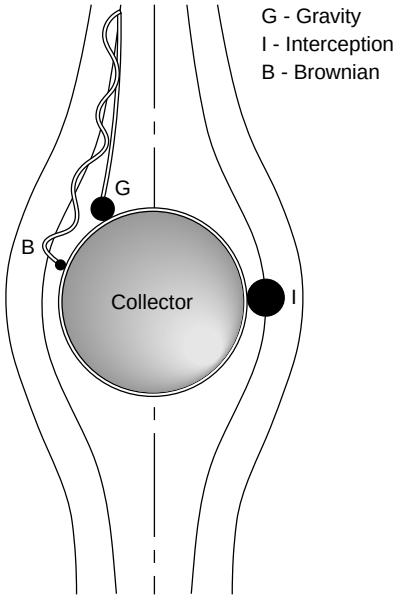

Figure 3. Particle transport mechanisms toward a single collector in water filtration. The thick line represents the particle trajectory. The thin line represents the fluid streamlines (after Yao and coworkers (2)).

The effects of process variables on removal efficiency of particles by granular filtration are presented in Figure 4 as functions of particle size. Process variables include coagulation condition, filtration rate, medium diameter, filter depth, and water temperature. Input parameters

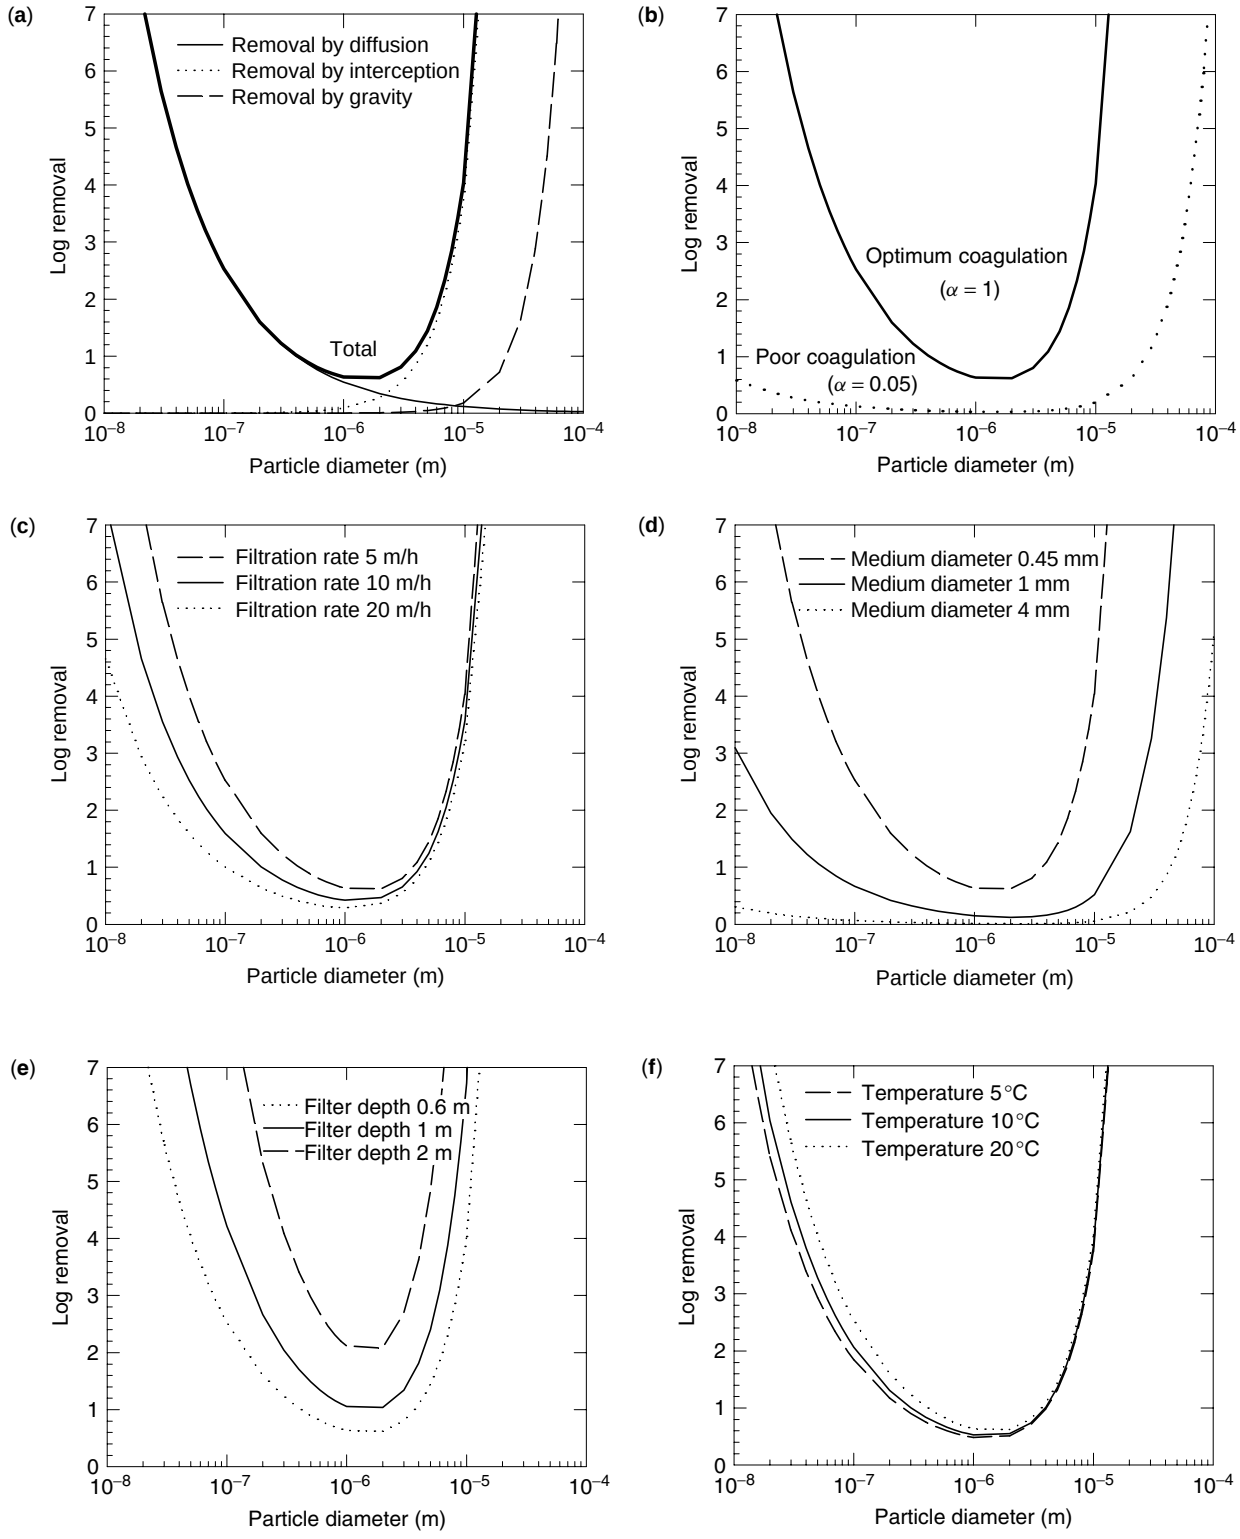

Figure 4. Effects of process variables on removal efficiency of granular filtration (simulation parameters are shown in Table 2).

used in these simulations are tabulated in Table 2. These theoretical results are interpreted to discuss the removal of microbial pathogens by granular filtration. However, limitations of the model should be realized. The model is developed for a clean bed and for a monodisperse suspension, meaning that temporal variation in filter performance is not considered. Furthermore, the model is developed for passive (nonmotile) particles. Some microbes, such as some species of coliform bacteria, are motile. Cell motility may result in different transport

Table 2. Parameters Used in Model Calculations for Figure 4

Process Variables	Values
Coagulation condition (α)	1.0[a]
Filtration rate	5 (m/h)[b]
Medium diameter	0.45 (mm)[c]
Filter depth	0.6 m[d]
Water temperature	20 °C[e]
Media configuration	Monomedia
Particle density	1.05 (g/cm^3)
Hamaker constant	10^{-20} •(Joule)
Filter porosity	0.4

Note: [a]1.0 and 0.05 in Figure 4b.

mechanisms and removal efficiencies. The effects of cell motility on filter performance are not well known and are not considered by the model. This model has been tested experimentally for nonmicrobial particles, with great success. However, there is no systematic experimental testing of the model for microbes.

Model calculations indicate that removal mechanisms and efficiency are determined dramatically by particle diameter (Fig. 4a). Microbes in submicron sizes such as viruses are removed (transport) by Brownian diffusion. Removal efficiency of these small particles decreases with increasing particle size as smaller particles diffuse faster than larger particles. With an optimum coagulation condition ($\alpha = 1.0$) and the assumption that the sizes of microbes do not change before entering the filter, this filter can theoretically remove 6.38 logs of MS2 bacteriophage (2.5×10^{-8} m), 3.21 logs of rotavirus (7.0×10^{-8} m), and 2.53 logs of PRD1 bacteriophage (10^{-7} m).

Microbes with a diameter larger than about a few microns, such as protozoan cysts, algae, and some bacteria, are removed by interception (Fig. 4a). Removal efficiency of these larger particles increases with increasing microbial size because larger particles can be easily intercepted by the filter medium. When the filter is operated under an optimum coagulation pretreatment condition, the theoretical removal efficiencies are 1.44 logs for Cryptosporidium oocysts (5×10^{-6} m) and 4 logs for Giardia cysts (10×10^{-6} m). Higher removal efficiency of Giardia cysts when compared with that of Cryptosporidium oocysts has been observed by numerous experimental studies (9,10). Removal by gravity is never a dominant mechanism in these calculations, even for large microbes such as *Balantidium coli* cysts (6×10^{-5} m). This is because particle density (1.05 g/cm^3) is very close to the density of water. The insignificance of gravity effects is probably true for most microorganisms influent to filters, unless they are associated with dense particles.

A minimum in the theoretical removal efficiency is observed for microbes with size about 1 μm (Fig. 4a). Particles in this size range are too large for diffusion to be effective and too small for interception to be effective. For the same optimum coagulation condition, the model predicts that the filter only removes 0.64 logs of coliform bacteria (1.0×10^{-6} m). Although the sizes of some bacteria are in this minimum-removal size range, it should be emphasized again that the model does not consider cell motility.

The significance of chemical coagulation pretreatment on filtration performance is indicated obviously by the calculations (Fig. 4b). When coagulation conditions change from optimum ($\alpha = 1.0$) to poor ($\alpha = 0.05$), theoretical log removals deteriorate from 6.38 to 0.20 for MS2 bacteriophage, from 0.64 to 0.03 for coliform bacteria, from 1.44 to 0.07 for Cryptosporidium oocysts, and from 4 to 0.20 for Giardia cysts. These predicted effects of chemical coagulation on filtration performance are qualitatively consistent with many experimental results (6,8).

The effects of filtration rate on filter performance are either significant or slight, depending on particle size (Fig. 4c). For microbes with size greater than about a few microns and with a mass density close to water, increasing filtration rate from 5 m/h to 20 m/h only slightly decreases removal efficiency. A similar behavior has been observed experimentally by Al-Ani and coworkers (6). In these theoretical calculations, log removal of Giardia cysts reduces from 4.03 to 3.58 and to 3.22 when the filtration rate increases from 5 to 10 and to 20 m/h. This is because particle removal by interception is not strongly affected by filtration rate. The effects of filtration rate on removal efficiency are much more pronounced for submicron microbes. Theoretical log removal of rotavirus decreases from 3.21 to 1.27 when the filtration rate varies from 5 to 20 m/h. This is because particle removal by diffusion is a combination of convective diffusion process and is strongly affected by filtration rate.

Medium size (Fig. 4d) and filter depth (Fig. 4e) exhibit considerable effects on filtration performance for microbes of all sizes. Decreasing medium size and/or increasing filter depth increase removal efficiency. This is, in part, because the number of filter media grains increases with decreasing medium size and/or with increasing filter depth and thus favors the capture of particles. Decreasing medium size also enhances contact opportunity between particles and media grain by diffusion and interception. Temperature had some effects on the removal of submicron microbes and had almost no effect on the removal of microbes larger than 1 μm (Fig. 4f). When the temperature varies from 20 to 5 °C, theoretical removal efficiency of the MS2 bacteriophage decreases notably from 6.38 logs to 4.66 logs, whereas the removal of Cryptosporidium oocysts reduces from 1.44 log to only 1.31 logs. This is because particle removal by diffusion is a strong function of temperature. A higher temperature corresponds to a low water viscosity and to a higher diffusion. Particle removal by interception is, on the other hand, not affected by temperature.

CONCLUSION

A critical review of removal of microbial pathogens by high-rate granular filtration is provided in this document. Included are the operation principle, the

removal (transport) mechanisms and efficiency, and the process parameters affecting the performance. A clean-bed filtration model is used to elucidate the transport mechanisms of different microbial pathogens in granular filters and to predict the effects of process variables on treatment efficiency.

Under proper design and operation conditions, granular filtration is a consistent and effective barrier to pathogenic microbes. Providing proper chemical pretreatment to promote adherence of particles to the filter medium is the single most important factor in determining filtration performance. Proper engineering design establishes good physics, but it is difficult and expensive to remove microbes effectively if the particle surface is not properly adjusted by chemical pretreatment.

The rhizosphere is a concept that describes the physical location in soil where plants and soil microorganisms interact. From the perspective of soil microorganisms, the rhizosphere is an oasis in what is by comparison the barren desert of the bulk soil. The "rhizosphere effect" is the stimulation of microbial growth in the soil surrounding the root due to the release (exudation and secretion) of organic compounds from the root. As a result of these releases, intense microbial activity and larger microbial populations occur in this zone in comparison to the bulk soil, with microbial populations reaching up to 1×10^9 cells per cm^3, 10 to 100 times larger than the population in the bulk soil. Rhizosphere microorganisms include bacteria, fungi, flagellates, amoebae, mites, and viruses. An interacting trinity of the soil, plant and the soil organisms associated with the root system determines the rhizosphere environmental status (Fig. 1). Rhizosphere research can be separated out into three broad but distinct interrelated positions, (*1*) the influence of roots on microorganisms in the soil, and the influence of rhizosphere organisms on (*2*) plant growth, and (*3*) soil borne pathogens and plant disease (1).

THE RHIZOSPHERE; A DEFINITION

Lorenz Hiltner first defined the term *rhizosphere* in 1904 (3) as the volume of soil contiguous to and influenced by the plant root. Hiltner's initial use of the term was in reference to the zone of intense microbial activity around the roots of Leguminoseae, with an emphasis on the critical role of microbial activities in the rhizosphere, in the nutrition and general health of plants. He postulated that plant nutrition in general dependended on the composition of the soil flora in the rhizosphere. He also recognized that the attraction of beneficial bacteria by root exudates would be accompanied by the attraction of other less beneficial organisms that were also able to adapt to specific root secretions. This observation summarizes the focus of rhizosphere science research because of the influence of the rhizosphere to general plant nutrition, growth and development, and its role in plant pathogenesis.

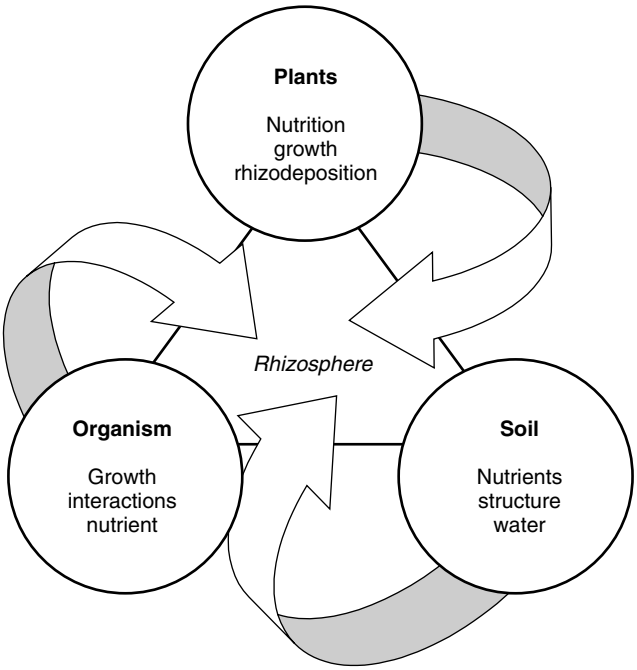

Figure 1. The rhizosphere trinity: the interacting factors that determine the environmental conditions of the rhizosphere. (After J. M. Lynch, in J. M Lynch, ed., *The Rhizosphere*, John Wiley & Sons, Chichester, U.K., 1990, 1–10.)

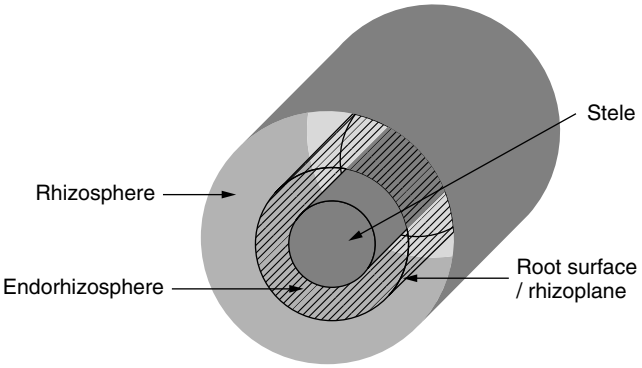

Figure 2. Schematic diagram of the rhizosphere (not to scale) showing the three spheres of microbial activity around the root.

The term "rhizosphere" is derived from the Greek word for root (*rhizo* or *rhiza*) and "sphere" meaning one's field of action, influence, or existence. While the rhizosphere is defined as the volume of soil contained within the sphere of influence around the plant root (Fig. 2), there is a lack of a precise physical delimitation. This is because the extent of the rhizosphere will by definition depend on factors such as the rate of exudation, and the mobility and consequent utilization impact that the released substrates have on the microbial population. This said it is generally acknowledged that the rhizosphere effect can be to a distance of 1 to 2 mm from the root surface, but can extend up to 5 mm. Subsequent research divided the rhizosphere into more defined spatial regions such as the outer rhizosphere, the inner rhizosphere (*endorhizosphere*), and the root surface (*rhizoplane*). Further definitions have been coined for more specialized regions such as the *mycorrhizosphere* where mycorrhizal fungi are in association with the roots and *actinorhizosphere* or *actinorhiza* when actinomycetes are associated with root nodules. Although these regions are theoretically defined, it is in practise difficult, and probably inappropriate, to study them apart.

The Rhizosphere Effect

The rhizosphere effect occurs because in most mineral soils, the activity and growth of the microbial biomass is limited by the availability of substrate, especially carbon. As such the entry of substrate into the soil around the root system, is a key factor governing the size and activity of the microbial biomass (4). Yet, while the extent to which the quantity and composition of exudates affect microbial community structure are largely unknown (4), it is suggested that the rhizosphere effect can be beneficial, harmful, or neutral (2) (Fig. 3).

An extensive variety of organic compounds originating from the plant have been found in the rhizosphere and are known as rhizodeposition products. These compounds have been classified under standard terms to help readily identify their organic nature and source. Rovira and colleagues (5) classified the compounds as follows:

Exudates. Chemically diverse low molecular weight compounds (i.e., sugars, organic & amino acids as well as more complex compounds such as vitamins and plant hormones) that leak from intact cells and into the soil, either directly through epidermal cell walls or into intercellular spaces and then into soil via cell junctions.

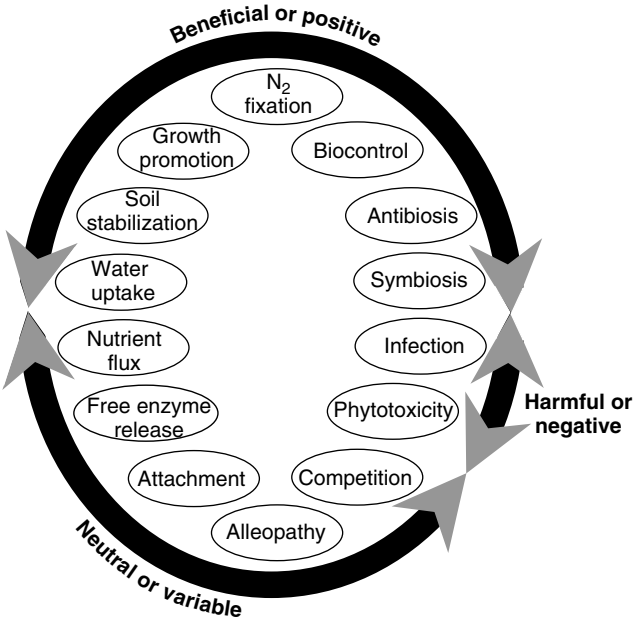

Figure 3. Process values of rhizosphere organisms. (After J. M. Lynch, in J. M Lynch, ed., *The Rhizosphere*, John Wiley & Sons, Chichester, U.K., 1990, 1–10.)

Secretions. Compounds that root cells actively release to the rhizosphere

Plant mucilage. From four sources from various parts of the root including

- Golgi bodies secretions predominately by the root cap cells
- Hydrolysates of the primary cell wall located between the root cap and the epidermis
- Secretions from epidermal cells and root hairs with primary walls, often augmented by the physical rupturing of the cells by soil minerals
- Compounds released as a result of dead epidermal cells undergoing microbial modification and degradation

Mucigel. A layer of gelatinous material on the root surface comprising natural and modified plant mucilages, bacterial cells and their metabolic products such as capsules and slimes, and also colloidal soil minerals and organic matter

Lysates. Material released through the lysis of older epidermal cells

Given the difficulties in distinguishing experimentally the source of these organic substances, often the concept of categorizing them in terms of their subsequent utilization as microbial substrate is used. For example, they may be classified as low molecular weight compounds that can be readily assimilated by the microbial biomass, or more complex compounds such as the polysaccharides, polypeptides nucleic acids, pigments and so on, which require extracellular enzymic activity before assimilation. Also, there are structural materials such as cell wall components that require saprophytic degradation activities before the carbon can be utilized by the general soil biomass. This latter approach to categorizing exudates has been suggested to be more appropriate to the study of rhizosphere microbial population dynamics (6).

Rhizosphere products are not liberated evenly over the root surface, their presence in the rhizosphere is dependent on the developmental stages of the root. The changes in root development gives rise to a longitudinal gradient of exudation that may reflect the gradient in microbial catabolism of root exudates and differences in root cell activity. The temporal and physical locations of their release are elaborated on in Figure 4. The heterogeneous nature of this release of organic material has implications for the bacterial populations that benefit from it, causing both numbers and types of organisms to fluctuate as the root grows. Work by Griffiths and coworkers (4) has shown that when compounds characteristic of root exudates are added to a soil at a range of concentrations, a consistent trend can be seen within the soil community structure with access to these exudates. Essentially, as the substrate quantity increased, both bacterial biomass and fungal biomass increased, with gram-negative bacteria responding differently from gram-positive bacteria, and fungi dominating over bacteria at high rates of release. Further examination of commonly accepted biomarkers indicated that the proportion of gram-positive bacteria remained more constant at lower substrate loading and declined as loadings increased, while gram-negative bacteria, increased with increasing substrate loadings only declining at the very highest inputs.

As the root cap zone develops there is a massive excretion of a carbohydrate rich gel that serves to lubricate the root tips development through the soil, and causing the outer cap cells to break off and become sloughed into the soil. From their development from root cap meristematic cells, they differentiate progressively through specialized stages before eventually becoming detached from the root cap (7). Consequently by the time they become external to the root, they have served several functions such as secretion and the sensing of gravity and other environmental signals. These sloughed root cap cells contain starch, and remain viable in the soil for up to three weeks, during which time they continue to secrete mucilage (8) and possibly perform other functions.

More recent work on root cap cells has allocated a further and more defensive function to these sloughed cells and renamed them 'root border cells' in recognition of their bacterial border role. The previously accepted wisdom was the constant shedding of these cells was to prevent physical damage to the root cap per se. However, Hawes and coworkers argue that there is no experimental data to support the role of these cells as lubricants (9,10). Further, it is suggested that border cell production is turned off and on at the plant's will, without hampering the roots ability to penetrate solid media (9,11). Hawes and colleagues postulated that border cells serve the plant by enabling the root to define its own ecology, with their best-characterized properties involving specific recognition and responsiveness to soilborne microflora. They can in a genotype-dependent manner attract zoospores (12), synthesize defensive structures in response to fungal attack (13), repel or bind pathogenic bacteria, and control growth and gene expression in symbiotic bacteria. Such chemotactic attraction and recognition might create 'biased rhizospheres' by dictating which populations can colonize the plant root system, with direct and indirect influences for virtually all of the consequent physical and chemical parameters (7). Border cells have also been implicated in acting as decoys to attract both nematodes and fungi away from the advancing root tip, until the zone of elongation has passed thus reducing their chances of infecting the root system (7).

Behind the cell cap in the zone of elongation the epidermal cells emerge and begin to elongate. At first these cells have only the primary wall, although once elongated they develop a secondary wall. Root hairs develop in the region behind this and they function for a relatively short period before autolysis, with an accompanying proliferation of bacterial cells that utilize the products. These microorganisms also invade the epidermis and cortex, and while at stage no physiological damage occurs, the outer cortex ceases to function. This final stage in rhizosphere development represents the state of many crop species just before harvest with the root material left in the soil becoming part of the soil organic matter on harvest. A more detailed account of the stages in the life

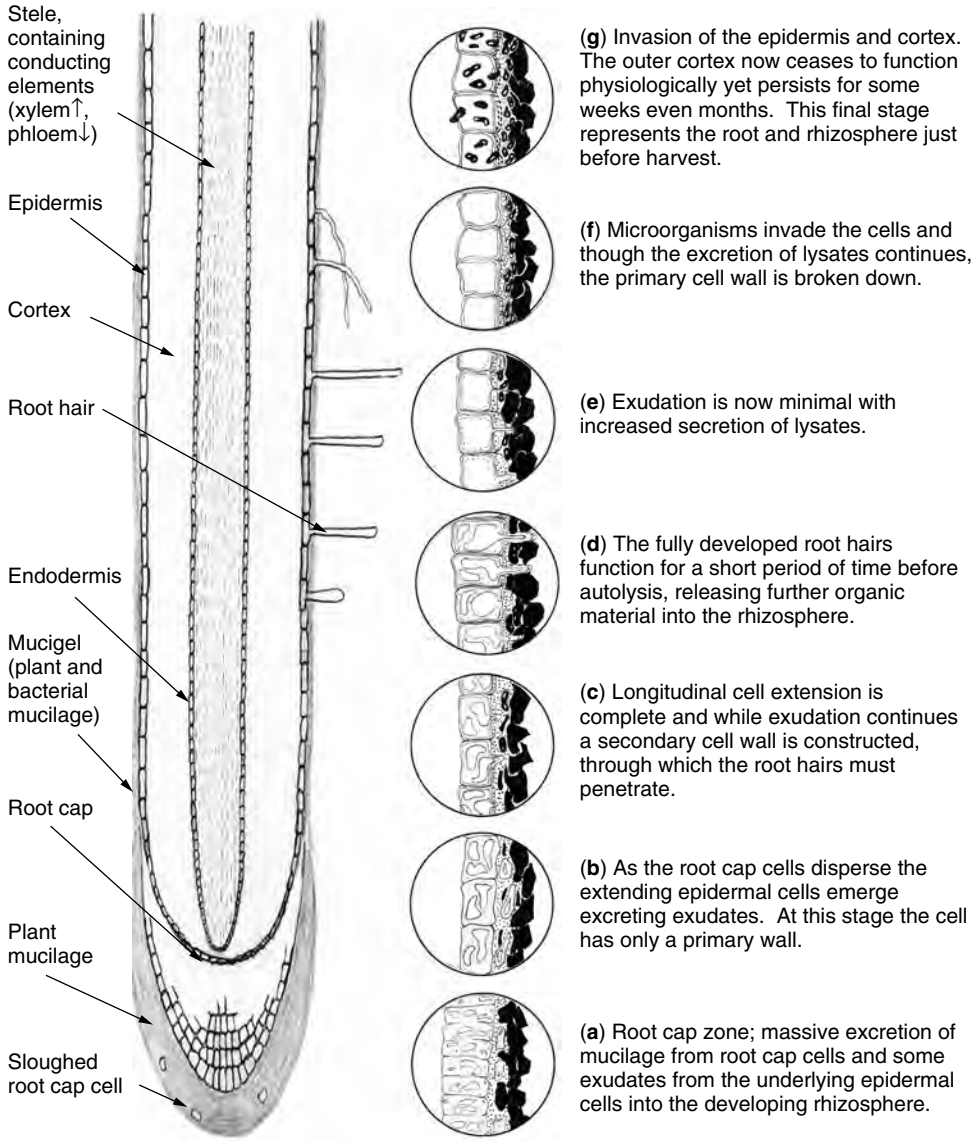

Figure 4. Temporal and physical locations of release of root exudates (Drawing not to scale) (Adapted from A. D. Rovira, R. C. Foster, and J. K. Martin, in J. L Harley and R. S Russell, eds., *The Soil Root Interface*, Academic Press, New York, 1979, 1–4.)

cycle of a root surface cell is given by Foster, Rovira, and Cook (8).

The Nature of Rhizosphere Exudates and Secretions

Root exudates include carbohydrates, amino acids and other organic acids, vitamins, nucleic acid derivatives, and various miscellaneous compounds. Among the carbohydrates, at least ten sugars have been identified as being exuded from a wide range of plants species, with hexoses glucose and frucose as being the most abundant (14). Others include the pentoses; xylose, ribose, and arabinose and the disaccharides sucrose and maltose. This wide range of sugars found in exudates suggests that the exudation of sugars is a general phenomenon with little if any effect in determining the composition of the microbial population it attracts to the rhizosphere (14).

In contrast to the exudation of carbohydrates, plants differ widely in the range and amounts of amino acids that are exuded. A total of 22 amino acids have been found in pea root exudates compared with up to fourteen in oat-root exudates. The most abundant amino acids produced by pea (10- and 21-day old) are homoserine, threonine, and glutamine and by oats, lysine, serine, and glycine. In addition to this, the total amount exuded by peas far exceeds that produced by oats. Such qualitative and quantitative differences between the composition of exudates from different plant species when grown under the same conditions are likely to have far reaching effects in the composition and density of the microbial population

that inhabit the rhizosphere (14). Other organic acids including members of the tricarboxylic acid cycle occur in the exudates of several plant species. These acids are suggested to not only provide the rhizosphere microflora with substrate, but to also have important secondary effects in altering the rhizosphere environment, such as changing the pH and chelating metal ions.

The chelation of metal ions is considered an important function of root exudates, and the organic ligands secreted, termed *phytometallophores* with a subclass called *phytosiderophores* specializing in iron chelation, particularly so. These compounds serve to enhance the uptake by the plant of essential metals. Research into the production of *phytometallophores* has shown that the interaction between the plant and the root environment can change the composition of the exudate. Fan and coworkers showed that as iron deficiency increased, the total quantity of exudate per gram of root remained unchanged, but the relative quantity of carbon allocated to phytosiderophores increased to approximately 50% of the total exudate (15).

Of the vitamins, the most common vitamins found in the exudates of roots are biotin and thiamine, although the levels recorded are not deemed as sufficient to meet the requirements of all vitamin-requiring microbes within the rhizosphere. This said the B-group vitamins, are produced at what is considered biologically active levels by most bacteria and fungi isolated from soil or plant root systems (16,17). Their production by rhizosphere organisms has been shown to be related to the potential of organisms such as *Pseudomonas* and *Azotobacter* to enhance nitrogen-fixation and the growth of legumes nodulated by *Rhizobium* (18). It has also been shown that the application of the herbicide simazine considerably affects the production of this vitamin group by *Azotobacter* (19). The nucleic acids adenine, guanine, uridine, and cytidine are also present in root exudates as well as exoenzymes such as phosphatase and invertase. Recent work shows that inoculation of pea rhizosphere with *P. fluorescens* F113 significantly increases alkaline phosphatase, sulfatase, and urease activities (20).

Among the great variety of other compounds found in root exudates, are compounds such as phenol derivatives and other substances toxic to microorganisms, emphasizing the important point that not all plant exudates are necessarily beneficial to microorganisms. The rhizosphere is colonized by plant growth promoting rhizobacteria (PGRB) and deleterious rhizobacteria (DRB), which may serve to inhibit plant growth. The detrimental action of these bacteria is primarily through the production of phytotoxins (21), but may also be through phytohormone production, competition for nutrients and the inhibition of mycorrhizal function. Furthermore, it is suggested that the function of rhizobacteria may alternate from that of plant growth promotion to inhibition, depending on their interaction with the plant, mycorrhizal fungi, and the changing environmental condition of the soil. As such, the influence, that rhizobacteria have on plant growth should be assessed on the net consequences after both positive and negative effects have been considered (21). There is also evidence that DRB are often associated with yield declines in continuous monocultures (22,23), and in growth depression in minimum tillage systems (23).

The composition of the exudates will be subjected to change as the plant itself experiences changes, whether this is due to the changes that occur throughout the plants life cycle or from physical changes in it's environment such as drought. For example, recent work (24) utilized HPLC to identify and quantify exudates from tomato plants, and has shown that the total amount of sugar carbon considerably increases during development from seedling to plant root. While sugars were being exuded during all stages of development, the composition of the sugars changed. The sugars glucose, maltose, and xylose were the major sugars in seed exudate, with fructose and glucose in seedling exudate, and glucose and xylose in root.

In terms of external influences, it is known that factors that alter the rate of production and translocation of photosynthate have an indirect effect on the release of organic substances from the root (14). For example, defoliation of sugar maples causes changes in the amount of sugar, amino compounds, and organic acids exuded (25) and water stress to pine seedlings results in diminished exudation (26). In contrast to this, an increase in the amount of mucilage exuded from roots under increasing soil water stress has been shown in wheat plants (27). Additionally, if field soils are allowed to approach permanent wilting point and subsequently rewetted, a rapid release of amino acids from roots has been shown as the plants regain turgor (28).

Rhizosphere Bacterial Population

The bacterial population of the rhizosphere differs from that in the bulk soil both in terms of population numbers and composition. It contains large numbers of gram-negative non-spore-formers with a higher proportion of chromogenic and motile forms, and more ammonifiers, nitrifiers, denitrifiers and aerobic cellulose decomposers. However, it sustains a lower number of gram-positive cocci, and organisms capable of utilizing aromatic acids than found in the bulk soil (29). Short gram-negative rods respond most to rhizosphere conditions and invariably constitute a greater percentage of the rhizosphere than bulk soil communities. The three genera *Pseudomonas*, *Achromobacter*, and *Agrobacterium* are examples of gram-negative rods that are greatly stimulated within the rhizosphere (14).

Given that the rhizosphere exudations and secretions serve to enhance and maintain a higher microbial population than that found in the bulk soil it must also be assumed that there is a high level of microbial competition within the rhizosphere. This in turn enhances selective pressure for those microorganisms most suited to the rhizosphere environment. Most favored are rapidly growing and biochemically versatile organisms over slower growing less diverse organisms. Such selection was shown by Wallace and Lochhead (30), who utilized an empirical scheme to recognize seven nutritional groups of bacteria as determined by their ability to grow on media of varying complexity. The media contents ranged from only glucose and mineral salts to preformed amino acids and vitamins or unidentified growth factors contained in soil and yeast

Table 1. Incidence of Bacterial Nutritional Groups, Comparison of Oat Rhizosphere and Bulk Soil

Requirements for Maximum Growth	Rhizosphere/Bulk Soil (R : S) Ratio	
	% of Whole Population $\times 10^{-6}$	Total Count Soil g^{-1} $\times 10^{-6}$
Sugar and inorganic salts only	2.5	21.6
Amino acids	5.5	46.0
B vitamins	1.2	10.5
Amino acids & B vitamins	0.5	4.2
Yeast extract	0.7	6.0
Soil extract	0.8	6.7
Yeast and soil extract	0.3	2.5

Increasing complexity of medai

extracts. Organisms requiring no special growth factors or requiring amino acids only were enhanced in the rhizosphere (Table 1). Selection of amino acid utilizing bacteria reflects the larger amount of amino acids in the rhizosphere than bulk soil. In general terms, bacterial populations within the rhizosphere are considered less fastidious than those found outside. More recent work by Fan and coworkers (15) has demonstrated that barley roots grown in iron-limited nutrient solution produce more amino acids, suggesting that amino acids play some role in Fe acquisition.

The R:S ratios indicate consistent, preferential enhancement within the rhizosphere of bacterial groups requiring either no special growth factors or amino acids only.

In contrast to the quantitative effect that the rhizosphere has been demonstrated to have on bacteria, the rhizosphere has little effect on fungal numbers but does enhance certain genera of fungi. For example, imperfect fungi *Fusarium* spp. are prominent members of the rhizosphere and a common example of this phenomenon, but numerous other genera such as *Trichoderma* and *Aspergillus* are represented. There are also ecological links between fungal and bacterial members of the rhizosphere community. For example, different microbial inocula can affect the colonization of pea roots by mycorrhizae (32). The mycorrhizal component of the soil and its mutualistic symbiosis with the plant root system was first critically documented by Harley (33), but there have been many subsequent reviews (34–37).

Root Colonization. Organisms associated with seeds, such as the common fungi (Penicillium spp., Aspergillus spp.) and bacteria, contribute very little to the established rhizosphere (1). The young seedling is first colonized by chance by bacteria that first encounter the influence of the developing root. A more species rich community characteristic of the rhizosphere establishes as the root matures. The developing root tip and root hairs are commonly free of microorganisms, with bacteria colonizing at sites of lateral root emergence from the main root stem. The rhizosphere effect then increases with the age of the plant, reaching a peak at the height of vegetation and declining as senescence approaches. This succession varies among plant species with the timing at alternative periods during their life cycles, with crop species generally exhibiting a greater rhizosphere effect than trees. The most pronounced population increases involve the amino acid requiring bacteria and other organisms with simple nutritional requirements and rapid growth rates (1). The dominance of specific bacteria with certain plants is also a phenomenon that has been noted.

As previously noted, the nature of the secretions changes through the root life cycle, and consequently the root associated microbial populations undergoes changes. Most root colonization is triggered as the root tip advances through the soil, with the root tip releasing substrate that stimulates the growth and activity of the dormant bacteria within the sphere of its influence. The process of root colonization can be conceptually divided into a series of steps: migration toward plant roots, attachment, distribution along the root, and growth and establishment of the microbial population (38). A number of microbial traits involved in these steps have been postulated, including chemotaxis, agglutination potential, the use of flagella, and the ability to utilize complex carbohydrates. Which of these characteristics is most important in root colonization was determined by Hozore and Alexander (39) working with bacteria isolated from both bulk soil and the rhizosphere of soybean. They found that the rhizosphere and soil isolates differed significantly in their ability to move along soybean roots, with rhizosphere isolates better able to colonize root segments further from the point of inoculation than the soil isolates. They suggested that there were no significant differences in adhesion to root tips, or in chemotactic response to exudates, tolerance of low osmotic potentials or the agglutination of cells by exudates. While concluding that mobility along the root

is important to successful colonization of the rhizosphere, none of the other characteristics is individually sufficient to ensure rhizosphere competence.

In a study of the colonization of barley roots grown in sterile soil, Hansen and coworkers (40) used two *P. fluorescens* strains (DF57 and Ag1) and a confocal laser scanning microscope with the ability to detect single bacteria of both strains on the roots. They demonstrated that seed-inoculated bacteria rapidly colonized the root surface (rhizoplane) by active migration. After one day, the anterior part of the root was densely covered by the inoculated bacteria, occupying the crevices between epidermal root cells. As the roots elongated, the rhizoplane bacterial population formed long strings of closely associated cells. After seven days, however, these string-forming cells became partially detached, developing a patchy distribution along the root.

THE BENEFITS OF THE RHIZOSPHERE

Nutrient Cycling

The rhizosphere is an environment created and maintained by the plant at cost to the plant, but the plant receives considerable benefits from this energy input. The acquisition of nutrients is the preliminary goal of the investment that the plants make in modifying their environment modifications. The interactions with the rhizosphere microbial populations enhances the availability and uptake of nutrients that might otherwise have been unavailable to the plant root system. This happens in a number of ways and for a number of nutrients, but probably the most important nutrient is nitrogen, the discussion of which can be generalized to other nutrients.

Plant roots and the microbial populations that inhabit them are integral to the nitrogen cycle (Fig. 5). Although the microbial population of the bulk soil is involved in the conversion of nitrogen through its various forms in the nitrogen cycle, it is the enhanced populations within the rhizosphere that provide the majority of the readily available forms of nitrogen to the host plant. Nitrogen, that is subsequently released when the plant dies or is consumed.

Nutrient cycling in soil is extremely dependent on the supply of energy to the soil biota. Given that the source of this energy is carbon from organic compounds, it can be seen that the nitrogen and carbon cycles are inextricably linked with carbon as the impetus. This carbon and nitrogen link is often referred to as the carbon nitrogen ratio.

Mineralization and Immobilization. The decomposition of plant material, with the accompanying mineralization and immobilization of the organic nitrogen it contains, are key processes in the soil nitrogen cycle. Once incorporated into the soil matrix, plant residues bring about a rapid increase in microbial biomass as the material is colonized. The progressive decomposition of nitrogen-containing compounds by heterotrophic microorganisms using organic material as a source of combined carbon for both respiration and cell synthesis results in ammonium for use by the organism itself, with the excess released as waste. If insufficient nitrogen is contained within the substrate then the organisms will utilize soil mineral nitrogen, resulting in nitrogen immobilization. The balance between the release of nitrogen and immobilization depends on the carbon-to-nitrogen ratio

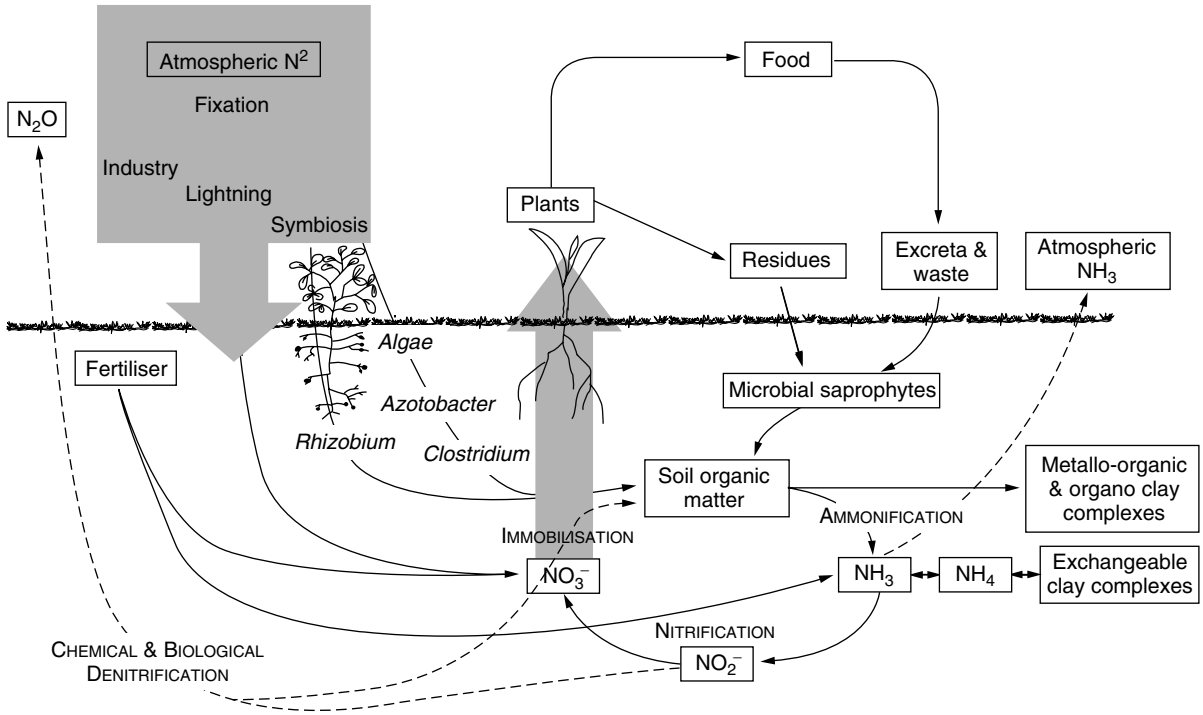

Figure 5. Ecology of the nitrogen cycle. (After J. M. Lynch, *Soil Biotechnology, Microbiological Factors in Crop Productivity*, Blackwell Scientific Publications, London, U.K., 1983.)

of the material being decomposed, the energy efficiency of the organism and the carbon-to-nitrogen ratio of the cells being synthesized. The carbon-to-nitrogen ratio of the substrate is the most influential of these factors, with ratios varying from 5:1 for animal wastes to 100:1 for cereal straws. The ratio at which nitrogen undergoes neither net mineralization nor immobilization is approximately 35:1. Thus this microbial-mediated process is important, because it supplies nitrogen to plants in a preferred form, which is less susceptible to leaching, and provides the raw material for nitrification, the next step in the nitrogen cycle.

Given that ammonifying bacteria have a high R:S ratio (in excess of 50:1) (31) one would expect a greater mineralization of organic matter within the rhizosphere than bulk soil. In the field situation, however, less mineralization occurs under crops than in a fallow soil, even when correcting for the nitrogen taken up by the plants. This anomaly is explained by ^{15}N studies (42) that show that although the net mineralization rate in cropped soil is only half of that in fallow soil, the total quantity mineralized is greater under the crop. The difference is due to rapid assimilation of the mineralized matter by the microbiota within the rhizosphere of the crop.

The aforementioned illustrates that the availability of nitrogen to the plant is a result of the opposing processes of mineralization and immobilization and the plant's ability to compete for available nitrogen. This suggests that the overall microbial effect in the rhizosphere is detrimental as often as it is beneficial, with nitrifying bacteria being suppressed by root exudation (43). However, experimental comparisons of rhizosphere and nonrhizosphere soils has demonstrated that the rhizosphere effect on net N mineralization from indigenous soil organic matter is positive in many cases but not in all (44). The actual amount of microbial nitrogen immobilized by root-derived carbon seems to be counterbalanced by stimulation of nitrogen mineralization by promoted grazing of protozoa, the consequential release of ammonium by assimilation, as well as by higher microbial turnover of soil organic matter. It is hypothesized that the effect can also be beneficial, as a consequence of the nitrogen form involved (nitrate), and because the continual cycling of the nitrogen compounds within the microbial community prevents their loss from the system through leaching, thus providing a more constant supply to the plant (14).

Dinitrogen Fixation. Biological dinitrogen fixation is the enzymatic reduction of dinitrogen (N_2) from the atmosphere to ammonia. Nitrogen fixing bacteria have the capacity to produce the enzyme system nitrogenase, an enzyme system that confers the ability to fix N_2. The nitrogenase system consists of two proteins, the iron (Fe-) protein and the molybdenum-iron (MoFe-) protein that together catalyze the ATP-dependent reduction of atmospheric N_2.

The biological fixation of molecular nitrogen is carried out by several "free-living" bacterial genera, some of which are rhizosphere-associated, and by several other genera that are mutualistically associated with plants. In terrestrial systems, however, the largest contribution of combined nitrogen comes from the symbiotic fixation of dinitrogen by rhizobia, with fixation rates often two to three orders of magnitude higher than those exhibited by free-living bulk soil dinitrogen fixers (See Nitrogen Fixation in Soils (Free-Living Microorganisms), Nitrogen Fixation in Soils — Free-Living Microbes this Encyclopedia.). Estimates of the amount of dinitrogen fixed biologically range from 139 to 170 million tonnes N_2 annually, (45,46) with the symbiotic associations of arable land accounting for 25 to 30% and permanent pasture for another 30%. Such increases in plant-available nitrogen are a consistent consequence of growing both crop and pasture legumes, resulting from the combination of conserved soil nitrogen, greater mineralization potential and the return of the fixed nitrogen (47). Consequently the benefits of crop legumes can be considerable.

The best studied examples of symbiotic nitrogen fixation are the soil bacteria of the genera *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium*, collectively referred to as rhizobia. These organisms have the ability to induce the formation of nodules on the roots of leguminous plants. In these nodules the host plant provides the bacteria with their nutrient requirements and an environment conducive to nitrogen fixation. In return the bacteria fix dinitrogen in excess of their requirements, which is subsequently released as ammonia and taken up by the plant. (See Nitrogen Fixation in Soils (Symbiotic), this Encyclopedia.)

The nodule development begins with the attachment of rhizobia to the host root hairs causing deformation of the hair, resulting in its curling (Fig. 6). Then infection threads form within the curled hair and allow the bacteria passage into the root. Accompanying the infection process is the inducement of cell divisions in the root cortex leading to primordium formation. The infection threads are then attracted to centers of increased mitotic activity of the primordium cells and release bacteria into these cells by endocytotic processes. The now infected cells differentiate and mature into nodules thus providing the environment for dinitrogen fixation (48). Nodulation is, however, host specific, with each rhizobia species restricted to a subset of plant species.

While the rates of nitrogen fixation for free-living bacteria are relatively low in comparison to those in a symbiotic or mutualistic relationship, the bacteria that conduct fixation under such conditions are widespread in soils and do contribute to soil nitrogen inputs. The rate of free-living bacteria such as *Azotobacter* and *Azospirillum* are increased under rhizosphere conditions, because of their increased efficiency as a result of more readily available organic compounds exuded from roots (49). Consequently, it can be seen that the symbiotic fixing of dinitrogen in the rhizosphere causes a substantial benefit to the plant system's ability to acquire and utilize nitrogen. The large biological significance of nitrogen fixation and the importance of the process for agriculture continue to prompt major fundamental research in this area. Research on the mechanisms of fixation and the regulation of its activity, is motivated by the aim of developing more effective systems and to optimize the use of nitrogen fixation in agriculture.

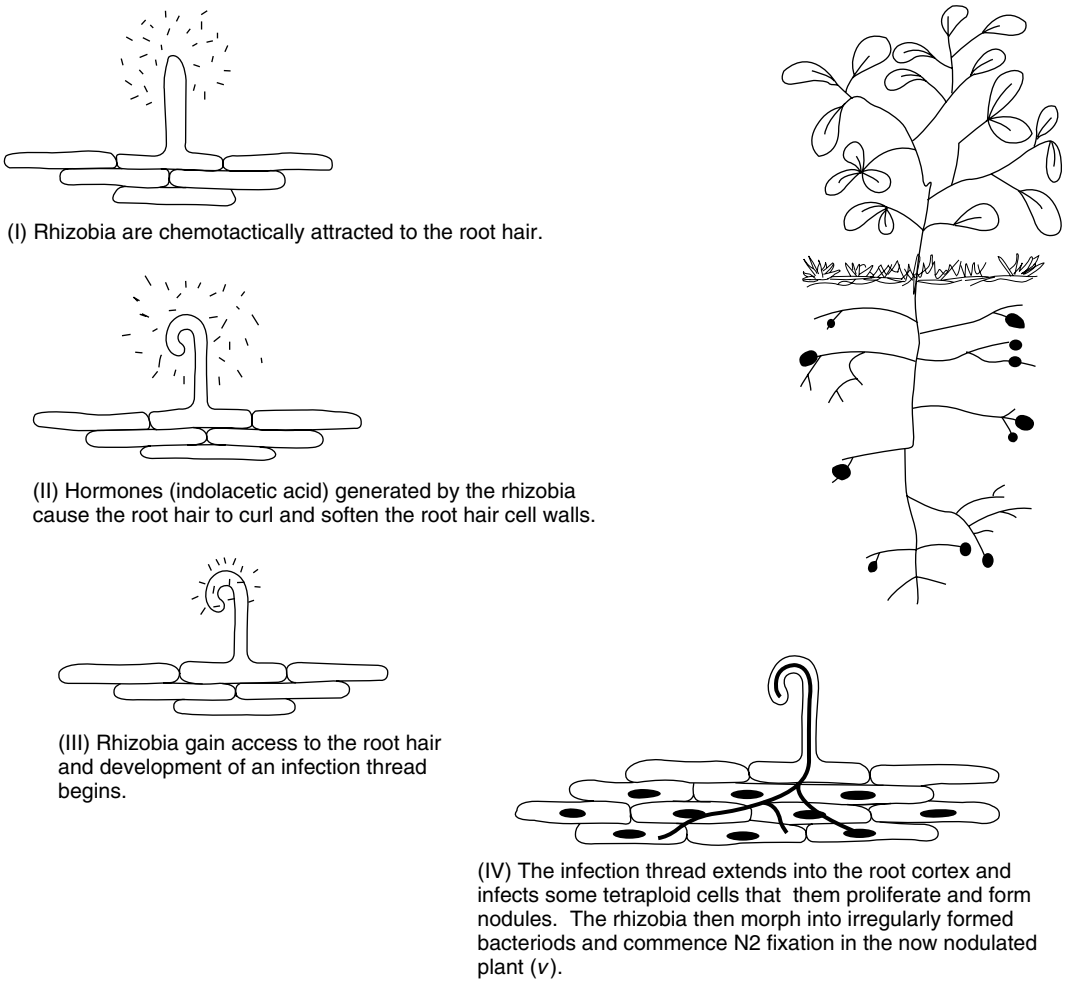

Figure 6. Infection process of a leguminous plant root system.

Global Warming. There is intensifying interest in the effect of rising global temperatures, due to global warming, on mineral cycling. The concern, involving the linked cycling of carbon and nitrogen, is that the predicted increases in the ambient temperature will lead to decreases in the organic matter content of soils (50). Furthermore, as the products of organic matter decomposition, such as carbon dioxide, are implicated in generating global warming, the process will induce a positive feedback effect on global warming. Increased levels of carbon dioxide and temperature are predicted to affect both the activity and the community structure of the rhizosphere microbial community. It is generally accepted that plants grown in atmospherically elevated carbon dioxide levels substantially increase their carbon input into the rhizosphere. And although it is known that elevated carbon dioxide enhances rhizosphere respiration more than root biomass, the fate and functions of this extra carbon input to the rhizosphere are not clear (51). Cheng and Johnson (52), using carbon isotope techniques, found that elevated atmospheric carbon dioxide in a wheat-soil system significantly increased substrate input to the rhizosphere due to both increased root growth and increased root activities per unit of roots. They also found that nitrogen treatments changed the effect of elevated carbon dioxide on soil organic matter decomposition, thus indicating that soil nitrogen status was important in determining the effect of elevated carbon dioxide on soil organic matter decomposition (52). Similar results were found by Elhottova (53), who also noted that there was an accompanying change in the rhizosphere bacterial community toward nutritional groups utilizing more complex organic material.

Nutrient uptake by plants may also be increased because of modifications to root architecture, physiology, and or mycorrhizal symbiosis (54). The relationship between enhanced nitrogen uptake and biomass production under elevated carbon dioxide is highly significant (55). Such a relationship indicates that plants have the ability to enhance their nitrogen uptake through modifications in their physiology, morphology, architecture, or mycorrhizal associations. Such changes could be a determining influence in how individual species respond to increased carbon dioxide levels, especially with regard to increased biomass production.

Carbon dioxide concentration may also influence exudation by roots (54). In microcosms with yellow birch (*Betula alleghaniensis* Britt.), Berntson and Bazzaz (56) showed

that elevated atmospheric carbon dioxide significantly altered the cycling of nitrogen plant carbon-to-nitrogen ratios were significantly increased, gross mineralization and NH_4^+ consumption rates were decreased, and relative microbial uptake of NH_4^+ was increased. Such changes represent a suite of nitrogen cycling negative feedback on nitrogen availability due to increased atmospheric carbon dioxide levels. Enzyme activities in the rhizosphere of wheat have also shown changes under elevated carbon dioxide levels, with 3- to 24-fold increases in potential denitrification activity in roots grown under elevated carbon dioxide compared with ambient levels. This indicates that atmospheric carbon dioxide concentration can influence rhizosphere denitrifier activity (57). Elevated atmospheric carbon dioxide may also increase infection by both ectomycorrhizal and arbuscular mycorrhizal fungi (58).

The primary negative feedback of increased carbon dioxide levels generally reduce the amount of nutrients available to plants. Such negative feedback include increased C/N ratios in litter, and subsequently reduced mineralization rates, increased immobilization of available nutrients by a larger soil microbial pool, and increased storage of nutrients in plant biomass and detritus due to increases in net primary productivity. The principal positive feedback, however, are mostly plant-mediated, with the exception of the hypothesis that increased microbial biomass will have a concurrent increase in mineralization rates. For a review of impacts of increased carbon dioxide levels on microbial communities, see Berntson (55).

These rhizosphere-based changes have enormous implications for the wider environment. For example, it has been demonstrated that the single largest and most dominant species within a plant community was reduced in biomass and nitrogen content by elevated carbon dioxide levels, whereas several smaller less dominant species showed enhancement (55). Such evidence suggests that in time, elevated atmospheric carbon dioxide levels may have significant consequence on community composition, leading to ensuing changes in ecosystem functionality. For example, if elevated atmospheric carbon dioxide levels cause reductions in nitrogen cycling because of the accumulation of nitrogen in plant biomass or reductions in mineralization rates, long-term forest productivity may be constrained (59).

Crop Production and Disease Resistance

The acquisition of nitrogen and other nutrients is not the only way in which the rhizosphere benefits the plant. Plant productivity can also be enhanced by other direct and indirect effects stimulated within the rhizosphere. The most notable of these effects is termed biocontrol. The subject matter of biocontrol is founded on the principles of microbial competition, amensalism, parasitism, and predation, or a combination of two or more of these interactions. Although these interactions are clearly important in rhizosphere ecology, they are among the least well understood of rhizosphere processes (60). This is partly because microbial community dynamics in soils seldom mirror simple positive or negative interactions. Consequently, conditions at any point reflects the aggregate total of numerous interactions set in motion by a supply of an exploitable nutrient source and the absence of environmental extremes. In this case, the environment is provided by the plant root system.

Early studies on the potential of siderophores to mediate bacterial control of root disease led to the use of the term "plant growth promoting rhizobacteria" (PGPR), or "plant growth promoting bacteria" (PGPB) (41). Another term in common usage is that of deleterious rhizobacteria (DRB). The effects of DRB on field grown plants are often subtle, so consequently have attracted less scientific interest than have PGPR (21). PGPR control the damage inflicted on plants by phytopathogens via a number of mechanisms. These include outcompeting the pathogen for resources or habitat space, physical displacement, synthesis of antibiotics or other small molecules that inhibit pathogenic growth, production of enzymes that inhibit pathogen growth and stimulation of plant systemic resistance (61,62)

The increasing need for a steady and healthy food supply begets a compelling need for the control of plant diseases. Current methods for disease suppression are dominated by synthetic pesticides, breeding programs, and management of the plant's environment. With growing concerns over the environmental fate of synthetic pesticides and the development of pathogenic resistance to such controls, there is a need for novel solutions that can provide effective disease suppression while minimizing negative effects on human health and the environment.

The rich diversity within the microbial world offers many opportunities to modify the rhizosphere microbial communities and thus provide powerful biological alternatives to the use of synthetic pesticides in disease control. Use of such biological control agents may be more robust than synthetic methods because of the complexity of the microbial interactions involved and the sheer number of mechanisms utilized by a single organism (63). Many adaptations of the organisms suited to the rhizosphere environment, refined over many millions of generations, maybe useful in biocontrol. Consequently the commercial exploitation of PGPR has, and continues to be, a goal of considerable microbiological research.

Pseudomonas species, particularly the fluorescent pseudomonads, are the most studied biocontrol rhizosphere competent bacteria (23). Beneficial pseudomonads suppress pathogens through their capacity to produce a diverse array of microbial metabolites including antibiotics, siderophores, and volatile compounds (2). For example, under Fe (III) starved conditions, fluorescent pseudomonads produce the iron-sequestering siderophore pyoverdine, or utilize plant produced phytosiderophores (12). These capabilities allow the bacteria to usurp iron from within the immediate rhizosphere environment, reducing levels and depriving other deleterious and plant pathogenic organisms of this essential element. Of the range of antibiotics excreted by *P. fluorescens* 2,4-diacetylphloroglucinol has received the greatest attention (20,64–68). The metabolite 2,4-diacetylphloroglucinol (2,4-DAPG) is produced by many strains of fluorescent *Pseudomonas* spp. and has biocontrol activity against soilborne fungal plant pathogens. It has been shown to enhance root nodulation of pea roots and

produce larger and healthier (pink) nodules (32). Also, the bacterium increases mineralization rates and enhances nitrogen uptake from mineralized organic residues, whilst reducing soil microbial activity (69) and enhancing antagonism toward *Pseudomonas ultimum*, thus significantly increasing sugar beet seed emergence (67). However, such enhanced activities are species dependent (70). It has also been shown to be effective against a number of diseases, such as that caused by the potato soft rot agent, *Erwinia carotovora* subsp. *atroseptica* (66), the preemergence damping-off disease experienced by sugar beet (71). Fluorescent pseudomonads are also implicated in inducing systemic resistance in beans against halo blight disease (72) and viral diseases in cucumber, tomato (73) and tobacco (74–76), and in the suppression of "take all" of wheat with the antibiotic phenazine-1-carboxylic acid (77), or through modifications of soil populations and enzymes through DAPG-production (78).

Unfortunately, the use in agriculture of PGPR can be problematic. The transfer of results from the laboratory to the field has not realized initial expectations in agriculture. For example, it has proven difficult to optimize cost-effective mass production and application of *P. fluorescens* (77). So even with increasing interest in PGPR, (79) the success of microbial biocontrol is quite variable among trail results and are often unpredictable. Possible reasons for these failures include a lack of knowledge of the active biocontrol mechanisms and difficulties in preparing successful application formulas that remain viable through long-term storage (80). With regard to the latter problem, one solution is the use of sporulating gram-positive organisms that form spores and survive the heat and desiccation processes involved in preparing seed coatings. There is a substantial knowledge base and a wealth of experience in organisms such as *Bacillus* and *Streptomycetes*, both of which have been sources of industrial enzymes and antibiotics, and useful for insect control, for many years. In fact, *Bacillus thuringiensis* (Bt) now accounts for more than 90% of all marketed biopesticides (for foliar application not root pests), representing a worldwide market of $110,000,000 annually (81). The organism *Bacillus polymxya* (renamed *Paenibacillus polymyxa*) has a range of plant growth promoting properties, including dinitrogen fixation, soil phosphorus solubilization, production of antibiotics, chitinase, and other hydrolytic enzymes as well as the enhancement of soil porosity (82). The gram-positive bacteria have received less attention than the fluorescent pseudomonads, in part because they are less amenable for genetic research and in part because less is known about their mechanisms of disease suppression (83). For a review of this topic see Emmert and Handelsman (63).

FACTORS INFLUENCING THE RHIZOSPHERE

Physical Factors

The rhizosphere is a dynamic environment, always in a state of change. The changes can be brought about by a number of events mediated by plants or by the soil organisms that the roots encounter. However, the rhizosphere is also subject to changes imposed by the wider environment in which the plant root system resides. These physical factors determine the rates and reactions of biochemical processes within the plant as well as interactions between roots and microorganisms, and within the microbial community. These factors include temperature, water availability and movement, oxygen availability, indigenous pH, light intensity (as encountered by the plant), salinity and pollution levels, as well as the influence of the soil structure itself.

pH. The rhizosphere exhibits pronounced changes in rhizosphere pH, often in excess of one or two units. Such differences can be seen by the use of pH-sensitive dyes and demonstrate that plants of different species grown in the same soil can create quite different pH environments. It has also been shown that the pH varies dramatically at different points along the root system (84). These effects are due in part to organic acids, low molecular weight carbon-, hydrogen-, and oxygen-containing compounds, distinguished by their retention of one or more carboxyl groups and detected in all organisms. Depending on the dissociation properties and number of carboxylic groups, these organic acids can carry varying negative charge, allowing the complexation of metal cations in solution and the displacement of anions from the soil matrix. Consequently these compounds are proposed to be involved in a number of soil processes ranging from the mobilization and uptake of nutrients such as P (81,85,86) and Fe, the detoxification of metals (e.g. Al 87,88), microbial proliferation in the rhizosphere and the dissolution of soil minerals leading to pedogenesis (89). It is also suggested that pH mediated weathering rates are significantly faster in the rhizosphere than in bulk soil (90) and are enhanced by ectomycorrhizal associations.

Increasing pH levels may also render the rhizosphere environment unsuitable to certain pathogenic organisms. A 30% increase in growth of *Asparagus officinalis* under greenhouse conditions was observed with seedlings inoculated with *Pseudomonas putida*, an organism known to be antagonistic to the crown rot pathogen *Fusarium moniliforme*. The increased growth was suggested to occur as a result of the plant growth–promoting effect of organic acids secretion, such as succinic and lactic acids, and creating conditions in which the populations of pathogens are reduced (91).

Changes in pH alter the solubility and diffusion coefficients of a number of compounds essential to biological health, including compounds containing micronutrients such as zinc, chromium, nickel, manganese, selenium, cobalt, copper, and molybdenum (92). Consequently, plant or microbial populations can utilize nutrients previously unavailable to them by actively adjusting the surrounding pH. However, the release of such compounds are generally in response to specific environmental stresses (e.g. Fe, Al, and P or anoxia) and are species-specific. pH changes will also affect the efficacy of biocontrol organisms, as has been shown for the production of DAPG by *P. fluorescens* (93). For a review on the influence of pH on soil microorganisms see Lynch (94), and for a more specific review on organic acids in the rhizosphere see Jones (89).

Temperature. Temperature affects all chemical and biochemical processes in the rhizosphere, whether directly in its effect on chemical reaction rates of enzymes, or indirectly through effects on growth or exudation rates of the plant itself. Plants are adapted to optimum temperature ranges, above and below which growth is inhibited or permanently halted. Similar restrictions apply to microbial populations. For example, the optimum temperature for the production of chitinase enzyme by *Streptomyces lydicus* occurs at 25 to 30 °C (95).

Although it is not clear how temperature affects root exudation it is influenced by both increases and decreases in temperature, with sudden changes causing increased exudation (96). Composition and exudate quantity, are affected by temperature changes. (97) This was demonstrated in, *Zea mays* seedlings in which a seven fold increase in exudation was noted, with a release of three new oligosaccharides and sucrose, when cooled from 19 to 5 °C (98). It is hypothesized that a decrease in temperature affects the permeability of the root cells, giving rise to increased exudation.

In general, PGPR colonize the rhizosphere and root system more efficiently at higher root zone temperatures (99) and suboptimal root zone temperature has been shown to adversely affect growth, development, dry matter production, and grain yield (100). Infection and early nodule development processes are most sensitive to temperature. In fact nitrifiers are thought to be more susceptible than common heterotrophs to low temperatures, because of the inefficient nature of their metabolism (101). Increased temperatures also retard nodulation, (102) delaying the development of lateral roots and root hairs and disintegrating the infection threads of *Sinorhizobium* sp. at 42 °C. Temperature changes have also been shown to affect carbon allocation with leaves favored above storage organs at higher temperatures (103).

Freezing of soil pore water also affect water and nutrient uptake, locking nutrients up in a solid medium. However, certain PGPR can survive freezing temperatures, (i.e., −20 and −50 °C) and retain the ability to grow and promote root elongation of both spring and winter canola at 5 °C. To determine the mechanistic basis for this behavior, it was discovered that *P. putida* GR12-2 synthesized and secreted to the growth medium a protein with antifreeze activity (104). At temperatures below 0 °C, freezing injury will also occur. This is a consequence of the formation of ice particles physically destroying the surrounding structures. The effect is irreversible and on thawing a considerable leakage of metabolites will occur in addition to cell death. To induce frost damage and benefit from the discharged metabolites, some organisms, however, have evolved ice-nucleation mechanisms, that can increase the temperature at which ice particles form inside plant and root systems. Water in plant tissues can be supercooled to around −5 °C without causing damage. However, in the presence of ice nucleating bacteria, such as *Pseudomonas syringae*, which produce a protein complex in its outer membrane, which serves as a nucleus for ice formation, ice formation can begin at −1 °C (105). While this phenomena occurs in phyllosphere bacteria; there may be undiscovered parallels in the rhizosphere.

Light Intensity. Given that light through photosynthesis is the source of energy for plants it is of no surprise that changes to light levels and leaf cover have concurrent changes in the exudation patterns of the root system. Investigations have shown that under high light intensity, there is a significant increase in the partitioning of ^{14}C labeled material into the root system but that incorporation of recently assimilated carbon into the microbial biomass is not altered. Under higher light intensity, there was preferential allotment of carbon into the root system and a reduction in specific leaf area, without an increase in total plant mass (106). It has also been shown that under zinc deficiency, increases in light intensity markedly enhances the release of phytosiderophores from Triticum aestivum L. (cv. Aroona) (107). The same work showed that iron deficient barley (Hordeum vulgare L. Europe), when first grown at low light intensity followed by exposure to high intensity for 24 and 48 hours, enhances the release rate of phytosiderophores by about four and seven fold, respectively. The results demonstrate a particular role of light intensity in phytosiderophore release from roots under both zinc and iron deficiency.

Changes in received light levels as a result of aboveground herbivore grazing can also affect carbon fluxes. Grazing increases belowground carbon fluxes (roots, root exudates, and rhizosphere respiration), thus increasing resources (e.g., root exudates) available to soil organisms, especially microbial populations (108). This work also suggested that although herbivory increases respiration, it does not affect patterns of translocation. There is an increasing body of information attesting to the importance of plant physiological responses to herbivory in regulating soil organisms and, consequently, key soil processes such as decomposition and nutrient mineralization. For a review of the influence of herbivory effects on soil organisms, see Bardgett 1998 (109).

Water and Oxygen. Water is essential for all life. It makes up a large percentage of the biomass of all life-forms retaining cell turgidity and, in the case of soil, serves as a carrier of water-soluble minerals and other compounds as well as facilitates the dispersal of metabolites and waste products. Accordingly, changes in the soil water content have substantial effects on the rhizosphere microbial population. As moisture content drops, competition for this essential resource increases, the supply of utilizable substrates declines, and dispersal of toxic by-products is slowed. These processes result in reduced microbial numbers and activity. As plants and microbes differ in their abilities to capture and retain water, the community structure of the rhizosphere will also change. Decreasing soil water may indirectly affect microorganisms by altering the types and quantity of exudates released into the rhizosphere (110).

Oxygen also plays a vital role in sustaining biological life of organisms adapted for its use, that is aerobic organisms. Oxygen and water content are closely linked because oxygen has a low solubility in water. Consequently, as the water content of soils increases, a greater portion of the soil pore volume becomes saturated, creating anoxic zones.

The small amount of oxygen that is able to diffuse into these anoxic zones is under intense competition from aerobes. Soil oxic-anoxic interfaces arise within the plant root system, separating aerobic from anaerobic processes. Such interfaces arise in virtually all environments. An explanation of the basic principles involved and specific examples can be found in Brune (106).

Certain plants, such as rice, have evolved to modify the oxygen content of their rhizosphere by bringing oxygen down from the leaf surface. This is performed via aerenchyma, which is a porous tissue connected with the aboveground parts of the plant. Such root aeration can be performed by efficient pressure driven ventilation (111–113) or, as in the case of rice (*Oryza sativa*), by simple molecular diffusion (114). While the primary function of this root aeration is to provide the subsurface plant tissue with oxygen for aerobic metabolism, it has repeatedly been shown that oxygen is also exuded from their root systems, (115) thus creating aerobic zones in a water saturated environment (116).

The rhizosphere microbial population has also been implicated in inducing modifications to the rhizosphere that affect water dynamics (107). The production of exopolysaccharides by bacteria can help protect them from drought stresses by enhancing water retention (117). The exuded polysaccharides increase aggregate stability of the soil, which helps maintain soil porosity (108), which in turn provides hydraulic conductivity allowing water to penetrate the soil and fill soil pore spaces. In contrast, rhizosphere organisms have been shown to produce water-repellent exudates, which alter the hydraulic characteristics of the soil, with consequential effects on water runoff, the disruption of soil aggregates on rapid wetting and increases in the flow of water between the aggregates (118).

THE FUTURE OF RHIZOSPHERE SCIENCE

Rhizosphere research generally concerns three major but interrelated areas; the influence of roots on soil microorganisms, the influence of rhizosphere organisms on plant growth, and soil borne pathogens and plant disease. Many questions remain in these areas, however, recent advances in technologies and knowledge may advance our achievement of these objectives.

The main obstruction to obtaining reliable and pertinent data from the rhizosphere is the difficulty in conducting in situ sampling. Even recording essential information such as rhizosphere pH is fraught with problems regarding the purity of sample and temporal variations. Consequently, there is a pressing need to further develop nondestructive techniques to sample from the rhizosphere soil without contamination from the bulk soil and using methods to sample on a microscale. Noninvasive techniques have been developed, such as image analysis, utilizing X-rays and nuclear magnetic resonance to elucidate root structure at a greater spatial resolution and to potentially calculate water fluxes (119). Such techniques combined with chemical and fluorescent dyes could also be used to investigate a wide range of root induced changes in chemical conditions at the root-soil interface. There is also a recognized need for more quantitative data on rhizosphere dynamics measured in more natural experimental systems (119), especially with regard to nutrient movement.

Ten years ago predictions regarding the future of biocontrol looked forward to "research undoubtedly showing biocontrol to be safe, effective, and economically feasible" (120). However, scientific endeavors have yet to achieve this, in part due to public concern about genetic modifications, including public disquiet in Europe and elsewhere over the release of genetically modified organisms to the wider environment and their inclusion in food production.

Genetic manipulation of plants and microorganisms is generally seen as contributing greatly to the advance of rhizosphere research (120,121). Again, the fluorescent pseudomonads have been the focus of much of this research (69,78,122–128). "Marking" the organism in a way that allows easy detection facilitates tracking of organisms in the rhizosphere and under field conditions. Such marking is often carried out by conferring the chosen organism with the ability to resist certain antibiotics to which the indigenous population are susceptible. It is this practise of developing resistant organisms that is the foundation of public unease about genetic manipulation of microorganisms. The use of organisms modified in this way is unsuitable for field release or greenhouse trials given the risks of transfer of this ability to indigenous organisms and the resulting consequences. Consequently, alternative methods of marking inoculants have been developed. For example, the organism *P. fluorescens* F113 and its DAPG negative mutant contain what has been described as the most utilized genetic marker system, that of *lac* ZY (129). This marker confers the ability to utilize lactose as a sole carbon source. In the case of *P. fluorescens*, this allows the organism to be distinguished from indigenous populations. This marking system is further enhanced with the use of a chromogenic dye (5-chloro-4-bromo-3-indolyl-β-D-galactopyranoside (X-gal)) that confers a blue color into the organisms carrying the *lac* ZY gene cassette.

The system described earlier has been used successfully in European Community funded field trials by the IMPACT consortium on biocontrol organisms, which investigated interactions between microbial inoculants and resident populations in the rhizosphere of agronomically important crops. (For further information see the web site *http://www.ucc.ie/impact/index.html*) Such research is needed because the ecological effects of releasing genetically modified organisms (GMOs) into the environment are not known. For example, modifications to the rhizosphere brought about by the introduction of a modified *Pseudomonas* with enhanced biocontrol abilities could interfere with nutrient cycles (69,70).

An example of an inoculant, modifying nutrient cycling was reported by Brimecombe and coworkers who studied how inoculation of pea (69) and wheat (70) seeds with *P. fluorescens* F113, modified as described earlier, influenced nitrogen uptake. Their findings indicated that the cycling of nitrogen was affected by the DAPG positive inoculant, which enhanced nitrogen uptake from

mineralized residues, despite its reduced activity in the soil. In contrast, nitrogen uptake by wheat seeds in a subsequent experiment was decreased by inoculation. Further work utilizing the same organisms sought to explain the apparent contradiction by examining the effect of plant-microbe interactions on bacterial-feeding nematodes and protozoa (130). It was found that pea seeds inoculated with either *P. fluorescens* F113 or the DAPG negative strain gave rise to an increase in the number of nematodes and protozoa in comparison to noninoculated seeds. Introducing the bacteriophagous *Caenorhabditis elegans* into noninoculated germinating pea seeds exerted a nematicidal effect on *C. elegans*. Inoculation with *P. fluorescens* arrested this effect, which suggested that the active nematicides were being metabolized by the inoculant. Inoculated wheat seeds, however, displayed lower nematode populations and unaffected protozoan numbers, with no nematicidal effects detected in either inoculated or noninoculated systems detected. Given the significant role attributed to the soil microfauna in nitrogen cycling, any disturbances to this part of the soil biota brought about by inoculation with *P. fluorescens* become very pertinent.

Such work highlights the need for further investigations, especially given the importance of nitrogen in agroecosystems and the globally increasing nitrogen inputs such systems receive, with possible implications for nitrogen leaching.

Despite the vast amount of research already conducted on rhizospheres, the new techniques mentioned earlier and the rapidly expanding knowledge presently being unveiled make it unequivocally clear that there is an extensive amount of work yet to be conducted, with many opportunities remaining. One particular realm of opportunity, is that concerned with bridging laboratory work with field based experimentation. Augmenting laboratory-based findings, achieved in microcosms, with field based work is difficult. Often the original findings are unsupported by work carried out in the more complex and less manageable environment. The use of a "halfway" approach is often required, using larger systems (macrocosms) to replicate the field environment whilst still maintaining some control over the experimental conditions. Rhizosphere microbiology and rhizosphere science in general remains incomplete, with much exciting work to be accomplished.

The structural ribosomal RNA genes and gene products have become the targets of choice for microbial ecologists trying to uncover novel variations in uncultured microbial species, relate microbial community structures to environmental processes, and monitor anthropogenic effects on microbial diversity and community structure. As the term suggests, ribotyping refers to a number of established methods that rely on the manipulation and analysis of ribosomal nucleic acids to characterize microbial isolates or communities. Although several ribotyping techniques are also useful in classification and taxonomy of microbial isolates, this discussion is confined to the characterization of unknown microbial communities, and the manipulation of nucleic acids extracted directly from environmental samples. These methods form part of a suite of methods designed to avoid the biases inherent in culture-based analyses of microbial communities (1) and attempt to take into account the fact that the microorganisms most relevant to environmental processes are commonly unknown and resistant to laboratory cultivation (2–4). Ribotyping strategies differ widely in their complexity and demand on human and material resources. They also differ in the amount and type of information they can provide, as well as their potential for introducing artifacts and biases.

These properties are summarized in Table 1. Thus, the choice of approach adopted is not trivial, and utilization of more than one approach to analyze a given sample is generally guaranteed to provide more information and reliability than any single method. The methods described here are ideally combined with those described in the chapters by Macnaughton and Sharp and Sutton, and are summarized in Figure 1. Factors influencing choice of technique(s) include the taxonomic level of focus (domain, phylum, genus or species), the amount of information available a priori for this taxon, the number of samples to be analyzed, the type of environmental sample, and the biomass and diversity of target and nontarget organisms in the sample.

Ribotyping methods generally target the small subunit ribosomal RNA or RNA gene (SSU rRNA or SSU rDNA). These are typically termed 16S in Bacteria and Archaea, and 17S or 18S in Eukarya. These terms, which refer to sedimentation rates, are rather inaccurate, as variation in the sizes of these molecules between species can

Table 1. Summary of Ribotyping Methods

Method	Potential for Artifacts	Technical Difficulty	Recovery of Sequence Data	Reproducibility	Suitability for Large Sample Sets	Recovery of Phylogenetic Information
Forward array	Medium	High	No	High	High	Yes, can be quantitative
Reverse array	Medium	High	No	High	High	As above
Shotgun clone analysis	Low	Medium	Yes	Low	Low	Excellent
PCR-clone Analysis	High	Medium	Yes (dependent on primer choice)	Medium	Low	Excellent, but prone to artifacts
DGGE/TGGE/TTGE	Medium	Medium	Yes (dependent on primer choice)	Medium-High	Medium	Good, but only short sequences from most abundant target organisms
SSCP	Medium	Medium	Yes (dependent on primer choice)	Medium-High	Medium	As above
RISA	Low	Medium	Yes (dependent on primer choice)	High	Medium	Poor
ARDRA	Medium	Low	No	High	Medium	Poor
T-RFLP	Medium	High	No	High	High	Fair, with good future potential

DGGE = denaturing gradient gel electrophoresis; TGGE = temperature gradient gel electrophoresis; TTGE = temporal thermal gradient electrophoresis; SSCP = single strand conformational polymorphism; RISA = ribosomal intergenic spacer analysis; ARDRA = amplified ribosomal DNA restriction analysis; T-RFLP = terminal restriction fragment length polymorphism.

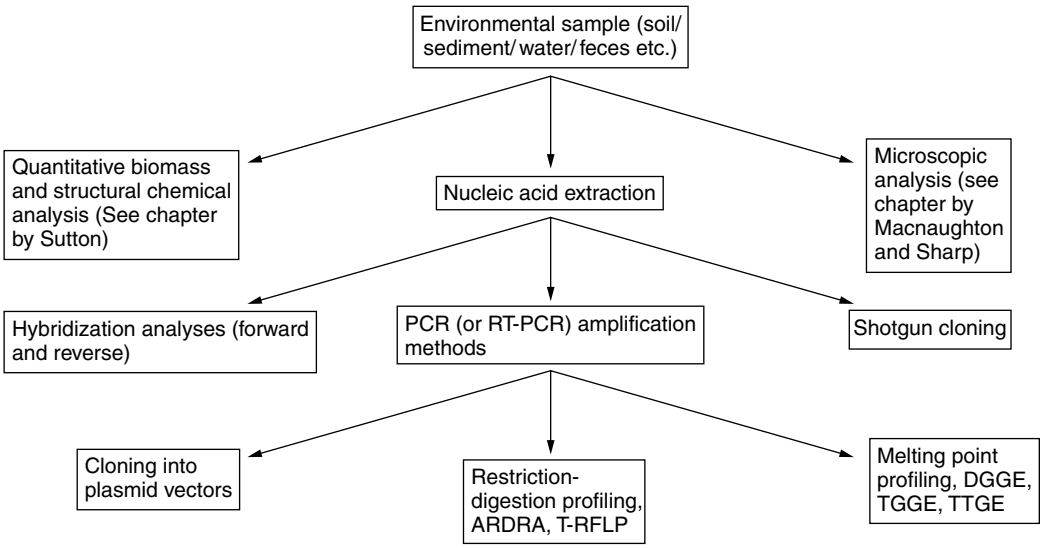

Figure 1. Schema representing the major subgroups of culture independent microbial community assessment procedures. Using methods from more than one category in analysis of a sample will almost certainly improve confidence in the quality of the data recovered.

be quite considerable, but are used here as common designations and terms of convenience. The use of small submit ribosomal RNA markers as targets for the analysis of microbial communities carries a number of important advantages that include the following:

- It is a ubiquitous marker, with a homologous function across all organisms.
- Conserved secondary structure facilitates the alignment of nucleotide sequences.
- The presence of both highly conserved and variable domains allows targeting of both broad and narrow taxonomic groups, respectively.
- The relatively high target number (multiple gene copies in many organisms, and high copy number or 16S rRNA per cell) makes detection relatively easy.
- 16S and 18S sequences carry sufficient information to allow phylogenetic inference.
- Phylogenetic inferences based on this molecule commonly match well with other taxonomic methods, such as morphology, phage sensitivity, chemotaxis, and so on.
- There is a large and expanding comparative sequence database (5).
- The relationship between rRNA production and protein synthesis rates means that rRNA levels can provide a first-order approximation of cell activity (6,7).

The use of large subunit rRNA or rDNA offers many of the same advantages, and this target actually possesses a greater degree of phylogenetically useful information. It is, however, less widely used because of the difficulty of amplifying and sequencing this larger target, and the ever-increasing advantages provided by the vast SSU database. The final product-encoding portion of the ribosomal operon is the 5S rRNA gene, whose small product was used in some of the earliest nucleic acid sequence comparisons between microorganisms (8–10). Although this target can be used for some ribotyping strategies, its scant phylogenetic content has limited its use. The portions of the ribosomal operon that do not code for structural RNAs, (the internal transcribed spacers [ITS] I and II) are highly variable and thus offer the possibility to discriminate between even very closely related species or strains (11,12). A given cell containing more than one ribosomal RNA operon is likely to contain appreciable variation in these regions (13). However, the lack of structural homology in ITS regions across taxa makes broad comparison of sequence information difficult or impossible. The relative use of different ribosomal operon targets will be reflected in the amount of attention they receive in this chapter, that will primarily address SSU-targeted strategies.

Currently, popular ribotyping methods can be divided into two subgroups, PCR-independent, and PCR-dependent. Quantitative PCR-independent ribotyping strategies depend on the hybridization of defined probes to membrane-bound environmentally derived nucleic acids, or vice versa, and are also covered in the chapter by MacGregor. The remaining PCR-independent method, analysis of shotgun-clone libraries, is now rarely employed, but has some unique advantages. PCR has revolutionized the ability to recover genes from the environment, but the amplification of complex mixtures of nucleic acids involves the generation of potential biases and artifacts. An in-depth discussion of the advantages and risks of PCR-mediated methods falls outside the scope of this chapter (14,14a), but certain potential limitations and artifacts are discussed in the context of the specific approaches presented in later sections. Community ribotyping methods either use rRNA molecules or the genes that encode them (rDNA) as the target of analysis. The targeting of either RNA or DNA has important implications not only in the interpretation of results, but also in terms of methodological constraints. RNA is less stable than DNA, and rRNA levels may therefore provide information concerning general levels of cell activity (15,16), although it is not yet known precisely how well rRNA levels per cell correlate with metabolic activity in natural samples. RNA is also less stable than DNA during laboratory manipulations, so extra care must be taken when analyzing rRNA samples (17). Furthermore, rRNA templates must first be reverse-transcribed into DNA for methods that require enzymatic amplification.

The stability of DNA in environmental samples is not fully known. Nonactive, dead or even partially destroyed cells may still have some DNA intact, and the longevity of free DNA in natural samples is highly influenced by the nature of the environmental matrix. Trevors (18) reviewed the stabilizing effect of the soil matrix on free DNA. Thus, it must be remembered that rDNA can be recovered from organisms that do not have ecological significance in the sample at the time of sampling. Further, rDNA copy number per genome varies between different microorganisms, and these differences must be taken into account when trying to extrapolate rDNA levels to cell numbers. These differences in gene copy number also influence the capacity for community ribotyping methods to detect a given cell type (19,20).

The majority of ribotyping techniques rely on the use of previously recovered sequence information. Thus, one must bear in mind that all primers and probes used in ribotyping studies are based on extant sequence information. The accuracy of such oligonucleotides in identifying their desired targets within uncharacterized environmental samples is only as good as the comprehensiveness of the database used to design them, and must be kept under constant revision (21,22,22a). Therefore, all ribotyping studies utilizing so-called "signature sequences" are liable to both detect nontarget organisms and fail to detect target organisms when applied to samples containing an unknown mixture of species. This highlights the importance of acquiring novel sequence information from both pure cultures and environmental samples, especially within phylogenetic lineages that are poorly represented at present.

PCR-INDEPENDENT METHODS

PCR-independent ribotyping methods may be quantitative or nonquantitative. The quantitative methods are based

on hybridization of genetically informative labeled probes to environmental nucleic acid targets. As hybridization of probes to targets within intact cells (in situ hybridization) is covered elsewhere in this Encyclopedia (FLUORESCENT PROBES FOR IN SITU ANALYSES OF MICROBIAL COMMUNITIES), this discussion is limited to methods requiring hybridization to nucleic acids extracted from environmental samples.

Perhaps the greatest advantage of PCR-independent ribotyping approaches is that no in vitro amplification of nucleic acid targets is necessary, thus circumventing any potential biases or artifacts that such amplifications may introduce. Nucleic acids extracted from the environment are analyzed directly. One of the major limitations, however, can be in the amount of sample necessary to carry out the ribotyping analysis, which can be especially problematic when targeting microorganisms that are low in numbers or only represent minor components of the community. Secondly, the quality of hybridization support is critical, as variations within a given membrane may seriously affect the quality of quantitative interpretations from the results (23).

Forward Sample Array Hybridization

This ribotyping method generally involves the spotting of extracted nucleic acids onto a membrane, which is subsequently hybridized with a battery of oligonucleotide probes that are specific to different taxonomic groups under highly defined conditions of stringency. Protocols differ in regard to how the probes are labeled, the type of membrane used, and the detection of hybridization products. The strategy usually involves the use of a hierarchical set of hybridization probes, which allows definition of the total amount of extracted 16S rRNA or rDNA to be defined and divided among the probe-targeting taxonomic groupings (Fig. 2). The decision as to which taxonomic groupings are to be included depends on the discretion of the researcher, and the availability of suitable probes. The taxonomic level of the study also influences the number of hybridization probes used. Repeat-probings of a membrane or set of replicate membranes can vary between just a few, if one is interested only in the relative amounts of eukaryotic, bacterial and archaeal target, for instance, to several hundred in theory, if one were interested in subdividing to fine taxonomic levels. In practice, most analyses focus on major microbial groups and a small number of subgroupings, functionally important in the samples under investigation (24).

As mentioned earlier, the accuracy with which probes detect their target group is difficult to predict when examining environmental samples. The level of uncertainty

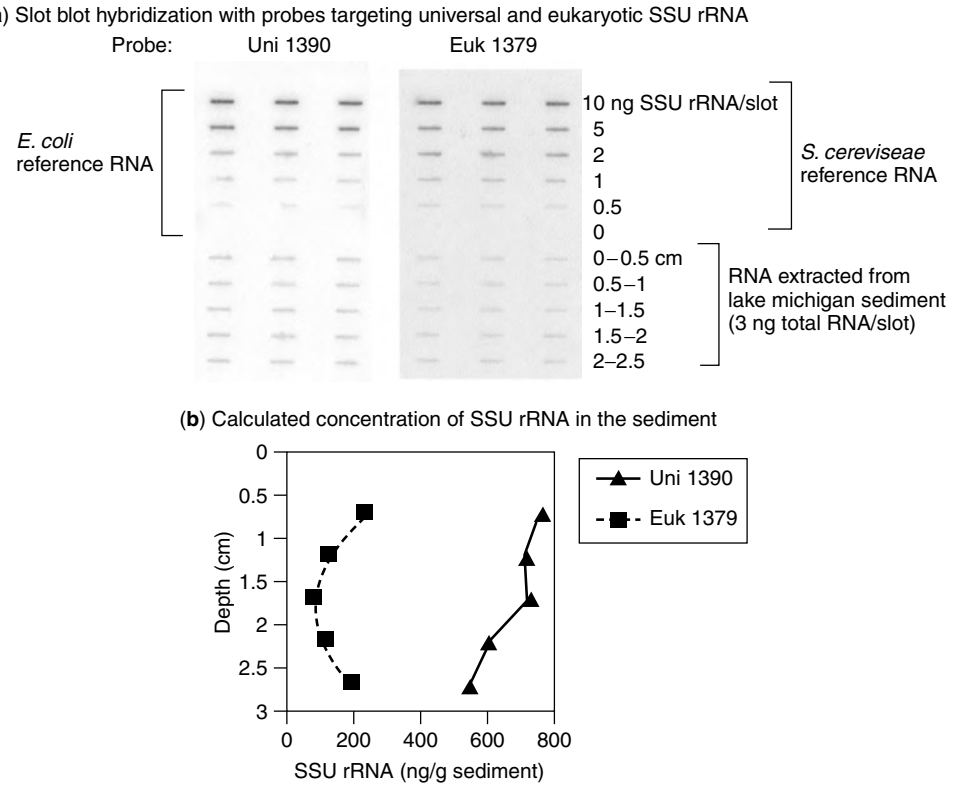

Figure 2. Quantitative membrane forward-array hybridization. (a) Raw data; (b) quantified data. This experiment quantified the numbers of all microorganisms (Bacterial, Archaeal, and Eukaryotic) using a universal probe, and the numbers of eukaryotic microorganisms with depth in a freshwater lake sediment. The amount of probe bound was compared to the level of probe bound to standard quantities of Eukaryotic (*Saccharomyces cerevisiae*) and prokaryotic (*Escherichia coli*) SSU RNA. The quality of both the RNA and hybridization membrane are of crucial importance in such studies (17,23). Courtesy of Barbara J. MacGregor, Max Planck Institute for Marine Microbiology, Germany. See color insert.

decreases as more information is gathered on a taxon, but such limitations are inherent to all techniques that use oligonucleotide probes or primers to examine incompletely defined environmental samples. Furthermore, the determination of optimum hybridization conditions can be a difficult task, and cross-hybridization with closely related target groups can affect the accuracy of results, even when using optimum hybridization stringencies. Thus, although results may allow quantitative interpretation of nucleic acid abundance, the accuracy of the analysis is still limited to the reliability of the probes used. The use of an hierarchical approach, however, can provide an indication of the coverage of some probes. Where all known subgroups within a taxonomic unit are represented in an analysis, the summed hybridization results of the subgroups can be compared to the result of the group-specific hybridization. The use of such internal checks usually reveals that not all organisms can be recognized by a defined set of probes, resulting in a certain amount of "undefined" rRNA or rDNA signal. Conversely, use of partially degraded RNA can lead to quantification difficulties, which falsely suggest that subgroups are in fact far more abundant than the major taxonomic groups of which they are a part (17). Such an artifact occurs when the probe site defining a given subgroup is protected from degradation relative to the probe site defining the parent taxon. The accuracy of such analyses will continue to increase with continued DNA–RNA-extraction and probe development. Such development not only increases the accuracy with which currently screened groups can be quantified, but also will expand analysis to include additional, currently not known, microbial groups.

The number of times that such a membrane can be hybridized can be limiting, and sequential hybridization can be time-consuming. In practice, several replicate membranes are therefore usually made for concurrent analysis. Membranes typically contain several samples to be compared, and spots containing known concentrations of nucleic acids derived from control organisms of known phylogenetic affiliation. Such controls allow for standardization of hybridization signals and comparison across duplicate membranes.

This approach has typically been used for the broad-scale characterization of microbial communities (25), although it can also be applied to detect shifts between closely related taxa in some cases (26). Forward array hybridization experiments have also been highly illustrative in examining the discrepancies between direct ribotyping surveys and those relying on the culturing of bacterial colonies on solid media (3).

Forward sample array hybridization has also been carried out after the introduction of a PCR step and, for example, denaturing gradient gell electrophoresis (DGGE) analysis (27). Although this is usually not desirable because of the possible introduction of PCR artifacts, and the loss of quantitative data inherent in this, it may be necessary in cases involving very small sample volumes or low target numbers.

Reverse Sample Array Hybridization

Typical forward dot blot hybridization studies fix the sample of interest to a membrane and use specific oligonucleotides to probe the sample for signature sequences of interest. However, as the number of microbial groups to be identified increases, it becomes unwieldy to strip membranes and reprobe for each target group. Reverse sample array hybridization allows for the detection of multiple bacterial groups, at various taxonomic levels, within a single analysis.

As the name suggests, reverse sample array hybridization switches the placement of sample and probe with respect to forward array probing. In this case, the environmental sample is typically labeled in some way, and allowed to pass over a surface to which probes have been fixed. Labeled DNA (RNA or cDNA, if the starting material is rRNA) fragments that hybridize with the attached probe sequences remain in association with the surface, whereas nonmatching sequences are washed away. The depth and breadth of the analysis depends on the number and the taxonomic level of probes spotted on the hybridization surface. When using a battery of species-specific probes, such arrays have typically been used for strain identification (28,29). Alternatively, nucleic acid extracts from mixed microbial communities can be used to detect and quantify specific community members (30–32) or characterize a microbial community across several taxonomic levels.

The number of taxon-specific probes can vary from a few to potentially hundreds or even thousands. The nature of these "reverse probes" can also vary from specific oligonucleotides to total DNA extracts from pure cultures. The specificity of the probes used depends on the desired breadth and depth of the analysis. Reverse array hybridization analysis has been applied to detect shifts both between domain-level groups (33) and within specific bacterial groups (32), as well as to detect the presence and changing distribution of specific microbial populations (34).

Nucleic acids acting as reverse probes can be pipetted to a membrane (35) or, in a rapidly developing new technology, applied to fixed supports such as DNA chips (see Biochip-Based Devices and Methods in Microbial Community Ribotyping, this Encyclopedia). The method used will depend on the number of reverse probes to be used and the facilities available. In the near future, it is likely that reverse probing of oligo- and polynucleotides bound to microchips will become the dominant form of nucleic acid community monitoring, although currently the capital costs of such systems are prohibitive for their widespread use.

Shotgun Cloning

Some of the first 16S rDNA sequences recovered from uncultured organisms were derived from shotgun cloning experiments. In this technique, total environmental DNA or reverse-transcribed RNA is cloned into a phage or plasmid vector to create a library. The library is then hybridized to a suitable probe using plaque or colony lifts to select clones of interest, followed by

subcloning and/or sequence analysis (36). Such cloning strategies have revealed novel microbial diversity, and sequence information so recovered may be more reliable than sequences recovered after PCR (14). However, few laboratories can afford to carry out the laborious screening required for the examination of direct environmental clone libraries. The increasing sensitivity of screening procedures may make this strategy a more viable option for some environments in the future.

PCR-DEPENDENT METHODS

The chief advantages of PCR-mediated methods over those not employing amplification steps are provided by the specificity of PCR methods and the added sensitivity afforded by target amplification. Thus, such techniques enable analysis of microbial communities or certain parts thereof, using only small portions of sample. The goals of a particular study and the available target group(s) determine the choice of PCR primers used, and this choice is critical. The use of primers targeting broad taxonomic groups can be employed to track a wide variety of microbial populations, but results may become unwieldy for highly complex communities. On the other hand, primer combinations specific for groups at lower taxonomic levels can be used to study particular monophyletic subsets of a community (37). Such approaches can be very useful in reducing complexity and focussing on certain groups of interest. However, phylogenetic groupings do not always correspond to functional groupings (e.g., nitrate-reducing bacteria, or traits carried by plasmids), and such approaches cannot reveal information about community members falling outside the specific group. Also, not all primer combinations can be used equally well for all methods because of technical constraints. In principle, all PCR-dependent techniques can also be applied to the analysis of RNA molecules by the addition of a reverse transcriptase step before enzymatic amplification.

The major drawback of PCR-based approaches is the potential introduction of artifacts during the enzymatic amplification of target molecules. Even assuming a perfect match between the primers chosen and the target group of interest, it is seldom reasonable to assume that the ratio of recovered sequences faithfully represents the ratios of the source organisms in the environmental sample tested. For example, two of the most conserved regions in the bacterial 16S rRNA gene were targeted by Muyzer and coworkers in the seminal use of PCR-DGGE to profile bacterial communities (20), yet heterogeneities exist within these sites (22,38). Figure 3 shows the consequence of trying to amplify a 16S gene fragment from a γ-proteobacterium with mismatches to one of these primers in the presence of sequences with perfect matches. This demonstrates that even when present at 20% of the starting templates, the product from this organism is negligible in competition with sequences with perfect matches.

Replication errors may also occur during PCR, and further errors may be introduced during cloning, such that recovered sequences may differ substantially from the original target molecules. The relative seriousness of potential artifacts depends on the technique and

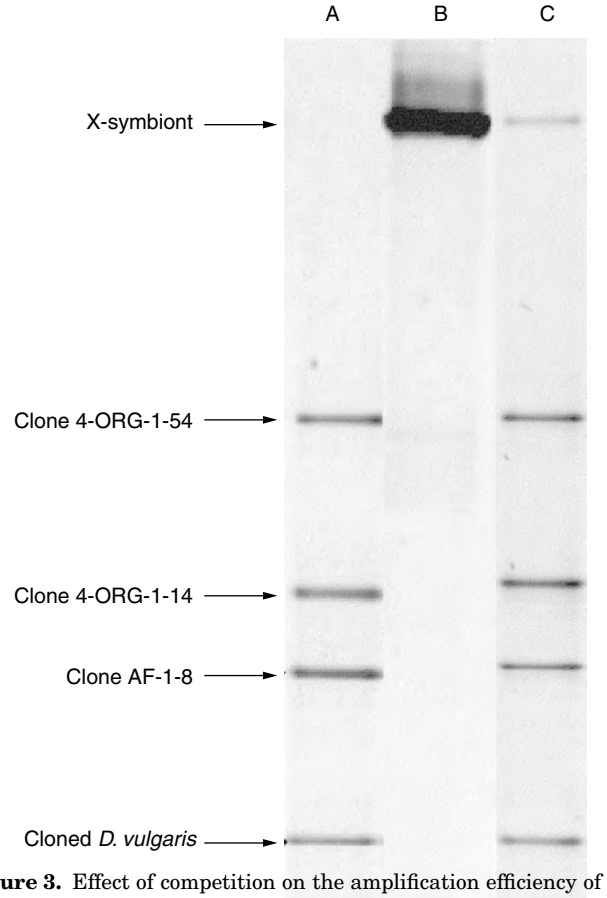

Figure 3. Effect of competition on the amplification efficiency of tempates with imperfect primer matching on PCR-DGGE profiles. The 16S rDNA sequence of the X-symbiont of *Anomoneura mori* has mismatches to the forward PCR-DGGE primer described by (20). The other sequences used have perfect matches. When mixed in equal proportions prior to PCR, the X-symbiont 16S rDNA fragment was not detected (A), although it amplified efficiently in reactions containing no other templates (B). When the priming site was modified to encode a perfect match to this primer, it coamplified with competitor templates with an efficiency approaching that of the competitors (C). From experiments described in (38).

methodology involved, and the limitations of PCR must always be kept in mind when interpreting the results of the ribotyping techniques discussed in the following sections. More detailed descriptions of potential PCR artifacts can be found elsewhere (14,39–42b), and this chapter only focusses on specific advantages and disadvantages of the presented techniques.

In Situ PCR and In Situ RT-PCR

Structural information and localization of bacterial cells and activities in situ is lost using the destructive methods of most ribotyping strategies. In fact, the ability to detect structural aspects of microbial communities is perhaps the most interesting feature of the in situ hybridization techniques described in the entry Fluorescent Probes for In Situ Analyses of Microbial Communities, this Encyclopedia. One problem with some in situ hybridization protocols is the lack of sufficient

signal for accurate detection. Recent technical advances have made it possible to combine the structural resolution of in situ hybridization with the detection sensitivity of PCR techniques. In some cases, it is possible to perform amplification reactions, targeting either DNA or RNA templates, without the disruption of structural features of the sample (43–45). Amplified target nucleic acid is then detected by subsequent use of internal hybridization probes. While such techniques show promise for revealing structural aspects within certain microbial communities, the procedures can be technically demanding and difficult to reproduce. It remains to be seen if these in situ amplification strategies will become viable ribotyping methods for widespread use.

Clone Library Screening

Ribotyping of bacterial communities by cloning near-full-length rDNA fragments has the potential to generate more novel information than any other ribotyping method (46). Compared with the gel-based profiling methods described later, a greater length of sequence can be retrieved from clone libraries, providing stronger phylogenetic inference. Compared with hybridization analyses that do not generate novel sequence information, the information recovered is more additive and easily accessed by other researchers from public sequence databases. Cloning-based approaches typically address two issues, (*1*) the identity of community members, and (*2*) the diversity within the targeted community.

The first of these issues is addressed by phylogenetic analysis of recovered sequences. Such analyses can usually provide satisfactory information as to the identity of the microorganism from which the sequence was recovered, but as mentioned previously, it is difficult to correlate the frequency of sequence recovery with cell numbers. Furthermore, sequence anomalies introduced during PCR, cloning, or sequence determination can affect the fidelity of results. In addition to polymerase errors, the creation of chimeric DNA fragments and heteroduplex DNA molecules can result in novel sequences not present in the original target pool. Chimeric molecules are PCR artifacts in which the 5′ and 3′ ends are derived from different source organisms. These might be interpreted incorrectly as being derived from novel microbial lineages, and may contribute to overestimations of diversity (39). Although careful analysis may detect such artifacts (e.g., the "Check Chimera" program, 5), many such sequence anomalies no doubt escape detection, and the introduction of artifactual sequences in clone libraries has in some cases been estimated to be quite high (47–47b). Resolution of the problem of cloning heteroduplices may be overcome by digestion of PCR products with T7 endonuclease I before ligation (47c).

The issue of community diversity can be addressed by comparing the redundancy within rDNA libraries obtained from different samples. Ecological theories such as "collectors' curves" used to estimate "coverage" can be employed in such comparisons. Coverage is calculated by compiling the sequences generated, then calculating the likelihood that the next clone sequenced already exists within the database. In a simple mixture of two species, it will quickly become apparent that each sequence derived is identical to one previously recovered. However, for environments such as soil, where the species diversity has been estimated at 5,000 to 10,000 distinct species per gram (48), the number of clones that need to be analyzed to provide a good picture of community structure is enormous and prohibitive. Where such attempts have been made, coverage has generally been assessed by the method described (49–51), and diversity using the Shannon index (52).

It is possible to define two samples as different using a cloning-based strategy by demonstrating that the slope of the Collector's Curves are different (different diversities, Fig. 4), or that the distribution of sequences is different (different community structures). However, given the number of clones that must be analyzed to achieve a reasonable estimate of community structure in a highly complex system such as surface soil (50), comparisons between samples can become highly impractical using such a strategy. Where only the recovery of novel sequence information is sought, it is possible to reduce the number of clones to be sequenced by screening clones by restriction analysis (53) or denaturing gradient gel electrophoresis (54) to avoid the sequencing of duplicate or highly related clones. Also, clones above a given level of identity can be grouped into operational taxonomic units (OTUs) to reduce the complexity of data for the Collector's Curve analysis (50). Nevertheless, cloning strategies are most often limited to a mere glimpse into some of the types of microorganisms present in a sample, except when applied to relatively simple communities such as laboratory enrichment cultures (55). Comparisons can become more manageable and meaningful when the cloning strategy employs specific primers to target a specific microbial group of interest (37,56).

Community Fingerprinting Techniques

Any given stretch of rDNA between conserved PCR priming sites is likely to differ in length between certain groups of organisms, but separation of rDNA fragments

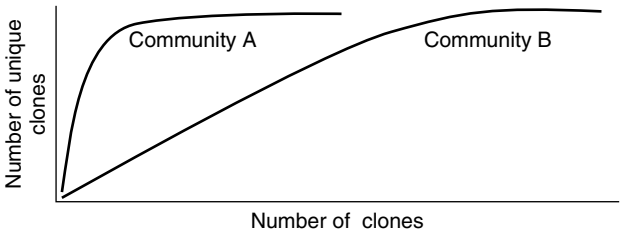

Figure 4. Schematic "Collector's Curves" of cloned rDNA fragments OTUs. Community A is less diverse than community B. Defining this relies on the repeated recovery of operational taxonomic units (OTUs) and statistical proof of difference between the curves. An OTU may be considered as a unique sequence, or a group of sequences within a limit of sequence identity (generally 97%). Alternatively, OTUs have been defined as clones with identical restriction–digestion patterns, DGGE or SSCP migration behavior, which may not equal sequence identity. Defining diversity by this type of analysis is as strongly influenced by community evenness as DGGE/SSCP/T-RFLP and RISA analyses. None of these methods are ideal for the measurement of species richness, an equally important aspect of diversity.

on the basis of length is too crude an approach to provide details regarding differences between environmental communities. The following section describes the generation of community "fingerprints" based on exploitation of sequence differences between the rDNA fragments of different species. The following rule of chromatography should be kept in mind while reading the technique descriptions mentioned in the following sections: Two samples generating different patterns are different, but two samples generating identical patterns are not necessarily identical. This rule applies to any single-dimension chromatographic procedure; there are no exceptions. It is therefore imperative that assumptions of community or band identity are supported by additional data.

One of the major advantages of community fingerprinting approaches is that entire populations of nucleic acids are analyzed together, instead of individually, as in clone library analysis. This allows for a far more rapid comparison of multiple communities. As with other approaches, analyses can target either rRNA or rDNA templates by RT-PCR or PCR respectively, and RNA- and DNA-based community profiles can be readily compared.

As only the most dominant DNA molecule types will be detected (those comprising at least 1–2% of the entire target population; 20), individual sequence anomalies introduced during the PCR amplification of complex samples are typically present in concentrations that are too low to affect the analysis. However, this level of detection can also be considered as a major drawback of community profiling methods because some ecologically significant microbial populations may constitute only a small fraction of the total rRNA or rDNA of a sample and therefore escape detection.

Profiling Amplified rDNA Fragments by Separation on the Basis of Melting Point: DGGE, TGGE, TTGE

DNA fragments differing in sequence by as little as a single base pair can have easily identifiable differences in melting point. Denaturing gradient gel electrophoresis (DGGE), termperature gradient gel electrophoresis (TGGE), and temporal thermal gradient electrophoresis (TTGE) all operate on this principle and are considered together here. The mixed (RT-) PCR products generated by 16S rRNA- or rDNA-specific amplification reactions typically contain populations of DNA fragments that contain differences in nucleotide sequence. However, because of nearly identical lengths, such fragments cannot be separated based on size as in a standard agarose or acrylamide gel analysis. DGGE, TGGE, and TTGE all rely on the sequence-specific differences in melting behavior between DNA fragments and separate such mixed (RT-) PCR products into bands containing the constituent populations of DNA sequences. When DNA fragments become partially single-stranded (ss), mobility is drastically impaired with respect to double-stranded (ds) DNA. This partial denaturation can be induced by elevated temperature or denaturing chemicals such as urea and formamide, and is dependent on the G : C content of the fragment and other structural aspects determined by the nucleotide sequence. In a gradient of denaturing potential, DNA fragments with low melting points will effectively stop moving earlier than fragments with a higher melting point, thus leading to the separation of these DNA species. Gradient gel methods usually employ the use of a denaturation-resistant clamp to anchor one end of the PCR product and to help stabilize its melting behavior. The clamp can contain a string of G:C base pairs introduced at the 5′ end of one of the primers (57) or a photoreactive cross-linking group (psoralen), which is activated after PCR (58).

The differences between DGGE, TGGE, and TTGE reside in the manner in which double-stranded DNA fragments are induced to melt. DGGE employs a gradient of chemicals, usually a mixture of urea and formamide, which interfere with DNA base-pairing, held at a constant temperature (usually 60 °C) submerged in a buffer-filled waterbath throughout the procedure. As double-stranded DNA passes through the gel during the course of electrophoresis, it comes to a concentration of denaturants that, in combination with the elevated temperature, induces the amplified fragment to denature. TGGE employs a more specialized apparatus, in which the gel is cast with a constant concentration of these chemicals, and is run horizontally against a hot plate. The hot plate increases in temperature toward the end of the gel, with the effect that double-stranded DNA passing through the gel is exposed to a linearly increasing gradient of heat, until it denatures and is retarded within the matrix. TTGE is a similar concept. The gel is again made with a constant concentration of denaturant and submerged in buffer. As the gel-run proceeds, the buffer tank increases in temperature in a linear fashion, such that DNA fragments of increasing melting point migrate longer before denaturation and retardation.

These are rapid and powerful methods for monitoring changes in community structure over time or space. Multiple samples can be compared side by side and across gels, provided that migration standards are included in each run (20,59). Comparison of banding patterns can give some measure of similarity among different samples analyzed, often expressed as dendrograms based on band sharing or total lane similarity (60–62). Sequence information can be obtained from individual DGGE bands by band excision, DNA elution, reamplification, and sequence determination. The partial 16S rDNA sequences obtained can be subjected to phylogenetic analysis, thus providing clues to the identity of dominantly present or active community members (63–66). Alternatively, phylogenetic information can be derived from DGGE banding patterns by hybridization analysis. In this procedure, DNA from the DGGE gel is blotted onto a support membrane, and hybridization follows with a number of phylogenetically informative probes, in a fashion similar to forward sample array hybridization (20,27,67).

However, some severe limitations exist. Not all DNA fragments are suitable for denaturing gradient analysis, because of unstable melting behavior or size limitations. The typical maximum size of DNA fragments used in such analyses is 500 to 600 base pairs, although adaptations allowing analysis of fragment sizes of up to 1.5 kb have been reported (68). Also, not all DNA fragments exhibit stable melting behavior, potentially leading to fuzzy bands or multiple-banding patterns. Many PCR strategies use

degenerate primers, which can lead to multiple bands from a single-template sequence, especially when degeneracies are located in the primer not containing the GC-clamp (66). Furthermore, base pair differences that do not affect fragment melting behavior (and thereby mobility) may go undetected, and multiple sequence differences that have opposing affects on fragment mobility may serve to cancel each other. Thus, identical band migration does not necessarily indicate sequence identity, and distance between bands cannot be used as an indicator of phylogenetic relatedness. In all cases, it is essential that the parameters for optimum band separation be determined empirically for each set of primers to be used.

A common mistake made when interpreting DGGE banding patterns is to assume that the number of bands recovered accurately provides a measure of microbial diversity. This grossly oversimplifies the issue of diversity, which has been controversial among ecologists for many years. Diversity seems an intuitively obvious concept, but is difficult to quantify. It consists of two parameters, species richness and the evenness of the distribution of species in a given sample. A sample containing 100 species of even distribution is considered more diverse than one containing numerically 99% of one species, and an even distribution of the remaining 99. Gel patterns, as currently interpreted, are not adequate to assess microbial diversity. First of all, only the most common community members are represented in the banding pattern (ribotypes that represent at least 1 to 2% of the entire target community). DNA fragments that are represented in low numbers will fall into the background. The most diverse communities (i.e., with many evenly distributed species) will produce so many faint bands that the end result will be a smear across a range of denaturant concentrations. Figure 5 shows an example of a community approaching this state. The bacterial community of a sample site highly contaminated with chromium was analyzed at three depths by PCR-DGGE. The surface community was too diverse for any dominant ribotypes to be identified by band excision. The pattern simplified with depth, such that at the greatest depth, the most abundant organisms were easily identified by band excision and sequence analysis. Counting the visible bands alone would suggest that the community became less diverse with depth. However, the richness of the species may have remained equal, or even have increased. DGGE cannot assess this. Such methods assess only the evenness of species distribution (69). Øvreas and coworkers (70) provide a good example of how the issue of diversity can be approached by combining methods, during a study of the effects of methane on microbial communities in soil. In this case, the native microbial community, whose diversity was determined to be high by total DNA reassociation (a gram of soil containing about 8,000 fold the complexity of an *E. coli* genome), produced a smear on PCR-DGGE with bacterial specific primers. Methane treatment reduced the diversity of the soil community by about 20 fold, resulting in some distinct bands by DGGE. More sensitive detection systems, such as those employing fluorescent dyes and digitized imagers (71), may help to increase the resolution of DGGE gels, but such problems are difficult to solve for highly complex systems.

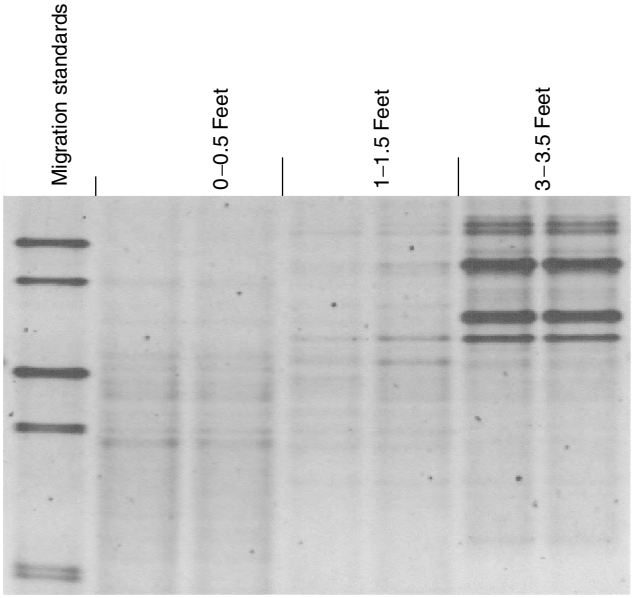

Figure 5. PCR-DGGE profiles from a chromium contaminated soil by depth. The complexity of the banding pattern decreased with depth, indicating a decrease in the evenness of distribution of the species present. All species indicated by bands in the surface sample may have been present at equal numerical abundance in all samples, but their signal was lost due to the increasing relative abundance of a few organisms. The "usefulness' of the method may have been considered to have increased with depth, as the remaining bands could be excised and sequenced to provide information on the phylogenetic positions of the source organisms, that were mostly ε-proteobacteria and members of the *Bacteroides-Flexibacter-Cytophaga* phylum. GenBank accession numbers AF188401-AF188413.

One way of reducing the complexity of community analyses to a manageable level is to target only certain monophyletic groupings within a particular PCR-DGGE analysis. Specific PCR primers have been used in combination with DGGE to study the distribution and diversity of a variety of bacterial groups (66,72,73). Such analyses can also be designed to target eukaryotic microorganisms (61,65).

An additional complicating factor is the possible presence of rDNA sequence heterogeneity within a single bacterial cell. Slight sequence differences between rRNA operons can lead to the production of multiple DGGE bands from a single pure culture (74). Furthermore, the presence of heteroduplex molecules may lead to additional artifactual DGGE bands. Such molecules occur when single-stranded DNAs of less than 100% complementary anneal to each other instead of to their exact complements during the PCR stage. This can easily occur within mixed PCR products, especially if amplification conditions are less than optimum and complementarity between DNA fragments is high. Such heteroduplex molecules exhibit different melting behavior than their homoduplex counterparts, leading to the detection of spurious bands. The heteroduplex nature of DGGE bands can be examined by cutting out the band in question, reamplifying it, and subjecting the subsequent product to another round of DGGE. Homoduplex bands produce a single band, whereas

heteroduplex bands form two to four bands (75). Thus, one must exert caution when interpreting DGGE gels with respect to diversity assessments. Similar warnings also apply to the use of other community fingerprinting techniques, such as those described below.

Single Strand Conformational Polymorphism (SSCP)

Like the techniques described earlier, single strand conformational polymorphism (SSCP) analysis uses sequence-dependent mobility differences to separate mixed PCR products into their constituent DNA populations. In this technique, all PCR products are first denatured. The resulting single-stranded DNA (ss-DNA) molecules are then allowed to fold upon themselves, thus producing a sequence-dependent secondary and tertiary structure, that is determined by the potential for intramolecular base pairing. The mobility of these folded ss-DNA molecules in a nondenaturing polyacrylamide gel is determined by the shape and size of each molecule. Thus, each population of DNA molecules of a given sequence should in theory produce two bands on a gel, one for each DNA strand (76,77). Clearly, the analysis of ss-DNA eliminates the problem of heteroduplex bands present in other profiling methods.

Visualization of ss-DNA can be performed by a number of methods. Ethidium bromide detection is less efficient for ss-DNA than ds-DNA. Silver staining or stains that bind equally well to ss-DNA and ds-DNA are therefore most often used. Alternatively, radioactive or nonradioactive label can be incorporated during the PCR for DNA detection. One of the major advantages of SSCP is that each ds-DNA population produces two markers that can be used for comparative identification. For example, this may be helpful in using SSCP analysis to track an organism added to an environment. Although the sharing of two bands between samples by no means proves identity, the predictive value of two bands is far better than one. In practice, banding patterns can become highly complex, to the point where it becomes impossible to determine the bands that should be analyzed as pairs. The complexity of SSCP patterns can be reduced by labeling only one of the primers used in the PCR (78). This can simplify banding patterns significantly, but detects only one of the two ss-DNA molecules per DNA species. With the advent of automatic gel systems that can recognize multiple fluorescent dyes in a single gel lane, it should become possible to label both primers with different dyes to maximize the clarity and information of SSCP banding patterns.

As with DGGE, it is not valid to deduce biodiversity from the number of SSCP bands. In addition to the limitations addressed for DGGE, artifactual bands can be produced by competing single-strand formations of some molecules. Such additional bands have been referred to as unstable conformers (79) and can lead to multiple bands derived from a single DNA sequence. Also, the changes induced by sequence differences can range from minor (or none) to major, depending on how the overall base-pairing of a ss-DNA molecule is affected. Phylogenetic distances therefore cannot be inferred from differences in SSCP mobility.

The sensitivity of SSCP for the detection of sequence differences is thought to be comparable or slightly less than that of DGGE (80). Because SSCP relies on changes in intramolecular base pairing to detect sequence differences, base changes that do not affect the secondary and tertiary structure of the rDNA being analyzed may go undetected. This is a very real possibility given the conserved secondary structure of ribosomal gene products, and care must be taken to avoid targeting of regions with high levels of conserved complementary. In practice, ITS regions are often targeted by SSCP, where such de facto intramolecular complementarity is not present.

Like DGGE, SCCP analysis can also be coupled with the use of primers that are specific for microbial groups of interest and eukaryotes (81). In practice, SSCP is most useful in the description of either simple communities or a narrow subset of the total community. Although it can be used as an effective tool to detect and track known isolates (by comparison to standards), SSCP results can become very difficult to interpret when applied to more complex issues of community structure.

Community Profiling Based on Restriction Digestion: ARDRA and T-RFLP

Amplified ribosomal DNA restriction analysis (ARDRA) is based on cleavage of PCR amplified rDNA products with a suite of Type-II restriction endonuclease enzymes chosen to cleave rDNA in the less well-conserved regions of the molecule (82–84). The cleavage products are separated by size using gel electrophoresis. Like the other fingerprinting methods described here, ARDRA generates an "at a glance" view of how similar or different multiple bacterial communities are, without prior knowledge of the organisms involved. This method, in its simplest form, does not require any specialized equipment over that which is normally found in a molecular biology laboratory, which is its primary advantage. Its primary disadvantage is that, although it conveys useful information on whether large differences between communities exist, the nature of those differences in terms of the species or phylogenetic groups effected is not readily available. Carrying out hybridization analyses with probes specific for conserved rDNA regions before excising bands from a duplicate gel may help overcome this, but the complexity of these operations removes the advantage of speed from ARDRA as an analytical approach. Some of these objections can be overcome by discarding the majority of ARDRA products and analyzing only those corresponding to either the 5′ or 3′ end of the molecule, a technique termed *terminal-restriction fragment length polymorphism* (T-RFLP).

(T-RFLP) analysis of rDNA amplified from bacterial communities provides the same "at a glance" evaluation of community differences as those methods described earlier (Fig. 6). However, the potential to derive some phylogenetic information directly from the banding pattern is currently unique to T-RFLP. Its growth in popularity is due to the ready availability of the necessary equipment, the generation of patterns that are easily compared between gels, and the ability to make phylogenetic predictions from the fingerprint generated. This area has recently been reviewed by T. L. Marsh (85),

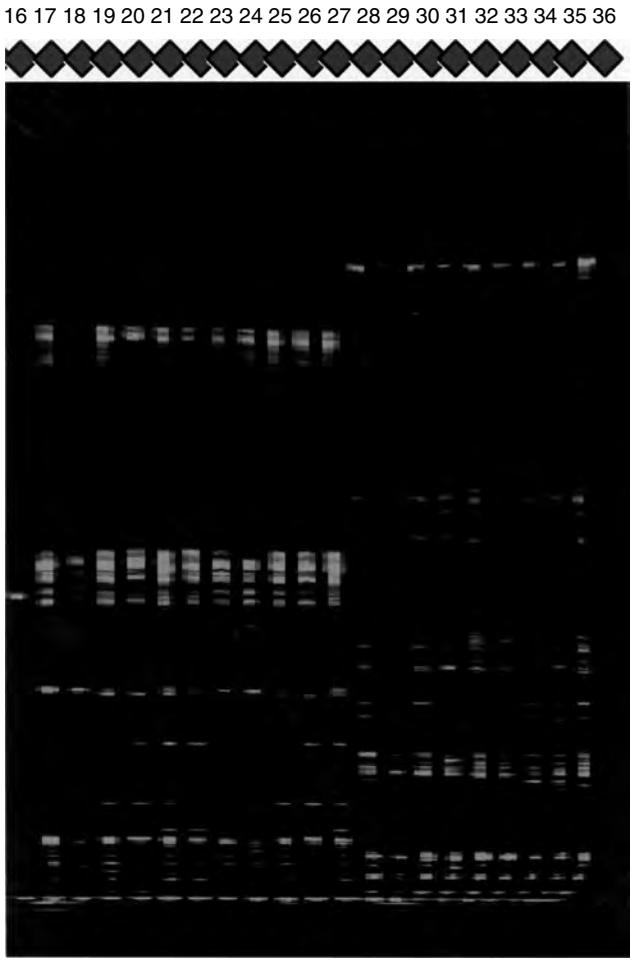

Figure 6. T-RFLP analysis of bacterial communities. This digital image was generated by an ABI377 automatic sequencing apparatus and shows lanes 16–36 of a T-RFLP gel. Lane 16, the single band was produced from a pure culture of *Alcaligenes eutrophus*. Lanes 17–27 are profiles from multiple DNA extractions from subsamples of a control soil, and lanes 28–36 are from a contaminated plot. The profiles of the control and contaminated soils are clearly different, demonstrating that the bacterial community has responded to the presence of the contaminant. Courtesy of Terrence L. Marsh, Department of Microbiology, Michigan State University, U.S.A. See color insert.

who largely developed the method (86). Of the gel-based PCR-ribotyping methods, this shows the greatest potential for generating additive information allowing researchers to compare their results to those of others. A facility allowing phylogenetic inference from T-RFLP banding patterns by comparison to those predicted from published data has been created by Michigan State University at *http://www.cme.msu.edu/RDP/html/analyses.html* (5).

T-RFLP begins in the same manner as ARDRA, with the exception that one of the PCR primers is 5′ end labeled with a fluorescent tag. Restriction endonuclease digestion is carried out with a single enzyme for each gel run. The choice of enzyme is usually based on a priori knowledge of the first occurrence of a recognition site for a given enzyme in a given taxonomic group. This is 3′ to the 5′ end of the molecule if the forward PCR primer was labeled, and 5′ to the 3′ end of the molecule if the reverse PCR primer was labeled. rDNA fragments amplified from a given community are usually digested with several enzymes to recover information pertaining to a range of taxonomic groups. Accurate sizing of the terminal restriction fragments is essential for taxonomic purposes, and cannot be achieved by conventional agarose gel electrophoresis. Rather, the digested products are mixed with a molecular weight ladder prestained with a different fluor, then separated using an automated DNA-sequencing apparatus. The apparatus detects both fluors as they pass a laser-detection system, and custom software can determine the length of T-RFLP fragments to within 1 to 2 bases by comparison to the molecular weight standards. It is this level of sizing accuracy that provides strong advantages of T-RFLP over the other PCR-based ribotyping methods described in this article.

A major criticism of this approach is the dependence on published data for phylogenetic interpretation. Currently, environmental samples are usually dominated by organisms that have no close relatives in the sequence databases, and therefore placement within this frame of reference based on T-RFLP patterns may be seriously flawed. Phylogenetic conclusions based on T-RFLP data must, at present, be complemented by the use of another community profiling method capable of recovering sequence information directly.

None of the methods mentioned earlier are capable of discriminating between very closely related organisms within a sample–an unavoidable consequence of the slow rate of mutation of rDNA genes. Most mutations in the regions between rDNA genes, however, including large insertions and deletions, have no effect on the fitness of the cell. Such approaches have a number of acronyms, but the term RISA is preferred.

Ribosomal Intergenic Spacer Analysis (RISA)

Ribosomal intergenic spacer analysis (RISA) is another PCR-based community profiling method, and exploits conserved sequences within the 16S and 23S rRNA genes as priming sites to elucidate the sequence of the region separating them. This region is so variable that even a single organism with multiple rRNA operons may show considerable sequence differences in the spacer regions separating its 16S and 23S molecules (12,13,87). Several suitable sites exist in the 16S rDNA for the design of PCR primers facing the 23S rRNA gene; the 23S rRNA gene encodes a single conserved site at its 5′ end suitable for a PCR primer oriented toward the 16S rDNA. Thus, for a given isolate, several fragments can be amplified by RISA, containing varying amounts of the 3′ end of the 16S rDNA, the entire intergenic spacer, and a short fragment of the 5′ end of the 23S rDNA. The intergenic spacer may vary considerably in length between even closely related species. When analyzing a complex mixture of species therefore, as in an environmental sample, a simple size fractionation of the PCR amplification product by polyacrylamide gel electrophoresis is sufficient to generate a fingerprint of the dominant species within the target group. When considering unknown bacterial communities, the sequence of the highly variable intergenic spacer is

not likely to be useful in determining the phylogenetic placement of the source organism. However, the 16S rDNA portion of the product can be used for this purpose, and the intergenic spacer then provides a fine-scale marker for the dominant organisms found in the sample. This subject has been reviewed recently (11).

Rather than relying solely on size separation, this approach can be combined with other fingerprinting techniques such as DGGE, although fragment size restraints may be a limiting factor (88).

Quantitative Interpretation in PCR-Based Community Fingerprinting

Making quantitative statements relating a gel band to cells per gram of environmental matrix is complex, contentious, and has not been frequently attempted. Even the assumption that the source organism of a strong band was more abundant in the environmental sample than one generating a weaker band is open to considerable criticism, and must be experimentally justified (20,66,89). Reasons for this include uncertainties over lysis efficiency, DNA–RNA recovery and the relative efficiency of the PCR–RT-PCR in recovery of different sequences (14,90). Such difficulties are by no means restricted to the environmental microbiology laboratory, and have spawned lively debates in many branches of the life sciences (91). The reader is directed to the following articles as an introduction to this subject (14,39–42,92). An obvious concern is the level of match between primers and the target sites in the 16S rDNA of a largely unknown and complex template. Figure 3 demonstrates that while a given primer pair may amplify a single target in isolation efficiently, amplification of that target may be completely abolished in competition with sequences that have a better match to the primers used. Compared to questions of lysis efficiency of unknown organisms during nucleic acid extraction from environmental samples, investigation of the dynamics of the PCR step is a relatively simple area of study. Recently attempts have been made to introduce a quantitative aspect to this using defined mixtures of templates (40), "Real-Time" PCR (93), and the inclusion of a specially designed internal standard (38). All studies agree that the use of more PCR cycles than are necessary to generate a useful product damages the fidelity of the ratio of templates within the reaction. Few laboratories currently have the facilities to optimize the number of cycles used in the PCR routinely. This is not a trivial operation when handling large numbers of environmental samples from diverse sample types, as the amount of template DNA used in the reaction is hard to standardize, and the extent of inhibition of the polymerase by sample-derived contaminants is not uniform between samples. This problem can be overcome by using real-time PCR equipment, which can monitor the point at which log-linear amplification ceases; however, such equipment is not yet standard even in the best-funded laboratories. The use of internal standards may have a more widespread applicability, as no additional equipment is required over that necessary for standard PCR-based ribotyping. However, the extent of PCR optimization and characterization of amplification efficiencies required is difficult and time consuming, and therefore eliminates many of the advantages that these methods hold over non-PCR-based ribotyping attempts. These problems are compounded by the variety of subtle differences in procedure between laboratories, that include differing nucleic acid extraction protocols, thermocyclers, enzymes, enzyme enhancers, and gel visualization equipment. In the absence of standard procedures, quantitative interpretation of ribotype banding patterns is not likely to become a common procedure, and investigators must word their findings carefully to reflect these concerns.

CONCLUSION

From the foregoing, it should be clear that no one ribotyping method can be guaranteed to provide a complete overview of a bacterial community. These methods have evolved rapidly over the last decade, and refinement continues to be rapid. The power of gel-based methods has not been fully realized as yet because of the need to develop mathematical frameworks to compile profiles such that they can be used in descriptive modeling of field-scale microbial communities (94,95). It is likely that in the near future, PCR-based methods may be entirely superseded by hybridization-array technologies, which avoid the uncertainties and biases of the amplification step. However, it is clear that the understanding of microbial diversity, even at the rRNA gene sequence level, is still far from complete. As the design of hybridization arrays depends entirely on the available sequence information, the continued use of PCR-based methods to generate sequence data and complete our view of microbial diversity is a prerequisite to the development of comprehensive arrays. Ribotyping information also provides an invaluable insight into the function of unculturable organisms, providing direct links to their functional genomics (96). A major technological constraint to the generation of sequence data from the gel-based ribotyping methods is recovery of bands, which usually requires manual excision. Related sections in this volume describe the application of capillary electrophoresis as an improvement to the use of polyacrylamide gels (see Capillary Electrophoresis in Genetic Analysis and Ribotyping of Microbiota in the Environment, this Encyclopedia), and development of microchip hybridization arrays for automated analysis (see Microarrays: Applications in Environmental Microbiology, this Encyclopedia).

RISK ASSESSMENT OF ENVIRONMENTAL EXPOSURE TO VIRUSES

Kristina D. Mena
University of Texas–Houston
El Paso, Texas

Risk is the possibility or likelihood of an adverse effect occurring due to consequences set forth from a particular hazard or hazards. A hazard may be a chemical, a landfill, a person's behavior, or a microorganism such as a virus. Such hazards may affect the survival of an ecosystem or the quality of human life. Potential hazards may be defined and evaluated using a risk assessment methodology to determine associated risks. A risk assessment paradigm has been developed considering chemical hazards (1,2), but this approach has been modified and implemented to address the human health risks associated with exposure to microorganisms such as bacteria, protozoa, and viruses found in the environment (3–7). Viruses, in particular, are of interest because of their role as waterborne agents of disease and to the wide range of human health outcomes associated with viral infections. Information from virus risk assessments can be used to help policy makers make informed decisions concerning the risks that such hazards pose.

THE RISK-ASSESSMENT APPROACH

The Development of the Risk-Assessment Paradigm

Risk assessment is a component of the risk analysis process that involves risk assessment, risk management, and risk communication (8). Risk management is a decision-making process that applies the information learned from a risk assessment and incorporates judgment in interpreting and evaluating the results. Risk managers then attempt to convey this information to the public (risk communication) in a way that all interested persons understand.

The science of risk assessment involves evaluating the risks posed to a society or the environment for a better understanding of the scope of the problems that may result from exposure to such hazards. The National Research Council (NRC) has attempted to improve the policy-making process of the U.S. government by developing the methodology necessary to evaluate risks posed by various hazards. The risk assessment paradigm was initially developed in the early 1970s to form a partnership between science and government that would help educate the government on current scientific issues. This was in response to the need for improved hazard identification to meet the mandates of the Safe Drinking Water Act and Clean Air Act Amendments. This framework was developed considering chemical hazards and has been used to assess chemicals in the environment for more than 25 years (1).

MICROBIAL RISK ASSESSMENT: ITS DESIGN AND APPLICATION FOR VIRUSES

The risk-assessment paradigm initially developed by the NRC to address human exposure to chemical hazards has been used to evaluate the human health impact of exposure to microorganisms in food and various water supplies (4–7,9–17). Human health outcomes from exposure to microorganisms can be evaluated quantitatively through a formal risk-assessment approach using dose-response information for specific microorganisms.

There are four fundamental steps in the risk-assessment framework: (*1*) hazard identification, (*2*) dose-response assessment, (*3*) exposure assessment, and (*4*) risk characterization (1). Each of the first three steps is an integral component of the fourth step, risk characterization. The original (chemical) NRC risk-assessment paradigm provides the foundation for the risk-assessment methodology for microorganisms; however, there are various factors pertaining to microorganisms that need to be considered when conducting a risk assessment. The following sections discuss each of the four steps of the risk-assessment process, the issues that should be addressed while considering risks associated with microorganisms (e.g., viruses), and associated human health information obtained from such assessments of viruses.

Hazard Identification

A substance is determined as harmful or otherwise on the basis of laboratory and field data as well as information obtained from epidemiological studies. In the original (chemical) risk-assessment approach, hazard identification defines a hazard by presenting evidence of a causative relationship between the agent and the adverse effect. However, in microbial risk assessment, a broader scope of information is used. A complete description of the resulting human illnesses are identified (both chronic and acute), including severity ranges and the immune status of the populations affected. Morbidity, mortality, hospitalization ratios, and any information on endemic and epidemic diseases are also included here. It is important to present this information when conducting risk characterizations to provide a more complete description of the hazard. Completing the hazard identification step of the paradigm can be challenging if there is no available epidemiological surveillance information. This is often the case for viruses in terms of fully understanding associated endemic and epidemic disease. Waterborne outbreaks are not reportable in the United States, so the available information of such events probably represents only a small fraction of what actually occurs.

Human Health Outcomes Associated With Viral Infections. Human exposure to enteric and respiratory viruses can cause a wide range of health outcomes. "Infection" is the colonization of growth of a microorganism in the body. Infection does not ensure that clinical illness will result from that infection; often infections with enteric viruses are associated with asymptomatic infections, particularly infections with some of the enteroviruses. Whether clinical illness (morbidity) will manifest from a viral infection will depend on the type, strain, and infectivity of the virus, its route of transmission, and the immune status and age of the host (9,10,18). Morbidity ratios (which represent the number of individuals who become ill from all those infected) for enteric viruses of 10% (for poliovirus) and of as high as 97% (observed with hepatitis A virus) have been documented (Table 1) (19–21). In children less than five years of age, hepatitis A virus infections are usually asymptomatic but the morbidity ratio among adults is 75%. Conversely, children infected with rotavirus are more likely to show signs of symptomatic illness (gastroenteritis) than adults (22). The amount of exposure (level of dose) has not demonstrated a role in illness development when

Table 1. Occurrence of Clinical Illness for Viral Infections (19–26)

Virus	Morbidity Ratio (%)
Astrovirus	12.5
Coxsackievirus type A16	50
Coxsackievirus type B	5–96
Echovirus	50
Hepatitis A (adults)	75
Hepatitis A (children)	5
Poliovirus type 1	0.1–1*
Rotavirus (adults)	40–56
Rotavirus (children)	72

*paralysis

considering a highly infective virus such as rotavirus (23). Therefore, it is assumed that developing a clinical illness from an infection is a "conditional probability" that is independent of exposure level (6).

Depending on the particular virus and the serotype, a wide range of health outcomes can result from a viral infection. There are two types of coxsackievirus (types A and B) and 29 serotypes, and this virus in particular is associated with a greater number of serious illnesses when compared with any waterborne virus, including aseptic meningitis, respiratory illness, myocarditis, pericarditis, pleurodynia, encephalitis, insulin-dependent diabetes mellitus, and gastroenteritis (27–33). While considering the other enteroviruses, echovirus infections also cause gastroenteritis, respiratory infection, myocarditis, pericarditis, and aseptic meningitis, but outcomes are not as severe as those associated with the coxsackieviruses (18,32). Poliovirus infections can result in paralysis but has not been a serious public health concern since the introduction of the poliovirus vaccine in the 1950s.

Rotavirus is the most common cause of viral gastroenteritis worldwide and is considered the most infectious waterborne agent known (4). Adenovirus is considered only second to rotavirus in terms of its significance as a pathogen of childhood gastroenteritis (34,35). There are 49 types of adenoviruses and human health outcomes resulting from infections include acute respiratory disease (ARD), conjunctivitis, urethritis, cervicitis, and hemorrhagic cystitis. Norwalk and Norwalk-like viruses are the primary agents responsible for adult gastroenteritis (36,37) and astrovirus-related diarrhea has been observed throughout the world in children and the elderly (38–43). Infections with hepatitis A virus cause liver damage and jaundice. Hepatitis E virus (formally known as enterically transmitted non-A, non-B hepatitis) is responsible for more than 50% of the acute cases of hepatitis occurring in developing countries (44). Typical clinical signs of infection include abdominal pain, nausea and/or vomiting, fever, and jaundice with the highest percentage of symptomatic cases occurring in young-to-middle-aged adults (20–40 years of age) (45).

Viruses causing respiratory-related illnesses include the influenza and parainfluenza viruses, rhinovirus, coronavirus, adenovirus, and respiratory syncytial virus (RSV), RSV being a leading cause of lower respiratory tract illness in children (18). RSV may also be responsible for as many as 40% of cases of childhood pneumonia and as much as 90% of bronchiolitis cases (46). RSV infections may result in bronchitis, otitis media, and upper respiratory disease. The parainfluenza viruses contribute significantly to illnesses of the lower respiratory tract in children (47). The different types of parainfluenza viruses can cause a variety of health outcomes in children including croup, pneumonia, and bronchiolitis. The influenza viruses account for worldwide epidemics of febrile respiratory disease that result in persons seeking medical attention and hospitalization. Health outcomes of infection can range from asymptomatic infections to flulike symptoms (fever, chills, myalgia, and sore throat) to death. Influenza illnesses can lead to secondary bacterial infections that result in myocarditis, pericarditis, pneumonia, meningitis, encephalitis, and Guillain-Barré syndrome. There are more than 100 serotypes of rhinovirus with most infections causing symptomatic respiratory illness (18). Common symptoms include cough, sneezing, sore throat, and nasal congestion. Children are more prone to infections, particularly children under one year (48). It has been suggested that as many as 35% of common colds are caused by coronaviruses (49,50). Many of the 49 adenovirus serotypes cause respiratory-related illnesses including acute respiratory disease (ARD), acute febrile pharyngitis, and pneumonia (51). Adenoviruses are attributable to 2 to 7% of all lower respiratory tract illnesses (52) and as many as 10% of the cases of childhood pneumonia (53).

Some viral illnesses may require hospitalization and thus the severity of specific viral infections is measured as a "hospitalization ratio." Hepatitis A virus, for example, can cause severe damage to the liver and is associated with the highest hospitalization ratios when compared with other waterborne viruses (18). Diarrhea caused by rotavirus has been shown to be the most common cause of hospitalization for childhood diarrhea in the United States (54) with an estimated hospitalization ratio of 0.5% per year for rotavirus-related illness in children below than five (55). Hospitalizations for coxsackievirus aseptic meningitis have occurred during common source outbreaks involving as many as one of every three with the illness (56). A hospitalization ratio of 2.2% has been documented during a food-borne outbreak of Norwalk virus affecting students on a college campus (almost half of persons ill sought some medical attention) (57). Hospitalizations are also observed during epidemics of influenza in the United States in which 16.9 per 10,000 cases were hospitalized during the 1980 to 1981 outbreak (58).

Death can result from viral illnesses and mortality (case/fatality) ratios from 0.0001% to as high as 0.94% have been observed for the waterborne viruses (Table 2). It is estimated that 300 deaths caused by diarrheal illnesses occur each year in the United States among children less than five years of age and approximately 20 to 40 of these deaths can be attributed to rotavirus diarrhea (62–65). Mortality ratios greater than 50% have been observed in transplant patients with rotavirus illnesses (66). It is important to realize that information on mortality for many of the viruses such as the enteroviruses actually refers to hospitalized cases because of the lack of a

Table 2. Mortality Ratios for Viruses (9,26,59–61)

Virus	Mortality Ratio (%)
Adenovirus	0.01
Coxsackievirus type A	0.12–0.5
Coxsackievirus type B	0.59–0.94
Echovirus type 6	0.29
Echovirus type 9	0.27
Hepatitis A	0.60
Norwalk	0.0001
Poliovirus type 1	0.90
Rotavirus	0.01

reporting system in the United States for these viruses (except for poliovirus); thus *mortality ratios* reflect those who died from an illness severe enough to require hospitalization. Death due to hepatitis A virus is twice as high among the hospitalized cases than among the nonhospitalized cases (26).

Age and immune status of the host as well as the virus characteristics that determine whether illness will manifest from an infection also influence the probability of mortality from that illness. Persons above 40 years of age, for example, have a greater chance of dying from a hepatitis A infection than younger cases (67). The elderly (persons above 65) have a greater risk of dying from enteric and respiratory virus infections (36,61) and as many as 90% of deaths caused by influenza occur in this population (58). Mortality is also higher among other immunocompromised populations, such as AIDS patients, transplant recipients, and pregnant women. Mortality because of adenovirus infections has been observed to be as high as 60% among transplant patients (68,69). Hepatitis E virus infections are associated with an unusual high case-fatality ratio among pregnant women (17 to 33%) (70,71) with death resulting from hemorrhage.

Transmission. Viruses may be transmitted from host to host through person-to-person (direct) contact or through transmission routes that involve more than one medium (e.g., water, food, and fomites) (18). The main routes of entry into the host include ingestion or inhalation, with some viruses (e.g., the enteroviruses) being able to enter the host via both the respiratory tract and through a fecal-oral transmission route (gastrointestinal tract). Ingestion of microorganisms (e.g., viruses) may be achieved through contaminated drinking water, recreational water, food, soil, and fomites. Fomites, in particular, may contribute to the complex transmission routes of some viruses. Depending on the type of virus and its medium, the type of inanimate surface, and the temperature and humidity, enteric viruses are capable of surviving on inanimate objects for a few hours to as long as many days (72). It is important to understand the transmission route of a particular virus while conducting a human health risk assessment because the infectivity of a microorganism may differ from one route to another. Specifically, the number of microorganisms required to infect the respiratory tract is usually less than that required for infection when transmittance is by ingestion.

Secondary transmission, subsequent person-to-person transmission, magnifies the impact of exposure to microorganisms (73–75) and is not a consideration while assessing risks associated with chemical exposures. Secondary attack rates for enteric viruses have been reported to range from 30% for Norwalk virus to greater than 90% for poliovirus (10). Person-to-person transmission is not commonly observed in the case of some viruses that are transmitted fecal-orally such as hepatitis E virus.

Disease Outbreaks. Both waterborne and food-borne outbreaks of viruses have been documented in the United States and throughout the world. In most outbreak situations, the etiological agent of disease is not identified. It has been estimated that as many as 10,000 cases of microbial waterborne disease occur each year in the United States with three to five outbreaks associated with community drinking water systems documented annually (18). Outbreaks involving water systems that meet microbial quality standards have occurred (76–79). From 1946 to 1980, the responsible agent was not identified in more than 50% of the documented waterborne outbreaks in the United States (76); enteric viruses were identified as the cause of 12% of these outbreaks. Although waterborne disease outbreaks have been documented for some of the enteric viruses, the occurrence of these outbreaks are underestimated due to the underreporting of outbreaks involving water. When an outbreak investigation is conducted, however, it may be particularly difficult to identify the causative agent because of the lapse of time that may have occurred between exposure of a population to contaminated water and the onset of the water analyses. In many cases when the causative agent of an outbreak is not identified, enteric viruses are suspected to be the cause of the outbreak because of the nature of the resulting disease and the attack rates observed (36).

Waterborne outbreaks have been associated with Norwalk and Norwalk-like viruses (36,37,80), rotavirus (81–84), adenovirus (85–88), coxsackievirus (89–90), hepatitis A and E viruses (90–93), echovirus (94), and astrovirus (95). Norwalk viruses are the primary agents responsible for adult gastroenteritis and it has been estimated that 33 to 65% of the nonbacterial gastroenteritis outbreaks in the United States are due to Norwalk viruses (36,37,96). Norwalk has also been implicated in outbreaks involving contaminated commercial ice (97). Outbreaks of waterborne rotavirus have been associated with either direct fecal contamination of a water supply or improper treatment. Hepatitis A and E viruses have been responsible for numerous waterborne outbreaks worldwide with hepatitis E outbreaks occurring in countries with poor sanitation (98). Disease outbreaks involving recreational water caused by adenovirus, coxsackievirus, and echovirus result in cases of gastroenteritis, conjunctivitis, and/or pharyngoconjunctival fever.

As with waterborne outbreaks, the etiological agent in nearly half of the documented food-borne outbreaks in the United States is never identified (7) (see VIRUSES AND PROTOZOAN PARASITES IN FOOD, INCLUDING METHODOLOGY, this Encyclopedia). Although the majority of the food-borne outbreaks are caused by bacterial pathogens, viruses have also been associated with food-borne outbreaks, particularly Norwalk and Norwalk-like viruses, hepatitis A virus, and astrovirus (95,99–105). Consumption of contaminated shellfish and the unhygienic practices of food handlers have contributed to their occurrence. Norwalk-like viruses are considered the most common food-borne pathogens (106) and Norwalk/Norwalk-like viruses are identified in 90% of the food-borne outbreaks of viral origin (107). These viruses have been implicated in outbreaks involving lettuce and bakery goods that possibly resulted from the contamination of food by food handlers (108–110). In one documented outbreak of Norwalk virus involving salad, the lettuce had been contaminated by raw shellfish that had been prepared in

the same sink (108). In England, gastroenteritis is commonly associated with the caliciviruses (which include Norwalk) that result from consumption of contaminated shellfish (100). Norwalk virus has also been implicated in outbreaks involving airborne transmission (111,112). Food-borne outbreaks of hepatitis A virus and astrovirus involving shellfish consumption have also been documented (95,99,103). Hepatitis A has frequently been associated with contaminated salad items in the United States (113) and has recently been implicated in outbreaks in Finland (114); it is only rarely connected with food-borne outbreaks in the United Kingdom (115).

The risk assessment process may stop with "hazard identification" if no adverse effect is found or if it is decided, based on current information, that a regulatory action take place. It is pertinent that the assessor should be able to recognize fallacies or biases in the available information on a particular hazard and be selective about what information is used. The ability to accurately interpret the information presented in the scientific literature is critical.

Dose-Response Assessment

The dose-response assessment involves describing the relationship between the dose of the virus and the incidence, or the extent of the adverse human health effect. The goal of this step is to determine the probability or likelihood of a human health consequence occurring from exposure to different levels of microorganisms. The human health consequence may be infection, illness, or death. As mentioned earlier, infection is the colonization or growth of the microorganism in the host, which may or may not lead to clinical illness. The probability of illness depends on several factors related to the particular virus and the host. The type and strain of the virus can influence whether clinical illness will develop but there does not seem to be a correlation with the level of dose a host receives through ingestion, as shown with a highly infectious virus such as rotavirus (23). Host factors influencing disease outcome include age, nonspecific host factors (such as preexisting state of nutrition), and preexisting immunity (10).

Dose-response studies using human volunteers have been conducted for several viruses including rotavirus (23), coxsackievirus (116,117), hepatitis A virus (118), poliovirus (119–122), echovirus (123), and adenovirus (124). This is unlike the dose-response assessment of chemical risk, which involves the extrapolation of animal data to humans. This has not been a primary issue in microbial risk assessments because dose-response models have been developed based on studies involving humans. In human dose-response studies, volunteers are exposed (via ingestion or inhalation) to variant doses of a microorganism and the fraction of volunteers that become infected are observed and recorded. It is necessary to use high concentrations of pathogenic microorganisms in order to observe high frequencies of infections with a minimum number of volunteers. Although the application of lower doses of microorganisms would reflect a more realistic picture of exposures to a population, studies involving greater numbers of volunteers (i.e., increasing the costs) would be required to demonstrate a dose-response relationship. Mathematical models must therefore be used to extrapolate the available data from human-feeding studies to demonstrate the effects of exposure to low doses of microorganisms.

Mathematical models have been evaluated for their plausibility in representing or simulating the microorganism–host interaction; in particular, a quantitative evaluation of risks of waterborne microorganisms has been conducted (3). A model is considered biologically plausible in describing the microorganism–host interaction if it considers two factors (18). A model must first consider that a human exposure contains a random distribution of microorganisms; therefore, an exposed population would experience a distribution of doses. The second factor to be considered is the ability of microorganisms in an exposure to initiate infection at a particular site within the host. This is dependent on the host ingesting at least one pathogenic microorganism and that a proportion of the consumed microorganisms will overcome the host's defenses and initiate infection (3). Infection (as opposed to illness or death) is the human health end point of interest in the dose-response assessment, which leads to a more conservative assessment of human health risks. Risks associated with illness and death can be assessed by incorporating morbidity and mortality ratios in the models.

The formulation of mathematical models that may represent a microorganism–host interaction has been described elsewhere (18). Humans may be exposed to pathogenic viruses through the consumption of water or food or through inhalation of aerosols. A proportion of individuals exposed to the microorganism, P_i, will become infected. Two mathematical models in particular have been shown to adequately describe the infection process demonstrated in dose-response studies of pathogenic microorganisms, including viruses. The exponential model

$$P_i = 1 - \exp(-rd) \tag{1}$$

(where P_i = the probability of infection, r = the number of microorganisms that survive and are capable of initiating an infection, and d = the number of microorganisms ingested or inhaled) assumes a random distribution of microorganisms in the exposure and a constant microorganism–host interaction. The parameter r is further defined as:

$$-r = \ln(0.5)/N_{50} \tag{2}$$

with N_{50} = the median infectious dose. The exponential model can therefore be rewritten as

$$P_i = 1 - \exp[\ln(0.5)(d/N_{50})] \tag{3}$$

to represent a dose-response relationship. If the microorganism–host interaction is a heterogeneous interaction where parameter r is not a constant but is defined by a beta-probability distribution (3,125,126), the infection process can be represented by the beta-Poisson model (a modified exponential model):

$$P_i = 1 - (1 + d/\beta)^{-\alpha}, \tag{4}$$

Table 3. Dose-Response Parameters for Specific Viruses*

Virus	Model	Parameters	Reference
Adenovirus	Exponential	$r = 0.4172$	124
Coxsackievirus type B4	Exponential	$r = 0.007752$	116
Echovirus type 12	beta-Poisson	$\alpha = 0.374$	123
		$\beta = 186.69$	
Echovirus type 12	Exponential	$r = 0.012771$	128
Hepatitis A virus	Exponential	$r = 0.548576$	118
Poliovirus type 1	beta-Poisson	$\alpha = 0.1097$	120
		$\beta = 1524$	
Poliovirus type 1	Exponential	$r = 0.009102$	122
Poliovirus type 3	beta-Poisson	$\alpha = 0.409$	121
		$\beta = 0.788$	
Rotavirus	beta-Poisson	$\alpha = 0.26$	23
		$\beta = 0.42$	

*α, β, and r are parameters of the dose-response interaction.

where P_i = the probability of infection, d = the number of microorganisms ingested or inhaled, and α and β represent parameters of the microorganism–host interaction. β can be further defined as:

$$\beta = N_{50}/(2^{1/\alpha} - 1), \tag{5}$$

which results in the following equation for the beta-Poisson model:

$$P_i = 1 - [1 + (d/N_{50})(2^{1/\alpha} - 1)]^{-\alpha}. \tag{6}$$

The exponential and beta-Poisson models are evaluated using the method of maximum likelihood (6) to determine which best fits the data obtained from dose-response studies. Parameters of the best-fitting model are then determined for each microorganism as well as upper and lower confidence limits. Such parameters and confidence limits for specific viruses have been reviewed elsewhere (127). Table 3 lists the best-fitting model and model parameters for specific viruses.

The beta-Poisson model is shallower than the exponential model but approaches the exponential model as α increases (and as the number of microorganisms required to initiate an infection increases), which represents a decrease in the variability of the microorganism-host interaction (Fig. 1). The beta-Poisson model represents a more gradual host response to exposure and this model best fits the dose-response data sets for many of the viruses (Table 3). Both the exponential and beta-Poisson models assume that only one pathogenic microorganism can cause infection in a host; threshold models have not been shown to reflect the dose-response relationship observed in experimental studies (18). Annual and lifetime risks of infection can be determined using the following equations:

$$P_{\text{year}} = 1 - (1 - P_i)^{365} \tag{7}$$

$$P_{\text{lifetime}} = 1 - (1 - P_i)^{25550} \tag{8}$$

Risk estimates of illness and death can also be computed from these models by incorporating morbidity and mortality ratios of that particular microorganism (6). The probability of developing clinical illness from an infection ($P_{D:I}$) is a conditional probability that an individual displays disease, given that they were infected. The development of symptoms depends on the type and strain of virus and host age. Morbidity ratios for viruses are listed in Table 1 again depending on the virus and host age. A morbidity ratio of 50% (the midpoint value) has often been incorporated in risk modeling for the enteric viruses (6). The risk of illness is determined by multiplying the risk of infection (P_i) by the morbidity ratio.

As discussed previously, mortality can result from illnesses caused by viruses with the conditional probability of such an occurrence ($P_{M:D}$) depending on the same factors connected with the development of clinical illness. Immunocompromised populations (which include the elderly, the very young, transplant recipients, and HIV-infected individuals) have a greater chance of dying from illnesses associated with enteric and respiratory viruses. Mortality ratios ranging from 0.0001% to 0.94% have been observed (Table 2). Host age, in particular, accounts for the observed range of mortality ratios for some of the viruses. For example, the probability of dying from a hepatitis A

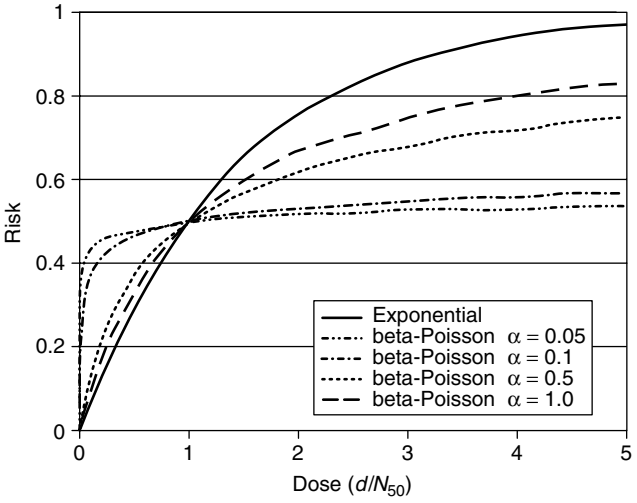

Figure 1. Exponential and beta-Poisson models on an arithmetic scale.

infection increases for individuals above 40 years of age (from 0.3% to 1.0%) (67). For viruses associated with nonreportable diseases in the United States such as some of the enteroviruses, the mortality ratios are based on hospitalized cases. The risk of death is calculated by multiplying the risk of illness ($P_{D:I}$) by the mortality ratio.

Multiple Exposures and Immunity. The effect of multiple exposures is not completely understood. Both infection and disease have been used as an end point in human-feeding and human-inhalation studies; however, the effects of multiple exposures have not. In microbial risk assessment, it is assumed that each exposure is statistically independent of another, however, the development of temporary or permanent immunity may alter this assumption. The immune status of the host also influences the human health outcome associated with most microbial exposures as has been observed among immunocompromised populations. The dose-response models described earlier reflect data formulated for a single exposure of microorganisms, however, there is the obvious circumstance of multiple exposures. Data obtained from human dose-response studies represent a single dose but do not address the issue of multiple exposures, which is a potential occurrence when dealing with microorganisms transmitted through the environment.

Haas and coworkers (1999) addressed the possible effects of multiple exposures using two approaches (18). The first approach assumes that the risk posed by an exposure is statistically independent of a risk associated with another exposure. This traditionally has been an assumption made in microbial risk assessments to date because of the lack of data that address such issues (6). This means that the risk of a health outcome (infection, illness, or death) from an exposure is not related to a prior exposure. A second approach is to sum individual doses (to represent the multiple exposures) and incorporate that dose into the appropriate dose-response equation to determine the overall risk. For both these approaches, additional information is needed to address the issue of immunity or the development of hypersensitivity resulting from an initial exposure. Dose interactions (of similar and dissimilar microorganisms) as well as the dose-host relationship need to be assessed.

Exposure Assessment

Exposure assessment determines the intensity and frequency of human exposure to the hazard. The concentration of viruses in the dose (e.g., food, water, and aerosol), the volume of the dose, and the number of times a person is exposed to that dose are assessed. Routes of exposure and issues characterizing the exposed population are also addressed. Other factors that should be included (which are not applicable to chemical hazards) are the survivability of the virus in the environment and its susceptibility to inactivation by treatment or disinfection.

One objective of the exposure assessment is to determine the average concentration of viruses in or distribution of viruses throughout an exposure. Data are often lacking on the occurrence of viruses in the environment although epidemiological investigations of waterborne and food-borne outbreaks caused by viruses can provide some occurrence information. Detection methods for viruses are not 100% efficient (129) and therefore the concentration data available may be an underestimation of the true concentration levels. The implementation of sensitive laboratory techniques that can detect the low levels of viruses capable of initiating infection can be a useful tool in developing a virus database during surveillance studies. The characterization of concentration distributions of microorganisms in water and food samples has been previously described (18).

Many of the enteric viruses have been isolated from water supplies, including groundwater, surface water, and drinking water. Often, however, specific viruses are not identified; most studies have evaluated water supplies for the presence of enteroviruses as a group. Surface waters exposed to sewage can become contaminated with viruses but the types and concentration levels of viruses present in the contaminated water depend on the source of contamination (raw sewage, treated effluent, or natural reservoir), the time of year of sampling, the amount of rainfall, and the incidence of enteric viral disease among the source population (130). The unhygienic practices of food handlers and sewage contamination of shellfish-harvesting areas greatly contribute to the likelihood of an exposure to contaminated food (115).

The outcome of an exposure assessment depends on the capability of the virus to withstand environmental stressors and its susceptibility to inactivation by treatment. Specific viruses exhibit unique capabilities to survive in the environment and resist inactivation by water treatment or disinfection. Rotavirus is capable of surviving on inanimate surfaces for more than one hour (131). Coxsackieviruses are very stable in the environment (132,133) and are more resistant to chlorine and ultraviolet light disinfection than most of the other enteroviruses (134,135). Adenoviruses are the most resistant of the enteric viruses to ultraviolet light disinfection and the enteric adenoviruses appear to be the longest surviving enteric viruses in water (136). Hepatitis A virus is reported to be a thermally stable enteric virus and studies have shown hepatitis A to survive for extended periods in groundwater (137). Viruses spread via aerosols can also overcome environmental stressors. Respiratory syncytial virus can remain viable for up to six hours on household surfaces and on skin for as long as 20 minutes (138,139). Influenza A and B viruses can survive on inanimate surfaces for hours and are more readily transmitted through aerosols during conditions of low temperature and humidity (140–143).

Not only is the concentration of the virus an important component of the exposure assessment step but also understanding the amount of dose and the frequency of exposure is also essential. Both of these may be defined as point estimates or distributions. Information is available on consumption or contact distribution for media containing microorganisms and this database has been reviewed elsewhere (18). The specific transmission route of the microorganism is first identified (e.g., ingestion of fish, inhalation during showering, ingestion of drinking water, etc.) and then the dose and exposure frequency are

determined. The U.S. EPA uses an exposure of 2 L/person per day for risk estimates of drinking water that is based on a survey conducted in the United States on water ingestion of defined age groups (144). An exposure of 113 g/meal may be used to assess risks associated with ingestion of fish, for example, or an exposure of 130 ml/swim may represent the amount of surface water ingested during swimming (145).

Characterizing the exposed population is also important. Roseberry and Burmaster (1992) observed an increase in tap water intake by persons above 65 years of age; an exposure of 4 L/person per day (as opposed to 2 L/person per day) is used in risk assessments for this subpopulation, which was given as the water intake for the 97.5th percentile of the elderly (144). Pregnant women have also demonstrated higher tap water consumption than the general population (146). Shellfish consumption, for example, is higher among some populations than others (147). Inhalation rates of potential virus-contaminated aerosols range from 15 m^3/day for children to 20 m^3/day for adults (145).

Risk Characterization

The objective of the risk characterization step (which can be qualitative or quantitative) is to estimate the risk of an adverse health effect occurring on the basis of exposures determined in the exposure assessment. Using a mathematical model that reflects the dose-response relationship of the microorganism–host interaction and best estimates of exposure, a quantitative measure of the human health risks can be achieved. Point estimates of risks or risk distributions can be determined. It is important to state any assumptions and uncertainties made during the first three steps.

Ideally, human health risks should be characterized for specific viruses (e.g., coxsackievirus) rather than groups of viruses (e.g., the enteroviruses). As is described throughout this chapter, the human health consequences of exposure to different viruses vary greatly. This necessitates the desire for more information on the occurrence of specific viruses in the environment. Risk assessments for coxsackievirus type B4 (148) and rotavirus (15), for example, have been conducted. By applying the appropriate dose-response model and assuming a 2 L/person per day exposure of drinking water, risks of infection, illness, and death for various concentrations of coxsackievirus and rotavirus can be estimated (Table 4). The estimated daily risk of infection from exposure to one coxsackievirus and one rotavirus in 1,000 liters of drinking water is approximately $1 : 100,000$ and $1 : 1,000$, respectively. Annual risks of infection for the same concentrations would increase to $5.6 : 1,000$ for coxsackievirus and $3.6 : 10$ for rotavirus. These annual risk estimates for both viruses do not meet the U.S. EPA's recommendation that microbial risks of infection should not exceed $1 : 10,000 (10^{-4})$ per year (149). These exposures result in lifetime risks of infection of $3.3 : 10$ for coxsackievirus and $9.9 : 10$ for rotavirus. At the same concentrations, risks of clinical illness for both coxsackievirus and rotavirus are comparable to those for infection. Lifetime risks of death range from approximately $5 : 100,000$ to $4 : 1,000$ for both viruses at all concentrations in Table 4.

A goal in any risk assessment is to avoid overestimating or underestimating the risks imposed by a hazard. The assumption of exposure levels (e.g., 2 L/person per day) may provide a degree of conservatism for some populations and employing consumption distributions (as opposed to point estimates) in the exposure assessment may address exposure variability. The U.S. EPA's focus on infection (as opposed to illness or death) in the recommendation that microbial risks of infection should not exceed $1 : 10,000 (10^{-4})$ per year (149) introduces a level of conservatism in the risk analysis of microorganisms

Table 4. Risks of Infection, Illness, and Death for Coxsackievirus Type B4 and Rotavirus*

Virus Concentration per 1,000 L	Coxsackievirus			Rotavirus		
	Daily	Annual Infection	Lifetime	Daily	Annual Infection	Lifetime
0.1	1.6×10^{-6}	5.7×10^{-4}	3.9×10^{-2}	1.2×10^{-4}	4.4×10^{-2}	9.6×10^{-1}
1	1.6×10^{-5}	5.6×10^{-3}	3.3×10^{-1}	1.2×10^{-3}	3.6×10^{-1}	9.9×10^{-1}
10	1.6×10^{-4}	5.5×10^{-2}	9.8×10^{-1}	1.2×10^{-2}	9.9×10^{-1}	9.9×10^{-1}
100	1.5×10^{-3}	4.3×10^{-1}	9.9×10^{-1}	9.6×10^{-2}	9.9×10^{-1}	9.9×10^{-1}
		Illness			Illness	
0.1	1.2×10^{-6}	4.2×10^{-4}	2.9×10^{-2}	6.9×10^{-5}	2.5×10^{-2}	5.4×10^{-1}
1	1.2×10^{-5}	4.2×10^{-3}	2.5×10^{-1}	6.9×10^{-4}	2.0×10^{-1}	5.5×10^{-1}
10	1.2×10^{-4}	4.1×10^{-2}	7.4×10^{-1}	6.7×10^{-3}	5.5×10^{-1}	5.5×10^{-1}
100	1.2×10^{-3}	3.2×10^{-1}	7.4×10^{-1}	5.4×10^{-2}	5.5×10^{-1}	5.5×10^{-1}
		Death			Death	
0.1	6.9×10^{-9}	2.5×10^{-6}	1.7×10^{-4}	6.9×10^{-9}	2.5×10^{-6}	5.4×10^{-5}
1	6.9×10^{-8}	2.5×10^{-5}	1.4×10^{-3}	6.9×10^{-8}	2.0×10^{-5}	5.5×10^{-5}
10	6.9×10^{-7}	2.4×10^{-4}	4.3×10^{-3}	6.7×10^{-7}	5.5×10^{-5}	5.5×10^{-5}
100	6.9×10^{-6}	1.9×10^{-3}	4.4×10^{-3}	5.4×10^{-6}	5.5×10^{-5}	5.5×10^{-5}

*Assuming 2 L/person per day exposure, morbidity ratios of 0.75 (coxsackievirus) and 0.56 (rotavirus), and mortality ratios of 0.0059 (coxsackievirus), and 0.0001 (rotavirus).

but provides protection for the immunocompromised populations who may be more likely to develop severe health consequences from the microbial exposure. Human health risks may also be an overestimation for those with preexisting immunity to that particular virus. The estimated risks, however, do not reflect the phenomenon of secondary and tertiary transmission, which greatly contribute to the likelihood of exposure to microorganisms.

A degree of uncertainty exists in all risk assessments. An analysis has been conducted to measure the uncertainty in the estimation of risks using the microbial risk assessment models. A Monte-Carlo analysis was performed to compare the uncertainty that is attributed to exposure variability to the uncertainty associated with virus infectivity and morbidity and mortality ratios (6). It was concluded that the greatest degree of uncertainty is due to the variability in exposure and not because of the dose-response parameters used in the assessment. Surveillance studies are needed to create a database of virus occurrence in the environment to improve estimate host exposures. Such data obtained from virus monitoring would greatly enhance the exposure assessment step of the risk assessment paradigm, but the accuracy of the concentration values used for host exposure is dependent on the accuracy and frequency of the sampling.

Risk estimates have been compared to epidemiological data obtained from waterborne and food-borne disease outbreaks and from an intervention study to determine the accuracy of the predicted estimates in an attempt to validate the developed microbial risk models (7,18,150). Attack rates and duration of exposures from outbreak data were used to estimate the probable dosage that occurred to produce the observed attack rate. These exposure estimates were then incorporated in the appropriate microbial risk assessment model and the risk of infection (P_i) was calculated. The calculated P_i was compared with the attack rates observed from the outbreak. Such comparisons have suggested that the models can successfully predict outcomes from exposure to microorganisms. (It should be noted that P_i refers to the human health end point of infection and attack rates reflect illness among a population.) Model predictions of daily and annual risks of clinical disease of rotavirus have been found to be comparable with such risks observed in an epidemiological study (18,151).

Risk characterization was initially designed to be a summary of the information compiled from the first three steps of the risk assessment framework with the idea that the process of this step would be conducted without the influence of risk management. An attempt has been made to integrate these two processes with the belief that this would help include public participation, which would therefore increase the chance of reaching decisions that would generally be acceptable (152).

MICROBIAL RISK ASSESSMENT APPLICATIONS

A primary objective in developing a risk assessment approach for estimating the human health risks associated with exposure to microorganisms is to provide a framework that can be used by regulatory agencies to evaluate microbial water quality and to determine an appropriate level of treatment that will achieve an acceptable level of risk. This approach can also be used in the food safety arena to address human health issues of exposure to food-borne pathogens. Microbial risk assessment can be applied to provide information that can be utilized in setting standards and formulating regulations. This tool is the link between what is known and the action to be taken (Fig. 2). Estimated risk levels associated with waterborne or food-borne viruses can be used to determine what specific action should be taken (e.g., what levels of water treatment should be administered to a water supply) to achieve an acceptable level of risk or to evaluate the efficacy of current treatment practices. As mentioned in the hazard identification section, rotavirus has been identified as the most infectious virus based on available dose-response data. Rotavirus has been used in the development of standards for surface water treatment in the United States (4).

Microbial risk assessment provides a comparison for risks associated with other environmental hazards. A concern for the long-term health effects from exposure to disinfectants (e.g., chlorine) and disinfection by-products in water has tempted some experts to suggest altering doses of chlorine and chlorine compounds during disinfection. A decrease in the amount of disinfection administered could greatly hinder the microbial quality of water. This relationship was demonstrated in the reduced number of microbial outbreaks and deaths when disinfection was first implemented in water treatment. A comparison of microbial and chemical risks may be necessary before other forms of treatment are considered. Without an estimation of the microbial risks involved, the options and consequences surrounding this issue could never be fully addressed.

Results of risk assessments of specific microorganisms can also identify potential indicator organisms that can be used to target microbially unsafe potable waters. Current standards utilize coliform bacteria as indicators of contamination, but studies have demonstrated that there is no correlation between the prevalence of bacteria and the prevalence of viruses and parasites (153–155). By reviewing the data on the occurrence of viruses in water supplies and their ability to resist environmental influences and conventional water treatment practices, these microorganisms may be introduced to this role.

Perhaps the most useful aspect of microbial risk assessment is its application for all types of water and food sources and populations. The dose-response models can be used for populations in developing countries and in the industrialized areas and calculated risk estimates can be used to assess microbial water and food quality for different sources in all parts of the world. Most of the exposure data that is obtainable for viruses are from studies conducted in developing countries. However, this information can be incorporated in a risk assessment in which the risk estimates could also be useful in an industrialized setting. By including the nature of the population under consideration during the risk characterization, the estimated human health risks can be appropriately interpreted. Another outcome

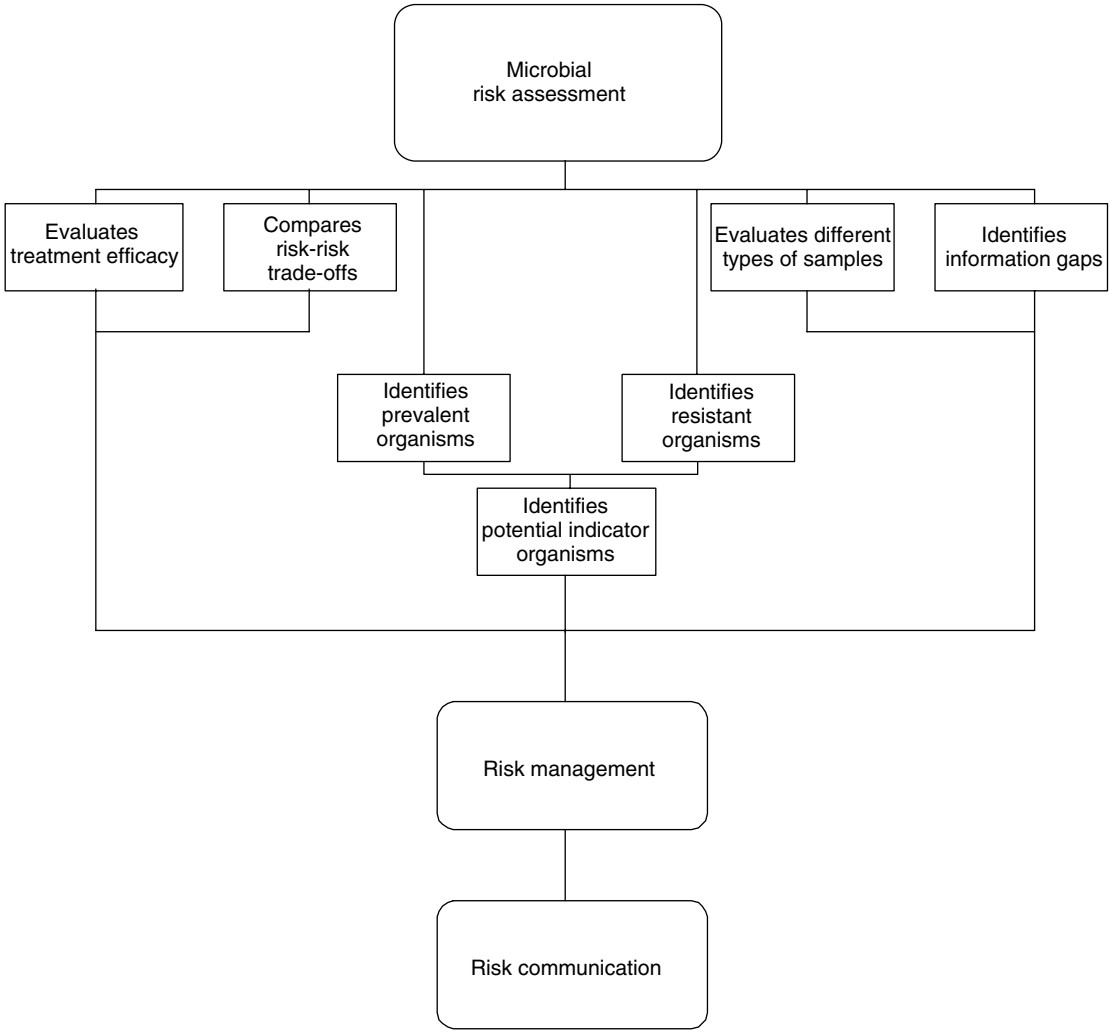

Figure 2. Microbial risk-assessment applications.

of a risk assessment is the identification of information gaps. Identifying what is not known about a microbial hazard may be just as important as the information that is obtained. These gaps highlight the areas in which more research and study are needed for a better understanding of the scope of the hazard.

Incorporating science with policy is a complex challenge. Because of the great variability of virus infectivity, pathogenicity, occurrence, and populations most affected, conducting risk assessments for specific viruses would provide invaluable information on the members of this diverse group of pathogens.

CONCLUSION

The microbial risk assessment framework can be used to identify and evaluate viruses as human pathogens; a task that traditionally relies on epidemiological data obtained during disease outbreaks. This approach helps to quantitatively define the human health significance of virus occurrence in the environment. The potential hazards associated with environmental exposure to different viruses indicate the need to evaluate specific viruses while considering human exposures. More data are needed on the occurrence and transmission of viruses in the environment to improve exposure assessment and thereby enhance risk characterization. Such assessments provide the necessary component for risk analysis of microorganisms. As an integration of science and policy, microbial risk assessment can offer risk managers a means of interpreting environmental quality data.

Baylor College of Medicine
Houston, Texas

Rotavirus is the principal etiologic agent of viral gastroenteritis in humans and animals. Rotavirus infects all children throughout the world and causes a life-threatening disease in children under five; however, the outcome of infection varies in different countries. In developing countries, rotavirus infections alone are responsible for approximately one million deaths annually, and death due to rotavirus infection is significant in Asia, Africa, and South America. In the United States, rotavirus infections account for 100 to 200 deaths annually, approximately 2% of infected children are hospitalized, and hospital costs exceed $1 billion each year (1,2). After replicating in the gastrointestinal tract, rotaviruses are excreted in large quantities and may be dispersed in water and soil (1–8). The stability of rotaviruses in the environment, and their resistance to physicochemical treatment processes in water and wastewater treatment plants facilitate their transmission. Rotaviruses can be found in freshwater, seawater, estuaries, groundwater, sewage and in effluents (advanced and waste treatment plant waters), drinking and tap water, water columns (as suspended or fluffy or compact sediments), shellfish, soils, sediments, sludges, flocs, vegetables, hospital equipment and toys (1–8). This widespread distribution may play a role in outbreaks of rotavirus gastroenteritis.

ROTAVIRUS CLASSIFICATION

Rotaviruses are classified in one of nine distinct genera in the Reoviridae family. This family contains the following genera: *Orthoreovirus, Orbivirus, Rotavirus, Coltivirus, Aquareovirus, Cypovirus, Fijivirus, Phytoreovirus, and Oryzavirus*. Viruses in the Reoviridae are icosahedral in structure (1,2,9). Rotaviruses have a distinct morphological appearance by negative-stain electron microscopy (EM). The name of the virus is derived from the Latin word "rota," meaning wheel because the virus particle resembles the rim of a wheel connected to spokes. Complete infectious virus particles are triple-layered nonenveloped icosahedral particles measuring approximately 100 nm in diameter when viewed by transmission EM (Fig. 1a); incomplete 70 nm in diameter double-layered nonenveloped icosahedral particles are not infectious (Fig. 1b). Animal rotaviruses were first identified in 1963 by EM in stool specimens from mice and vervet monkeys. In 1969, 70-nm virus particles were identified in diarrheal stools from calves, and the successful cultivation of the virus in primary cell cultures was first reported in 1971. Australian scientists discovered human rotaviruses in 1973 when they visualized the virus by EM in duodenal biopsies obtained from acutely ill infants and young children with diarrhea. Within a relatively short time, a clear association between gastrointestinal illness and the observed virus particles was established, and antigenic relatedness among animal and human rotaviruses was recognized (1,2).

The rotavirus genus is divided into seven antigenically distinct groups or serogroups (A to G) that infect mammalian or avian species based on serologic tests such as immunofluorescence (IF), enzyme-linked immunosorbent assay (ELISA), or immunoelectron microscopy (IEM) (2). Group A rotaviruses are the most important because of their high prevalence and pathogenicity in both humans and a variety of animals, including monkeys, cows, pigs, horses, sheep, goats, dogs, cats, rabbits, mice, turkeys, chickens, pigeons, parrots, as well as several zoo animals. Group B and C rotaviruses have been found in humans, pigs, and cows; group B rotaviruses have additionally been found in sheep, ferrets, goats, and rats. Group E rotavirus has only been identified in pigs, whereas group D, F, and G rotaviruses have been found in both chickens and turkeys (1,2,10). Unless otherwise noted, group A rotaviruses are the focus of this review.

Historically, the inner capsid protein VP6 was the first target of rotavirus classification. VP6 is the most immunogenic protein of the virion (after infection antibodies to VP6 are easily detected), and the most sensitive immunologic diagnostic assays are based on detection of this protein. VP6 bears the epitopes of the subgroup (SG) specificities that allow antigenic classification of rotaviruses into SG I, SG II, both SG I and II, or into neither SG according to reactivities with two monoclonal antibodies (MAbs) (1,2). A binary classification

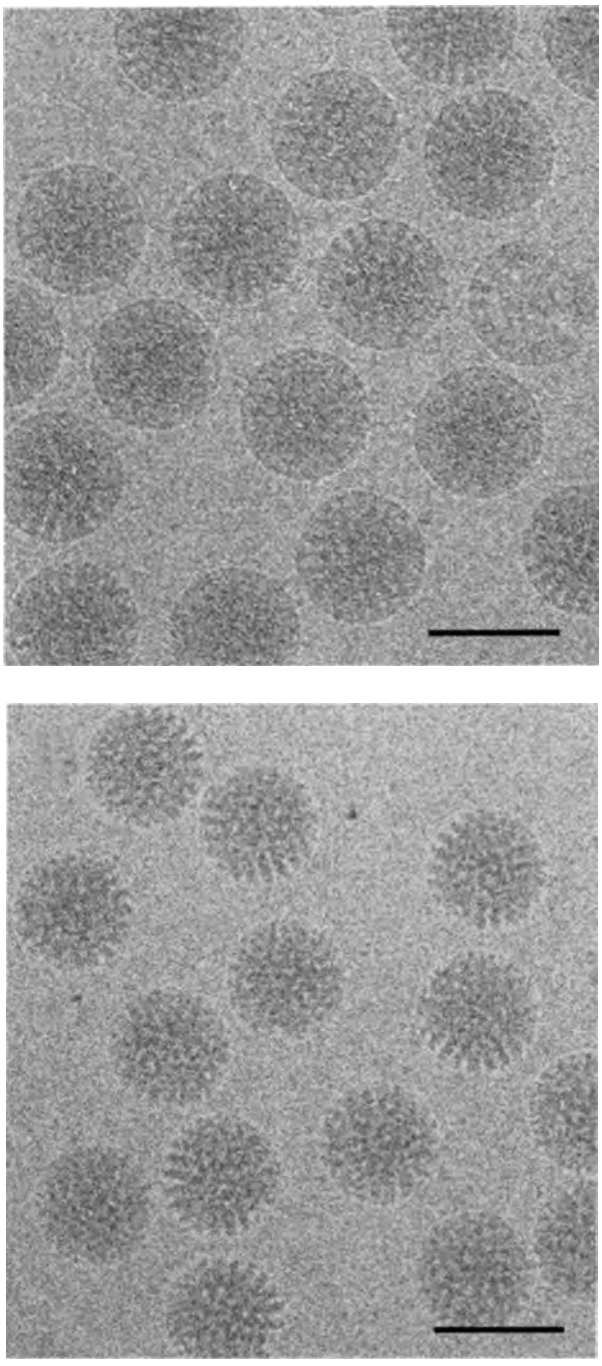

Figure 1. Electron microphotograph of triple-layered (**a**) or double-layered (**b**) simian SA11 rotavirus embedded in vitreous ice as examined by cryoelectron microscopy. Bar = 100 nm.

system reminiscent of the one used to classify influenza viruses has been established to characterize the two outer capsid proteins, VP4 and VP7 that independently elicit neutralizing antibodies (1,11). Thus, rotavirus strains are classified into VP4 or P-serotypes (for protease-sensitive) and VP7 or G- (for glycoprotein) serotypes. Classification of rotaviruses into VP4 or VP7 serotypes is performed by cross-neutralization assays using hyperimmune sera against VP4 alone or the whole virus, respectively. Traditionally, a distinct G serotype is defined as a reciprocal 20-fold or greater difference between the homologous and heterologous neutralization titer when a new strain is tested against antisera raised to prototype strains of known G serotypes. Alternatively, anti-VP7 serotype-specific monoclonal antibodies can be used to determine the G serotype of a particular strain. To date, 14 G serotypes have been identified and shown to belong to distinct G genotypes (defined by sequence analysis and/or nucleic acid hybridization data). G serotype designations coincide with G genotype designations (11). Rotavirus G serotype can be predicted with considerable accuracy by nucleotide sequence analysis of the VP7 gene because there is a high degree of conservation of sequence in variable regions among rotaviruses belonging to the same serotype. Similarly, rotaviruses are classified by P-serotypes or P-genotypes. P-genotypes are used more frequently because of the speed of sequencing and difficulties in producing good antibodies to distinguish among P-serotypes. However, not all P-genotypes correspond to a distinct P-serotype, and out of 20 different P-genotypes, only 13 P-serotypes have been identified with available antisera or anti-VP4 monoclonal antibodies that recognize specific VP4 neutralization specificities. Classification into VP4 serotypes is performed using the same criterion of the 20-fold difference in antibody titer (11).

Until all P-serotypes corresponding to all P-genotypes identified are determined, the following nomenclature is being used to identify the characteristics of rotavirus strains: The P-serotype (when known) is denoted by its number and the P-genotype is denoted immediately after the P-serotype number within square brackets. P-serotype and/or genotype must precede the G-serotype. For example, the human rotavirus Wa strain belongs to the P-serotype 1A, P-genotype 8, and G-serotype 1. Therefore, the serotype designation of the Wa strain is P1A[8],G1. In the case in which the P-serotype is not known, the P-genotype precedes the G-serotype. Rotavirus strains belonging to 10 G-serotypes (G1-G6, G8-G10, G12) and 9 P-serotypes (P1A[8], P1B[4], P2A[6], P2C[6], P3[9], P4[10], P5A[3], P8[11],and P11[14]) have been isolated from humans (1,2,11). Table 1 denotes examples of described human rotavirus strains with the indicated P/G serotype characteristics. When a particular "human serotype" is also commonly found in animal rotavirus strains, the specific animal silhouette is indicated next to the respective P-or G-serotype. Although not depicted, serotype G3 includes rotavirus strains isolated not only from humans but also from monkeys, horses, pigs, dogs, cats, mice, rabbits, and sheep (1,2,11).

Classification of a rotavirus strain can be described by using a cryptogram that contains the following information: serogroup or species of origin or place of origin or strain designation or year of isolation/P-serotype[P-genotype], G-serotype/SG specificity. Thus, the complete classification of the prototype rotavirus simian SA11 strain is A/Si/SouthAfrica/SA11/1958/P5B[2],G3/SGI. In the future, this cryptogram may be modified to include

[a]Table shows names of prototype or representative human rotavirus strains of the indicated P and G serotypes. Viruses with P or G serotypes predominantly associated with infection in humans and in certain animals species are indicated by the corresponding silhouette of the most prevalent species. Some G and P serotypes (shaded) have only been isolated from animals.

[b]The VP7 serotype G3 has been found in viruses from many species; it has been recovered from monkeys, dogs, cats, rabbits, pigs, horses, mice, and sheep. Detailed description of human and animal viruses are given in the 4th edition of Fields Virology (2).

other characteristics of gene products important in immunity or virulence (2,11,12).

ROTAVIRUS STRUCTURE

The rotavirus particle is composed of three concentric protein layers surrounding the 11 segments of double-stranded (ds) RNA that encode the six structural viral proteins (VP), VP1-VP4, VP6, and VP7, and six nonstructural proteins (NSP), NSP1-NSP6 (1,2,9). Each genome segment, with the exception of gene 11 that encodes two viral proteins (NSP5 and NSP6), codes for a single viral protein. The innermost core layer is formed by 120 molecules of VP2 and encloses a less well-defined subcore that contains the genomic dsRNA. The VP2 inner core also contains the proteins VP1 (the RNA-dependent RNA polymerase) and VP3 (a guanylyltransferase and methylase) that are organized as a complex inside particles at the icosahedral fivefold vertices (9). The middle layer is made up of 780 molecules of the rotavirus protein, VP6 (9). The outer layer consists of 780 molecules of the glycoprotein VP7 and 60 dimers of spikes of VP4, the hemagglutinin, and cell attachment protein. Complete infectious rotavirus particles that contain the outer capsid proteins VP7 and VP4 are referred to as triple-layered particles (TLPs) and are approximately 1,000 Å

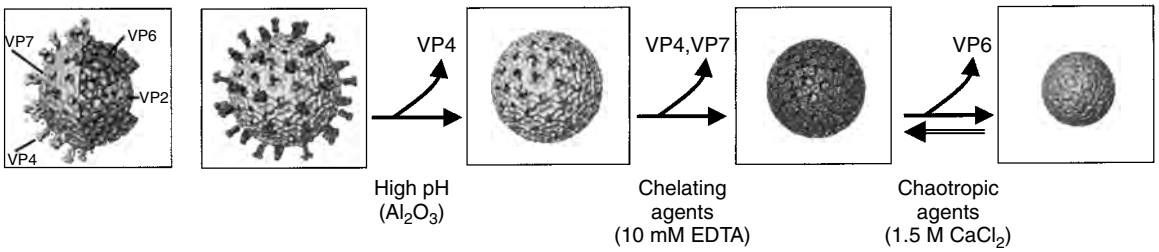
in diameter (9). Double-layered particles (DLPs), which are noninfectious, lack the outer capsid proteins and are approximately 705 Å in diameter. Rotavirus particles composed of VP2 (and VP1 and VP3) are called single-layered particles (SLPs) (2,9).

Electron microscopy easily distinguishes the three forms of particles, TLPs, DLPs, and SLPs that can be separated by centrifugation in gradients of cesium chloride (CsCl) (1,2,9). The physical property of virions used most often for purification is virion density. In CsCl gradients, virions are relatively stable and viral infectivity is stable to extremes of pH (3.5–9.0). Virion stability is strain-dependent and some strains, particularly human virus strains, may be less stable than viruses isolated from animals. Virion stability during purification and storage at 4 °C probably is determined by a particular gene 4 or its encoded protein VP4, and by specific interactions of VP4 with VP7 (1,2). The VP4 spikes can be removed by treatment of virions at pH 11.2 with ammonium hydroxide; removal of VP4 may also occur during other physical or chemical manipulations of particles such as treatment with organic solvents. The outer capsid proteins VP4 and VP7 of TLPs are removed by treatment of virions with chelating agents such as 10 mm EDTA, or with ethanol, resulting in replication-competent, but noninfectious, DLPs. Treatment of DLPs with chaotropic agents, such as 1.5 M $CaCl_2$, removes the VP6 protein and generates replication-incompetent SLPs (1,2). The structural and biological properties of rotavirus particles are summarized in Figure 2.

The existence of the different protein layers has been documented by studying properties of the rotavirus structural proteins VP2, VP6, VP4, and VP7 that have been cloned into recombinant baculovirus vectors, and the recombinant rotavirus proteins have been produced or coexpressed in insect cells infected with baculovirus vectors (2). Stable virus-like particles (VLPs) self-assemble following expression of VP2 alone. Coexpression of VP2 and VP6 alone or with VP4 results in the production of double-layered 2/6- or 2/4/6-VLPs, respectively. Coexpression of VP2, VP6, and VP7, with or without VP4, results in triple-layered 2/6/7- or 2/4/6/7-VLPs. All VLPs maintain the structural and functional characteristics of native particles (2). The production of rotavirus VLPs has represented a breakthrough to facilitate determining protein function and protein–protein interactions among the different viral capsid proteins. VLPs could be useful as noninfectious particles to monitor biophysical characteristics of virus migration in water or soils, as have VLPs of Norwalk virus, another gastroenteritis virus.

ROTAVIRUS GENES AND GENETICS

The sequences of all 11 genome segments of two rotavirus strains, human KU and simian SA11 have been determined (2). The simian rotavirus SA11 strain is considered the prototype rotavirus strain, and its genome segments range in size from 3,302 (segment 1) to 667 (segment 11) base pairs (bp). Sequences from different rotavirus strains show that each RNA segment starts with a 5′ guanylate followed by the 5′ end noncoding sequences, an open reading frame (or two in the case of genome segment 11), the 3′ noncoding sequences, and ends with a 3′ terminal cytidine. In addition, the plus-stranded



Structure:	Triple-layered	Triple-layered	Double-layered	Single-layered
Proteins:	VP 1, 2, 3, 4, 6, 7	VP 1, 2, 3, 6, 7	VP 1, 2, 3, 6	VP 1, 2, 3
Outermost protein:	VP4 and VP7	VP7	VP6	VP2
Infectious:	Yes	No	No	No
Active polymerase:	No	No	Yes	No

Figure 2. Structural and biological properties of rotavirus particles. Three-dimensional structures of a rotavirus, obtained by cryoelectron microscopy, show triple-layered, double-layered, and single-layered (core) particles. The cutaway diagram on the left shows the outer capsid composed of the VP7 shell and VP4 spikes, the intermediate VP6 layer, and the core VP2 layer that contains the subcore proteins VP1 and VP3 and the dsRNA genome. The double-layered and single-layered particles can be produced by sequential degradation of infectious triple-layered particles as depicted. (Reconstructions courtesy of B. V. V. Prasad, Baylor College of Medicine, Houston, Texas.)

RNA is capped at the 5′ end with m7GpppG$^{(m)}$Gpy, but there are no polyadenylated sequences at the 3′ end (2).

The rotavirus dsRNA genome segments can be extracted from viral particles and separated by polyacrylamide gel electrophoresis (PAGE) into eleven distinct bands (Fig. 3) (1,2,10,13,14). These 11 genome segments can be grouped in four size classes according to their migration in polyacrylamide gels: group I (segments 1–4), 1.5 to 2.2×10^6 Dalton (d); group II (segments 5–6), 0.8 to 1×10^6 d; group III (segments 7–9, a distinctive triplet), 0.5×10^6 d; and group IV (segments 10–11), 0.2 to 0.3×10^6 d. In total, the rotavirus genome possesses a molecular weight of 11 to 12×10^6 d (2,10,13). Each group A rotavirus strain has a characteristic RNA profile (or electropherotype), and for this reason, PAGE has been employed extensively in epidemiological studies of these viruses (1,2,10,13,14). PAGE is a simple and rapid method to determine if rotaviruses are present in a sample, provided that 10^5 particles/ml are present. In some human strains, the cognate genome segment 11 migrates between the cognate genome segments 9 and 10; these strains are said to possess a "short" electropherotype pattern of RNA migration, as opposed to those with a "long" (normal) electropherotype. In addition, the cognate genome segment 11 of several human strains migrates even more slowly than that of the "short" electropherotype strains, and these are referred to as "super-short" electropherotype strains (1,2,10).

Some rotaviruses do not display the distinctive RNA migration pattern, and these viruses have been identified as either nongroup A rotaviruses (formerly referred to as pararotaviruses) or group A rotaviruses with rearranged genome segments (Fig. 3) (2,10,13). In viruses with genome rearrangements, normal RNA segments are missing in an electrophoretic profile, and additional, slower migrating bands of RNA replace these. These new bands usually represent concatemeric forms of dsRNA containing sequences specific for the missing RNA segments (2,13). Genome rearrangements have been found in viruses from animals (pigs, cows, and rabbits) and from both normal and immunodeficient children. Rotavirus genome segments also undergo rearrangements in tissue culture, particularly when virus is passed sequentially at high multiplicity of infection (2,10,13).

Table 2 summarizes the gene-coding assignments and briefly lists the properties of the rotavirus proteins. The rotavirus proteins can be divided into structural proteins (found in virus particles) and nonstructural proteins (found only in infected cells and not in mature virus particles) (2). Among the rotavirus structural proteins, the inner capsid protein VP6 and the outer capsid proteins VP4 and VP7 are the ones that have been studied in detail, both molecularly and antigenically. In general, the nonstructural proteins play a role in

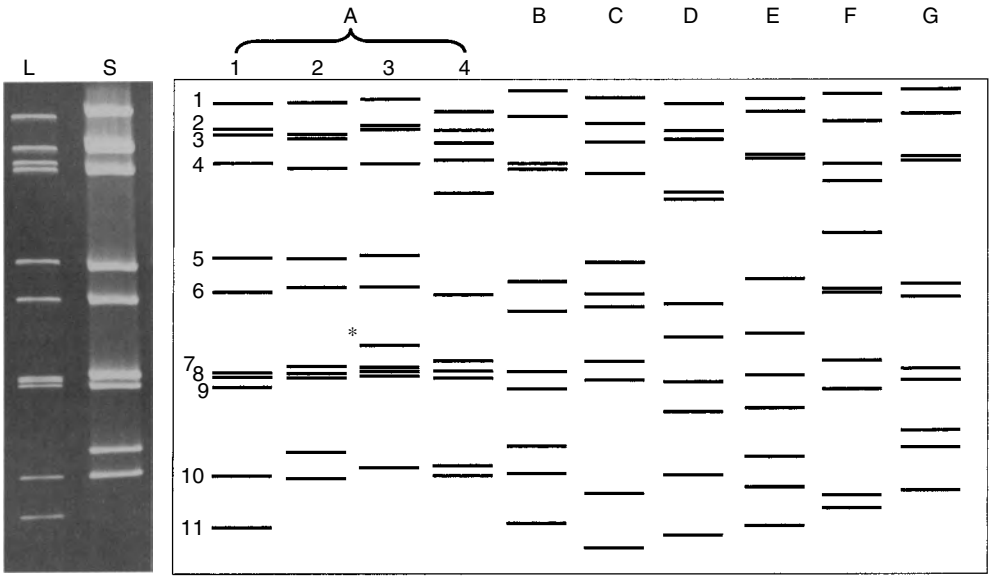


Figure 3. Schematic representation of the patterns of migration of the 11 segments of dsRNA of rotavirus serogroups A to G. The left panel shows the dsRNA electrophoretic patterns of group A human rotaviruses with either a long electropherotype (L) or short electropherotype (S). The right panel shows lanes with schematic representations of the dsRNA electrophoretic patterns of group A human rotavirus with long electropherotype (lane A1); human rotavirus with short electropherotype (lane A2); porcine rotavirus with rearranged (*) genome (lane A3); group A avian (turkey) rotavirus (lane A4); human group B rotavirus (lane B); human group C rotavirus (lane C); avian (turkey) group D rotavirus (lane D); porcine group E rotavirus (lane E); avian (chicken) group F rotavirus (lane F); and avian (chicken) group G rotavirus (lane G). The illustrated patterns are not exact, as all these antigenically-distinct rotaviruses have not yet been analyzed on a single gel to allow direct comparisons.

Table 2. Protein Coding Assignments[a] and Location and Functions or Properties Associated with Each Rotavirus Genome RNA Segment

Genome Segment	No. of Base Pairs[b]	Protein Product[c]	Molecular Weight[d]	No. of Amino Acids[e]	Properties or Functions of Encoded Protein
1	3,302	VP1	125 K	1,088	Subcore protein, single-stranded RNA-binding, slightly basic, RNA-dependent RNA polymerase
2	2,690	VP2	94 K	880	Core protein of SLPs, RNA binding, leucine-zipper, essential for polymerase activity of VP1
3	2,591	VP3	88 K	835	Subcore protein, ssRNA-binding, basic, guanylyltransferase, methyltransferase
4	2,362	VP4	88 K	776	Outer capsid spike protein, dimer, hemagglutinin, neutralization antigen (P), cell attachment protein, contains putative fusion region, virulence, protease-enhanced infectivity, cleaved into VP5* and VP8* protein products, VP5* permeabilizes membranes

[a]Coding assignments for group A simian rotavirus SA11 strain.
[b]Calculated from nucleotide sequence data.
[c]Determined by biochemical and genetic approaches. VP, viral protein; NSP, nonstructural protein.
[d]Estimated for the simian SA11 proteins from analyses on SDS-polyacrylamide gels.
[e]Calculated from the deduced amino acid sequences from nucleotide data and from the longest potential open reading frame.

genome replication and virion assembly but the precise role played in such processes has not been fully elucidated (2).

Genetic analyses of rotaviruses have contributed significantly to the understanding of the biology and function of the proteins of these viruses. Reassortment is the major distinguishing feature of rotavirus genetics (2,13). Genome reassortment occurs frequently among viruses with segmented genomes, and this property is responsible for the antigenic shifts of influenza virus strains, contributing to the evolution of pandemic strains. Reassortment occurs when genetically related viruses with segmented genomes exchange segments after coinfection. Dual infection of cells with more than one rotavirus strain occurs commonly in animals or humans and allows for the reassortment of genome segments. Mixed infections between two rotavirus strains lead to the generation of reassortant rotaviruses that contain specific combinations of genome segments derived from each of the parental rotavirus strains (2,10,13,14). Reassortment, a classical genetic technique, has been exploited as a powerful tool to map various phenotypes and viral mutations to specific genome segments, or to identify the protein product encoded by a particular genome segment because reassortant viruses (progeny) can be isolated by plaque assay (2,10,13). However, more detailed genetic analysis of rotaviruses is limited by the lack of a reverse genetics system in which synthetic transcripts derived from cloned DNA, corresponding to the entire genome of a segmented dsRNA virus, give rise to a replicating virus.

The overall genetic relatedness among each genome segment can be assayed by RNA-RNA hybridizations performed under high stringency conditions (2). RNA-RNA hybridization has provided molecular evidence to show close interspecies relationships between human and animal strains, or confirm the existence of naturally occurring rotavirus reassortant strains. Currently, there are three human genogroups, represented by the Wa, DS-1, and AU-1 prototype strains. Several animal genogroups have also been identified but the extent of their relationship among each other and to human strains has not been completely elucidated (15).

ROTAVIRUS BIOLOGY

In vivo, rotaviruses infect only the differentiated (mature) columnar epithelial cells covering the villi of the small intestine (1,2,16). Undifferentiated, replicating enterocytes in the crypts and lower portions of the villi are not susceptible to infection. The study of the virus–cell interactions was long hampered by the difficulty of growing

rotaviruses in vitro. Fortuitously, improved cultivation of these viruses came about when primary kidney cell cultures and cell lines derived from monkey, bovine, or canine kidney were identified to be highly permissive for rotavirus entry and efficient replication (1,16). The African green monkey kidney (MA104) cells are the best and most commonly cell line used to cultivate rotaviruses. Also, rotavirus infectivity is enhanced by proteolytic cleavage of the spike protein VP4 into two cleavage products, VP8* and VP5*, which remain associated with the particle (1,2). The spike protein VP4 is also involved in the early interaction of the virus with the cell and is the attachment protein (1,2,17–19). Other important biological functions of VP4 include the ability to agglutinate erythrocytes (hemagglutination) — mapped to a region in VP8*, restricted growth in cell culture, protease sensitivity associated with plaque formation, and virulence (1,2). The glycoprotein VP7 may be involved in the early events of rotavirus entry into cells, and possibly internalization (2).

The tissue- and cell type-specific tropisms displayed by rotaviruses indicate that a specific host cell surface receptor (or receptors) mediates virus recognition (2,17–19). Numerous reports provide strong evidence supporting the existence of specific rotavirus receptors. Most of these studies have implicated glycoconjugates (glycoproteins, glycolipids, and glycosphingolipids) as the putative rotavirus receptor(s) (2,17–19). Early studies suggested that animal rotaviruses require the presence of N-acetyl-neuraminic (sialic) acid (SA) residues on the cell surface for efficient binding and infectivity, whereas human rotaviruses do not (2,17). However, only a limited number of both human and animal strains had been tested, and recent analysis of a larger number of rotavirus strains for their dependence on SA for infectivity revealed that most animal rotavirus strains, such as the human rotavirus strains, are SA-independent (17). In addition, the isolation of variants of SA-dependent animal rotavirus strains that no longer depend on the presence of SA to bind and infect cells efficiently, indicating that binding to SA is not an essential step for rotavirus infection (17–19). Rotavirus entry into cells may occur by direct plasma membrane penetration, by receptor-mediated endocytosis, or by both mechanisms (2).

Rotavirus replication occurs entirely in the cytoplasm of infected cells (2). The replication cycle has been studied in cell lines that support rotavirus replication, and rotavirus infection can easily be detected by immunofluorescence using antibodies to either structural (Fig. 4a) or nonstructural proteins (Fig. 4b). Detection of rotavirus nonstructural proteins indicates that rotavirus replication has occurred because these proteins are not found in mature virions. Although the entire rotavirus replication cycle has not been completely elucidated, some steps of the replication cycle are known (2,20):

(*1*) Complete infectious virions bind to an unidentified cellular receptor(s) through interaction of the viral attachment protein VP4. (*2*) Following entry (by direct penetration or by receptor-mediated endocytosis), the outer capsid proteins VP4 and VP7 are removed by a mechanism that may involve low intracellular Ca^{+2} concentration ($[Ca^{+2}]_i$) that is required for the outer capsid stability. (*3*) Removal of VP4 and VP7 activates the virion's RNA-dependent RNA polymerase and the 11 mRNAs transcribed from the RNA genome segments are extruded from the channels on DLPs. (*4*) The mRNAs are translated by the cellular translation machinery and the rotavirus NSP3 protein regulates the switch from translation of cellular poly(A)$^+$ mRNAs to viral mRNAs. (*5*) Once all the viral proteins have been synthesized, the mRNAs interact with both viral structural (presumably VP1, VP2, and VP3) and nonstructural proteins in a complex, in an incompletely understood manner to form nascent (immature) virus particles. This process occurs at electron dense sites, called viroplasms, adjacent to the nucleus and the membrane of the endoplasmic reticulum (ER). (*6*) In the nascent particles, the mRNA is replicated to synthesize the 11 dsRNA genome segments. (*7*) The inner capsid protein VP6 is added to form DLPs that are formed

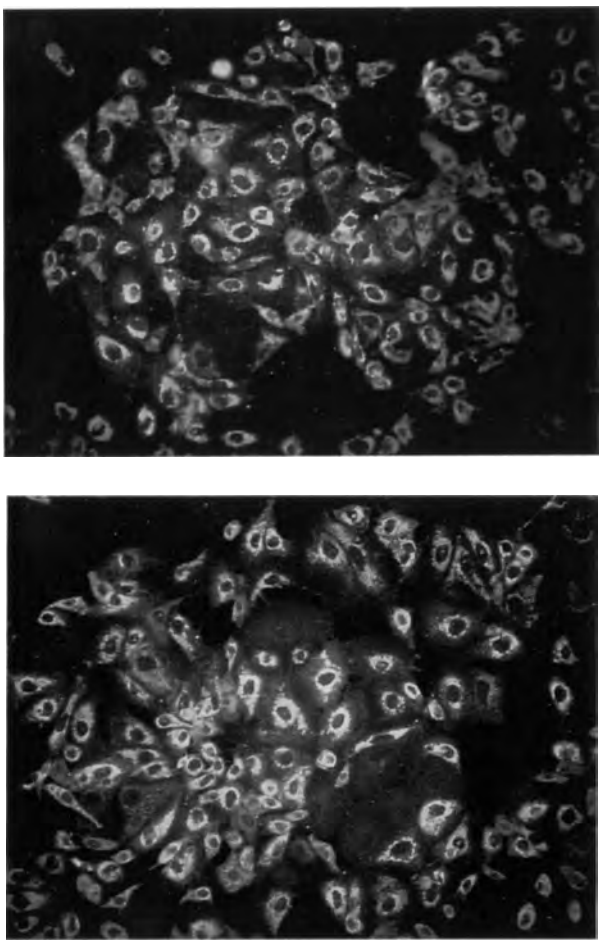

Figure 4. Embryonic African green monkey kidney (MA104) cells infected with simian rotavirus SA11 strain. Rotavirus-infected cells were fixed with cold (20 °C) methanol and (**a**) purified rotavirus-specific rabbit IgG (1 : 300) or (**b**) purified rotavirus NSP4-specific rabbit IgG (1 : 300) was used to detect viral antigen. A 1 : 150 dilution of a goat anti-rabbit IgG conjugated to FITC was used to develop the assay. Rotavirus replication is cytoplasmic. The detection of the nonstructural protein 4 (NSP4; B) shows that virus is replicating within cells.

at the periphery of the viroplasm and bud through the adjacent membranes of the ER. A cytoplasmic tail of the ER-transmembrane rotavirus NSP4 protein acts as an intracellular receptor for the newly formed DLPs. (*8*) During budding, the outer capsid glycoprotein VP7 is added along with VP4 to produce immature TLPs that contain a transient envelope that is later lost as the TLP matures in the lumen of the ER. (*9*) Infectious TLPs are released by cell lysis and by a newly described nonclassical vesicular transport mechanism (21).

ROTAVIRUS EPIDEMIOLOGY AND VACCINES

Rotavirus has a worldwide distribution. Data from epidemiological studies in the developed and developing countries have revealed that rotavirus is the major etiologic agent of serious diarrheal illness in infants and young children under two years of age throughout the world. All children in the world are infected with rotavirus (1,2). In general, symptomatic rotavirus disease predominantly affects young children, with the peak attack rate for severe diarrhea between 6 and 24 months of age. In some developing countries, the peak attack rate may be as low as three months of age. The incidence of hospital admission is greatest in children below the age of two, and then declines rapidly (1,2,16). In developed countries, mortality from these infections is low although approximately 2% of children are hospitalized. In developing countries, rotaviruses are the leading cause of life-threatening diarrhea in infants and young children (1,2,16). The burden of rotavirus diarrheal disease in infants and young children less than 5 years of age in developing countries has been estimated to be more than 125 million cases, and approximately one million infants and young children less than 5 years of age die from rotavirus diarrheal illness each year. The goal of rotavirus vaccination strategies is not the eradication of the disease, but the prevention of the severe, dehydrating diarrhea that leads to hospitalization or death (1,2,16).

The widespread distribution of rotaviruses in the community is supported by the universal acquisition of serum antibodies to these viruses at an early age (1,2,16). A high prevalence of rotavirus antibodies is maintained into adult life indicating that subclinical (mild or asymptomatic) rotavirus reinfection occurs throughout life. Frequent asymptomatic adult infections may be important in maintaining the transmission of infection in the community. For example, secondary infection in parents occurs from contact with young children actively infected with rotavirus, as evidenced by a high level of serum antibodies and seroconversion in parents. In addition, rotavirus infections and diarrhea illness have been reported in closed adult communities, such as geriatric hospitals or homes for the elderly. Primary rotavirus infections are usually symptomatic and are detected infrequently in individuals who are not ill (1,2,16). Usually, the peak of rotavirus infections occur during the winter months (along with the peak of respiratory diseases) in temperate climate regions, whereas rotavirus infections occur more prominently during the rainy season in tropical regions. However, regardless of geographic region, symptoms usually occur with the primary infection, which is followed by induction of protection against subsequent symptomatic infection. For this reason, the ratio of symptomatic to asymptomatic infection decreases with age. In newborns, rotavirus infection is common but results in either asymptomatic or mild disease due to protection provided by passively acquired maternal antibody (1,2,16).

Surveillance information is extremely important for planning, implementation, and assessment of disease control and prevention (1,2,16,22). In preparation for the release of rotavirus vaccines, molecular epidemiology studies characterized the circulating rotavirus strains in humans. Such studies have shown that temporal and geographic differences exist in the types of strains that circulate in the human population. In developed countries, more than 80% of rotavirus strains circulating in humans belong to G serotypes 1 to 4 in combination with P-serotypes 1A or 1B. However, other G-serotypes (G5, G6, G8-G10, and G12) and P-serotypes (P2A, P2C, P3, P4, P5A, P8, and P11) have been described, particularly in developing countries. In the developing world, G5, G9, and G10 strains in combination with P2A or P8 serotypes are becoming more prevalent. Currently, unusual G9 strains in the United States, France, Italy, and Australia indicate the appearance of more diverse G serotypes in the developed world as well (22).

After more than 15 years of testing and clinical trials, in August 1998, a three dose, live-attenuated tetravalent RRV vaccine, Rotashield^{TM}, was licensed in the United States (23). The vaccine was shown to be 80% effective in preventing severe life-threatening disease although the vaccine did not prevent rotavirus infection. Unfortunately, a possible association with intussusception (a bowel obstruction in which one segment of bowel becomes enfolded within another segment) following vaccination was noted postlicensure and the vaccine was withdrawn from the market in October 1999 (23). This was considered a major setback in the rotavirology field. Vaccination efforts using subunit (VLPs) and live-attenuated human or bovine-human reassortant vaccines continue to be pursued.

ROTAVIRUS CLINICAL SYMPTOMS AND PATHOPHYSIOLOGY

Although subclinical (asymptomatic) infections may occur, rotavirus infection causes a range of symptoms with diarrhea being the common denominator. Diarrhea may be mild to severe and may cause fatal dehydrating illness. The incubation period of rotavirus diarrhea is approximately 48 to 96 hours. In general, the clinical manifestations of patients hospitalized with rotavirus diarrhea include fever, dehydration, and vomiting (1,16).

Symptomatic rotavirus infection with severe dehydrating diarrhea is mainly observed in children between 6 to 24 months of age, in domestic animals between one to two months of age, and in mice, rats, and rabbits within the first 15 days of life (1,16). Several host-related factors may contribute to the age distribution of rotavirus–induced diarrhea: (*1*) Although the unidentified cellular rotavirus

Table 3. Environmental Samples in Which Rotavirus Has Been Detected

Type of Environmental Sample Tested	Method of Detection[a]		
	Genome	Infectious Particles	Antigen
Fresh (lake, river, creek) water	RT-PCR, IMC/RT-PCR	Cell culture	ELISA
Seawater	RT-PCR, IMC/RT-PCR		
Estuaries	RT-PCR	Cell culture	ELISA
Groundwater	RT-PCR	Cell culture	
Sewage	RT-PCR, RFLP	Cell culture, FFA	ELISA, EM, IEM
Waste treatment plant (secondary effluent)	RT-PCR, EM	Cell culture, FFA	ELISA, EM
Advanced waste treatment plant (tertiary effluent)	RT-PCR, EM	Cell culture, FFA	ELISA, EM
Drinking water	RT-PCR	Cell culture, FFA	EM
Distilled water	RT-PCR		ELISA
Tap water	RT-PCR		ELISA
Soil, sediments, sludges, flocs	RT-PCR	Cell culture	ELISA
Shellfish	RT-PCR	Cell culture	ELISA
Vegetables			ELISA
Moist surfaces, hospital equipment, toys	RT-PCR		ELISA

[a]Includes most common detection methods used, but does not exclude other detection methods.
RT-PCR, reverse transcription-polymerase chain reaction; *IMC/RT-PCR*, immunocapture/RT-PCR; *ELISA*, enzyme-linked immunosorbent assay; *FFA*, fluorescent focus assay; *RFLP*, restriction fragment length polymorphism; *EM*, electron microscopy; *IEM*, immune electron microscopy.

receptor is expressed throughout life, as evidenced by rotavirus infection in all age groups, a secondary cellular receptor involved in disease induction may be age-dependent and may account for the severity of disease in children and in the young of animal species. (*2*) The regulation and concentration of proteolytic enzymes, required for efficient virus entry into enterocytes, in the intestinal tract vary with age. (*3*) The composition of mucins in the intestine at the time of infection may play a role in determining the severity of rotavirus infection because the functional properties of mucins may also vary with age. Mucins in the intestine and in milk inhibit rotavirus replication in vitro and may inhibit replication and reduce duration of diarrhea in mice. (*4*) The rate of replacement of intestinal epithelial cells of the small intestine and fluid absorption in the large intestine increase with age. (*5*) Gut maturation is important in the pathophysiology of rotavirus infection and may be influenced in part by acquired immunity (1,16).

Rotavirus infection in the young is characterized by watery diarrhea, impaired D-xylose absorption, and abnormal gastric motor function, decreased levels of disaccharidases (maltase, sucrase, and lactase), and destruction of enterocytes consisting of shortening and atrophy of the intestinal villi, mononuclear cell infiltration in the lamina propria, distended cisternae of the endoplasmic reticulum, mitochondrial swelling, and sparse, denudation of microvilli (1,16). Several mechanisms by which rotavirus induces diarrhea have been proposed, and it is likely that a combination of these mechanisms contribute to diarrhea. The most prominent idea is that malabsorption occurs secondary to cell death (1,16). Although in some studies malabsorption correlates with histopathologic changes in the intestine, this does not explain the early watery diarrhea that occurs before villus blunting and other histopathologic changes. Moreover, mice infected with group A rotaviruses exhibit diarrhea in the absence of clearly defined changes in the intestine (1,16). Thus, lack of a clear association of mucosal damage and diarrhea supports other mechanisms of pathogenesis such as villus ischemia secondary to release of vasoactive agents from infected enterocytes, enterotoxigenic activity of the rotavirus NSP4 protein (24–27), and activation of the enteric nervous system (28) that result in or enhance Cl^- secretion (25).

Rotavirus deaths are usually associated with dehydration, electrolyte imbalance, and aspiration of vomitus although other preexisting conditions may contribute to death (1,16). It is likely that malnutrition plays an important role in increasing the severity of clinical manifestations of rotavirus infection. Rotaviruses can produce a chronic symptomatic infection or serious illness in immunodeficient children associated with prolonged shedding of rotavirus. During chronic infection in immunocompromised children, rotavirus can undergo marked changes in its genome, as indicated by abnormal electrophoretic migration patterns of rotavirus RNAs (1,10,14,16). Rotavirus infections have been associated with other syndromes, including necrotizing enterocolitis and haemorrhagic gastroenteritis in neonates, and pneumatosis intestinalis and hyperphosphatasemia in infants. However, these associations are very rare and further studies are needed to confirm the significance of these findings (1). The live-attenuated tetravalent RRV vaccine was withdrawn from the market because of a possible association with intussusception, but the possibility that intussusception is associated with natural rotavirus infections remains to be documented (23).

MODES OF TRANSMISSION OF ROTAVIRUSES

Rotavirus is mainly spread by the fecal-oral route (1,2,16). The primary source of infection of infants is contact with other infants with gastroenteritis in homes, hospitals, or daycare centers. Nosocomial infections play an important

role in transmission of rotaviruses (1,16). Another source of infection is contact with an infected sibling or parent with clinical or subclinical disease. The large number of viral particles shed in feces (10^{10-12} particles per gram of feces) and the resistance to physical inactivation may contribute to the persistence and easy spread of these viruses (1,2,16). Large quantities of rotavirus can be shed from the intestinal tract before and after cessation of diarrhea and consequently, infants may acquire the infection easily. Certain epidemiological features (the seasonal excess in cooler months and the rapid spread in both temperate and tropical zones; see previous section) have led to the suggestion that rotavirus may also be spread by the respiratory route (1).

The precise role of contaminated water in transmission of rotaviruses is uncertain and rotaviruses detected in water samples and raw or treated sewage have been suspected but not confirmed in rotavirus gastroenteritis outbreaks in several instances (Table 3) (1,3–8). Thus, rotavirus may be transmissible by contaminated water. Of special significance is the fact that wastewater treatment operations reduce the amount of rotavirus, but do not eliminate the virus, from the effluent (6,29,30). Therefore, infectious rotavirus may survive and come into contact with humans or animals via food, water, or aerosols generated by spray irrigation of wastewater. The mechanism of rotavirus transmission and the outcome of the viral infection depend on physicochemical or biological factors (1,6,7,31). Rotavirus transmission by water is often difficult to trace because of the lack of availability of routine laboratory services to confirm the viral etiology. However, the presence of rotaviruses in freshwater, sewage effluent waters, well- or groundwater, seawater, or sewage- or sludge-amended soils cannot be ignored. Routine use of epidemiologic criteria as an alternative to laboratory confirmation could allow better assessment of the importance of the presence of rotavirus in water samples and link its presence to outbreaks of rotavirus gastroenteritis until effective laboratory methods are widely implemented (6,7,32,33). Outbreaks of rotavirus gastroenteritis may be propagated by contamination of water supplies, and controlling such outbreaks depends on identifying and removing the source of contamination (32–34). Whether rotavirus spreads by contaminated waters or soils, the key question is how important is this spread in relation to other means of spread. In a few cases, rotavirus contamination of water has been implicated as the source of rotavirus epidemics. However, the importance of rotavirus spread by water can only be established if the presence of rotavirus polluted waters can be associated with the common and seasonal occurrence of rotavirus strains in the community (32–34). Currently, it is difficult to identify how rotavirus contamination of the environment plays a role in the distribution and occurrence of the rotavirus strains that circulate normally in a community or in outbreaks. Therefore, epidemiologists and environmentalists must work together to directly assess the role of rotavirus spread by water (or soil) relative to other mechanisms of rotavirus spread in the community.

ROTAVIRUS HOST RANGE AND RESERVOIRS

There has been speculation on the role of animals as a source of rotavirus infection of humans. Although rotaviruses do cause infection in a wide variety of animals, rotavirus infection does not appear to be predominantly a zoonosis (a disease or infection that is naturally transmitted between vertebrate animals and humans). Although certain naturally occurring animal rotavirus strains may infect humans, this type of interspecies transmission appears to be a rare event (1,2,15). Recent and widespread seroepidemiological data using improved assays to detect and classify rotavirus in field samples suggest that interspecies transmission does occur in nature, as exemplified by reports from India (cows to humans) and Brazil (pigs to humans) (15). Also, the possibility of reassortment occurring between animal and human strains has been suggested and evidence of transmission between humans and animals is accumulating. Examples of rotavirus interspecies transmission may include human Ro1845 (dogs to humans), feline FRV-1 (humans to cats), equine H-1 (pigs to horses), and the naturally occurring reassortant human/feline Cat2 rotavirus strains (15). However, no direct proof of interspecies transmission is available yet.

DETECTION, OCCURRENCE, AND PERSISTENCE OF ROTAVIRUSES

Rotaviruses have been detected throughout the world. Moreover, rotaviruses are the main etiologic agents of severe acute infantile gastroenteritis in every geographic region studied. In temperate-climate countries, rotavirus infection exhibits a seasonal pattern, with epidemic peaks occurring in the winter months every year (1,2). Rotavirus infections are almost absent during the summer months. The usual seasonal pattern of rotavirus infection observed in the temperate-climate countries is not necessarily observed in countries with less-marked seasons than climate-temperate countries. In tropical countries, rotavirus infection occurs predominantly during the slightly cooler or the dry season although rotavirus infection can also occur throughout the year or during the rainy season. The cause for the seasonal pattern of rotavirus infection is not known, but the low relative humidity during certain months has been suggested as a factor that enhances the survival probability of rotaviruses in the environment (1,2). However, it is important to point out that a correlation with the temporal pattern of infection and humidity has not been found in every epidemiological setting studied. Rotavirus infection may appear in one place in the fall and spread progressively until late winter or early spring (1). Rotavirus does not establish persistent infections unless the individual is immunodeficient, in which case a chronic infection is often established (1,2,10,13,14).

As a result of human activities, rotaviruses may enter the aquatic environment, soils, and sediments and threaten human health (1,6). However, before their entry into natural ecosystems, rotaviruses from humans or animals must first survive exposure to a variety

of adverse environmental factors of physicochemical or biological nature and the relatively harsh environment in wastewater treatment plants (6–8,31–34). The tightly organized structural protein coat protects the virion from the adverse action of temperature, sunlight and ultraviolet (UV) light, pH, divalent ions, or sewage microflora. Temperature probably is the most important factor involved in the destruction of rotaviruses outside their host cell. Although a temperature slightly above 60 °C may be adequate for protein denaturation and lead to rotavirus inactivation, rotavirus populations are heterogeneous and may include thermoresistant virions. Although it has been reported that 50 mJ of UV irradiation is sufficient to reduce viral titer to by more than 2.5 logs, data on the virucidal action of UV light on rotaviruses are limited. Nevertheless, the use of UV radiation has been proposed for the disinfection of water supplies and sewage effluents. Rotaviruses are stable at pH values encountered in natural waters (pH 5 to 9). Rotaviruses are not susceptible to acid in general, and they may survive in acidic waters (pH 3 to 5). In contrast, high pH exposure may result in virus inactivation due to loss of the spike protein from particles. Rotaviruses released into the environment may also be subjected to inactivation following the production of antiviral substances by the biota living in natural waters and wastewaters (6,7,31).

In wastewater treatment plants, rotaviruses are subjected to physical, biological, and chemical treatments that greatly help in their removal or inactivation, but still in certain treatment plants, infectious rotavirus can survive (6–8, 32–38). The survival of rotavirus both in fresh and marine waters depends on factors mentioned earlier. Rotavirus can survive for weeks in drinking and recreational waters and for a few hours on human hands (39). In air and on nonporous solid surfaces, the survival of rotaviruses benefits from a relative humidity of 50% and viral infectivity can be retained from several days to a few weeks. In natural waters, rotavirus particles may become associated with suspended solids and settle in the sediments and that can result in prolonged survival rates. In soil systems, the survival of rotaviruses has not been studied in sufficient detail to know the relative persistence of these viruses in this complex ecosystem. Rotaviruses have not been associated with shellfish-transmitted illness; this may reflect some property of the stability of these viruses (40,41). It is possible that shellfish take up rotaviruses but their infectivity is lost because the spikes are removed (40).

Rotaviruses are stable at ambient temperatures for a prolonged period (up to one year). Therefore, in hospitals and daycare centers, disinfection of contaminated material and hand washing are crucial to contain rotavirus infection. Among all disinfectants tested, ethanol (70–80%) is more effective than formaldehyde (10%) or sodium hypochlorite solutions at inactivating rotaviruses. Because rotaviruses are relatively resistant to chlorine, contamination of drinking water with low levels of rotaviruses may occur repeatedly, leading to sporadic cases of infection that may remain unreported (1,6,31–33). The fact that rotavirus is able to survive for prolonged periods on various surfaces under different conditions is likely to contribute to the rapid spread of these viruses. This is why rotavirus infections persist in newborn nurseries and an elevated number of nosocomial rotavirus infections occur in hospitals. The persistence of asymptomatic neonatal rotavirus strains over a long period plays an important role in the dissemination of the infection in neonates (1,2,16).

RECOVERY AND CONCENTRATION OF ROTAVIRUSES IN ENVIRONMENTAL SAMPLES

The number of rotavirus particles in raw sewage can vary greatly depending on several factors such as level of hygiene of the population, incidence of disease in the community, socioeconomic level, and the season of the year. A number of methods are available to recover rotaviruses in water and soil (6–8,29–31,34–38,42,43), but most of them suffer from one to several limitations. For example, no single method can be used to detect rotaviruses in all types of waters, whether natural, waste, or treated waters, and rotavirus recovery depends greatly on the water quality and is influenced by particulates, organics, and salts. The best method for rotavirus concentration from water should be sensitive enough to concentrate rotaviruses present in both water and wastewater, be capable of processing large volumes of a variety of waters in the least possible time, be straightforward to perform, be economical, and capable of detecting viral aggregates and virus adsorbed to suspended solids in water samples (6–8,29–31,34–38,42,43).

An important consideration is that rotaviruses, as all viruses, adsorb readily to a number of substances, including soils, sediments, fabrics, celite, starch, alumina gel, tricalcium phosphate, and various resins (6–8). Traditional methods to detect viruses in water samples generally use adsorption or entrapment, ultracentrifugation, adsorption to inorganic salts and clay minerals, adsorption to polyelectrolytes, soluble ultrafilters, hydroextraction, electroosmosis, and two-phase polymer separation to initially concentrate viruses (6–8). However, these methods have limited application to rotaviruses because they cannot be used in highly turbid waters or waters containing a high concentration of organics, and they can only be applied to small volumes of waters ($\leq$3 liters). With the advent of the microporous filter adsorption-elution technique, the detection of rotaviruses from a variety of water samples of different quality has improved. The main advantage of this technology is that it can be scaled up to test large quantities of water and can recover even low amounts of infectious rotavirus particles (6–8).

Because infectious rotavirus may not be entirely removed from wastewater by current sewage treatment processes, a method to recover and detect infectious rotavirus in any kind of water is critical to establish the effectiveness of water treatment processes and the public health significance of rotavirus in water (6–8,29–31,34–38,42,43). Concentration or recovery of rotavirus from a water source involves three basic steps: (*1*) Adsorption (concentration), (*2*) elution, and (*3*) reconcentration (recovery). The actual procedure varies depending on the source or type of water, but certain

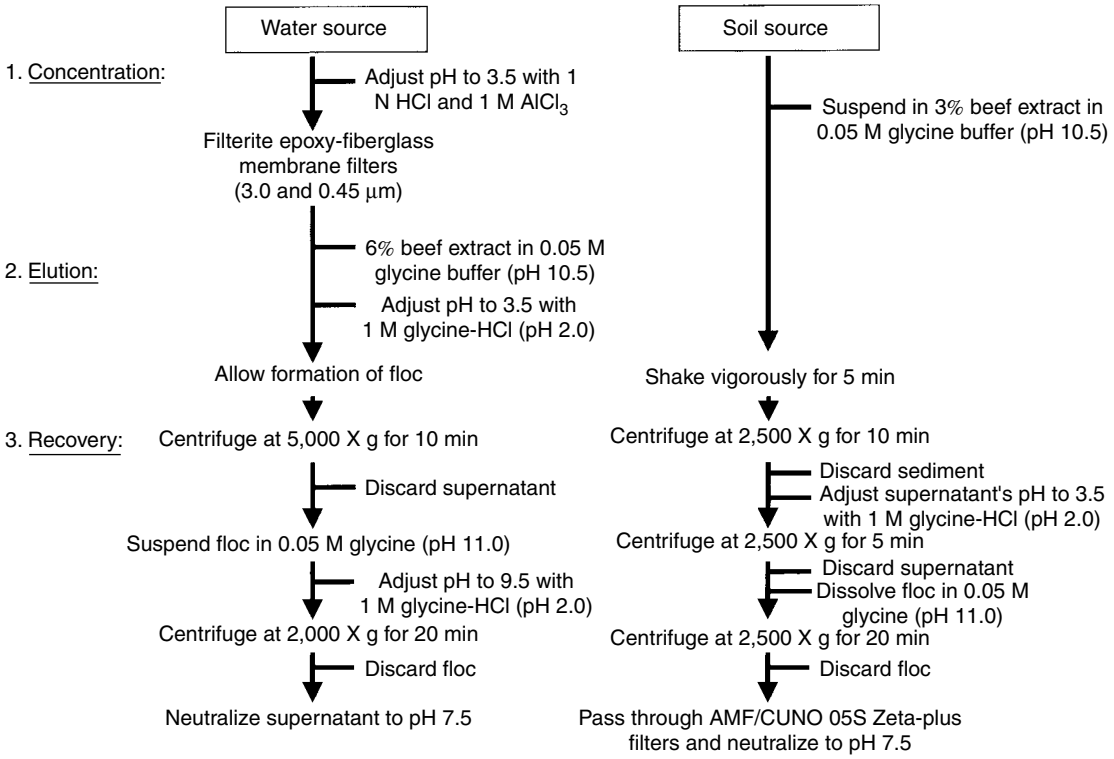

Figure 5. General procedures to recover and concentrate rotavirus from water or soil environmental samples.

general guidelines can be followed (Fig. 5) (6–8). In the adsorption step, the water sample is concentrated by passing the water through a combination of 3.0 and 0.45 μm Filterite epoxy-fiberglass membrane filters. Filterite filters are recommended because these clog less easily than other types of membrane filters such as acrylonitrile polyvinyl chloride copolymer, Cox epoxy-fiberglass-asbestos, or Millipore nitrocellulose filters (6–8). To enhance rotavirus adsorption to the membrane filters, the pH of the water sample must initially be adjusted to pH 3.5 with 1 N HCl and 1 M $AlCl_3$ to a final concentration of 1 mM or 0.5 mM $AlCl_3$ for seawater or others, respectively. In some cases, concentration of rotaviruses from sewage by microporous filters is often difficult because the high turbidities of these waters can rapidly clog the filters; therefore, during clarification, the native pH and salt concentration of sewage must be unaltered to prevent virus adsorption to suspended solids. Adsorbed rotavirus is then eluted from the filter by passing a small amount (2 to 4 ml) of 6% beef extract in 0.05 M glycine buffer (pH 10.5) for about one minute. This primary eluate is acidified to approximately pH 3.5 with 1 M glycine-HCl (pH 2.0) buffer to allow formation of the floc. Once the floc is recovered, it is neutralized prior to be assayed or stored at −80 °C. To recover rotavirus from sewage-contaminated seawater, the floc can be reconcentrated by centrifuging at 5,000 X g for 10 minutes. The supernatant is discarded and the floc is suspended in 0.05 M glycine (pH 11.0) to further concentrate to a smaller volume. Because the pH of the glycine will drop on contact with the floc, the pH must be adjusted to more than or equal to 9.0 before centrifuging a second time at 2,000 X g for 20 minutes. This time the floc is discarded and the supernatant is neutralized to pH 7.5 to avoid precipitates that may interfere with the rotavirus detection assays (6–8). The efficiency of recovery of rotaviruses from tap water, raw sewage, treated sewage, seawater, and drinking water is more than or equal to 30%.

Rotavirus concentration technology has made it possible to concentrate rotaviruses from sewage, tap water, seawater, and wastewater. However, the binding of these viruses to solids indicates that sampling of the water alone may not give a true indication of the potential disease hazard. Rotavirus present in sewage discharges can also be associated with solids, and rotavirus adsorbed to solids is known to remain infectious (6–8,29–31,34–38,42,43). Rotavirus can also adsorb specifically to soil particles after wastewater or sewage sludge is treated by recycling water through crop irrigation. Generally, viruses are removed using this method by percolation through the soil. The amount of rotavirus adsorbed to soil depends on the nature of soil (sand, clay, silt, etc.), the level of the water in which the viruses are suspended, and the flow rate of the virus suspension through the soil. The survival time of rotaviruses in soils is not known and this is an important concern in crop irrigation with wastewater and land management. Survival in the soils depends on factors such as temperature, soil moisture, pH, availability of nutrients, and the deleterious effect of the microflora present in the soil (6–8,29–31,34–38,42,43). The particulate matter to which rotaviruses can be associated may settle and accumulate in the bottom sediments of both freshwater and marine environments. Near marine sewage outfalls, rotaviruses and other viruses may settle into the sandy or slimy sediments and reach high concentrations. Because

rotaviruses can persist in soils and in sediments, these may represent a reservoir for rotaviruses. Therefore, the land disposal of wastewaters poses a potential risk that could lead to possible public health problems for humans and animals. The increasing demand for drinking water in many countries faces two main problems, that is, scarcity of drinking water and the proper processing and disposal of increasing amounts of wastewaters. The purification of wastewater has been and continues to be a prime environmental issue. Fortunately, groundwater, if contaminated, has the tendency to regenerate itself due to the adsorption processes in aquifers and to the metabolism of their microflora (6–8). This makes an underground recharge of tertiary wastewater an ideal last step before the wastewater is reused.

To recover rotaviruses from sediments or soils (Fig. 5), these are suspended in 3 volumes of 3% beef extract (in 0.05 M glycine buffer, pH 10.5) to elute the virus from the sediment or soil (filters cannot be used because of easy clogging), shaken well for five minutes and centrifuged at 2,500 X g for 10 minutes. The sediment is discarded, the pH of the supernatant is adjusted to 3.5 with 1 M glycine-HCl (pH 2.0), and it is centrifuged at 2,500 X g for 5 minutes. The supernatant is discarded and the organic floc is dissolved in 5 to 10 mL of 0.05 m glycine buffer (pH 11.0) to make a mixture whose final pH is around 9.5 to 10.0. The dissolved floc is centrifuged again at 2,500 X g for 20 minutes, and the sediment is discarded. Because toxicity to cell culture monolayers is a problem often encountered in the assay of eluents from sediments, the final supernatant is passed through AMF/CUNO 05S Zeta-plus filters at neutral pH (to avoid rotavirus adsorption to the filters) (6–8).

METHODS OF DETECTION OF ROTAVIRUSES

The clinical symptoms of rotavirus illnesses are not sufficiently specific to allow diagnosis on this basis alone. Therefore, laboratory confirmation is required to distinguish between rotavirus infection and other causes of gastroenteritis. Diagnosis of rotavirus requires detection of virus, viral genome or viral antigen, and/or demonstration of a serologic response. Several assays have been developed for the detection of rotaviruses in stools. Stool specimens, collected between one and four days of illness and stored at 4 °C, are ideal for virus detection because the peak of and amount of viral shedding usually coincide with clinical disease (virus shedding can continue once symptoms have stopped). If stool samples are not available, rectal swabs or diapers can also be used.

Detection of rotavirus is also possible in environmental samples such as freshwater, groundwater, seawater, wastewater (i. e., sewage), and soil. New methods capable of detecting rotaviruses in large liquid volumes are now available, but the precise concentration of rotaviruses (or other viruses) in water that can produce disease in humans has yet to be determined although it is thought to be low (6–8,29–31,34–38). In animals, the minimal amount of virus necessary to produce disease or infection in germ-free gnotobiotic piglets is one plaque-forming unit. Therefore, it is difficult to set standards of permissible rotavirus content of waters. In the meantime, waters continue to be monitored for the presence of bacteria according to certain bacteriological standards. Methods to detect rotaviruses in shellfish have also been developed, but as mentioned previously, shellfish have not been shown to play a role in the spread of rotavirus to humans (41,44). The advantage of being able to detect and type rotaviruses in environmental samples is that the information obtained is useful in molecular epidemiology studies monitoring the transmission of a particular rotavirus strain. The ability to detect rotaviruses in water provides a means to identify suspected sources for rotavirus contamination in outbreaks of gastroenteritis. Although numerous efforts have been made to detect rotaviruses from contaminated streams, in sewage, and in effluents from sewage treatment plants, rotavirus surveillance in water is not routinely monitored. Because rotavirus infections are seasonal in areas with a temperate climate, such changes are likely to be reflected in a given community's sewage.

There are several assays or laboratory procedures available for the detection of rotaviruses in stool or environmental (water or soil) samples (Table 4), and the most common are: cell culture (cultivation and isolation), electron microscopy (EM), immune electron microscopy (IEM), enzyme-linked immunosorbent assay (ELISA), polyacrylamide gel electrophoresis (PAGE), RNA-RNA-hybridization, and reverse transcription-polymerase chain reaction (RT-PCR) (6–8,29–31,34–38,42,43). These assays are discussed in details in the section that follows. Cell culture is specific and sensitive but impractical for many settings. The method of choice in many laboratories is ELISA because it does not require specialized equipment and it is easy to control for nonspecific reactivity. However, unless rotaviruses can effectively be concentrated from the environmental samples, ELISA is not sensitive enough (10^4 to 10^5 particles/mL are required). Conversely, RT-PCR is the most sensitive of all available assays (32), and the detected viral sequences can be characterized by analysis of the restriction fragment length polymorphism (RFLP) of the amplification products to detect the strain diversity in the samples without actual sequencing of any genes (33). However, it is important to keep in mind that detection of viral sequences cannot be correlated with virus infectivity because the presence of viral sequences in a particular sample does not mean the viruses are infectious. Currently, laboratory or commercial diagnostic tests (ELISA and RT-PCR) are available for rotaviruses of groups A, B, and C.

ASSAYS TO DETECT ROTAVIRUS

There are numerous assays available to detect rotavirus or immune responses to rotavirus. Among all the assays available to detect rotaviruses, only a few have been (or could be) used to detect the presence of rotavirus in environmental samples. Therefore, this section focuses on those assays that have been used or have potential to detect rotavirus in environmental samples.

Table 4. Methods Available for Detection of Rotaviruses[a] in Environmental Samples

Method	Sensitivity	Detection of Infectious Virus	Availability
1. Recovery in cell culture	≥1 IPP	Yes	Not routinely used
2. Fluorescent focus assay	≥50–100 IPP	Yes	Not routinely used
3. Electron microscopy	10^5–10^6 PP	No	Not routinely used
4. Immunoelectron microscopy	10^4–10^5 PP	No	Not routinely used
5. Immunologic:			
A. Enzyme-linked Immunosorbent assay	10^4–10^5 PP	No	Routinely used
6. Molecular:			
A. Polyacrylamide gel electrophoresis	10^5–10^6 PP	No	Rarely used
B. RNA hybridization	10^5–10^6 PP	No	Not routinely used
C. Reverse transcription — polymerase chain reaction	10^1–10^2 PP	No	Routinely used
D. Immunomagnetic capture reverse transcription polymerase chain reaction	5–10^1 PP	No	Not routinely used[b]
E. Restriction fragment length polymorphism	5–10^1 PP	No	Not routinely used[c]

[a] Probably strains belonging to all serotypes may be transmitted via water or soil.
[b] *IPP*, infectious physical particles; *PP*, physical particles.
[c] New assays that should be used in the future.

Recovery in Cell Culture

Rotaviruses can be recovered from stool specimens or environmental samples directly in cell culture with acceptable efficiency. However, cultivation of rotaviruses is not routinely performed because isolation of rotaviruses is very laborious, and four to seven blind passages may be needed to succeed. Some animal strains grow efficiently in cell culture, in contrast to human strains, and pretreatment of inocula with trypsin (always present in the normal habitat of rotaviruses, the small intestine), inclusion of a lower concentration of trypsin (and no serum because it contains high levels of trypsin inhibitors) in the culture maintenance medium, and rolling of cell cultures during incubation assist in primary isolation of rotaviruses in cell culture. RNA analysis to rule out the possibility of "re-isolation" of a laboratory cultivable strain is necessary, as cell cultures are susceptible to cross-contamination by "airborne" rotaviruses routinely cultivated in the laboratory. When dealing with large numbers of samples, it is very useful to obtain the electropherotypes first and then choose a few representatives of selected RNA pattern for further study. Although infectious rotavirus particles present in environmental samples can be unequivocally detected (and amplified) in cell culture, this method is not practical with most environmental samples.

Although many cell lines support the growth of group A rotaviruses, primary or continuous monkey kidney cell cultures are the most commonly used for their propagation. The most widely used cell line to propagate rotaviruses is the African green monkey (MA104) cell line. Other commonly used cell lines include rhesus (RhMK, LLC-MK_2), African green (AGMK, BSC-1, Vero), and Buffalo green monkey (BGM) kidney cells (1,2,16). Also, rotaviruses can grow efficiently in human adenocarcinoma cell lines, such as Caco-2, HT-29, or T-84, which despite their colonic origin, spontaneously differentiate into cells displaying many of the morphologic and biochemical properties of mature enterocytes. These characteristics include cellular polarization with the appearance of brush border and tight junctions, as well as the expression of intestinal hydrolases such as sucrase isomaltase, neutral aminopeptidase, and dipeptidyl dipeptidase IV (2,21). These intestinal cell lines are currently being used to cultivate other enteric viruses and therefore are useful to detect a variety of potential pathogens (21).

Fluorescent Focus Assay (FFA)

FFA is reliable, inexpensive, and practical for testing large numbers of stool or environmental samples (1,35,40,41). FFA provides an excellent method to detect infectious virus particles in stool or concentrated environmental samples. FFA permits for one round of virus replication without further virus amplification in cell culture. Fecal or environmental samples are trypsin-activated before inoculating confluent MA104 cell monolayers. The inoculum is removed and cells are incubated overnight in medium containing no serum or trypsin. On the next day, the cells are fixed with cold methanol (−20 °C) and a diluted anti-rotavirus hyperimmune serum is added to the cells for 2 hours at 37 °C. Appropriately diluted antispecies specific immunoglobulins conjugated to fluorescein isothiocyanate (FITC) are then added and incubated for 2 hours at 37 °C. The fluorescent foci are counted in an inverted fluorescence microscope, and the infectious virus titer is determined by averaging the number of foci in duplicate wells of each sample (11). Virus replication is exclusively in the cytoplasm (Fig. 4). The number of foci are then adjusted according to the volume and dilution of the inoculum to allow determination of the titer as focus-forming units (FFU) per milliliter (FFU/mL). The sensitivity of FFA is approximately greater than or equal to 50 to 100 FFU/mL, but sensitivity may decrease or be hampered because toxic inhibitors may be present in the test sample. The main disadvantage of using FFA to detect rotaviruses in stool or environmental samples is that many clinical virus strains may have limited ability to replicate in vitro without adaptation, and the amount of infectious virus may be underestimated. FFA requires

assaying large volumes of concentrates to detect low levels of virus contamination. This technique is not widely used but is a powerful technique to detect infectious rotavirus particles in environmental samples.

Electron Microscopy (EM)

EM of stool suspensions was the first routine method for diagnosis of rotavirus infections and allows for direct visualization of the virus in stool specimens (1,40). Usually a 10% suspension of feces is made in distilled water or phosphate buffer saline (PBS), clarified by centrifugation, stained with phosphotungstic acid (PTA) or uranyl acetate, and examined directly by EM (1). EM has the advantage of high specificity because rotaviruses have a distinctive morphological appearance, but 10^5 to 10^6 particles per milliliter are necessary to detect the virus. Direct EM examination of stools permits detection of rotavirus in 80% to 90% of the virus-positive specimens because rotavirus is excreted in such large numbers. The main advantage of using EM is that it detects rotaviruses of all serogroups (A to G) and other enteric viruses that would not show up in regular serological rotavirus tests. One important consideration when performing EM is that detection of intact particles requires the pH of the PTA or uranyl acetate to be less than 5.0. A pH greater than or equal to 5.0 may result in the loss of the outer capsid of group A, B, or C rotaviruses or in the disappearance of particles altogether (1,2). It is recommended that 1% uranyl acetate (pH 4.3) or 2% PTA (pH 4.5) be used for negative staining of rotaviruses. Currently, EM is used mostly as a confirmatory assay and is not frequently used as a primary method for rotavirus diagnosis unless EM is performed as part of a comparison of several diagnostic tests. In this case, EM is used as a reference standard to identify false-positive results. Although EM is rarely used to detect rotavirus in environmental samples, it has been used to detect rotavirus from sewage concentrates. However, the number of rotavirus particles present in the concentrate of sewage samples has to be amplified in cell culture before detection by EM. Therefore, the applicability of EM to detect rotavirus in environmental samples is limited and requires concentration or cultivation of the virus present in the sample.

Immune Electron Microscopy (IEM)

IEM, based on aggregation of virus-antibody complexes in solution followed by centrifugation and negative staining of the pellet increases the sensitivity of rotavirus detection to approximately that of standard enzyme immunoassays (1,2,40). Although IEM is not necessary for the detection of rotaviruses, it was used in early studies to demonstrate the relationship between different rotaviruses and the location of group antigens. For IEM studies, PTA (pH 4.5) is superior to uranyl acetate because it allows a defined visualization of antibody and virus. More recently, solid-phase IEM for specific detection of group A rotaviruses has been developed. Grids are first coated with protein A, then with an antirotavirus antibody by floating the grid on a diluted hyperimmune antiserum; later, the grids are rinsed and floated on stool or the test specimen containing virus before negative staining. Compared with direct negative staining, IEM enhances trapping of rotavirus particles on the grids and decreases adsorption of unrelated debris (1). IEM has been rated as 30 times more sensitive than direct EM and 10 times more sensitive than enzyme immunoassays (see the section that follows), and has the potential use to identify these viruses in water samples. By changing the antiserum placed onto the grid, IEM has been extended to allow for subgrouping and serotyping of rotaviruses, and can be used to differentiate among the morphologically identical group A, B, and C rotaviruses. However, IEM is labor-intensive when used for a number of specimens and is not widely used for environmental samples.

Immunological Assays

A variety of immunological assays have been successfully used to detect rotaviruses in fecal or concentrated environmental samples.

Enzyme-Linked Immunosorbent Assay (ELISA). Many varieties of ELISAs for rotavirus antigen detection have been developed, and this is now the most commonly used technique. Early tests were not sensitive enough to detect rotaviruses in environmental samples (1,6,30,32). However, modifications have allowed the use of ELISA to detect rotaviruses in environmental samples. Enzyme-linked immunosorbent assay frequently uses broadly reactive antibodies or monoclonal antibodies to the inner capsid protein VP6 to detect rotaviruses. The basic design of the assay is simple and does not vary considerably from laboratory to laboratory. First, a solid phase, usually a polystyrene microtiter plate is coated with antibodies against rotavirus. Then, the sample (stool specimen or environmental sample containing the antigen) is added and the unbound material is washed away. Bound antigen is then detected and quantitated by adding either enzyme-conjugated antirotavirus antibody (direct test) or a second unlabeled antirotavirus antibody (that must be from a species different from the one in which the coating antibody was made) followed by an enzyme-labeled antiimmunoglobulin specific for the second antibody (indirect test) (1). In either case, a chromogenic substrate for the enzyme is finally added and the bound enzyme (indicating bound antigen underneath) is detected by a colorimetric reaction that is quantitated on a commercial ELISA plate reader.

Direct ELISAs are commercially available and have the advantage that only one antiserum is required (part of it must be enzyme-conjugated), and that the test is faster than an indirect ELISA test. Indirect ELISAs have the advantage that the second antibody has an amplifying effect, thus rendering these more sensitive than direct ELISAs. Eventually, the choice of procedure will depend on whether the aim of the test is a field diagnosis or a definitive epidemiological study. The type and quality of plastic affects binding of the coating antibody and thus the sensitivity and reproducibility of the whole assay. Gamma-irradiated polystyrene appears to give the best results, and it is no longer necessary to avoid using the outside row of wells of microtiter plates that was not economical.

The quality of the coating antibodies is also very important. High-titered hyperimmune antisera are prepared by immunizing rabbits, mice, or guinea pigs that are devoid of antibody to rotavirus with purified virus particles. Immunization of hens followed by extraction of immunoglobulins from the yolks of their eggs, is also efficient. Group A rotavirus-specific monoclonal antibodies, which for general diagnostic purposes must be cross-reactive, offer increased sensitivity and reproducibility. Horseradish peroxidase is the most popular enzyme for antibody conjugates. Peroxidase is inexpensive and easy to conjugate to immunoglobulins. A variety of commercial antiimmunoglobulin conjugates are available and antirotavirus conjugates are available too. A variety of substrates are available: 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), o-phenylene diamine (OPD), and 3,3′,5,5′-tetramethyl benzidine (TMB). If necessary, results can be read visually, but spectrophotometers (ELISA plate readers) provide precise results. Figure 6 shows a diagram illustrating the indirect ELISA protocol for rotavirus antigen detection.

Each series of tests should include known positive and negative samples as controls. To determine cutoff values for rotavirus-positive samples, it is common practice to average a number of negative control optical density (OD) readings and to take the mean plus two or three standard deviations as the cutoff value. This value is then subtracted from test readings. Alternatively, each test reading can be divided by the mean of the negative (N) control OD readings; the sample is considered positive (P) if this P/N ratio greater than or equal to 2. False-positive reactions can occur in rotavirus ELISAs, owing either to particular reagents, rheumatoid factor or similar substances in stools, or the presence of interfering contaminants in environmental samples. To control for this problem, at the coating stage, alternate rows of wells in a microtiter plate can be coated with the usual capture antibody and, ideally, a preimmunization serum from the same animal at the same dilution. Each sample is tested in each row, and samples giving a color reaction in both rows are considered to be false-positives. Most commercially available rotavirus detection test kits are direct immunoassays, and numerous comparisons between commercial ELISA tests, previously published ELISAs and EM (see the section that precedes) have been reported in the literature. One major obstacle faced by environmental virologists is that the virus concentrations in water samples rarely reach the detection level of ELISA. Therefore, concentration of water samples is necessary prior to testing. In addition to detecting rotavirus antigen in fecal, water, soil, or tissue culture-medium samples, ELISA can easily determine the G serotype, P-serotype, or SG of a particular rotavirus strain.

Serotyping. Rotavirus serotyping involves the detection of specific epitopes on VP7 and on VP4. G- and P-serotypes are defined by the reactivity of antibodies to each of the two outer capsid proteins, VP7 and VP4, respectively. With rotavirus strains that are cell culture-adapted and grow well, G-serotyping can be carried out using conventional plaque reduction neutralization assays (PRNAs), or fluorescent focus neutralization assays (FFNAs) (1,2,11). The neutralization titer is taken as the reciprocal of the greatest dilution of antiserum that reduces the fluorescent cell focus count by at least 66% (11). The test can also be applied directly to fecal or environmental (water or soil) samples but there are practical limitations. Successful G serotyping is possible only if the water, soil, or fecal sample has an infectivity titer of at least 10^3

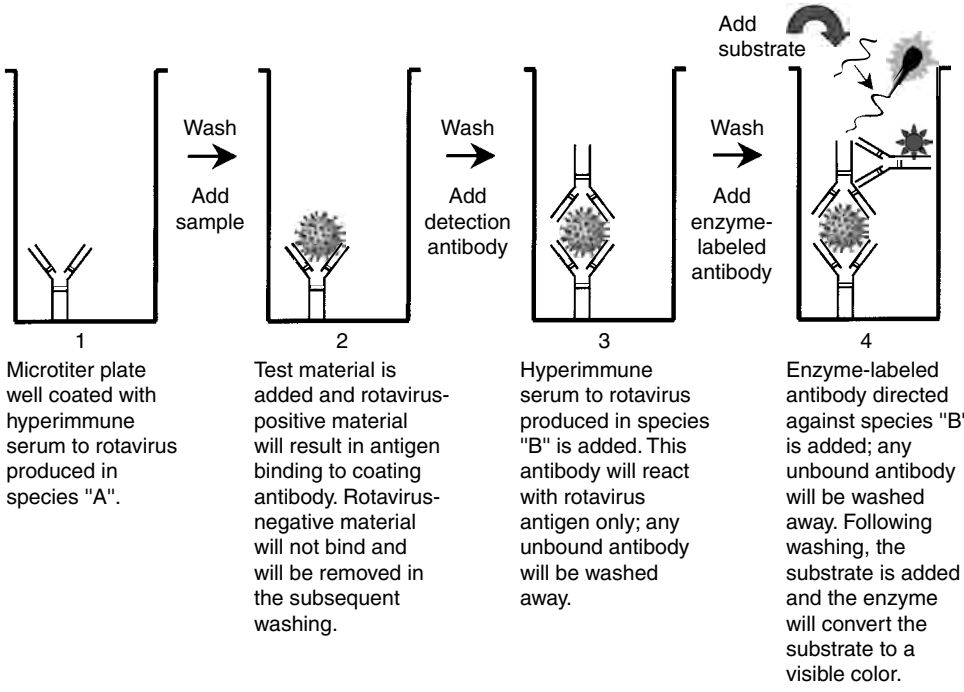

Figure 6. General procedure for indirect ELISA to detect rotavirus antigen.

focus-forming rotavirus units per milliliter. Therefore, water and soil samples must be concentrated prior to testing (6–8). Furthermore, many strains are untypable because of marked cross-reactions with different sera, some of which may be due to shared VP4 types. Twenty-fold homologous/heterologous titer ratios are required for distinguishing rotavirus serotypes with hyperimmune sera. An ELISA procedure for serotyping is the ideal test because of the limitations mentioned earlier regarding application of the PRNA and FFNA to environmental or fecal samples and the amount of work required for cell culture adaptation of human rotaviruses as well as the amount of work involved in the neutralization tests themselves. Currently, MAbs specific for both G- and P-serotypes are available for characterizing rotavirus directly in concentrated environmental or fecal specimens by ELISAs (1,2). However, ELISA is less sensitive than molecular assays (see the text that follows).

MAbs to almost all G serotypes are now available (1). MAbs may be used as coating or detection antibodies because serotype-specific antigens are located on the outer capsid of rotavirus particles, in serotyping ELISAs, EDTA, or EGTA must not be included in the sample diluent because these chelating agents will remove the outer capsid proteins (Fig. 2). Similarly, care must be exercised not to include EDTA or EGTA during the concentration of environmental samples if serotyping information is thought by using ELISAs (1,9). More frequently because of the low concentration of virus in environmental concentrates, epidemiological surveys of rotaviruses in sewage, marine waters, and drinking waters will use molecular assays (see text that follows) to determine the G type of the rotaviruses present in the environmental samples. Approximately 65 to 85% of rotaviruses present in stool samples are typable by G serotyping ELISA. Because of the existence of intraserotypic variation among strains of a particular G serotype, it is important to use a panel of MAbs to different neutralization epitopes to detect all rotavirus strains of a G serotype. For the same reason, if hyperimmune sera are used in the test, they must contain neutralizing antibodies against each of the serotypes to be detected (1,11). In all sample types, the amount of group-specific VP6 greatly exceeds that of VP7, therefore, serotyping ELISAs are never as sensitive as ELISAs to detect the group antigen. Nevertheless, serotyping ELISAs are already a great improvement over the infectivity/neutralization-based assays.

MAbs to VP4 are not yet available for all VP4 serotypes (1,2). VP4 serotype classification is based on neutralization assays using hyperimmune sera raised to reassortant rotavirus strains. Also, many of the MAbs to VP4 are only reactive to a subset of strains within a P-serotype, can cross-react with other P-serotypes, or give high background readings. MAbs to VP8* are better immunological reagents for P-serotyping than those directed to VP5* the other proteolytic cleavage product of VP4 (1). ELISAs to determine the P-serotype of a rotavirus strain requires the presence of intact infectious TLPs. It is likely that the spike protein VP4 may be lost during the procedures used to concentrate viruses from environmental samples. This may explain why P-serotyping of rotaviruses present in environmental samples has not been performed although P-genotyping (see below) has been employed (32).

Subgrouping. Rotavirus subgrouping detects specific antigenic epitopes expressed on the major inner capsid protein VP6 that are distinct from shared common (group A) epitopes. SG-specific MAbs are available, and ELISAs similar to that described above for antigen detection are the method of choice for subgrouping (1,2). Some MAbs can be used for coating plates, whereas others function better as detection antibodies. Polyclonal group-specific antibodies are used as the other part of the sandwich. Fecal or concentrated environmental (water or soil) samples are tested in parallel in assays involving SG I and SG II MAbs, results are read by spectrophotometer, and the ratio of reactivities is determined. The minimum ELISA ratio required for SG assignment will depend on the antibodies employed and has to be determined by testing a number of rotaviruses of known subgroup, but it is usually about two-fold. Rotavirus SG typing is not routinely performed in epidemiological studies, and much less in environmental samples, but when performed, it can provide interesting information about the distribution of antigenic combinations on rotavirus strains circulating at any given time.

Molecular Assays

The advent of molecular assays, that are sensitive and do not require cultivation of rotaviruses for their detection, is facilitating molecular epidemiological studies of rotaviruses. It is important to stress that although very sensitive, molecular assays do not detect infectious rotavirus particles (40). The presence or detection of the rotavirus genome or particular genes does not prove the virus is infectious (although it is potentially infectious).

Polyacrylamide Gel Electrophoresis (PAGE). Analysis of the dsRNA segments of rotaviruses by PAGE results in characteristic migration patterns of the 11 genome segments (Fig. 3). These patterns (or electropherotypes), which are easily recognized and reproducible for individual strains, cannot be directly correlated with serotype, but electropherotyping provides a rapid discrimination between rotavirus strains in an epidemiological study (1,2,10,13,14,16). This technique is not sensitive enough to be applied to environmental samples unless the samples are concentrated; therefore, its use is limited and is not recommended to detect rotavirus in environmental samples.

RNA Hybridization. RNA hybridization was first applied at a research level for investigating the sequence relatedness of genome segments among various rotaviruses, using electrophoresis and Northern blotting (40,41,44–45). For diagnostic purposes, the most interest is currently being taken in dot (or spot) hybridization assays ("dot blots") in which heat-denatured viral nucleic acid is immobilized on a solid support (nitrocellulose membrane) and probed with labeled complementary RNA or DNA. For general rotavirus detection, probes based on

genome segments encoding nonstructural proteins are the most useful because these generally show maximal sequence homology between strains. Although the specificity of rotavirus detection by RNA hybridization is good, the sensitivity is similar to that of electropherotyping with silver staining, EM, and ELISA. In a comparative study of ELISA and dot hybridization for the detection of rotavirus in various dilutions of fecal specimens, the dot hybridization method was 10- to 100-fold more sensitive than the ELISA (40,45). The applicability of this technique to detect rotaviruses in environmental samples depends on sample concentration and it is not used as routinely as it could be, but the assay can easily be modified for field assays.

The nucleic acid in rotavirus concentrated from large volumes of environmental samples can be detected using rotavirus-specific cDNA or mRNA probes. These probes are radiolabeled or labeled with nonradioactively with biotin. The nucleic acid extracted from each test sample is denatured and immobilized on filters, and the hybridization reaction is performed in sealed plastic bags containing filters and the probe in a solution that promotes association of complementary sequences. The plastic bags are floated in a water bath during the hybridization step, and after washing, the filters are exposed to X-ray films (if detected using radioactivity) or developed with streptoavidin (if detected using biotin) (40,45). Usually, a minimum of 10^5 particles can be detected using these assays.

G- or P-genotypes can be determined by hybridization with single gene substitution (VP7 or VP4) reassortants used as probes, or hybridization with oligonucleotide probes prepared from the VP7 or VP4 sequence of prototype rotaviruses of different G- or P- serotypes. However, among the molecular assays used to detect and classify rotaviruses, oligoprobe hybridization requires additional expertise. Although not widely used, this technique has successfully detected rotaviruses present in various types of water samples and shellfish.

Reverse Transcription-Polymerase Chain Reaction (RT-PCR). The rotavirus dsRNA genome can also be extracted from stool or concentrated environmental specimens and can be used for group-specific RT-PCR (32,33,44). This technique makes use of the PCR basic methodology by first extracting the dsRNA genome of rotavirus. After the dsRNA is extracted, it is used as a template in a reverse transcriptase-mediated PCR. The reaction mixture that contains the necessary buffer, dimethyl sulfoxide (to separate the strands of dsRNA), proper amount of deoxynucleoside triphosphates, and primers corresponding to both the 5′ and 3′ ends of the gene to be amplified, is heated at 95 °C for five minutes. Usually, RT from avian myeloblastosis virus is used initially to make the cDNA (for one hour at 42 °C) to be amplified for 40 cycles of denaturation, annealing, and extension using *Taq I* polymerase. RT-PCR assays are the most sensitive detection methods currently available for detection of rotavirus. Because nonspecific amplicons that are the same approximate size as virus-specific amplicons may be generated from clinical and environmental samples, a confirmatory test (dot or Southern blotting) must be performed following the RT-PCR reaction. The use of RT-PCR allows G- or P-genotyping of rotavirus-positive specimens (32,33).

The biggest challenge in the processing of environmental samples is the elimination of interfering substances (inhibitors) that may decrease the sensitivity of the assay or inhibit detection of rotavirus in rotavirus-positive samples. Therefore, the use of appropriate internal RNA standards as controls is essential to properly perform the assays. The addition of low concentrations of an internal standard RNA control allows the detection of inhibitory substances without compromising the sensitivity of the RT-PCR assay, and permits the identification of false negative results. The internal standard has the advantage of allowing differential detection between wild-type viral RNA and standard using internal oligoprobe hybridization. Although not yet widely used, this powerful technique has been used for the detection of rotaviruses in treated and untreated sewage, fresh and marine waters, and shellfish. The applicability of RT-PCR may permit the acquisition of clear and important epidemiological data on the predominant rotavirus G- or P-types in the environment and provide information on the occurrence of asymptomatic rotavirus infections in the community. Significant progress toward diminishing the possibility of waterborne rotavirus infections could be achieved by establishing correlations between the prevalence of certain rotavirus P- and G-genotypes in the environment and the incidence of the different serotypes/genotypes causing clinical infections.

Since RT-PCR is extremely sensitive, careful laboratory and experimental design must be upheld to avoid false-positive results that can be obtained due to laboratory and sample contamination. To avoid carryover contamination, it is important to physically separate the pre- and post-PCR working areas, and use separate reagents and equipment for pre-PCR sample processing. This problem cannot be overemphasized enough and all assays must contain several controls to monitor for possible contamination.

G Genotyping. RT-PCR of the cognate gene segment coding for VP7 (RNA segment 7, 8, or 9, depending on the strain) is used to detect and classify (G serotype) group A rotaviruses since G genotypes are conserved among strains of the same G genotype. In brief, G genotyping involves the amplification of fragments of the gene encoding VP7 using oligonucleotide primers complementary to the 5′- and 3′-ends of the variable regions that are very distinct between different G-serotypes, but highly conserved within each G-serotype. The determination of the G-genotype by PCR can be performed directly from the cDNA obtained after random priming-RT, either as a single round PCR or as a seminested PCR (32,33). In the nested PCR, the first round amplifies the whole length of the VP7 gene and the second round is a reaction that includes oligonucleotide primers that are specific for a certain G-serotype and a primer common to all G-serotypes. RT-seminested PCR generally is chosen for its specificity and sensitivity in detecting a low viral load in environmental or fecal samples. Highly

contaminated waters do not require virus concentration, and the inhibitors present in sewage extracts can be eliminated by nucleic acid purification onto granular cellulose — a purification technique also used successfully for detection of rotavirus in shellfish. G genotyping by RT-PCR have been employed to detect rotaviruses present in sewage and drinking water. Interestingly, amino acid sequences of a region of VP7 that predicts G serotype identified rotavirus strains of human, bovine or porcine origin in drinking water obtained from homes in France. These results question the efficiency of some drinking water treatments to remove rotaviruses. In addition, the detection of the rotaviruses in drinking water might be correlated with the occurrence of rotavirus infections in children from the same homes. The presence of viral sequences of animal origin in water intended for human consumption leads to the question of whether such water may transmit animal rotaviruses (32,33). Although not proven, animal rotaviruses in drinking water could participate in the occurrence of reassortant viruses in humans or interspecies transmission of rotaviruses from animals to humans.

P Genotyping. As for G-genotype determination, RT-PCR can be performed for P-genotyping using oligonucleotide primers complementary to the variable regions in the gene segment 4 (encoding VP4) that are highly conserved within each P serotype but distinct among different P-genotypes (32,33). Also, P-genotyping can be performed as a single-round PCR or as a seminested PCR. In the seminested PCR, the first-round consensus oligonucleotide primers amplify a fragment of the genome segment 4 common to all P-types. The second round PCR includes the 3′-end consensus primer and different oligonucleotide primers complementary to variable regions that are specific for each P-type.

Immunomagnetic Capture (IMC) Reverse Transcription-Polymerase Chain Reaction (RT-PCR). The use of immunomagnetic capture (IMC) RT-PCR (IMC/RT-PCR) has been used for concentration of rotaviruses from clinical and environmental samples (46,47). In this type of assay, paramagnetic beads are coupled to MAbs against the group A-specific inner capsid VP6 protein and used to "capture" and purify rotaviruses present in water samples. Following capture, the dsRNA genome is made available for RT by disrupting the particles with heat. Potential inhibitory substances are removed effectively from freshwater but not seawater; samples and rotaviruses are concentrated into a small volume during a single step (47). A single or nested PCR is capable of detecting low amounts of rotaviruses. This assay is rapid, specific for group A rotaviruses, and displays increased sensitivity over ELISA methods alone. IMC/RT-PCR is capable of detecting 0.005 PFU (approximately five particles as indicated by EM) in a sample provided the amplicon is less than 200 bp (47).

Restriction Fragment Length Polymorphism (RFLP). Rapid comparison of a large number of rotavirus isolates and establishment of relationships between some restriction sites on particular rotavirus genes can be made by RFLP (33). Presence of rotavirus is first detected in fecal or environmental samples (raw sewage or treated effluent) by RT-PCR to confirm rotavirus contamination, and then the viral sequences detected can be further analyzed genetically by RFLP. RFLP is extremely convenient for strain differentiation and classification of bacteria and DNA viruses (mostly adenoviruses), and has been used for further characterization of the VP7 gene and the G-serotype or species of origin of rotavirus strains rotavirus strains present in stool or environmental samples. The amplified cDNA copies of the rotavirus genes are digested with selected endonucleases (restriction enzymes). Differentiation and classification of rotavirus strains depends on the fact that small differences in DNA sequence can alter restriction-enzyme cutting patterns. A single base pair difference in a particular gene position, for example, may eliminate a restriction-enzyme cutting site, giving rise to a large difference in the lengths of certain restriction fragments produced from the DNA at that position. The small differences of the digested DNA fragments between different rotavirus strains are known as RFLP. RFLP is a fast and relatively inexpensive method to detect rotavirus strain diversity in the environment. The identity of the RFLP profiles can be used to establish a correlation between rotavirus contamination in water samples and the viral sequences obtained from clinical samples (33). Therefore, this technique is useful for studying epidemiological relationships between strains involved in human infections and those in rotavirus-contaminated waters. Because more than one rotavirus strain can be found in contaminated raw sewage and treated effluents, several RFLP are not unexpected. In one study in France, the RFLP profiles obtained from raw sewage and treated effluents were compared with those obtained from human rotavirus isolates involved in infections in children from the same area (33). Identical sequences were detected in both environmental and clinical samples suggesting that rotavirus contamination of environmental samples may be significant enough to warrant public health consideration. Also, this study revealed that the diversity of RFLP profiles was greater during the winter and spring months correlating with the seasonal variations in rotavirus infections (33). Combination of RT-PCR and RFLP provides a novel approach to compare the presence of rotaviruses in environmental samples for molecular epidemiological studies. In addition, direct sequencing of amplicons can identify rotaviruses of specific molecular characteristics.

CONCLUSION

In developing and developed countries, rotavirus diarrhea is the leading cause of diarrhea-associated deaths and hospitalizations of young children, respectively. In temperate regions, institutional outbreaks of the disease occur mainly in cold dry weather, whereas in tropical settings, the seasonality is less well defined. Transmission is by the oral-fecal route. Rotaviruses belong to the *Reoviridae* family, are segmented dsRNA viruses, they exhibit antigenic and genetic variability,

and can cause mixed infections. These nonenveloped viruses are resistant to the outside environment such as waters and soils that can serve as reservoirs for the spread of rotaviruses in the environment. Rotaviruses are found in several surface waters, groundwater, sewage and its effluents, shellfish, and soils. Sewage treatment methods are not efficient to eliminate rotaviruses and these viruses are able to persist and are discharged into fresh and marine environments with treated effluents. Rotaviruses are relatively resistant to commonly used hard-surface disinfectants and hygienic hand-washing agents. Many of the methods for rotavirus detection and quantification are time-consuming and labor-intensive. Molecular assays such as gene probes and RT-PCR methods detect rotavirus, but they cannot determine if the viruses are infectious and, therefore, whether they pose a definite risk to exposed individuals. RT-PCR-based methods for rotavirus genotyping have proven to be a useful tool for epidemiological investigations. The advent of new detection methods to identify rotavirus contamination of environmental samples should enable epidemiologists to demonstrate if rotaviruses circulating in environmental water or soil samples at any given time can be responsible, at least in part, for outbreaks of rotavirus diseases in some communities. Further optimization of molecular assays and their commercial availability and worldwide implementation is needed. In the future, use of microarrays to detect and genotype rotavirus in environmental samples will enable fast and comprehensive identification of rotavirus waterborne outbreaks. A better understanding of modes of transmission will be needed to properly direct public health policy about the significance of detection of genome sequences in environmental samples. Rotavirus outbreaks need to be linked to rotavirus-contaminated environmental samples, and existing surveillance systems need improvement. Efforts should focus on establishing a database or an electronic reporting network to exchange information regarding outbreaks that is to be made available to both epidemiologists and environmentalists so that comparison of clinical and environmental samples and geographic distribution of human and animal rotavirus strains can be known. The routine use of standardized techniques to detect rotaviruses in environmental water samples could identify seasonal variability, risk periods, virus strain variability, and possible sources of rotavirus outbreaks. Water is a precious resource and further work is required to build a strong scientific understanding of the importance of monitoring water quality and keeping this resource safe.

SALINITY EFFECTS ON THE PHYSIOLOGY OF SOIL MICROORGANISMS

Daniel Le Rudulier
Karine Mandon
Laurence Dupont
Jean Charles Trinchant
Université de Nice–Sophia Antipolis
Nice, France

The surface layer of the earth supporting plant life, the soil, is the product of two processes: the decomposition of rock and the decay of plant and animal life. Soils are solid matrices permeated to some degree by aqueous solutions and gaseous components. Materials existing in a solid state, soil minerals, and organic matter constitute the soil proper. The liquid and gaseous components, that is, water and air, in the interstices between the soil materials fluctuate continually and frequently with conditions independent of the soil itself. In addition, the organic fraction varies widely but seldom exceeds five percent by weight, except in soils formed mainly from plant remains. The soil compartment is dynamic and, usually, shows intense biological activity, chiefly in the soil zone influenced by plant roots, the rhizosphere. However, the extent and the properties of the soil microorganism population are permanently affected by various soil parameters such as temperature, pressure capillarity of soil matrix, pH, availability and the nature of its mineral composition (calcium, phosphorus, . . .) or organic requirement, presence of toxic metals (aluminum, cadmium, mercury, . . .), salinity and water content. Large variations in these parameters depend on the weather perturbations, the modifications of physical and chemical soil properties, the metabolic activities of microorganisms and plant roots, as well as human activities. Soil moisture is often the chief limiting factor for crop production and enormous efforts are made to increase and conserve the supply of available water. The moisture content of soils represents the balance between additions and removals of water. The main source of soil water, natural precipitations, is supplemented in certain areas by irrigation and by water brought up from deeper soil layers by capillarity. However, the latter process is generally too slow to be of real significance in supplying the water needs of plants. Removal of water from soils result from evaporation at the soil surface, transpiration from plants, percolation downward due to gravity, and surface runoff, which decreases the potential supply of soil water. Consequently, soil moisture shows marked differences in its movement and availability to microorganisms and plants.

Besides drought, salinity is a major problem in arid and semiarid areas, and nearly 40% of the world's land surface can be categorized as having potential salinity problems (1). The current estimates of the agricultural land affected by salt range from 400 to 950 million ha (2). Saline soils are those soils that contain less absorbed or exchangeable sodium and those that are high in nonalkaline salts such as sodium chloride and sodium sulfate. Another type of saline soils are those that contain enough salts such as sodium chloride to maintain flocculation and repress hydrolysis of the clay portion of the soil, which is itself the insoluble salt of a strong base and a weak acid. The soil habitat is inherently heterogeneous, and it can be expected that a wide range of salinities might be present in any one saline soil (3). Saline soils appear to harbor mostly halotolerant rather than halophilic microorganisms, presumably reflecting adaptation to periodic episodes of relatively high dilution (4). In addition to naturally occurring in soils, an excess of salts can also derive from intensive irrigation. In regions of low rainfall, salts accumulate where drainage is poor and are derived from percolating moisture insufficient to wash out soluble salts added in the irrigation water. Many irrigation projects have failed because of salinization caused by lack of proper drainage facilities or failure to use enough water to move excess salts down or out of the soil profile.

In the presence of excess salts in the soil solution, that portion of the soil in which the microorganisms and the plant roots obtain nutrients, the uptake of water by living cells is limited and yields are strongly reduced. Although definite limits cannot be set for the amount of soluble salts required to reduce the yield of plants, less than 0.2% of salts in a soil is usually harmless to agricultural salt-tolerant crops, such as sugar beets, alfalfa, cotton, tomatoes, and barley. However, such values or lower percentages are harmful for less tolerant plants including beans, peas, soybeans, vetchs, and oats. In the case of microorganisms, the range of salt concentration allowing growth in saline soils vary from 0.5% NaCl to almost 20%, reflecting the heterogeneity of this environment. It should be emphasized that the salinity of the soil from which the microorganisms are isolated does not correlate with the salt concentration, allowing growth of these organisms in vitro (5). The salt most dominant in soils are not only the carbonates, chlorides and sulfates of sodium but also of magnesium and calcium, or mixtures of two or more of these salts. However, salinity mainly refers to an excess of sodium chloride.

In this entry, the focus is mainly on the physiological responses of soil bacteria to increased salinity. The mechanisms that have been developed by soil bacteria to survive and proliferate in saline environments, and the molecular characteristics of various systems involved in these responses are covered.

SOIL MICROBIOLOGY AND STRESS CONDITIONS

Soil Microorganisms

As mentioned previously, it is obvious that the soil is not an inert material and one gram of soil may contain billions of living microorganisms. The organic

matter that is already present in the soil, and that being constantly added by higher plants, animals, and microorganisms, provides carbon and energy for soil microorganisms. In general, highly productive soils contain an abundance of microorganisms, whereas less productive soils support small populations. Although these facts do not prove that soils are productive because of their high microbial populations, or vice versa, there is much experimental evidence showing that microorganisms contribute to the productivity of soils through their various activities. Evidently, one of these activities is the decomposition of organic matter added to the soil through the use of green manures, animal manures, crop residues, and microorganisms. Among other activities associated with microorganisms in the soil, their contribution to cycles of matter is particularly important, both quantitatively and qualitatively. For example, certain steps in the nitrogen cycle (ammonification, nitrification, denitrification, nitrogen fixation) are exclusively carried out by microorganisms.

The soil microorganisms that have received the most attention are bacteria, including actinomycetes, algae, fungi, and protozoa. In fact, soil algae and protozoa occur in relatively small numbers in soils when compared with bacteria. Their numbers have been estimated at 2.7×10^4 and 1×10^3 per gram of soil for algae and protozoa, respectively, in comparison with 5.3×10^7 and 1×10^5 per gram of soil for bacteria and fungi, respectively (6). Fungi exist in soils in many different forms (microscopic or macroscopic), and their numbers and kinds depend on moisture, temperature, composition of the soil, and amount of organic matter present (see "SOIL FUNGI: NATURE'S NUTRITIONAL NETWORK," this Encyclopedia). Some fungi are capable of living in association with higher plants, particularly trees, forming the mycorhiza, which benefit the host plant by increasing the capacity of the roots to absorb nutrients. Within the soil, the size of the population of fungi is greatly enriched (12-fold) in the rhizosphere, but a much more dramatic effect (23-fold increase) is observed on the bacterial population (6). Clearly, the rhizosphere soil is a zone of intense microbial activity not only for symbiotic bacteria (rhizobia) but also for free-living bacteria. The importance of organic exudates from plant roots as an energy substrate for microbial colonization has long been known. Roots exudates are complex mixtures of many compounds that vary with plant species, plant age, and environmental conditions. However, they are not simply building blocks for microbial cells or common growth cofactors, which can be used by nearly all microorganisms. In fact, some root exudates can be degraded only by some, but not other, soil bacteria and are considered as nutritional mediators, which contribute to specificity in the rhizosphere (7).

Usually, the predominant bacteria found in the rhizosphere of most plants are gram-negative nonsporulating cells, which include the symbiotic rhizobia (*Rhizobium*, *Bradyrhizobium*, *Sinorhizobium*, *Mesorhizobium*, *Allorhizobium*, and *Azorhizobium*), the associative bacteria (*Azospirillum*), the free-living bacteria (*Pseudomonas*, *Azotobacter*, *Xanthomonas*, *Erwinia*), and the plant pathogen (*Agrobacterium*). On the contrary, the populations of gram-positive soil bacteria are typically higher in bulk soil than in the rhizosphere, with the exception of some *Bacillus*, such as *B. polymyxa*, *B. megaterium*, *B. circulans*, and *B. brevis* (8). Because the effects of salinity have been examined only in a small number of soil genera, the section on the molecular aspects of bacteria adaptation to salinity will focus mainly on rhizobia (*Sinorhizobium meliloti*) as models for rhizosphere bacteria, and on *B. subtilis* as model for bacteria from the bulk soil. As pointed out previously, microorganisms can be subjected to salinity problems within the soil ecosystem, and increasing salt concentrations may have a detrimental effect on soil microbial populations as a result of direct toxicity, and through osmotic stress. Bacteria have developed mechanisms for adaptation to high osmolarity to survive and proliferate in saline soils or rhizospheres. A brief overview of the osmolarity and osmotic pressure of the soil is provided here, and the next section examines the osmoadaptative mechanisms in soil bacteria. Effects of osmotic stress on soil fungi has received little attention so far.

General Features of Soil Osmolality and Osmotic Pressure

Water is an essential component of the soil system, and soil water is intimately involved in controlling physical parameters of the soil (temperature, aeration, ...). Water with its dissolved salts constitutes the soil solution. A typical soil has an osmolality (= osmotic pressure of a solution expressed as moles of solute per kilogram of solvent or osmolal) estimated at less than 50 milliOsm/kg of water (9). This osmolality is equivalent to the solute concentration that would yield its osmotic pressure, and for a particular solute depends on the degree of its dissociation in water. Instead of being measured with osmometers, osmotic pressures are often approximated by calculated osmolarities as the sum of the concentrations of osmotically active solutes in the solution (expressed as moles of solute per liter of solutions or osmolar). The osmotic pressure is directly related to the water activity (a_w), which is simply the thermodynamic activity of the solvent water, and represents an index of the amount of water that is free to react. More definitions about these parameters have been discussed in some previous reviews on bacterial osmoregulation (8,10,11) and desiccation tolerance (12). In the presence of an excess of sodium chloride, the soil solution has a high solute content, which contributes simultaneously to both osmolality and ionic strength. In addition, Na^+ and Cl^- may also have an ion-specific effect on bacterial physiology. Such a soil solution restricts the movement of water through the bacterial membrane, and results in decrease in the water available to the bacteria. Because biological membranes are permeable to water but not to most other metabolites, the decrease in the external water causes an instantaneous efflux of water along the osmotic gradient. This process results in a partial dehydration of the cytoplasm and a decrease in the cytoplasmic water activity, and consequently leads to a decrease in the cytoplasmic volume, a phenomenon known as plasmolysis (Fig. 1). Ultimately, such plasmolysis affects metabolic

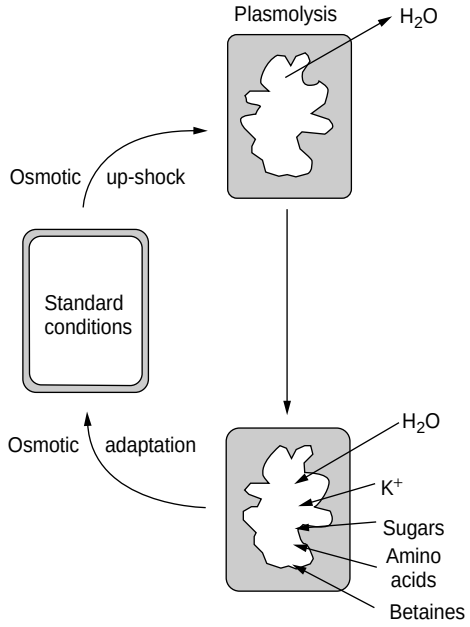

Figure 1. Scenarios following osmotic upshock and osmotic adaptation. When exposed to increased salt concentration, bacteria will primarily experience plasmolysis followed by osmotic adjustment because of accumulation of compatible solutes via uptake or biosynthesis.

systems and functions of cytoplasmic macromolecules and results in the cessation of growth.

Microbial Strategies for Adaptation to High Osmolality

To survive and proliferate in environments of high salinity, cells must respond by modulating their cytoplasmic osmolality, and as a result of intracellular osmotic adjustment, the initial cytoplasmic volume is restored (Fig. 1). The turgor pressure, which is the hydrostatic pressure exerted by the cytoplasmic membrane on the peptidoglycan, is also restored. This mechanical force is critical for the expansion of the cell wall during growth. Turgor pressures have been estimated in bacteria and are much higher in gram-positive bacteria (15 to 20 atmospheres) than in gram-negative bacteria (0.8 to 5 atmospheres) (13).

To deal with environments of increased salinity, bacteria have evolved two different strategies: (*1*) the intracellular accumulation of inorganic ions such as K^+; the most conspicuous representatives of bacteria adopting this strategy (salt in cytoplasm) are extremely halophilic *Archaea* (*Halobacteriales*), which will not be considered here, (*2*) the accumulation of selected organic molecules, the so-called compatible solutes; this response to osmotic stress (salt-out or organic-osmolyte type) is prevalent not only in *Bacteria* and *Archea* but also in fungi, plants, and animals (14,15)

COMPATIBLE SOLUTES AND OSMOPROTECTANTS

Properties and Mechanism of Action

Compatible solutes can be accumulated to high levels (several moles per liter) in the cytoplasm of stressed cells by de novo synthesis or transport without interfering with vital cellular processes. In many bacteria, most compatible solutes are metabolic dead-end molecules not subjected to catabolism or incorporation into macromolecules. In general, compatible solutes are polar, highly soluble molecules, and they usually do not carry a net electrical charge at physiological pH. Because of their accumulation, the water activity of the cytoplasm is reduced, and thus, cell volume and turgor can be restored (Fig. 1). As a result, an important stimulation of the growth rate of the cell is observed. Some of these solutes that alleviate the inhibitory effect of increased osmotic stress on microorganisms when they are added to the growth medium are also called osmoprotectants. A typical example is given in Figure 2: addition of low concentration of glycine betaine (1 mM) in a medium of high osmotic pressure restores the growth of *Sinorhizobium meliloti* which is inhibited by an excess of NaCl (14). In addition to growth, the presence of intracellular glycine betaine also stimulates specific enzyme activity such as nitrogenase. For instance, nitrogen fixation by the soil bacterium *Azospirillum brasilense* is totally inhibited by the presence of 0.3 M NaCl, and glycine betaine greatly stimulates this activity (Fig. 3), whereas this compound does not affect the same activity in cells grown in minimal medium (16).

Although there is generally a good correlation between intracellular accumulation of the supplied osmoprotectant

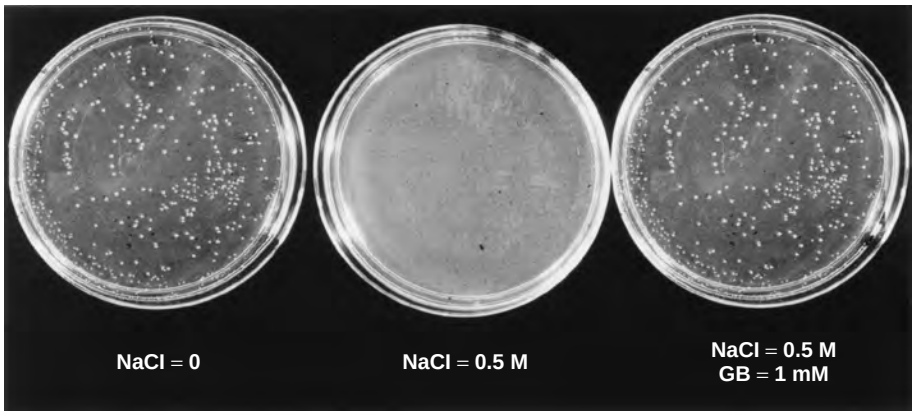

Figure 2. Glycine betaine as an osmoprotectant for *S. meliloti*. The presence of glycine betaine (GB) in a medium containing inhibitory level of salt (NaCl 0.5 M) allows normal bacterial growth as in the absence of salt (NaCl 0).

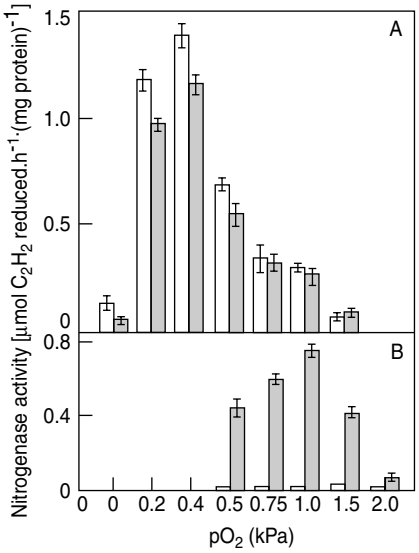

Figure 3. Stimulation of specific nitrogenase activity of whole cells of *A. brasilense* sp7 by glycine betaine. Cells are grown in the absence of salt (a) or in the presence of 0.3 M NaCl (b) without glycine betaine (open bars) or with glycine betaine (shaded bars). Nitrogenase activity is measured as acetylene reduction at various pO_2 (16).

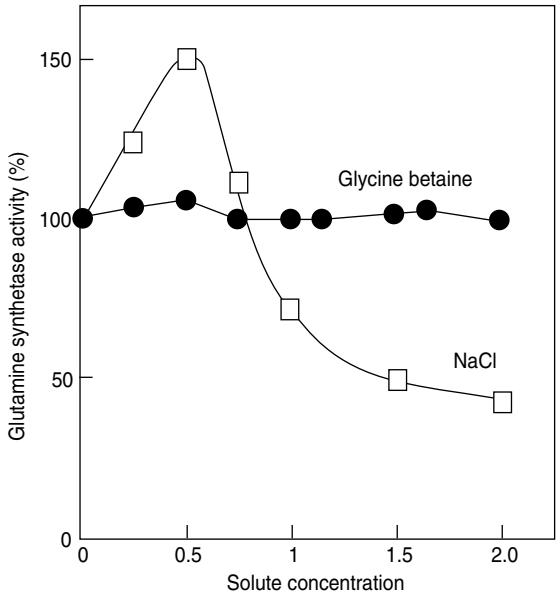

Figure 4. Glycine betaine as a compatible solute preventing protein denaturation. Specific glutamine synthetase activity is measured in vitro in the presence of increased NaCl or glycine betaine concentrations. Taken from S. R. C. Warr, R. H. Reed, and W. D. P. Stewart, J. Gen. Microbiol. 130, 2,169–2,175 (1984) with permission.

and growth restoration under osmotic stress conditions, this does not hold true for a few compounds such as ectoine and sucrose, at least in the case of *S. meliloti*. None of these compounds are accumulated by this bacterium, whereas both improve the growth at high osmolality (17,18). However, it is noteworthy that ectoine, for example, is accumulated in the halophilic bacteria, *Ectothiorhodospira halochloris* (19).

In addition to the obvious predominant role compatible solutes play in cellular osmotic adjustment, some of them serve as stabilizers of proteins and cellular components against the denaturing effects of high osmotic strength. The first suggestion of such property was made by Schobert (20), who had proposed that the aliphatic portion of the proline ring binds to the nonpolar residues on protein via hydrophobic interactions. Such an interaction would result in coating the protein with a hydrophilic shell that would enhance its solubility. In fact, the protective and stabilizing effects of compatible solutes on in vitro protein denaturation have been reported (21), and is illustrated in Figure 4. In this example, glutamine synthetase activity is strongly inhibited by increased concentrations of NaCl, whereas glycine betaine, even at 2 M, is totally compatible with full enzyme activity. Recently, it was demonstrated that glycine betaine plays an important role in the behavior of cellular macromolecules, and may actively assist in vivo protein folding in a chaperone-manner (22). Compatible solutes also display a general stabilizing effect by preventing the denaturation of proteins also caused by heating, freezing, and drying (23).

Spectrum of Compatible Solutes

Theoretically, a vast number of compounds could serve the function of osmotic balancing agents. However, an organism may use only a few compounds to fill this need. Figure 5 presents the structure of the main compatible solutes used by soil bacteria and Table 1 shows a list of soil bacteria together with the compatible solutes used by each bacteria. It should be noted that two major techniques, high-performance liquid chromatography (HPLC) and natural abundance ^{13}C-nuclear magnetic resonance spectroscopy (NMR), have been used to characterize these compounds, and to demonstrate their accumulation in cells. The prominent compatible solutes or osmoprotectants found in soil bacteria are potassium ions, few amino acids (glutamate, proline), sugars (trehalose, sucrose, and mannosucrose), polyols (glucosylglycerol and mannitol), quaternary ammonium compounds (glycine betaine, proline betaine, carnitine, γ-butyrobetaine, crotonobetaine, choline-*O*-sulfate), sulfonium compounds (dimethylsulfoniopropionate, DMSP, and dimethylsulfonioacetate, DMSA), ectoine, and a small peptide (N-acetylglutaminylglutamine amide, NAGGN).

Two important points should be emphasized:

1. Under salt-stress conditions, a given bacterium can accumulate a selection of several compatible solutes, and the importance and the composition of its compatible solute pool can vary in response to growth phase and growth conditions such as salt concentration in the medium. For example, in *S. meliloti* cells subjected to moderate salt stress (0.15 M NaCl) and growing in the absence of osmoprotectant, only biosynthetic accumulation of glutamate is detected (Fig. 6). As the NaCl concentration is increased, the presence of NAGGN (35) is also observed, but at a lower concentration than glutamate. At the highest

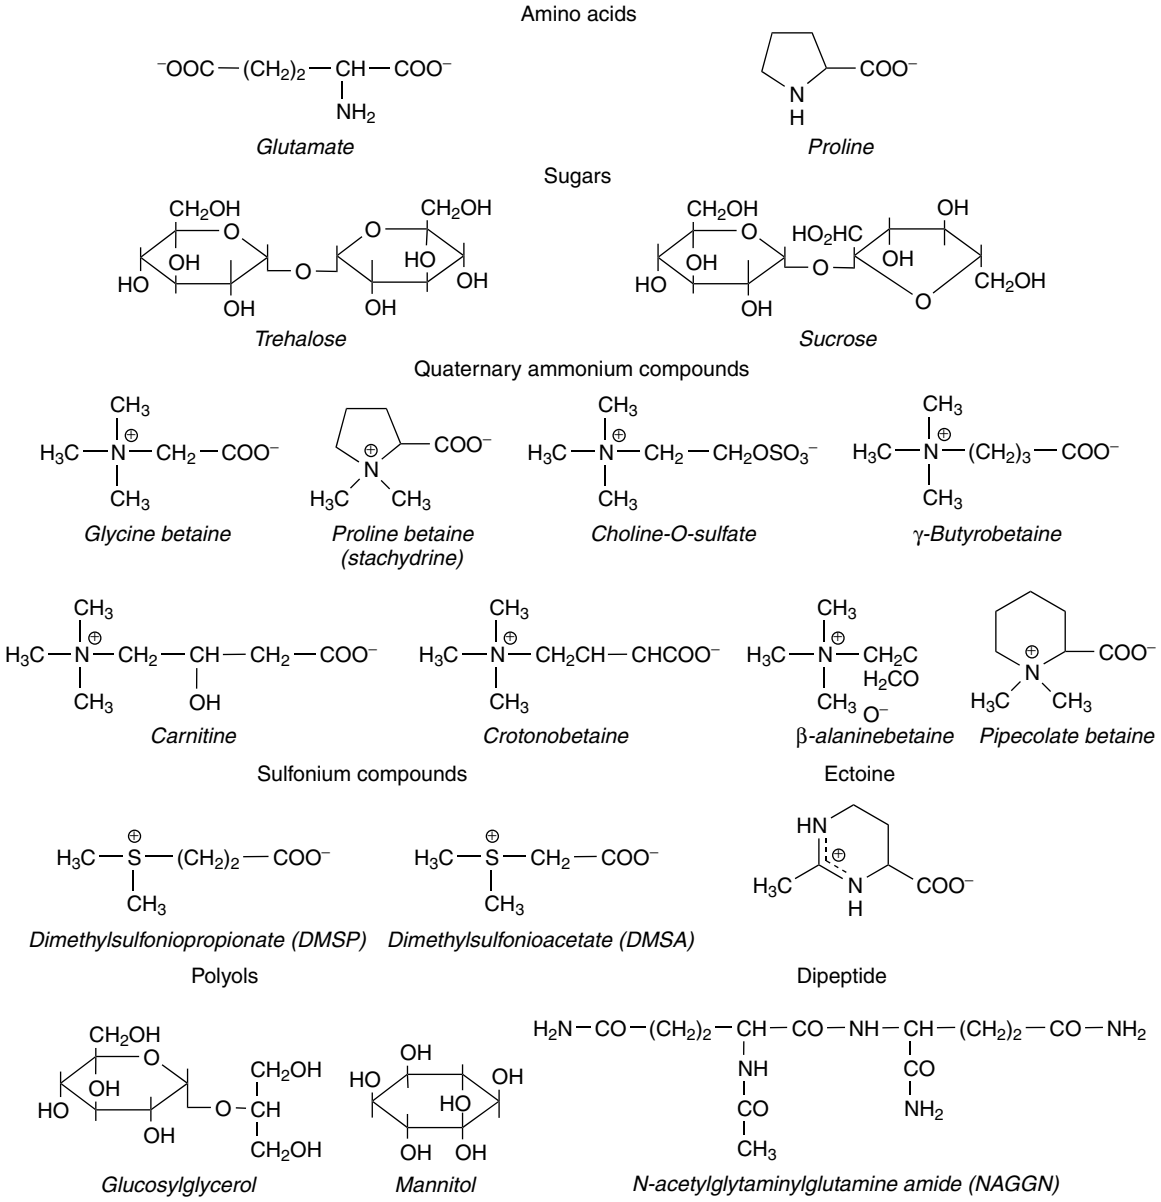

Figure 5. Compatible solutes and osmoprotectants in soil bacteria.

salt concentration tested (0.6 M NaCl), the glutamate level falls, whereas that of NAGGN continues to rise, so that NAGGN dominates the spectrum, and a third osmolyte, trehalose is detected (29). Thus, each of these osmolytes is elicited at a characteristic osmotic threshold. In the presence of an exogenous osmoprotectant such as glycine betaine, the buildup of the previous osmolytes (glutamate, NAGGN, and trehalose) is suppressed, and high cytoplasmic levels of glycine betaine are accumulated through the action of osmoregulatory transporters. Such shifts in osmolyte preference from de novo biosynthetic osmolytes to exogenous osmoprotectants can be related to the energy cost in terms of the number of ATP molecules required for both mechanisms, biosynthesis or uptake. The bioenergetic aspects of osmotic adaptation to high salt concentration have been the subject of a recent review (46).

2. A hierarchy exists among the compatible solutes, not all of them are equal. Potassium and glutamate inhibit many enzymes at high concentrations, and they serve to regulate the cytoplasmic osmolality only at relatively low external osmolality. At high salt concentration, the cells preferentially accumulate neutral compatible solutes, and one of the most commonly encountered is glycine betaine, which can be accumulated at very high concentration, 1 or 2 M. The advantage of being able to accumulate "cocktails" of compatible solutes is obvious, and the regulation of the synthesis or the uptake of each of the solutes is optimized according to the external conditions and the needs of the cells.

Table 1. Solutes Used by Soil Bacteria Subjected to Salinity

Compatible Solutes	Bacteria	Reference

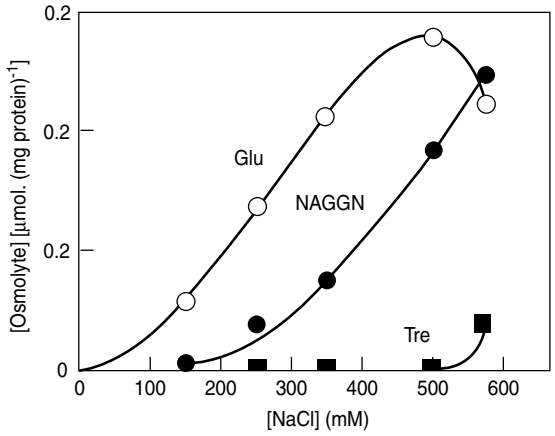

Figure 6. Intracellular compatible-solute composition of *S. meliloti* as a function of NaCl concentration in the growth medium. Cells were grown in the absence of exogenous osmoprotectant and accumulate glutamate (Glu), N-acetylglutaminylglutamine amide (NAGGN), and trehalose (Tre). Taken from L. T. Smith et al., J. Exp. Zool. 268, 162–165 (1994) with permission.

Phases of Osmotic Adjustment

The mechanisms by which bacteria sense osmotic variations, osmosensory mechanisms, are still poorly defined. As defined recently by J. M. Wood (11), "an osmosensor is a device that detects changes in extracellular water activity (direct osmosensing) or the resulting changes in cell structure (indirect osmosensing)." There is already good evidence that osmosensors are mainly integral cytoplasmic membrane proteins, which may detect and control a temporal cascade of cellular changes and osmoregulatory responses. Because a detailed overview of osmosensing based mainly on the intensively studied enteric bacteria has been proposed very recently by Poolman and Glaasker (47), Wood (11), and Csonka and Epstein (48), only a brief illustration of the timescales of well coordinated physiological responses to elevated osmolality is presented here (Fig. 7). The prime signal is turgor pressure, which either directly or probably through its effects on membrane proteins or on protein-lipid interactions, controls the movement of potassium. Thus, the primary response to an osmotic upshock is a massive uptake of K^+, such as observed in the enteric bacteria, mediated by the Kdp and Trk transport systems. This response is considered to occur within milliseconds to minutes of the osmotic shift. To maintain electroneutrality of the cytoplasm, the glutamate pool is increased by de novo synthesis, but other processes such as putrescine and proton efflux may also contribute. It has been proposed that K^+, and its counterion glutamate, act as a second messenger, which can inform the cytoplasm about the external osmolality (48). Although this concept presents a unified explanation of the responses of osmotic regulation, it may be difficult to test. The second phase, which may occur shortly after the osmotic upshock, is characterized by the accumulation of compatible solutes, allowing displacement of K^+ and counterions through specific and nonspecific efflux systems. In the absence of exogenous osmoprotectants, such accumulation depends on full expression of enzymes involved in biosynthetic pathways of various compatible solutes (proline, glycine betaine, trehalose, NAGGN, ...), whereas in the presence of osmoprotectants, this accumulation is mediated by direct uptake as a consequence of induction of genes encoding specific transporters.

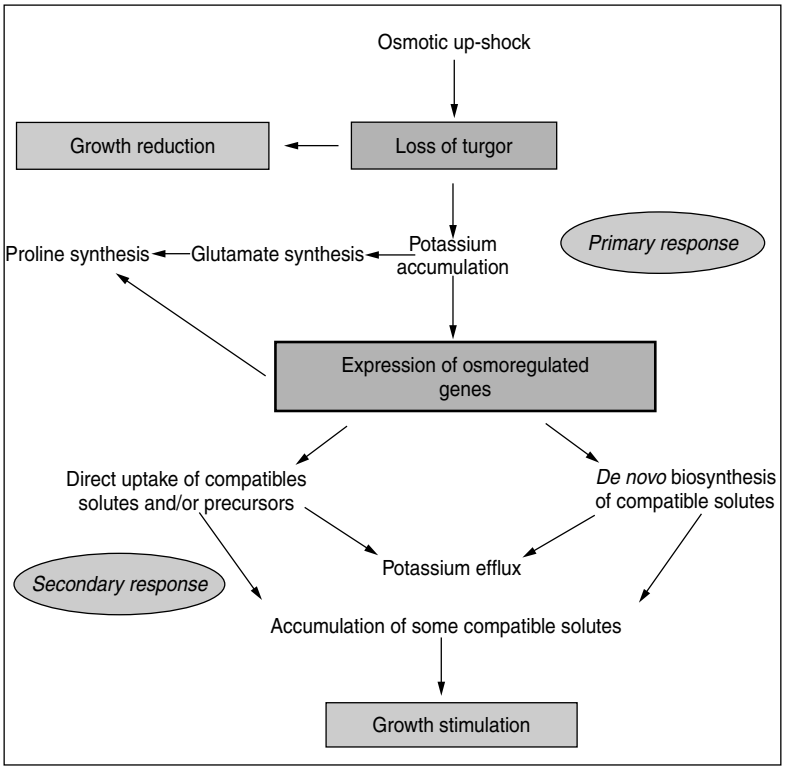

Figure 7. Phases of osmotic stress responses in bacteria.

Besides increased salt concentration, rain, and flooding/irrigation in soil subject bacteria to osmotic downshocks, which invoke a substantial remodeling of the cells. These changes include alterations in membrane and/or periplasmic protein composition, lipid composition, periplasmic glucan levels, and extracellular or capsular polysaccharide biosynthesis (8). In addition, the increase in turgor, produced by downshocks, and because of sudden water influx, requires the cell to rapidly reduce its pool of compatible solutes. Because most of these compatible solutes are metabolically inert in the majority of soil bacteria, and thus cannot be degraded, efflux systems should respond to high turgor. In severe downshock, mechanosensitive channels play a primary role in massive compatible solute expulsion; however, in smaller increases in turgor, specific export systems allow moderate rates of efflux (31,48).

Accumulation Versus Nonaccumulation

The concept of durable compatible solute accumulation within the cells exposed to osmotic upshock was established on the basis of studies of enteric bacteria, along with other gram-negative bacteria and several gram-positive bacteria. However, it is not entirely applicable to the symbiotic soil bacterium, *S. meliloti*, which has the capability to catabolize most of the osmoprotectants known to date, including glycine betaine, proline betaine, and ectoine. When this bacterium is subjected to salt stress both betaines are accumulated at high concentrations. This is not the case for ectoine, which is however, very protective against osmotic stress (17). When cells are grown under high-osmolarity conditions (0.5 M NaCl), in the presence of ectoine, this compound is not accumulated and its intracellular concentration remains too low (12 mM) to make any significant contribution to cell osmotic equilibrium. Ectoine, unlike glycine betaine, does not repress the synthesis of endogenous compatible solutes such as glutamate, NAGGN, and trehalose. Moreover, the intracellular glutamate level is strongly increased during the growth of the cells, and glutamate itself is very significantly involved in the osmotic balance restoration. Thus, it was proposed that ectoine may belong to a new class of nonaccumulated osmoprotectants, which act as chemical mediators (17). It is also noteworthy that ectoine is also capable of protecting other rhizobia insensitive to glycine betaine. Sucrose also acts as a powerful osmoprotectant for *S. meliloti* without being accumulated by osmotically stressed cells (18). On the contrary, sucrose is actively catabolized, and, like ectoine, does not suppress the accumulation of the major endogenous compatible solutes, and increases the level of cytosolic glutamate. How sucrose and ectoine stimulate the accumulation of glutamate in stressed cells of *S. meliloti* is not known, but it has been shown that both osmoprotectants do not act as close precursors to glutamate.

As previously mentioned, the accumulation of compatible solutes in soil bacteria cells subjected to increased salinity is dependent either on direct uptake from the soil solution (or the rhizosphere) or on biosynthesis, either de novo synthesis or production via the uptake of a direct precursor. Both mechanisms occur simultaneously in a majority of bacteria. In the following two sections, the focus (*1*) is on salinity tolerance in the gram-positive bacteria, mainly *B. subtilis* as an example of very well studied bulk soil bacteria and (*2*) on osmoprotection in the gram-negative bacteria, chiefly *S. meliloti* a typical representative of the rhizosphere and the microsymbiont of alfalfa root nodules. The biosynthesis and catabolism of glycine betaine have been examined in great detail in this bacterium. During the last decade, much attention has been focused on the molecular mechanisms of osmotic adaptation in these two soil bacteria.

SALINITY TOLERANCE IN GRAM-POSITIVE SOIL BACTERIA

Bacillus subtilis, A Typical Bulk Soil Bacterium

In addition to de novo biosynthesis of compatible solutes, most bacteria have developed transport systems used to acquire osmoprotectants. These compounds are naturally found in various soils because of natural decay of microbial, plant and animal cells, and also in the rhizosphere because of root exudates. However, these compounds are always present at very low concentrations. Thus, bacteria have evolved uptake systems with very high affinities (K_m values in the micromolar range), to allow the accumulation of nanomoles or micromoles of exogenous osmoprotectants to molar concentrations in the intracellular compartment. To deal with soils showing different compatible solute contents, bacteria are able to accumulate a large variety of osmoprotectants or precursors of compatible solutes, either because of a large spectrum of substrates transported by a given transporter or the presence of several highly specific transporters.

Bacterial transporters involved in osmotic regulation belong to two groups, depending on their structural complexity and the driving force used for substrate uptake:

*symports are composed of a single membrane-spanning protein that is highly hydrophobic and transports a substrate together with an ion, either H^+ or Na^+.

*ABC (ATP Binding Cassette) transporters are multicomponent systems, which usually consist of three different proteins: a binding protein located either in the periplasm of gram-negative bacteria or linked by a lipid anchor to the outside face of the cytoplasmic membrane of gram-positive bacteria, a dimeric hydrophobic protein spanning the inner membrane, and a peripheral ATPase (dimeric) located on the cytoplasmic side. Substrate translocation across the cell membrane is dependent on direct ATP hydrolysis.

These two types of osmoregulated uptake systems were first described in the enteric bacteria, *Escherichia coli*, in which a H^+ symport (ProP), and an ABC transporter (ProU) were shown to be involved in the uptake of proline and glycine betaine under hyperosmotic conditions (48,49). In soil bacteria, transporters for osmoprotectants or their precursors have been studied at the molecular level only in *C. glutamicum* (50) and *B. subtilis* (31). Because of the large quantity of available data, *B. subtilis* is chosen here for further description. This bacterium, which is widespread in nature, is a low G-C content, facultative anaerobic endospore forming rod-shaped cell. The

natural habitats of *B. subtilis* are mainly the upper layers of various soils in which frequent fluctuations of water availability lead to large osmolality variations.

Molecular Characteristics of Uptake Systems. After a sudden increase in external osmolality, *B. subtilis* initially responds by a rapid uptake of K^+, followed by de novo synthesis of the compatible solute proline. This primary response contributes to the recovery of turgor and the resumption of bacterial cell growth. When the osmotic constraint remains, *B. subtilis* can accumulate various osmolytes, and develop five elegant osmoprotectant uptake systems (called Opu) for transport of a large variety of osmolytes or their precursors (choline). Single and multicomponent systems used by *B. subtilis* are shown in Figure 8. OpuD and OpuE are symport systems, highly substrate specific, that allow the uptake of the main osmoprotectants, glycine betaine (OpuD) and proline (OpuE) together with Na^+. In contrast, OpuA, OpuB, and OpuC belong to the ABC superfamily of transporters composed of an extracellular substrate-binding lipoprotein anchored to the membrane by the lipid group. When bound to its specific protein, the substrate is delivered to the integral membrane component, either composed of a unique protein for OpuA or two distinct proteins for OpuB, and OpuC. The substrate translocation across the inner membrane depends on direct ATP hydrolysis by associated ATPase present on the cytoplasmic side of the membrane. These transporters share different substrate specificities (Fig. 8). On osmotic shock, the transport of betaines is mainly assumed by the high specific OpuA system (narrow range of substrates) and to a less extent by OpuC (wide range of substrates) and OpuD, which are mostly devoted to glycine betaine uptake. The OpuC system plays an essential role in *B. subtilis* osmoprotection because it is the sole transporter carrying various osmoprotectants, which cannot be taken up by the other Opu systems. This includes ectoine transported with a low affinity, and compounds, such as carnitine, crotonobetaine, γ-butyrobetaine, choline-*O*-sulfate, and proline betaine, transported by a high-affinity system (40,41,44). The OpuA, OpuC, and OpuD transporters also play a major role in the uptake of 2-dimethylsulfonioacetate (DMSA), the sulfonium analog of glycine betaine, and of 3-dimethylsulfoniopropionate (DMSP), a dominant osmolyte in marine algae (43).

Depending on the availability of choline in the soil, *B. subtilis* is also able to synthesize glycine betaine. This synthesis occurs by a two-step reaction that first converts choline into glycine betaine aldehyde using a metal containing type III alcohol dehydrogenase (GbsB). The aldehyde is subsequently converted into glycine betaine by a glycine betaine aldehyde dehydrogenase (GbsA) (37). Like most microorganisms, *B. subtilis* does not synthesize choline that might be exogenously provided. Two different ABC systems allow high-affinity uptake of choline in *B. subtilis*: one is strictly specific for choline uptake (OpuB), whereas the other one (OpuC) is the less specific osmoprotectant transporter. It is noteworthy that, although they exhibit a striking difference in substrate specificity, the OpuA and OpuC proteins share high sequence identity (70 to 85%). As their corresponding genes, organized in operon, are located close to each other on the *B. subtilis* chromosome, it was suggested that these two systems have evolved from a duplication event of a primordial gene cluster (51).

Regulation of Uptake Systems. To allow quick intracellular accumulation of osmoprotectants after an increase in external osmolality, corresponding transporters display both a very high affinity (K_m) for their substrates and a high velocity of uptake (V_{max}) in cells grown at elevated salinity. This is typically the case for OpuA-mediated

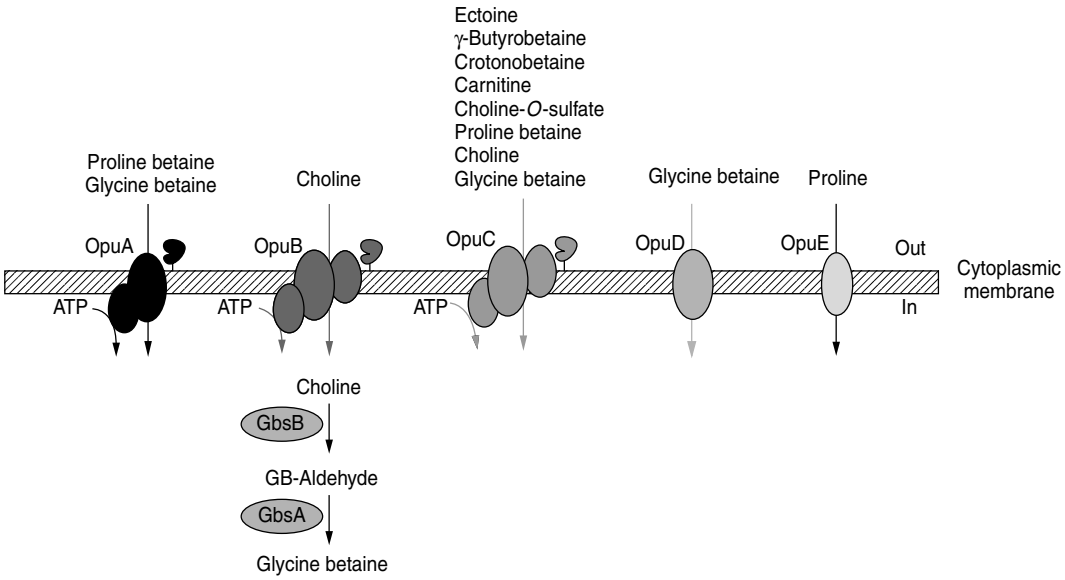

Figure 8. Transport systems involved in response to salt stress in *B. subtilis*. Taken from B. Kempf and E. Bremer, Arch. Microbiol. 170, 319–330 (1998) with permission.

glycine betaine transport in which initial uptake activity for [^{14}C]-glycine betaine is stimulated about fourfold in cells grown at high osmolality compared with control cells (52). The activation of transport depends on the degree of osmotolerance of the microorganisms considered, and the level of compatible solutes accumulated is adjusted on the intensity of the salt stress imposed. Salt stimulation could be due to either allosteric activation of preexisting proteins or to increased expression of transporter genes. It has been shown that, in a high-salt environment, glycine betaine transport through OpuD results from both de novo synthesis and allosteric activation, whose mechanism is still unknown (53). The other Opu transporters are also upregulated at the level of transcription in response to increased salinity. Expression analysis of *opuA* and *opuE* genes show that they are both under the control of two promoters: one strongly induced by salinity, whereas the other is constitutively expressed for *opuA* or transiently stimulated by salt for *opuE*. The nature of the osmosensor that coordinates transcription of these genes remains unclear in *B. subtilis*, as in the well-studied operon *proU* of *E. coli*. In this latter host, it has been suggested that supercoiling of DNA in the promoter region might contribute to the 100-fold induced expression observed in saline stress condition. Depending on the availability of osmoprotectants in the environment, transcription of the osmoregulated genes could also be turned off. For example, salt stimulation of the proline transporter OpuE is strongly reduced when the major osmoprotectant glycine betaine is present in growth medium. This reflects a preference based on the nature of the compatible solute used for osmoprotection.

Efflux of Compatible Solutes. In the soil or rhizosphere, bacteria are also exposed to hypoosmotic shocks mainly caused by rain or irrigation. The consequence is an influx of water into the cell followed by a quick reduction of the intracellular osmolyte pool to avoid a dramatic increase in turgor. In contrast to *S. meliloti*, which can use some osmoprotectants as carbon or nitrogen sources (see Osmoprotection in gram-negative rhizosphere bacteria), *B. subtilis*, like most microorganisms, does not catabolize these compatible solutes. They are instead rapidly released to adjust cell turgor to the new extracellular osmolality. In *E. coli*, it has been shown that the opening of mechanosensitive channels (Msc) allows the efflux of osmolytes in a few seconds. These channels display little ion or solute specificity but are crucial for managing hypoosmotic stress, even if they are not the only means of removing compatible solutes from the cell (see 31 for review). In soil bacteria, none of these channels have yet been characterized at a molecular level.

Other Gram-Positive Bacteria. *Corynebacterium glutamicum*, a soil bacterium used for industrial amino acid production, also accumulates a large variety of osmolytes by uptake from the environment. Compared with *B. subtilis* in which three of the five osmoregulated Opu transporters belong to the ABC superfamily, *C. glutamicum* is equipped with three secondary carriers composed of a single transmembrane protein, which plays a direct role in osmotic adaptation. EctP allows the translocation of ectoine, proline, and glycine betaine, ProP is a proline/ectoine carrier, and BetP is a high-affinity glycine betaine uptake system (50,54). This bacterium uses an additional proline transporter (PutP), but only for anabolic purposes, and not for osmoadaptation (32). As for *B. subtilis*, the capacity to use a large spectrum of compatible solutes may help the bacterium to adapt in soils of different salinities and compositions.

OSMOPROTECTION IN GRAM-NEGATIVE RHIZOSPHERE BACTERIA

Sinorhizobium meliloti, A Nitrogen-Fixing Root Endosymbiont

Betaines are among the most potent osmoprotectants for *S. meliloti*. Glycine betaine can be taken up from the external medium or synthesized from choline and its derivatives, choline-O-sulfate and phosphorylcholine. Proline betaine, which occurs widely in *Medicago* species, is also actively transported but cannot be synthesized by *S. meliloti*.

Transport of Betaine and Precursors. Glycine betaine uptake is strongly stimulated when *S. meliloti* is grown in the presence of NaCl or subjected to an osmotic upshock (36). In the latter case, a high-affinity uptake activity is increased fourfold within one minute, and this activation may involve a constitutively expressed transport system. Obviously, different betaine transport systems are present in this bacterium, but only one has recently been characterized at the molecular level (55). This system (Hut), an ABC-type transporter, is primary involved in histidine uptake, transcriptionally regulated by this amino acid, independently of the osmolality of the medium. However, Hut is also able to transport glycine betaine at low affinity, and proline betaine at high affinity. It seems mainly required for the transport of these three compounds when they are used as carbon or nitrogen sources. Previous studies have suggested that glycine betaine uptake in *S. meliloti* is mediated by a high-affinity system (K_m of 5 μM) probably related to the well-characterized ProU system of *E. coli*. A highly specific glycine betaine binding protein (GBBP) has been identified in periplasmic fractions of *S. meliloti* cells grown in the presence of added NaCl. This protein shows a mass of 32 kDa, similar to the GBBP ProX from *E. coli* (56). This second glycine betaine uptake system might be transcriptionally regulated because the GBBP is barely detectable in periplasmic fractions obtained from cells grown in the absence of NaCl, whereas it is abundant in salt-stressed cells.

High-affinity uptake of proline betaine (K_m of 10 μM) is also strongly stimulated by the addition of NaCl to the growth medium (39). Such uptake is strongly inhibited in the presence of an excess of glycine betaine in the assay, and it is more likely that proline betaine enters into the cells via an osmoregulated glycine betaine transporter. However, the presence of a periplasmic proline betaine binding protein could not be detected and, this betaine does not compete with glycine betaine for binding to the GBBP, even in the presence of a 100-fold excess of proline betaine.

Choline, the precursor of glycine betaine, is also imported from the external medium via high-affinity systems. Three kinetically distinct choline transport activities have been identified in *S. meliloti* (57). Two activities are constitutive, one of low affinity (K_m of 100 μM), and one of high affinity (K_m of 6.5 μM), which is inhibited at high salt concentration, and may be involved in the utilization of choline as carbon and/or nitrogen sources. A third choline transport activity has also high substrate affinity (K_m of 0.4 μM), and is most probably transcriptionally regulated by the substrate. Such a system is believed to play an important role in osmoregulation because it retains full activity under high osmolality. These three systems have not yet been characterized at the molecular level, but one could be an ABC-type transport system. The identification of a choline-binding protein in periplasmic fractions of *S. meliloti* grown under an excess of NaCl in the medium is consistent with this possibility (56).

Biosynthesis of Glycine Betaine. *Sinorhizobium meliloti*, as most microorganisms, is unable to de novo synthesize glycine betaine, and uses a two-step oxidation of choline to produce this compatible solute (58). Moreover, *S. meliloti* displays the unusual capability to transform choline derivatives, choline-*O*-sulfate and phosphorylcholine, into choline (59). Choline is a common constituent of the eukaryotic membranes in the form of phosphatidyl choline, and therefore, is widespread in different environments, including the soil and the rhizosphere. Thus, choline is available for the bacteria and can be taken up. The glycine betaine biosynthetic pathway from choline or its derivatives has been characterized at the molecular level in *S. meliloti*. Four genes, *betICBA*, most probably organized in one operon are involved (59,60). The *betA* and *betB* gene products are implicated in the conversion of choline into glycine betaine, and are well conserved with their homologs BetA and BetB of *E. coli* (60). The first step of choline transformation is performed by a FAD-containing membrane-bound choline dehydrogenase (BetA), which can also oxidize glycine betaine aldehyde (GBA) into glycine betaine. The second enzyme, BetB, is soluble and catalyzes the conversion of the toxic intermediate, GBA, into glycine betaine (Fig. 9). BetB is highly specific and presents a high salt-tolerant activity. Choline-*O*-sulfate and phosphorylcholine are hydrolized into choline via BetC, a choline sulfatase, which does not have any counterpart in *E. coli* (59). In contrast to *E. coli* and *B. subtilis*, *S. meliloti* does not use choline-*O*-sulfate or phosphorylcholine as osmoprotectant per se, because these compounds cannot restore growth of a salt-stressed *betC* mutant. It is tempting to argue that the presence of BetC in *S. meliloti* confers to this bacterium a selective advantage in the rhizosphere, as *S. meliloti* has the unique capacity to use choline-*O*-sulfate as an energy source, whereas *B. subtilis*, for example, can use this compound only to cope effectively with high salinity (40).

The expression of *betA* and *betB* genes is strongly induced by choline or choline-*O*-sulfate, independently of the osmolarity of the medium or of the presence of other carbon and nitrogen sources (61). The transcriptional

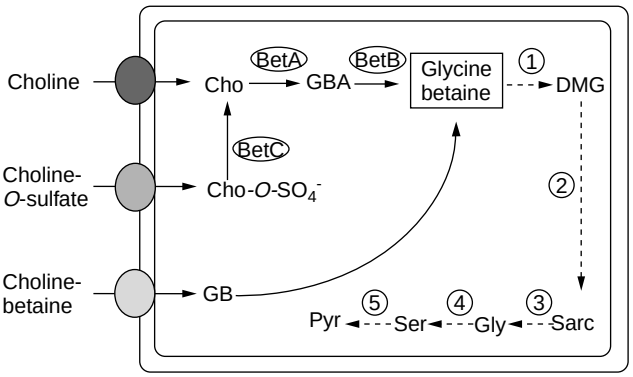

Figure 9. Biosynthetic and catabolic pathways of glycine betaine in *S. meliloti*. Symbols: GB, glycine betaine; Cho-*O*-SO_4, Choline-*O*-sulfate; Cho, choline; GBA, glycine betaine aldehyde; BetC, choline sulfatase; BetA, choline dehydrogenase; BetB, glycine betaine aldehyde dehydrogenase; 1, glycine betaine transmethylase; 2, dimethylglycine dehydrogenase; 3, monomethylglycine dehydrogenase; 4, serine transhydroxymethylase; 5, serine dehydratase.

regulation of the *bet* genes may involve the BetI protein, which displays 33% identity with BetI from *E. coli*; in this bacterium BetI is a repressor of the *bet* genes. Both BetI polypeptides are characterized by a conserved N-terminal region that contains an helice-turn-helice motif involved in binding to their DNA target sequence (62). In addition, the *betA* and *betB* genes are transcribed at all stages of nodule development in *Medicago sativa*, from the initiation of the infection thread to the mature nodule. Such finding is in good agreement with the BADH and CDH activities measured in bacteroids (63). This suggests that choline, and/or its precursor choline-*O*-sulfate, are available for the bacteria during the symbiotic interaction with alfalfa.

Catabolism of Betaines. A remarkable feature of *S. meliloti* is its ability to use glycine betaine and proline betaine as carbon and nitrogen sources when grown under low osmolality medium or following an osmotic downshock (36,58). The catabolism of glycine betaine involves successive demethylations of the quaternary ammonium, which are catalyzed by glycine betaine transmethylase, dimethylglycine dehydrogenase, and monomethylglycine dehydrogenase, before subsequent degradation into serine and pyruvate via a serine transhydroxymethylase and a serine dehydratase (Fig. 9). The specific activities of these enzymes are reduced when cells are grown at high salt concentration, thus permitting cells to maintain accumulated glycine betaine as a compatible solute. However, when the cells are grown in the presence of a high choline concentration (7 mM), glycine betaine degradation is still efficient, even in bacteria cultivated at high salinity (58). Consequently, intracellular glycine betaine levels in stressed cells begin to decrease during the second-half of the exponential phase especially if exogenous glycine betaine is no longer available (64). It should be pointed out that, in natural soils or in the rhizosphere, such high choline concentrations may never occur.

Proline betaine catabolism proceeds through two N-demethylations that generate monomethylproline and

proline, which enters the general metabolism (39). This pathway is also strongly inhibited in salt-stressed cells of *S. meliloti*. Two loci of the *S. meliloti* genome are essential for the degradation of proline betaine. The first locus, located on the symbiotic plasmid to the right of the *nod* regulator *nodD2*, contains four open-reading frames with functional homology to known proteins, including a putative Rieske monooxygenase (Stc2) and a putative NADPH-FMN-reductase (Stc4), which are necessary for the first demethylation of proline betaine (65). These enzymes may form a multienzyme complex that resembles the oxygenase complex involved in xenobiotic degradation in some gram-negative bacteria. Expression of the *stc2* gene is specifically induced by proline betaine, but not by other betaines, monomethylproline, or proline (66). The second locus *stcD*, located on the chromosome, is required for the conversion of monomethylproline to proline. The *stcD* gene encodes a putative demethylase, which belongs to the family of flavoproteins characterized as α/β-barrel oxidoreductase (67). The expression of this gene is also strongly enhanced by the presence of proline betaine in the growth medium. Because mutants incapable of growing on proline betaine as the sole carbon and nitrogen sources are less efficient at forming root nodules on *Medicago*, and less competitive against isogenic wild-type strains, it has been suggested that proline betaine catabolism contributes to rhizobial colonization of alfalfa seedling roots (67).

Others betaines including trigonelline, a secondary plant metabolite, carnitine, or γ-butyrobetaine are used by *S. meliloti* as carbon and nitrogen sources, and may act as osmoprotectants (36). The genetic loci responsible for the catabolism of trigonelline and carnitine, are also located on the symbiotic plasmid (66).

Other Osmoprotectants in *Sinorhizobium meliloti*. As in other bacteria, K^+ and glutamate accumulation are initiated immediately after an osmotic upshock (24). Glutamate synthesis does not implicate de novo protein synthesis. However, neither glutamate synthase (GOGAT) nor glutamate dehydrogenase (GDH) activities appear stimulated by salt. Attempts to show allosteric induction of GDH activity by salt or activation by K^+ have been unsuccessful. It was suggested that transaminases mediate glutamate accumulation during salt stress through the transfer of nitrogen from other amino acids to α-ketoglutarate. In addition, GOGAT activity does not contribute to the excess of glutamate made by *S. meliloti* in response to osmotic stress, because a mutant deficient in GOGAT retains full glutamate production under salt-stress conditions. As already mentioned, at increased salt concentration, *S. meliloti* also synthesize NAGGN and trehalose (Fig. 6).

The sulfonium compound, dimethylsulfoniopropionate (DMSP), acts as another powerful osmoprotectant in *S. meliloti*, whereas dimethylsulfonioacetate (DMSA) and dimethylthioethanol (DMSE) are toxic to stressed and unstressed cells as a consequence of their catabolism (42). In presence of exogenous DMSP, stressed cells accumulate this osmolyte as a dominant cytosolic compatible solute, and produce minor amounts of the other synthesized osmolytes (glutamate, NAGGN, and trehalose). Uptake of DMSP is osmoregulated, and a 2.5-fold stimulation is observed in cells grown at high salt concentration. This uptake is strongly inhibited by glycine betaine and DMSA, which suggests that the three compounds are apparently taken up via the same transporter. In contrast to glycine betaine and DMSA, DMSP is the only nonmetabolizable osmolyte found in *S. meliloti* (42).

The tetrahydropyrimidine ectoine appears almost as effective as glycine betaine in improving the growth of salt-stressed *S. meliloti* cells, although this compound is not accumulated (see section, Accumulation Versus Nonaccumulation). Ectoine transport displays a K_m of 80 μM, is highly specific, inducible by the substrate, periplasmic protein-dependent, and slightly enhanced by salt (17). Endogenous ectoine is catabolized and assimilated as carbon and nitrogen sources through a pathway, which is distinct from that described for glycine betaine.

The last nonaccumulated osmoprotectant identified in *S. meliloti* is sucrose, which is particularly efficient in promoting the recovery of cytoplasmic volume after plasmolysis as a result of high osmolality (18). Under osmotic stress conditions sucrose is catabolized but does not serve as precursor for the main osmolytes (glutamate, NAGGN, and trehalose). The uptake of sucrose is strongly reduced during the lag phase following osmotic upshock, but is progressively restored to the level of unstressed cells when the cultures enter the exponential phase.

Other Gram-Negative Bacteria

Besides *S. meliloti*, the osmoadaptative responses of other rhizobial species have not been thoroughly studied, and most of the studies have been conducted with isolates poorly represented in most culture collections. Recently, the taxonomy of the legume root-nodulating bacteria has undergone major revision and improvements, and still is in a state of transition. Based largely on sequencing of the 16S and 23S rRNAgenes, six genera have been recognized: *Rhizobium*, *Mesorhizobium*, *Sinorhizobium*, *Azorhizobium*, *Allorhizobium*, and *Bradyrhizobium* (68). Although bacteria of the genus *Bradyrhizobium* are more salt sensitive than other genera, marked variations in salt tolerance are observed among rhizobia. A number of strains of *B. japonicum* are growth inhibited by NaCl concentration lower than 100 mM, whereas growth of various strains of *S. meliloti* and *R. leguminosarum* still occurs at salt concentrations of more than 300 mM (69). Rhizobia isolated from woody legumes also show substantial salt tolerance: strains from nodules of *Hedysarum*, *Acacia*, *Prosopis*, and *Leucaena* plants can tolerate up to 500 to 800 mM NaCl (70). Nevertheless, many species of rhizobia adapt to saline conditions by the intracellular accumulation of compatible solutes. Thus, when grown in media of elevated osmotic strength or immediately after an osmotic upshock, a variety of rhizobia accumulate potassium via uptake (25,26), and glutamate via biosynthesis (29). Until now, K^+ transporters have not been characterized at a molecular level in rhizobia.

As in *S. meliloti*, exogenous supplies of glycine betaine and choline, enhance the growth of various rhizobia (*Rhizobium tropici*, *S. fredii*, *Rhizobium galegae*, *Mesorhizobium loti*, and *Mesorhizobium huakuii*)

subjected to salt stress (69). However, both compounds are inefficient for very salt-sensitive strains, such as *R. leguminosarum*, *Rhizobium etli*, and *B. japonicum*. Except for *B. japonicum*, all tested strains exhibit transport activity for glycine betaine and choline. Nevertheless, the main physiological role of both compounds in the family *Rhizobiaceae* seems to be as an energy source through catabolism, whereas their contribution to osmoprotection is restricted to certain strains. Because the capacity to use glycine betaine as a growth substrate has been reported only in a few soil species, including *Azospirillum lipoferum*, (71) and *P. aeruginosa* (72), it is tempting to speculate that the ability to catabolize glycine betaine could increase competitiveness of the rhizobia in the rhizosphere (69). Trehalose is also accumulated by various rhizobia (Table 1) grown in media of high salinity, whereas proline is not. This amino acid does not play a role in osmoregulation in rhizobia, and in contrast, is actively catabolized through the *putA* gene product (73). Ectoine, also improves the growth of *B. japonicum* and *R. leguminosarum* bv *viciae* and bv *trifolii* in high-salt medium (17) without being accumulated, and sucrose has a similar effect on *R. leguminosarum* bv *phaseoli* (18).

All the previous compatible solutes already mentioned in rhizobia have been observed in several other gram-negative bacteria (Table 1) including *A. chroococcum* (27), *A. tumefaciens* (28), various *Pseudomonas* (19,30,38,45), *A. brasilense*, and *A. halopraeferens* (16,27,45).

The other compatible solutes not yet examined here are represented by the polyols, which are accumulated in *Pseudomonas*, and the mannosucrose identified in *A. tumefaciens* (Table 1). In response to salt stress, *P. mendocina* accumulates O-α-D-glucopyranosyl-α-(1 $\rightarrow$ 2)-glycerol, also called glucosylglycerol (30). The intracellular concentration of this osmolyte increases with the quantity of NaCl in the growth medium, and its accumulation relies on de novo biosynthesis. Such a compound is not detected in rhizobia, and previous to that study, the pivotal role of glucosylglycerol in osmoadaptation had been shown only in photosynthetic bacteria. Another pseudomonad, *P. putida*, accumulates mannitol as a compatible solute (45) when subjected to osmotic stress induced by ionic and nonionic compounds. Accumulation of mannitol is a typical feature of salt-stressed *P. putida* strains, as this polyol is not detected in *P. aeruginosa*, *Pseudomonas cepacia*, and *P. fluorescens*. The mannosucrose (β-fructofuranosyl-α-mannopyranoside) has been identified as the major osmolyte in salt-tolerant strains of *A. tumefaciens* (28). The mannosucrose accumulation, which depends on biosynthesis, is osmoregulated and not observed in less tolerant biotypes. In the case of *A. tumefaciens*, as in the case of *P. putida*, addition of glycine betaine to the growth medium results in accumulation of the betaine with parallel depletion of mannosucrose and mannitol, respectively. This finding is in accordance with results already mentioned for other bacteria. Glycine betaine, when available, seems to be a better compatible solute than others because it reaches higher levels than does the sum of those solutes it displaces. In addition, the uptake of glycine betaine is probably less energy consuming than de novo synthesis of mannosucrose or mannitol.

PHYSIOLOGICAL EFFECTS OF SALINITY ON RHIZOBIUM-LEGUME SYMBIOSIS

Within the soil, a wide range of bacteria have the ability to fix nitrogen, that is, convert the stable nitrogen gas in the atmosphere into ammonia, via the aid of an enzyme complex, nitrogenase which catalyzes the following reaction:

$$N_2 + 8H^+ + 8e^- + 16\ ATP \rightarrow 2\ NH_3 + H_2 + 16ADP + 16Pi$$

The nitrogenase is expressed in free-living diazotrophs soil bacteria, such as *Azotobacter*, *Clostridium*, or *Azospirillum*, and in bacteroids, which are the symbiotic form of rhizobia. These rhizobia elicit on the roots or in some cases on the stems of their legume hosts, the formation of specialized organs called nodules. These nodules constitute an ecological niche in which the necessary conditions for the reduction of atmospheric nitrogen are provided, particularly concerning oxygen and energy availability for bacteroids. In infected cells of nodules, that is, cells invaded by the microsymbiont, free dissolved oxygen is supplied to bacteroids at very low concentrations (5 to 40 nM) by the presence of large amounts (3 mM in soybean nodules) of leghemoglobin. This hemoprotein binds free oxygen and avoids complete inactivation of the nitrogenase, which is extremely sensitive to oxygen. Inside nodules, bacteroids are surrounded by a peribacteroid membrane (PBM) of plant origin that effectively segregates the bacteroids from the plant cytoplasm, which contains leghemoglobin, and determines the type and quantity of compounds that are transferred between the two partners of the symbiotic association. Therefore, rhizobia are totally dependent on their plant hosts for nutrients and oxygen when living within the nodule. The organelle-like structure consisting of bacteroids, the peribacteroid space (PBS) and the PBM (Fig. 10) is referred to as the symbiosome (74). Although the principal exchanges between the symbiotic partners are reduced carbon from the plant host to the bacteroid and ammonia from the bacteroid to the plant, other important exchanges also occur (75).

Soil salinity is one of the major factors limiting legume production, particularly in arid and semiarid regions. Increasing salt concentrations in the soil affect the *Rhizobium*-legume symbiosis by osmotic stress (drought) and nonosmotic effects (toxicity and ion imbalance). This symbiosis and nodule formation on legumes are more sensitive to salt or osmotic stress than are the free-living bacteria (76). Both salinity and drought inhibit the expansion and curling of root hairs, the proportion of root hairs containing infection threads, and reduce the number and the size of nodules on *Vicia faba* roots (77). The inhibitory effect of salinity on soybean nodulation has been attributed to a decrease in rhizobial colonization, and a shrinkage of root hairs (78). When salt stress is applied to mature nodulated soybean, nitrogen fixation, determined by the reduction of acetylene into ethylene, rapidly decreased. This inhibition has been attributed to a direct effect on nitrogenase, or an indirect effect through decreases in leghemoglobin content, bacteroid respiration

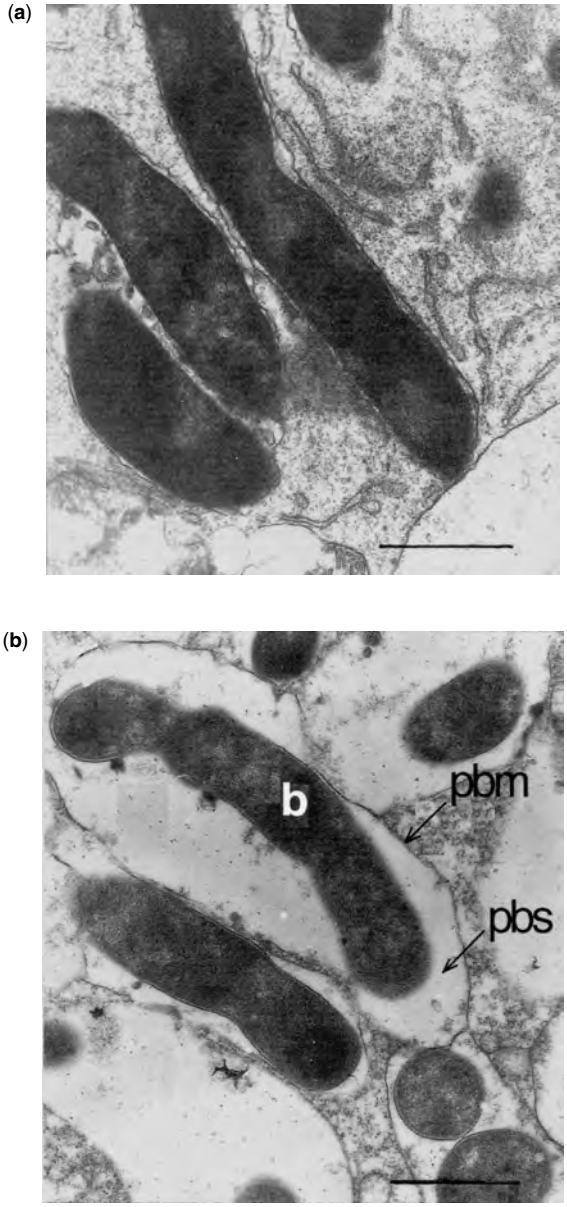

Figure 10. Electron micrographs of the nitrogen-fixing zone of a five-weeks-old alfalfa nodule. (**a**) control plants not subjected to salt stress; (**b**) plants submitted to 0.1 M NaCl during two weeks. Bars indicate 1 μm. Symbols: b, bacteroid; pbm, peribacteroid membrane; pbs, peribacteroid space.

rate, and malate concentration in nodules (79). Under salt-stress conditions, changes in structure occur in the nodule cortex, particularly a decrease in the surface of the inner cortex cells in parallel with the occlusion of intracellular spaces by glycoproteins (80). Consequently, the oxygen diffusion resistance in the nodule increases, and thus limits bacteroid respiration and energy production, which is crucial for nitrogenase activity. Such inhibition can be partly restored by increasing the partial oxygen pressure around nodulated roots from 20 to 60 kPa. Moreover, these structural changes also induced ions exclusion (Na^+ and Cl^-) from the central zone of the nodule, possibly through a K^+/Na^+ interchange within the cortex, especially in legumes known to be tolerant to salinity (81).

Exogenous glycine betaine application partially restores nitrogen fixation of salt-stressed alfalfa seedlings nodulated by *S. meliloti* (82). This betaine is rapidly taken up, and slowly translocated to the shoots. In unstressed plants, glycine betaine catabolism is extremely slow in shoots, but significant in roots, and even more important in nodules. Under salt stress, the rate of glycine betaine catabolism is significantly reduced, mainly in nodules. Experiments conducted with bacteroids isolated from alfalfa nodules demonstrate that the microsymbiont is able to actively take up glycine betaine, choline, and proline betaine (83). Moreover, these transport activities are stimulated in the presence of salt, and choline, which did not appear as an osmolyte per se for bacteroids. Free-living cells of *S. meliloti* further metabolized choline into glycine betaine, following the pathway described previously (63). Because the plant host has the capacity to produce choline and proline betaine, these compounds are probably available for the bacteroids during symbiosis. All these results are consistent with the in planta expression of *betA* and *betB* gene already mentioned (see section Biosynthesis of Glycine Betaine).

Besides quaternary ammonium compounds, the accumulation of various amino acids, particularly proline, is also a general response of plants to environmental stress. In legume nodules, proline is the most widely distributed osmolyte accumulated under salt stress (84,85). Proline is partly responsible for the osmotic adjustment in the nitrogen-fixing zone of nodules after its accumulation inside symbiosomes. As a consequence, the PBS volume increases two- to threefold (Fig. 10). In *V. faba*, an amide-producing legume, this accumulation results both in a passive diffusion through the PBM, and the very low rate of uptake by bacteroids. Thus, proline is not used as an energy-yielding substrate for fababean bacteroids, but may play a role in osmotic stress adaptation (85). The situation seems different in ureide-exporting nodules like soybean, in which nitrogen fixation by bacteroids isolated from stressed nodules could be enhanced by eight fold when exogenous proline is provided. In this case, proline catabolism may supply a significant fraction of the energy requirement for nitrogen fixation (86). In addition to proline, asparagine concentration is greatly increased in salt-stressed alfalfa nodules, whereas the level of other amino acids is very limited. Among carbohydrates, pinitol concentration is significantly enhanced, especially in bacteroids, and pinitol may contribute to the tolerance to salt stress. However, trehalose concentration remains low in salt-stressed nodules, and its role in osmoregulation appears unlikely in alfalfa (84).

CONCLUSION

The ability of soil bacteria to adapt to increased salinity is essential for their survival and proliferation. Clearly, the main physiological response to salinity is the accumulation of compatible solutes. Such accumulation depends either on de novo synthesis or uptake of osmoprotectants. However, the utilization of exogenous

osmoprotectants is preferred over biosynthesis of endogenous compounds, when available in the environment. The prominent compatible solutes used by soil bacteria are potassium ions, a few amino acids (glutamate and proline), sugars (trehalose, sucrose, and mannosucrose), polyols (glucosylglycerol and mannitol), quaternary ammonium compounds (glycine betaine and other betaines), sulfonium compounds (dimethylsulfoniopropionate and dimethylsulfonioacetate), ectoine, and a small peptide (N-acetylglutaminylglutamine amide). In most soil bacteria, glycine betaine is the preferred compatible solute and generally provides the highest level of salt stress tolerance.

The remarkable property of compatible solutes to overcome the inhibitory effects of salinity is the result of a dual function. These compounds are accumulated in the cytoplasm of the cells up to molar concentrations without affecting the physiological function of the living cell. Thus, they are used to restore and maintain cell turgor in media of high osmolality, a key condition for cell growth. Compatible solutes also have special interactions with proteins and serve as stabilizers, protecting proteins from denaturation at high ionic strength. Although it has been proposed recently that glycine betaine, for example, may actively assist in vivo protein folding in a chaperone manner (22), the protective property of compatible solutes on proteins is not fully understood.

The mechanisms by which soil bacteria sense osmotic variations in the environment are still poorly defined. However, it is more likely that the molecular mechanisms of osmosensing will vary among various osmoprotectant uptake systems, and full characterization of these mechanisms remains an exciting unknown area in the field of osmotic regulation. Studying this largely unexplored basic scientific area will provide a better insight not only into physiological, biochemical, and genetic mechanisms used in nature to maintain a functional cell under osmotic stress conditions but may also be exploited for biotechnological and agricultural purposes. Protection of enzymes against denaturation processes (heat, freezing, drying and inactivation) with compatible solutes has been already observed many times, and it is reasonable to assume that this protective effect has a wide range of potential applications in bio- and enzyme technology. On another line, there is currently a need to develop salt- and drought-tolerant plants, because increases in the salinity of soils or in water used for irrigation result in decreased productivity of most crop plants. Construction of salt-resistant plants carrying bacterial genes, which encode enzymes for the synthesis of glycine betaine, has been already employed with success (87). Henceforward, the metabolic engineering of biosynthetic pathways for osmoprotective compounds into agronomically important crop plants is a promising approach to enhance salinity tolerance in those plants.

TAXONOMIC POSITION OF *SALMONELLA*

Salmonella are facultatively anaerobic gram-negative straight rods, usually motile by means of peritrichous

flagella, included in the family *Enterobacteriaceae* (1). According to Bergey's Manual the genus includes two species, *S. bongori,* containing less than 10 extremely rare serovars or types, and *S. choleraesuis*, embracing more than 2,500 serovars, although the number of serovars continues to increase (1,2). The latter species is divided, on the basis of phenotypic and genetic characters, into six subspecies: *arizonae*, *choleraesuis*, *diarizonae*, *houtenae*, *indica*, and *salamae*. Serological studies of these organisms have resulted in the establishment of an identification procedure known as the Kauffmann-White scheme (3). This system arranges the organisms into serovars, on the basis of the nature and combinations of cell surface and flagellar antigens, and the organisms are designated by numbers and letters given to different O, Vi, or H antigens (3,4).

The names given to the salmonellae do not follow the usual rules of nomenclature for bacteria. The organisms were originally named by indicating the disease and the animal from which the organisms were isolated. Some of these names continue to be used, such as *S. choleraesuis* and *S. typhimurium*. More recently, this type of nomenclature has been abandoned because the older names imply a more limited pathogenicity than it is actually found. Currently, names are assigned indicating the city, state, or even the country where the organism was first isolated (e.g., *S. london*, *S. montevideo*, *S. panama*). It has been recommended that diagnostic laboratories report their isolates as named *Salmonella* serovars or, in the case of unnamed serovars, by their antigenic formulae and subspecies. Examples include *Salmonella typhi* or *Salmonella* serovar *typhi*; *Salmonella choleraesuis* subsp. *salamae* serovar 56:z_{10}:e,n,x (this antigenic formula represents the O antigens: the phase 1 H antigens and the phase 2 H antigens, respectively) (3,5). The taxonomy of the genus is under discussion because some authors consider that the genus should be formed by four species, *S. typhimurium*, *S. enteritidis*, *S. choleraesuis* (including six subspecies) and *S. bongori*, whereas others propose a reduction of the genus to a single neotype species *S. enterica* (6,7).

THE ROLE OF *SALMONELLA* IN HUMAN INFECTION

Members of the genus *Salmonella* are major international food-borne pathogens, approximately 30,000 cases being reported each year in the United Kingdom (8), and estimated cases in the United States range between 800,000 and four million each year, with approximately 500 fatalities (9). There are several reviews on the control of food-borne outbreaks of *Salmonella* and their prevention (4,10–12). Three major types of clinical symptomatology can be recognized: acute gastroenteritis, septicemia, and typhoid fever. Salmonellosis, or salmonella gastroenteritis is a widespread infection that often begins with a sudden headache, abdominal distress, diarrhea, nausea, and sometimes vomiting (4). Usually, the disease is self-limited, with recovery in a couple of days, although it can persist for a couple of weeks or more (12). Dehydration can occasionally be life threatening, particularly in very young or elderly people. Antibiotic treatment is necessary in less than 2% of clinical cases (13). Although the infection may initially be only a gastroenteritis, on occasions it may progress to an enteric fever that manifests itself as a systemic infection (4,12). Transient bacteremia occurs in less than 5% of adults presenting gastroenteritis, but at a somewhat higher rate in children and immunocompromised patients (10,14). AIDS patients are 19.2 times more likely to develop salmonellosis than others. The serotypes commonly isolated in these patients are *S. typhimurium*, *S. dublin*, *S. newport* and *S. enteritidis* (10). Salmonellosis is primarily acquired through the consumption of raw or undercooked contaminated food of animal origin (mainly meat, poultry, eggs, and milk). *Salmonella* are among the bacteria that are most commonly known to produce travellers' diarrhea (15,16). An important preventive measure in hot tropical climates is the avoidance of raw salads, food, and drink that are cold or have been cooled with ice cubes (16). The fecal-oral route principally spreads infection produced by *Salmonella*, either from animal to animal or animal to human. Although in developed countries human to human transmission is uncommon, it can occur in special care units and residential homes for the elderly (13). The incidence of salmonellosis has increased 20-fold over the last 10 to 15 years in some countries in Europe, with *S. enteritidis* and *S. typhimurium* being the most common serotypes (13). However, there is a possibility that this increase is merely due to the improvements related to detection and reporting. It is alarming that since the early 1990s, the presence of multiple drug resistant strains of *S. typhimurium* has increased considerably (13,17).

Typhoid and paratyphoid fevers are acute systemic diseases caused by *S. typhi* and *S. paratyphi*, respectively, which are exclusively human pathogens. *Salmonella typhi*, *S. paratyphi* A, and *S. paratyphi* B can invade tissues and cause septicemia (18) in patients suffering from high temperature rather than diarrhea. This is known as enteric fever. The other common symptoms being headaches, central nervous system disruptions, malaises, anorexia, splenomegaly, and rose spots on the trunk (12,19). The World Health Organization (WHO) (20) estimated that 17 million people worldwide are affected by typhoid fever every year, with approximately 600,000 deaths. Approximately 10% of untreated patients will discharge bacteria for up to three months and 2 to 5% will become permanent carriers. The mortality rate among untreated patients can be as high as 15%, but falls to around 1% after antibiotic treatment (12). It has been reported that no more than 20% of those exposed to *S. typhi* become infected with typhoid fever. The disease is mainly transmitted by food and water contaminated by the feces and urine of patients and carriers. Although infections produced by *S. typhi* have considerably decreased in the industrialized world, sporadic cases still appear, sometimes linked to visits to developing countries where typhoid fever is still common (15,21).

IMPORTANCE OF *SALMONELLA* IN WATER ENVIRONMENTS

Humans and animals excrete a great number of potential pathogenic microorganisms in their feces that can

contaminate the receiving waters, including bacteria, viruses, fungi, and parasitic protozoa (22). The microbiological quality of natural waters and the potential health risk has been reviewed (22–24). Ingestion of contaminated drinking water or the accidental ingestion of bath water contaminated by feces is the main cause of waterborne diseases. The use of contaminated water in any stage of food processing presents a serious risk to human health because food can provide an ideal growth medium.

As with many other enteropathogens, the importance of *Salmonella* in environmental waters, resides in its capacity to contaminate food products (e.g., shellfish, vegetables). However, *Salmonella* has to be present in sufficient concentrations to initiate infection and to develop the disease. In addition, the susceptible host has to come into contact with the pathogen at the minimum critical dose. Infective dose levels may vary from 10 cells (*S. typhi*) to more than 10^5 (*S. typhimurium*) (25) although greater or lesser doses have been indicated by other authors (4,12,26). Although feces of infected humans who either manifest clinical symptoms or are asymptomatic carriers are the major source of *Salmonella*, farm animals, animal pets, and wildlife serve as very significant reservoirs of this microorganism (16,23). The percentage of infected individuals within a given mammalian group (man included) ranges from less than 1 to 25% (23). The quantity of *Salmonella* excreted by infected individuals has been estimated as 10^6 per gram of feces (23), and the number of these organisms found in a liter of raw sewage ranges from 20 to 8×10^4 (27).

There are a great number of studies from a range of countries that have investigated the incidence of *Salmonella* in rivers, lakes, sediments, coastal waters, and beaches. In these environments some strains of *Salmonella* are predisposed to pathogenicity, whereas others are not. The factors that govern this behavior are not clear but are probably linked to the host and to the presence and activation of virulence mechanisms in the bacteria (28). Pathogenic strains can quickly become opportunistic, invading the human body under conditions of stress, weakened immunity, or general physical deterioration associated with advancing age. The severity of the disease relates to the serotype of the organism, the number of bacteria ingested, and the host susceptibility. The incidence of *Salmonella* in water environments varies worldwide because of its different prevalence in the human and animal population, and the level of sanitation and development of sewage treatments. In industrialized areas there has been an increase in the number of sewage treatment plants, some including disinfection, and a reduction in the number of carriers due to the introduction of antibiotic therapy (29). In developing countries with poor sanitary conditions, the disease remains frequent or endemic (30,31). As *S. typhi* and *S. paratyphi* exclusively colonize humans, their ecology is closely related to the distribution of human sewage, and *S. typhi* has been isolated from water and sewage when cases of enteric fever have been reported from the nearby populations (12).

Relationship Between Stormwater Runoff and *Salmonella*

Stormwater is often the major cause of water quality deterioration in receiving waters, especially in bathing areas. During heavy rains, animal wastes are washed down from pasture and forest, and from manure applied as fertilizer, often causing city sewerage systems to overflow. Sewerage systems and wastewater treatment plants have a finite capacity. Following prolonged or heavy rainfall, the capacity of either system may be exceeded and the excess flow will be diverted to an adjacent watercourse (32,33). Stormwater runoff can contain high densities of microorganisms of either human or nonhuman origin. The incidence of human source microorganisms is influenced by cross-connection between stormwater and urban sanitary sewers. Groundwater systems and shallow wells can be contaminated by surface-runoff. The overflow from old and/or poorly maintained sewerage systems after heavy rainfall with subsequent contamination of drinking water sources was the cause of an outbreak of typhoid fever in Tajikistan in 1997 (34). Remedial actions proposed in some studies that quantify the elevation in bacterial numbers caused by wet-weather discharges in recreational areas, include disinfection at the outlet or redirection of storm outfalls to separate them from the sewerage systems (35). Preventive measures based on model systems and planned location of discharge effluents have been proposed in order to minimize the impact of rainfall on the microbiological quality of the receiving waters, and thus avoid receiving waters posing a health risk (36,37). The health risk associated with stormwater contact in bathing areas has recently been investigated in Santa Monica Bay, California. Results indicate an increasing risk of adverse health outcomes associated with stormwater contact, including gastroenteritis (38). It is important therefore that the bathing population is aware of the fact that water quality can deteriorate considerably after heavy rain and this knowledge may influence their decision to bathe or not to bathe on rainy days (33). Stormwater runoff may also wash out fertilizers and food, which if prepared from animal products, may be highly contaminated with *Salmonella* (18).

Salmonella has frequently been isolated in receiving waters following wet-weather events (39,40,41,42,43,44). Identical serotypes have been detected in sediments at several locations within an estuary after heavy rainfall (42). For example, 4,500 *S. thompson* per 100 ml were recorded from stormwater (23), whereas concentrations ranged from 1 to 10^4 per liter in other urban runoffs (23,45,46). *Salmonella* transported by stormwater through a wastewater drain at the University of Wisconsin experimental farm were isolated regularly at a bathing beach 800 meters downstream (39).

The Role of Seagulls in the Spread of *Salmonella*

Salmonella have been commonly isolated in the feces of birds, particularly the gull species (16,47,48). Importantly, these birds have been involved in outbreaks of salmonellosis in humans and animals (46,49). Seagulls are scavengers that frequent open garbage dumps, eat contaminated food wastes, and contribute *Salmonella* in

their feces to overnight roosting sites on lakes, open water reservoirs, and coastal waters (23,48,50). Gull feces have been shown to contain a range of 1.5×10^2 to 1.2×10^4 *Salmonella* per gram and can therefore have an impact on the microbiological quality of freshwater reservoirs and beaches. Of special importance are freshwater reservoirs situated in upland areas where water is of high quality and treatment is therefore minimal (51,52,53). Levresque and coworkers (48) demonstrated that the deterioration of the microbiological quality of water through the presence of gulls at a lake-bathing site was directly proportional to the number of birds recorded. They were able to detect a decrease in the microbiological quality of the water when as few as 30 birds were present. Preventive measures proposed to lower the risk to bathers from contact with *Salmonella*, include the following: keeping the beaches free from litter, use of closed rubbish bins to minimize attraction of birds, and alerts to the population not to feed the gulls (48). Waterborne outbreaks of salmonellosis associated with bird droppings that are washed out from roofs leading to contamination of the water supplies have been described (25,50,54).

WATER TREATMENT AND *SALMONELLA*

The distribution of *Salmonella* in raw human sewage largely reflects its incidence in the nearby population. The same would apply for wastewater originating from farms or livestock (55). It has been indicated that a sewage collection network of 50 to 100 homes is the minimum size required to have a reasonable chance of successfully detecting salmonellae in the wastewater (56).

Wastewater Treatment

In small communities, sewage containing *Salmonella* may be discharged directly to the ground in septic tanks or be conducted to wastewater treatment plants (WWTP). Septic tanks are banned in many areas because sewage may contaminate groundwaters. Modern sewage treatment in WWTP involves three steps: *(1)* primary treatment, a physical process that implicates the separation of large debris, followed by sedimentation. *(2)* Secondary treatment is a biological process carried out by microorganisms. *(3)* Finally, the tertiary treatment is a physicochemical process that removes turbidity by removing nutrients, organic matter, metals, or pathogens (57). Microbial pathogens are not eliminated after the primary process unless disinfection is included. Secondary and tertiary treatments of wastewater are applied for additional environmental protection when the water is ultimately discharged into rivers and lakes. Sewage from large urban communities requires at least secondary or tertiary treatment with disinfection (such as chlorination, UV, ozone) for onshore or near-shore discharges in order to protect the receiving waters from pathogenic organisms such as *Salmonella*. Such measures are particularly necessary when the waters are used for recreation or shellfish farming (37).

Large bodies of water, particularly open coastal waters, offer a greater opportunity for effective dilution of wastewater outfalls when discharged through long sea outfalls (58). Sewage does not require chlorine disinfection if outfalls are well designed (length, depth, and diffusion). This is important because chlorine and chlorine derivatives can be hazardous to marine organisms and to the people who consume them (58). Discharge of either treated or untreated sewage through properly designed long sea outfalls may pose a very low risk to human health because of the low probability of the sewage plume reaching beach areas (37). The dilution of *Salmonella* in seawater together with the environmental factors affecting its survival in natural waters may considerably lower its concentration (59).

The removal of *Salmonella* after each step of sewage treatment is detailed in Table 1 (27,37,60). Mandatory requirements for processing municipal sewage to secondary treatment level have produced significant improvements in the quality of surface waters (23). Unfortunately, wastewater treatment is not always consistent because of processing difficulties and the occasional by-pass of raw waste inputs following major storm events (23).

It has been reported that several *Salmonella* serotypes showed improved adaptation to seawater stress after a period in wastewater (61), and that they may even be able to grow (62). Treated industrial waste effluents may contain considerably higher numbers of *Salmonella* than municipal sewage. Thus, 4.4% of viable *Salmonella* was detected in waste effluents compared with 2.1% in municipal sewage (63).

Although sewage can be an important resource for agricultural purposes, such as crop irrigation, it can pose an important health risk if inadequately treated. Cordano and Virgilio (64) reported that the serotypes isolated from water used for crop irrigation, including *S. enteritids, S. newport*, and *S. typhimurium*, coincided with those

Table 1. Removal of *Salmonella* During Sewage Treatment[1]

Treatment	Percent Removed	Organisms per Liter
Raw sewage (no treatment)	0	$5.0 \times 10^3 - 8.0 \times 10^4$
Primary treatment[2]	95.5–99.8	$1.6 \times 10^2 - 3.4 \times 10^3$
Secondary treatment[3]	98.65–99.996	$3.0 \times 10^0 - 1.1 \times 10^3$
Tertiary treatment[4]	99.99–99.9999995	$4.0 \times 10^{-6} - 7.0 \times 10^0$

[1]According to (27,37,60).

[3]Primary sedimentation, tricking filter/activated sludge and disinfection.
[4]Primary sedimentation, tricking filter/activated sludge, disinfection, coagulation, sand filtration and disinfection.

isolated from vegetables. There are indications that the *Salmonella* present in salad crops is a major contributor to the endemic nature of the pathogen (23,64). Monitoring of pathogenic microorganisms in raw municipal sewage may give an indication of their prevalence in the general population. This measure is recommended in case of outbreaks or epidemics in order to control their evolution in the population (37).

During municipal sewage treatment, sludge is produced. Sludge, or biosolids, is a by-product of physical (primary treatment), biological (activated sludge) and physicochemical (precipitation of suspended solids by chemicals) treatment processes (65). Recorded numbers of *Salmonella* spp. in primary and secondary sludge are 10^2 to 10^3 (dry weight) (66) and 9×10^2 (per gram), respectively. These high numbers would pose a health hazard when sludge is scheduled for agricultural reuse (67).

Drinking Water Treatment

Rivers, streams, lakes, and underground aquifers are all used as sources of drinking water. The important factors in choosing the best available raw source water for drinking water treatment supply include *(1)* adequate quantity throughout the year; *(2)* water quality that is amenable to treatment; and *(3)* measures of watershed protection from domestic, industrial, and agricultural pollution (46). Fluctuating microbiological characteristics of the raw water may compromise the water supply (23). Drinking water treatment of raw water sources includes pre- and postchlorination combined with other conventional processes such as flocculation, sedimentation, and filtration (67). Several serotypes of *Salmonella* (*S. enteritidis*, *S. anatum*, *S. infantis*, *S. montevideo*, *S. newport*, *S. give*, *S. infantis*, and *S. poona*) were isolated from the Missouri river at the intakes the of water treatment plant (46). Groundwater has long been considered to be of excellent quality because the soil barrier is considered effective in isolating the water source from surface pollutants (46). As a consequence, treatment is frequently nonexistent or limited to control water hardness, taste and odor removal, or simply disinfection (46). A variety of waterborne outbreaks have been attributed to untreated or poorly treated groundwater contaminated with pathogens, including *Salmonella* (12,46). As indicated previously, the concentration of salmonellae and the prevailing serotypes will be related to the disease prevalent in upstream human and farm animal populations at each specific community. Therefore, the quality of raw water at intakes of drinking water treatment plants may differ considerably (46). Water treatment technology can successfully process poor quality source water containing in excess of 2,000 fecal coliforms per 100 ml, producing potable water that meets drinking water standards, although any break in the chain of treatment could allow substantial levels of microorganisms to enter the finished product (46). Treated water, which is microbiologically safe when it enters the distribution system, may suffer deterioration before it reaches the consumer. Protection of drinking water from contamination by human or animal excreta, food processing water and stormwater runoff is of great importance for public health protection (46). Routine monitoring of drinking water for fecal indicator organisms is carried out according to the different regulations that apply in each country or region (53). According to Geldreich (23), although monitoring water quality is an important aspect, data gathering alone cannot protect public health. It provides a warning system that should trigger appropriate responses for the protection of the public from the potential presence of waterborne pathogens. Another way of anticipating pathogenic exposure is through increased national surveillance for waterborne outbreaks. In each situation it is important to characterize the etiological agent, to establish its occurrence and geographic distribution, and to identify control measures (46).

The Centers for Disease Control (CDC) in the United States has been recording data on waterborne outbreaks for many years. Since 1971, the CDC and the U.S. Environmental Protection Agency (EPA) have maintained joint surveillance systems for collecting and periodically reporting data on the occurrence and cause of waterborne disease outbreaks. Similar systems have been developed in the United Kingdom and in most other European countries.

Salmonella in Biofilms

Biofilm formation (the buildup of microbial communities on surfaces, such as the growth of microorganisms on the inner surfaces of pipes) is of special concern in the drinking water industry because pathogenic microorganisms can be protected from inactivation by chlorine disinfection due to the complex nature of the biofilm (53,68). The growth of bacteria on pipe surfaces is limited by the concentration of essential nutrients in the water, in particular assimilable organic carbon. WHO Guidelines (18) indicate that drinking water must be of low turbidity after treatment if adequate chlorination is to be achieved. In addition, a low load of assimilable organic carbon in treated water is considered to be an important factor in reducing survival time and preventing the regrowth of salmonellae within the distribution system. Reported survival times range from a few days to more than 100 days (18). It has been demonstrated that salmonellae are able to develop biofilms (69–71). Biofilms can detach from the inner surface of drinking water pipes and contaminate the drinking water. Biofilms have gained considerable importance in the context of water and food hygiene (68). Barker and Bloomfield (71) demonstrated that *Salmonella* could survive in biofilms associated with domestic toilets when family members had recently suffered an attack of salmonellosis. *Salmonella* could survive in toilet biofilm from 28 to 50 days after diarrhea had stopped or after experimental seeding.

SURVIVAL OF *SALMONELLA* IN AQUATIC ENVIRONMENTS

Allochthonous pathogenic bacteria are not well adapted to grow and survive in aquatic environments, mainly because of the lack of nutrients and to the exposure to biotic and abiotic factors of these ecosystems (72). The number of microorganisms discharged by sewage and industrial

wastewater into natural water environments are therefore rapidly reduced in the receiving waters as a result of different mechanisms, the two most important ones being physical dilution and microbial inactivation (73,74). These processes depend on various physicochemical and biological factors, such as water temperature (75,76), adsorption and sedimentation processes (77), toxic effects of heavy metals (78), action of sunlight (79–83), predation by bacteria, viruses, and protozoa (84–87), lack of nutrients (83,88), competition with autochthonous microbiota and antibiosis (80,85), and osmotic stress (89,90). Several of these factors provoke stress and sublethal injuries that prevent the growth of the microorganisms in the selective media used for their detection. In fact, detection of *Salmonella* is less efficient when a proportion of the bacterial population is physiologically injured (91). According to Singh and McFeters (92) microorganisms maintain their virulence and pathogenic characteristics even if they are stressed or injured. However, others authors indicate that changes produced in *S. typhimurium* after residence in seawater for a considerable time (32 days) decrease its capability to withstand the gastric barrier (93).

A number of studies have demonstrated that several pathogenic microorganisms can survive for longer periods than indicators because they may be less affected by environmental stress (94,95). For this reason, pathogenic microorganisms have been detected in waterborne outbreaks even when the level of indicator organisms have been low (96,97).

Environmental stress and sublethal injuries provoke the following effects on the allochthonous pathogenic bacteria of aquatic environments, including *Salmonella* (98):

1. Cellular damage, including a decrease in size and activity of the bacterial cell; changes in the cellular volume and shape; damage to the cellular membranes; alteration of superficial appendages, such as flagella and pili; loss of chemical cellular components (lipids, carbohydrates, proteins, RNA, etc.); and alteration of the LPS-carbohydrates on the outer layer wall.
2. Physiological alterations, including loss of intracellular ATP molecules, permeability of nutrients, reduced production of toxins, and an inability to grow in culture media.
3. Reduction of virulence.

Dutka and Kwan (99) compared the survival of *S. thompson* and two indicator organisms in Hamilton Bay (Canada) using membrane filter chambers. The results indicated that these three microorganisms could survive for at least 28 days. Using the same methodology, Moriñigo and coworkers (100) demonstrated that there were no significant differences ($p < 0.001$) in the survival rates in seawater among five serotypes of *Salmonella* tested (*S. enteritidis*, *S. infantis*, *S. potsdam*, *S. typhimurium* and *S. london*). In addition, low survival capability (less than 11%) was achieved after 48 hours of exposure to seawater, with an increase in sublethal injury on exposure to the seawater. Borrego and coworkers (59) reported similar survival characteristics of *Salmonella* and *Shigella* in a marine environment to those of fecal pollution indicators; however, it was observed that these pathogens do not have the ability to adapt well to seawater. Bakhrouf and coworkers (90) explained these results by the fact that *Salmonella* is very sensitive to osmotic down-shock, and the transit of this microorganism by wastewater can modify its behavior in the marine environment. It has been indicated that suspended matter drastically impairs the bactericidal effect of sunlight on pathogenic enteric bacteria (101,102). Cornax and coworkers (103) demonstrated that *S. paratyphi* showed a similar or even lower inactivation rate than that obtained by indicator microorganisms in seawater, the visible light and biotic components of seawater being the most important inactivating factors. Similarly, Rhodes and Kator (75) obtained a die-off of about 3 log and noted sublethal stress of *Salmonella* spp. in filtered estuarine water. These authors concluded that a reduction in *Salmonella* titers was associated with an increase in the number of microflagellates and plaque-forming microorganisms.

Xu and coworkers (104) and Grimes and coworkers (105) reported that indicators and enteric pathogenic bacteria, including *S. enteritidis*, exposed to salt-water microcosms could be recovered after a nonculturable state. Recovery was accomplished by harvesting viable but nonculturable (VBNC) cells from the seawater microcosm. Later, several authors demonstrated experimentally the existence of indicator and pathogenic microorganisms in the VBNC state in different aquatic environments (106–108). The VBNC bacteria remain viable in seawater for a long time (106,109,110) and maintain their infective capability and pathogenic potential (95,111,112). Therefore, the VBNC state of pathogenic microorganisms may constitute a serious hazard to public health because of the fact that these VBNC bacteria are not detected in water samples using conventional methods of detection and enumeration.

WATERBORNE OUTBREAKS CAUSED BY *SALMONELLA*

Waterborne transmission (especially when drinking water is involved) is a highly effective way of spreading infectious agents to a large population (53,113). At the beginning of the twentieth century, modern conventional drinking water treatment, involving filtration and disinfection, was shown to be highly effective in the control of important enteric diseases such as cholera and typhoid fever. Waterborne outbreaks have been closely associated with *S. typhi* and, much less frequently, with *S. paratyphi* B or other *Salmonella* serotypes (12,18). When attributed to heavy contamination, the onset is explosive and the majority of cases develop over a period of just a few days, and may be followed by a secondary peak of contact cases (18). In the United States, 486 outbreaks of typhoid fever were recorded between 1920 and 1991, however no further cases were recorded from 1991 to 1996. The majority of cases (466) occurred between 1920 and 1990 (114–116). In 1994, Galbraith (117) reviewed the reported outbreaks in the UK from 1911 to 1986.

Today waterborne outbreaks of typhoid fever (Table 2) and of other non-typhoid salmonellosis in industrialized

Table 2. Waterborne Outbreaks of Typhoid Fever (from 1970 to 2000)

Place	Cases	Year	Possible Source	Reference
British liner sailing into Vancouver	53	1970	Fecal contamination of drinking tanks	122
Washington (USA)	11	1972	Fecal contamination of a groundwater supply	123
Mexico	83	1972	Drinking from a sewage contaminated canal	124
Florida (USA)	225	1973	Failure of chlorinating of the water supply	125
Saugli (India)	9,000	1975–1976	Endemic situation, sewage contamination of wells and poor chlorination	119
Chile	—	1977–86	Endemic situation	120
Taiwan	52	1983	Drinking from a river or well	126
Krayot (Israel)	77	1985–1989	Drinking non-chlorinated well-water	127, 128
Baramullah (India)	230	1988	Fecal contamination of a groundwater supply	129
Kieng Giang (South Vietnam)	9,179	1990–1992	Endemic situation and lack of clean water supply	121
Saudi Arabia	81	1992	Fecal contaminated aquifer/poor maintenance of filters and lack of chlorination	130
Catalonia (Spain)	9	1994	Sewage contaminated drinking fountain	118
Dushanbe (Tajiskistan)	8,900	1997	Contaminated drinking water after treatment	34

parts of the world are relatively rare and their occurrence is associated with breakdown of water treatment processes (118), when water is contaminated after treatment (34) or when nondisinfected drinking water was consumed (57). Table 2 also records the outbreaks of typhoid fever in different parts of the world from 1970 to 2000 (12). In some of these typhoid outbreaks (Chile, India, Israel) the disease was endemic in the population or had produced intermittent outbreaks for several years (119,120). Some outbreaks went on to become real epidemics, as in South Vietnam, where between 1990 and 1993 a total of 12,228 cases were recorded with 33 mortalities (121).

Salmonellosis has been a reportable disease in the United States since 1942, and the CDC through its *Salmonella* surveillance system has collected data since 1963. The incidence of reported cases was 8 per 100,000 in 1963, whereas in 1983, 19 cases per 100,000 were reported (131). Waterborne cases of salmonellosis were not recorded from 1920 to 1940, probably obscured by the *S. typhi* outbreaks, but from 1941 up to 1994, 26 cases were reported (12). No drinking water outbreaks attributed to *Salmonella* were recorded during 1995 to 1996. It is likely, however, those reported cases represent only a small fraction of the total number of infections that actually occur. It has been estimated from outbreak data that only one in 75 to 100 cases of salmonellosis in the United States is reported (132,133). However, the increase in reported cases is also likely to be unrepresentative because of the improvement in reporting and recognition of salmonellosis. Studies in developed countries indicate that more than 80% of all salmonellosis occurs individually rather than as outbreak (18). In recent years, an increased number of outbreaks have been observed in small community and noncommunity systems (114). In the United States the proportion of reported outbreaks associated with community drinking water systems in which the cause was attributed to problems at water treatment plants has steadily declined since 1989 (e.g., 72.7% in 1989 to 1990; 62.5% in 1991 to 1992; 57.1% in 1993 to 1994 and 30% in 1995 to 1996) (134). This decrease most likely reflects improvements in the operation of treatment plants; however, the CDC recommends that efforts should be increased to prevent cross-connection, in particular by installing and monitoring backflow prevention devices (134).

Outbreaks in Recreational Waters

At the beginning of the twentieth century, swimming-associated outbreaks of *Salmonella* were quite common, but incidents declined progressively. According to Dufour (29), this decline was due to a steady increase in the number of sewage treatment plants with a disinfection step, especially in large population centers, and a widespread use of newly discovered antibiotics that helped to limit the spread of disease and, thereby the number of infected individuals in the discharging population. Although there is a broad spectrum of illnesses that have been associated with swimming in marine and fresh recreational waters, *Salmonella* does not appear in the list of disease outbreaks in the United States between 1985 and 1994 (12). Of the 37 outbreaks associated with recreational water (1995–1996) only one, with 3 cases, was attributed to *S. java* and was due to inadequate chlorination of a swimming pool.

Swimming and other recreational activities in which the accidental ingestion of water can occur are known to

increase the risk of gastrointestinal illness, even in non-outbreak settings (135–137). According to Geldreich (23), waterborne pathogens are a worldwide problem that require urgent control through environmental protection to avoid further escalation of their occurrence. The release of pathogens is, and will be, a constant threat because it is unavoidable for people or animals to be, to a greater or lesser extent, infected by pathogenic microorganisms. The introduction of multiple barriers to provide maximum public health protection is, therefore, essential. This can be achieved by the management and maintenance of wastewater treatment, control of runoff and the adequate treatment of water supply to prevent pathogens infecting increasing numbers of people and thus becoming more prevalent in the population and the environment (23).

The improvement in the sanitation systems of developing countries, plus improvements in surveillance systems on an international scale and information derived from previous outbreaks will help reduce the incidence of waterborne outbreaks of *Salmonella* in the new century (138).

SALMONELLA IN SHELLFISH

Bacterial and viral disease outbreaks have been associated with all major types of edible bivalve mollusks, and human enteric pathogens have been isolated from shellfish collected from both natural waters and harvesting areas (19,139–144). Bivalve mollusk shellfish are filter feeders and use siphoning organelles and mucous membranes to sieve suspended food particles from the aquatic environment as a source of food. If bacteria or viruses contaminate their surrounding water, these mucous membranes may entrap the pathogens and transfer them to the digestive tract. Shellfish, because they are usually consumed whole and raw or only partly cooked, may act as passive carriers of human pathogens (145).

The presence of *Salmonella* spp. in shellfish is predominantly due to fecal contamination of harvesting sites or cross-contamination by human carriers, particularly food handlers (146). In the United States, most outbreaks of salmonellosis are traced to contaminated products of terrestrial animals. However, a frequently identified vehicle for *Salmonella* is shellfish, although current data are inadequate to make any attempt at estimating attributable risk (147). The annual food-borne disease incidence data taken from the epidemiology-based food-borne disease outbreak surveillance system for the 14-year period from 1973 to 1986, documents an average of 55 food-borne outbreaks of non-typhoidal *Salmonella* infections affecting a total of 3,944 people per year. In the same time frame, only six shellfish-borne outbreaks involving 147 cases were reported (148).

The NETSU database that attempts to document all occurrences of shellfish-borne disease outbreaks has, since 1894, reported only two shellfish-associated outbreaks of confirmed non-typhoidal salmonellosis between 1894 and 1973 (149). A 100-case outbreak occurred in Florida in 1947, traced to contaminated oysters. The other outbreak, with 22 cases, occurred in New York in 1967 and was associated with oysters imported from England (150). However, several sporadic cases of salmonellosis associated with shellfish occurred in 1989 and 1990. In 1989, three cases of salmonellosis were associated with mussels harvested in Maine and consumed in Connecticut, *S. infantis* being isolated in two of the cases. In October and December 1989, and later in 1990, oyster-associated cases were reported in Florida (149). Outbreaks of salmonellosis have been associated with shellfish in other countries. Thus, an outbreak of salmonellosis that involved 50 persons in Italy was associated with the clam *Venus verrucosa* (151), and the causative agents were *S. typhimurium* and *S. mbandaka*. Although the NETSU database on shellfish-associated outbreaks reports only a few outbreaks caused by *Salmonella*, this microorganism has been detected frequently in contaminated shellfish (152,153,154,155,156).

On the contrary, the historical association between shellfish and *S. typhi* was identified early in the nineteenth century. During the first quarter of the twentieth century, 22 typhoid fever outbreaks were reported in the United States (157). In 1925, there was a large outbreak of typhoid fever associated with the consumption of raw oysters, resulting in a 10% fatality rate and the establishment of the first national program on shellfish sanitation (157). However, several typhoid fever outbreaks have been reported involving consumption of raw mollusks before 1980 (150,158).

Mollusks may acquire *S. typhi* from sewage-polluted water. However, in the United States, seafood-related typhoid fever is unlikely because there are few cases or carriers to discharge *S. typhi* into sewage or estuaries (19). The risk associated with imported seafood may vary, depending upon the rates of infection in the country of origin and the degree of pollution of the harvest waters. Sporadic cases have been reported in consumers of raw shellfish in the Mediterranean area (159) and, on the basis of the incidence of typhoid fever in local populations, the risk associated with products imported from developing countries would appear to be elevated (160).

In addition to the risk posed by contaminated harvest waters, carriers can also introduce *S. typhi* and other non-typhoid salmonellae into seafood during processing or preparation. Available data suggest that at least 10^5 *S. typhi* in foods is necessary to cause disease (161). Therefore, only shellfish from grossly polluted waters and ready-to-eat seafood contaminated during preparation and then affected by temperatures high enough to allow bacterial growth are likely to transmit typhoid fever.

DETECTION AND ENUMERATION METHODS

Many regulations for different kinds of water have been developed at national or state level all over the world with the aim of protecting human health and reducing the impact of wastewater in water environments (18,37). Drinking water regulations stipulate that water should be supplied to the consumers free of any risk to human health (free of any toxic substance and/or pathogenic microorganism).

Because the analysis and detection of all potential pathogenic microorganisms present in water is impractical

on a routine basis, surrogate indicators are used. These are indicators of fecal pollution (total coliforms, fecal coliforms, *Escherichia coli* and fecal streptococci or intestinal enterococci) that, if present indicate a risk of the presence of pathogenic microorganisms. Regulations rely on analysis of one or more of these indicators to evaluate the microbiological quality of the water (18,162).

The advantages and disadvantages of indicators of fecal pollution as surrogates of pathogenic organisms are broadly reviewed in the literature (24,53,163). However, there is not always a direct correlation between the presence of fecal indicators and that of pathogens. In fact, *Salmonella* had been proven to be present under circumstances in which indicators were not detected or were at very low numbers (23,43,44,100,164–169). The direct detection and enumeration of *Salmonella* will be necessary when there is a suspicion of a potential health risk attributable to this microorganism.

The detection and enumeration of *Salmonella* from water samples is a difficult process, mainly because this genus includes a variety of serovars that have different physiological and cultural characteristics. In addition, *Salmonella* is usually present in small numbers compared with coliforms and it may be sublethally injured reducing efficiency of isolation. Therefore, an optimum methodology that overcomes all these difficulties and that can be useful for all types of water samples is still not available. Conventional methods for the detection (presence or absence or nondetection) generally consist of the following steps: *(1)* concentration, *(2)* preenrichment in nonselective media, *(3)* selective enrichment, *(4)* isolation, and *(5)* identification.

Concentration: *Salmonella* is usually present in water samples in small numbers, therefore it is necessary to examine a relatively large volume of sample (usually one liter) to isolate the organism. Several concentration procedures have been described, including the swab technique, the diatomaceous earth technique, use of borosilicate glass microfibres bonded with epoxy resin, and a membrane filtration technique, the latter being the most commonly employed.

Preenrichment: Preenrichment in nonselective broth medium for 16 to 24 hours at 35 to 37 °C facilitates the recovery of stressed and sublethally injured *Salmonella*, and increases its low numbers with concurrent growth of competitive microbiota. Quarter-strength Ringer's solution, buffered peptone water (BPW), nutrient broth and lactose broth are among the most common preenrichment media (170–172).

Selective enrichment: This step promotes the growth of *Salmonella* with a concomitant suppression of background organisms (173). No single enrichment medium can be recommended that allows optimum growth of all *Salmonella* serotypes. The use of two or more selective enrichment media in parallel is advised for optimum detection; the most commonly used media are selenite broths, tetrathionate broths, and Rappaport broths. Growth of interfering organisms is reduced by the high selectivity of these types of media and incubation at elevated temperatures (41 to 43 °C for 16 to 24 hours) (171). Tetrathionate and Rappaport broths will inhibit the growth of *S. typhi* and therefore, when this serotype is targeted, selenite broth will have to be used. Several semisolid media, including Diagnostic semisolid *Salmonella* agar (DIASALM) (174), Semisolid Rappaport-Vassiliadis (SRVA) (175), and Modified semisolid Rappaport-Vassiliadis (MSRV) (176) have been used in the selective enrichment step. On the other hand, the addition of nitrofurantoin to semisolid media resulted in higher isolation rates of the *S. enteritidis* serovar (174,177).

Isolation in plating media: Solid selective media are used after initial isolation steps to further inhibit the competitive microorganisms and to allow presumptive distinction of *Salmonella* colonies by cultural characteristics. Plating media commonly used for *Salmonella* detection may classified into three groups: *(1)* differential media with little or no inhibition toward nonpathogenic bacteria, such as eosin methylene blue agar (EMB); *(2)* selective media containing bile salts or sodium deoxycholate as inhibitors, such as MacConkey agar, deoxycholate agar, xylose lysine deoxycholate agar (XLD), Hektoen agar (HE) or *Salmonella-Shigella* agar (SS); and *(3)* selective media containing brilliant green dye, such as brilliant green agar (BG), or bismuth sulfite agar (BS), and novobiocin brilliant green-glucose agar. Some serotypes such as *typhi* and *dublin* are sensitive to media that contain malachite green, and therefore, the use of at least two selective media in parallel is recommended (178).

Identification: The identification of *Salmonella* by colony characteristics on selective plating media has limitations inherent in the biological variations of certain organisms and cannot be relied on even for tentative identification. Suspected colonies grown on selective solid media must be subcultured and further characterized by biochemical confirmation. Final verification is based on serological identification (3).

The procedures described earlier are those used to analyze for the presence or absence of *Salmonella* in a water sample. However, if the concentration of the organism has to be estimated, a quantitative procedure is required such as the one described in the Standard Methods (179). This procedure involves concentrating of the water sample by the membrane filtration technique. After blending the membrane in peptone water, a quantitative 3- or 5-tube Most Probable Number (MPN) method with selective enrichment broth is used. After incubation, an amount from each tube is streaked onto BG and XLD agars. Colonies suspected of being *Salmonella* are biochemically identified from each plate and serologically verified (3). From the combination of *Salmonella* negative and positive tubes, the MPN of *Salmonella* of the original sample is calculated.

Several modifications have been performed on some of the steps of this standard methodology. Moriñigo and coworkers (172) proposed a method for the specific detection and enumeration of *Salmonella* from polluted natural waters. The method consisted of preenrichment of the filtered sample in buffered peptone water (BPW), selective enrichment in Rappaport-Vassialidis (RV) broth and Selenite cystine broth, and plating on XLD and TSBG agars. Weber and Rackelmann (180) evaluated

the 1-2 Test demonstrating that it had higher specificity (97.7%) and sensitivity (94.7%) than the classical method. Later, Cherrington and Huis-in't-Veld (181) proposed a new method named 24-hour Screen that involved an overnight enrichment of the sample in Muller-Kauffmann tetrathionate broth, subcultured for 4 hours in M broth with novobiocin, and detection of *Salmonella* by Bactrace and Salmonella-tek ELISA. Bernagozzi and coworkers (182) used two different procedures for detecting *Salmonella* spp. in environmental water samples: a rapid method (enrichment in Salmosyst broth and plating in Rambach agar) and a longer assay (preenrichment in BPW, enrichment in selenite cystine and plating in BG agar). The results obtained demonstrated that the rapid method seemed more effective. Recently, Hoorfar and Baggesen (183) compared the performance of the internationally accepted standard method to two new (1-day) culture methods, Salmonella Enrichment Broth (SEB) and Revive, and an alternative preenrichment broth, named Universal preenrichment Broth (UB). The classical protocol was more efficient, but the preenrichment of the samples in UB may substantially increase its sensitivity.

Several improvements have been proposed in the different steps of the quantitative determination of *Salmonella*. In the preenrichment step, the supplementation of BPW with ferrioxamine E or G or ammonium-iron (III) citrate significantly increased the motility of *Salmonella* and allowed its detection after six hours (177,184).

Moriñigo and coworkers (178,185) compared the selectivity and efficiency of several enrichment broths for the recovery of *Salmonella* spp. from polluted natural waters. The results indicated that several *Salmonella* serovars grew slowly in tetrathionate broth and in media containing brilliant green dye, and *S. typhi* growth was completely inhibited by these media. The enrichment medium that resulted in a higher detection of *Salmonella* from freshwater and seawater was RV broth incubated at 43 °C and its modifications, to which sodium novobiocin had been added.

Several comparative studies have been conducted on the efficiency and differential ability of the selective media used for the *Salmonella* isolation after the enrichment step (172, 175,186,187). Moriñigo and coworkers (186) concluded that XLD and brilliant green-phenol red-lactose-sucrose agars were the most selective media for all *Salmonella* serotypes. Semisolid plating media were used to isolate *Salmonella* spp. from different sources, including feces (187), food (175) and water samples (172) and appeared, in general, to be more effective than broth media. These media have been used in the selective enrichment step, allowing the detection of *Salmonella* in one day (184) or the specific recovery of *S. enteritidis* by the addition of nitrofuratoin (174,177,188). New plating media have been designed, such as B × LH (189) and XLT-4 (190).

Traditional culture-based methods for analysis of *Salmonella* in food and water sources are relatively slow and cumbersome, and results can be ambiguous owing to the poor sensitivity with samples contaminated with low levels of this organism (191). A number of rapid methods have been developed in past few years to overcome this problem. These rapid methods fall into three groups: (*1*) immunofluorescence antibody technique; (*2*) enzyme-linked immunosorbent assay (ELISA); and (*3*) DNA probes.

The direct fluorescent antibody (FA) technique is a rapid and effective means of detecting salmonellae in fresh and seawater samples. It may be used as a screening technique to provide rapid results from large numbers of samples, but because of potential cross-reactivity of antibodies, positive FA results should be confirmed by other methods. Modifications of this technique have recently been applied to detect *Salmonella* spp. in environmental water systems (192,193).

The Salmonella-Tek ELISA test system was compared to conventional bacteriological isolation for specific detection of *S. enteritidis* and *S. gallinarum* (194,195). This screen system provides a promising test for the detection of *Salmonella* antigens in samples, even when they are present at low concentrations (196).

DNA probe methods are based on the detection of specific nucleic acid sequences using labeled DNA-fragments (300–1,500 base pairs) or short oligonucleotides (15–30 bp) to probe for the presence of salmonellae in mixed cultures. The preparation of polynucleotide probes is laborious because it involves isolation, purification, and labeling of a DNA fragment from recombinant bacteria. By contrast, oligonucleotides are easily synthesized and have highly reproducible quality. In addition, the hybridization time can be reduced with these short probe molecules because of a higher concentration of DNA probe. Several sets of oligonucleotide primers (phoP, Hin, H-1, sef A, iroB, ST1 and ST15) in conjunction with the polymerase chain reaction (PCR) assay have been applied to detect *Salmonella* from food and water (197–201). The results demonstrate that the PCR-based methods can favorably replace the culture-based methods because they are quicker, less labor-intensive, reproducible, and provide results that match perfectly those obtained with the standard culture methods (202,203).

CONCLUSION

Members of the genus *Salmonella* are major food-borne and waterborne pathogens; several serotypes are usually involved in salmonellosis or salmonella gastroenteritis. Serovars *typhi* and *paratyphi* are the etiological agents of enteric fevers (typhoid and paratyphoid fevers), affecting exclusively to human population. Outbreaks of enteric fevers are generally associated with inadequate drinking water treatment processes.

Salmonella in water environments is considered as the main source for human infection, following ingestion of contaminated water or food products. Although feces of infected humans (either diseased or asymptomatic carriers) are the major source of *Salmonella*, farm animals, animal pets, and wildlife serve as significant reservoirs of these microorganisms. Sewage from human populations or wastewater originating form farms or livestock, along with stormwater runoff and gull feces, are the main contamination sources of natural waters. A matter of special concern is the fecal contamination of bivalve

mollusks harvesting areas because shellfish has been frequently identified as a vehicle for *Salmonella*.

Secondary and tertiary treatments of wastewater are required for discharges into aquatic natural environments in order to protect the receiving waters from *Salmonella*. However, special efforts must be made to avoid biofilm formation in drinking water distribution systems.

The survival of *Salmonella* in aquatic environments is also reviewed and compared to that of indicator microorganisms. Although *Salmonella*, as other allochtonous pathogenic bacteria, is not well adapted to grow and survive in aquatic environments, several studies demonstrated that *Salmonella* presents similar or even lower inactivation rate than those obtained by indicators in water ecosystems. The recovery of *Salmonella* in a viable but nonculturable state that maintains its pathogenic potential is also of concern.

Finally, current *Salmonella* detection and enumeration methods are examined. The specific detection and enumeration of *Salmonella* from polluted natural waters can be achieved by preenrichment of filtered sample in buffered peptone water, selective enrichment in Rappaport-Vassiliadis broth and selenite cysteine broth, and plating on selective and differential solid media. Enzyme-linked immunosorbent assays and PCR-based methods have been applied for the specific detection of *Salmonella* in samples, even when they are present at low concentrations. These techniques will probably replace the culture-based methods because they are quicker, less labor-intensive and highly reproducible.

SALT PRODUCTION

JOSEPH S. DAVIS
The University of Florida
Gainesville, Florida

HISTORICAL SKETCH

Sea salt can be produced from the ocean by evaporating seawater to dryness in shallow ponds or containers. The product, mainly sodium chloride, will be gritty with gypsum and bitter with compounds of magnesium, potassium, chloride, and sulfate. Seaside pools carved into rocks along the Mediterranean coasts and remnants of ancient cauldrons for boiling seawater attest to the use of this method to produce salt by civilizations in antiquity. Prior to the Middle Ages, saltmakers improved the method by using large ponds or natural lagoons in which seawater was evaporated by sun and wind (1). Use of shallow connected concentrating ponds through which seawater flowed, evaporated, became increasingly salty, and deposited salt in crystallizing ponds was introduced in the early Middle Ages (2) and constituted a significant technological advance for salt production. (This innovation resulted in today's solar saltworks or salinas.) Early saltmakers (briners) advanced the process further by relying on indicator organisms and communities in the ponds for critical aspects of management, particularly brine (concentrated seawater) clearing, storage and transfer, harvest facilitation, and seepage control. For example, the saltmakers used brine shrimp (*Artemia*) to clear brine of undesirable suspended substances (3,4) prior to salt deposition. The death of brine shrimp and the appearance of pink colors caused by bacteria provided clues that brine had become highly saline and was ready for transfer to crystallizing ponds (crystallizers) where the salt would precipitate (5). However, prior to placing concentrated brine in crystallizers, the briners had allowed microorganisms to grow an organic layer on the floors to reduce water loss through seepage (6) and to facilitate harvest of the salt without contamination by the native black muds (5,7,8). Other events of biological origin recorded for early solar saltworks and their products include excessive accumulation of sediments in ponds (9) that resulted in abandonment of salinas, unpleasant odors arising from the ponds (10), damage to fish preserved with sea salt (11), and use of black sediments for medicinal purposes (12).

MODERN METHODS

The twentieth century has seen few fundamental innovations for producing sea salt in salinas. However, mechanical equipment has replaced manual labor formerly used to pump water, prepare crystallizer floors after harvest for a subsequent season, and to harvest, wash, and stockpile salt (Fig. 1). Also, modern instrumentation has replaced biological clues to determine salinity, move and store brine, calculate evaporation, monitor weather, and check product quality. In some salinas, this data is managed in computer programs (13) to optimize depths, facilitate brine management, and improve the efficiency of the salt harvest and washing processes. Modern salinas and their production methods are largely responsible for decreasing the once highly expensive price of salt to the current level of about twenty dollars per ton.

The size and production capacity of solar saltworks and the competitiveness of salt from seawater have increased significantly during the twentieth century. Salinas that manufacture from 100,000 to more than 1 million tons

Figure 1. A modern salt harvesting machine. (With permission of Shark Bay Salt Joint Venture.)

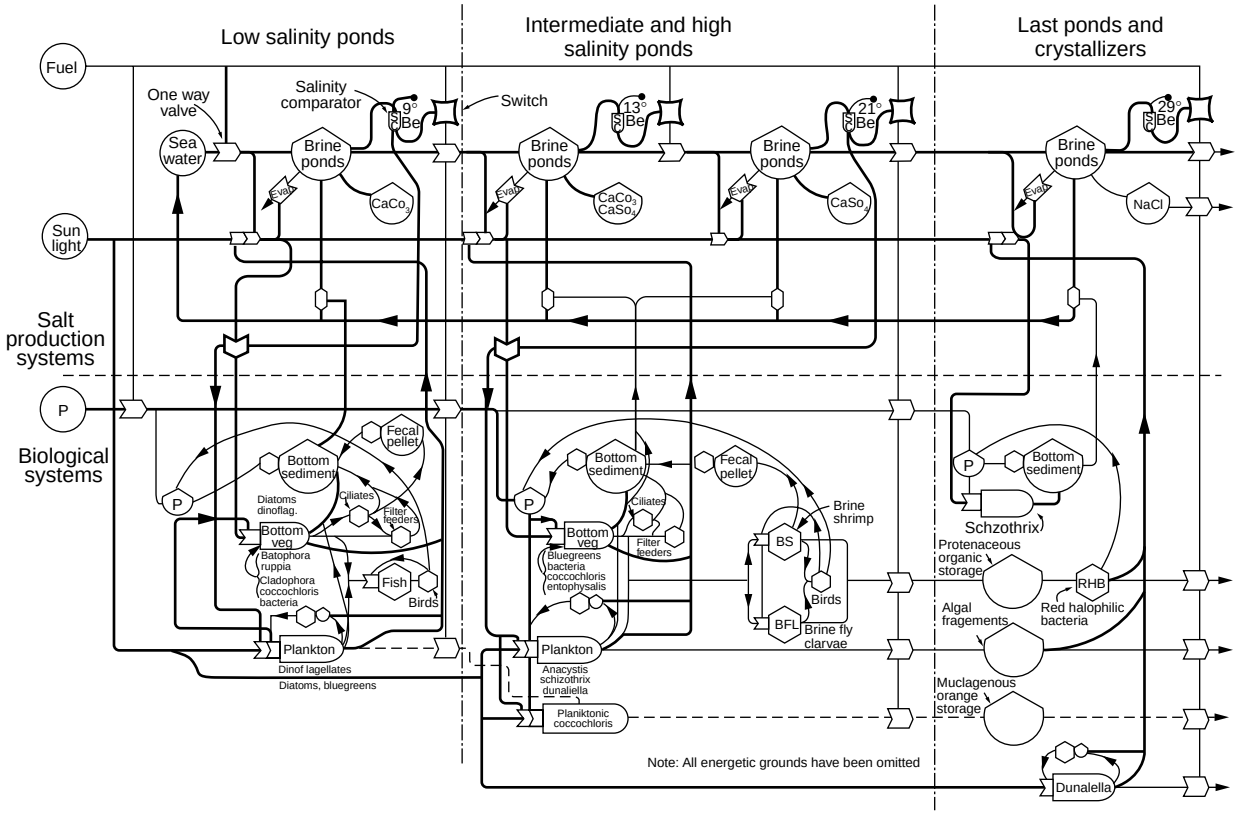

Figure 2. A conceptual model depicting close proximity and interaction of the physical and biological systems (18). (With permission of *Introduction to Applied Phycology*, 1990.)

yearly are common, and their salt now accounts for about one-third the annual worldwide production (about 200 million tons) of sodium chloride. Expansion to increase production is underway in many saltworks, and several large, new salinas are currently under construction or planned for the near future. Because the energy for evaporation of water is without cost, the reserves (seawater) inexhaustible, and water transport of the product from seaside locations relatively inexpensive, solar salt is more economical to produce and distribute than mined salt. In addition to producing salt, the ponds and adjacent dry properties provide habitat free of human disturbance for terrestrial and aquatic plants, microorganisms, and animals (2). Liquid wastes or bittern (the supernatant solution above the salt in crystallizers) of many salinas are processed to produce fertilizers or magnesium compounds, used to seal new crystallizers against seepage, or retained permanently in storage ponds on salina property. Solid wastes (salt and insoluble substances produced by the salt-washing process) are placed in special ponds where the salt is dissolved, recrystallized, and harvested; gypsum on floors of high salinity ponds is harvested on a regular basis in specially designed salinas.

Physical aspects of saltworks (e.g., brine flows, water depths, salinity management, and harvest processes) are generally well understood (13–16), but biological systems essential to salt production are less well appreciated. Because organisms living in the brine ponds strongly influence water evaporation (16), precipitation of calcium carbonate and gypsum ($CaSO_4 \cdot 2H_20$) along the salinity gradient, and salt quality and quantity (15,17), knowledge of the interaction and relationship of the physical and biological systems (Fig. 2) are essential for the salt producer. This article reviews selected physical processes and systems of commercial salinas, describes practical aspects of the macroscopic and microscopic life in brine ponds and their involvement in salt production, offers information to manage the biological systems to enable continuous and economical production of high-quality salt at design capacity, and provides proactive methods to deal with disturbances and other problems common to saltworks.

THE PHYSICAL SYSTEM OF SOLAR SALTWORKS

Modern solar saltworks consist of one or more series of connected concentrating ponds (40 to 70 cm deep) through which seawater flows, evaporates, becomes increasingly salty, and deposits sodium chloride in crystallizer ponds (30 to 50 cm deep). In the downstream flow of water in the concentrating ponds, salts of low solubility (in respect to sodium chloride) precipitate, with calcium carbonate first dropping out near three times (Specific Gravity 1.060) and calcium sulfate (gypsum) first appearing near four times seawater salinity (S.G. 1.107). Shortly before saturation with sodium chloride (S.G. 1.210), brine is repeatedly pumped (or continuously flows) into crystallizer ponds and

allowed to evaporate, and the supernatant liquid (bittern) above the salt is periodically (or continuously) removed after the brine reaches S.G. 1.252. As the salt is deposited, small amounts of calcium and magnesium sulfate also precipitate, but the highly soluble compounds (with respect to sodium chloride) remain in the bittern solution. After 5 to 20 cm of salt has accumulated, the bittern is removed, and the crop is harvested, washed, and stockpiled for a time. The wash machinery moves the salt on a woven steel belt or along a perforated screen sprayed with seawater or brine. Washing removes much of the calcium, magnesium, sulfate and insoluble substances; about 12 to 15% of the salt is lost during the process. On the stockpile, salt increases in quality as the water and soluble contaminants continue to drain away. Salt is reclaimed from the stockpile with bulldozers or other equipment that push the crystals onto continuous belts, which load the product into ships or trucks.

In many solar saltworks, this physical process results in continuous and economic production of 1,000 metric tons of high-quality salt per hectare of crystallizer surface per year. On a dry basis, the purity of the washed salt may exceed 99.7%. [High quality salt (= world standards) maintains contaminants and water in the following ranges: Ca = 0.03 to 0.05%, Mg = 0.02 to 0.04%, sulfate = 0.11 to 0.16%, insolubles = 0.01 to 0.02%, and H_2O = 2.5 to 3%. A typical sample of the salt contains a high percentage of solid, large crystals, and a low percentage of small, hollow, or pyramidal crystals.]

TYPES OF SOLAR SALT WORKS

Most commercial solar saltworks are either seasonally or continuously operated. Most seasonal saltworks operate in temperate or tropical climates with hot, dry summers where 65 to 80% of the annual precipitation occurs during the winters (e.g., shores of Atlantic Europe, the Black Sea, East Africa, Mediterranean, San Francisco Bay in California, U.S.A.). A desired salinity gradient (from seawater density to saturation with sodium chloride) is maintained throughout the system of ponds only in summer, and the crop deposited on floors of soil or marl is harvested at the end of the summer. After harvest, concentrated brines remaining in the salina are stored in deep ponds where they will be used to reestablish the salinity gradient at the beginning of the next salt-producing season (19). (The reader is also referred to the entire set of articles in Volume 9, number 4, 1982, of Géologie Méditerranéene.).

Continuously operated saltworks, common in the dry tropics with low annual rainfall (Western Australia, Southern Africa, Central and South America), maintain a desired salinity gradient throughout the year, and the crop is deposited above salt floors. The salt floor (pavement) is a 5- to 10-cm layer of salt deposited above the native bottom substance of the crystallizers. Salt floors are not harvested; they provide structural strength to support heavy equipment; and they permit harvest of the crop free of mud and pebbles. Harvest may be continuous or confined to the summer season.

In both types of saltworks, tides and pumps may assist entry of seawater at the intake; concentrating and crystallizer ponds are placed along the contours of the land to allow gravity to assist flow of water and brines; and pumps are used in the circuit where flow by gravity cannot occur. For most saltworks, the ratio of surface area of concentrating to crystallizer ponds is about 10 to 1, but ratios of 15 to 1 are common.

THE BIOLOGICAL SYSTEM

Plants, fish, small animals, and microscopic organisms inevitably develop a biological system composed of planktonic (floating) and benthic (bottom-dwelling) communities in the ponds of every solar saltworks. Both communities include organisms (e.g., plants, algae, bacteria) able to manufacture organic matter from carbon dioxide, water, inorganic nutrients, and sunlight, and organisms that consume organic substances (e.g., bacteria, protozoa, and crustaceans).

Kinds of organisms and concentrations of dissolved substances occurring from the seawater intake to brine saturated with sodium chloride divide a solar saltworks into low, intermediate, and high salinity ponds. Species diversity decreases as salinity increases in each successive pond of the three groups. Although notable differences exist among the seaweeds, seagrasses, fish, and some crustaceans of solar saltworks in the various continents, the microorganisms composing biological systems show little variation in species from place to place.

The biological system in solar salt works can either aid or harm salt production. The biological system can help salt production (*1*) by manufacturing quantities of organic matter sufficient only to aid evaporation, to reduce water loss through seepage, and to furnish nutrients for all ponds at desired levels, (*2*) by maintaining bottom-dwelling (mat) communities at desired and well-functioning conditions (e.g., desired species diversity and thickness, and ability to sequester inorganic and organic nutrients), and (*3*) by allowing calcium carbonate and calcium sulfate to precipitate and remain at appropriate places along the salinity gradient. These biological systems (favorable systems) consist largely of organisms adapted to narrow salinity ranges, and they are associated with saltworks that continuously and economically produce high-quality salt at design capacity.

The biological system can harm salt production by producing and accumulating excessive quantities of organic matter. The organisms of these unfavorable systems are adapted to wide salinity ranges; their activities result in salt production at less than design capacity; and they necessitate increased expense and effort (e.g., for pond maintenance, and during salt harvest, transport, washing, and stockpiling) to bring the quality of the product to world standards.

Characteristics of Biological Systems in Low Salinity Ponds

Of the ponds in a saltworks, those of low salinity (S.G. 1.025 to S.G. 1.074) have the most surface area, contain the greatest volume of water, and produce the largest biomass and variety of organisms. More organic substances are produced than retained or consumed in these ponds.

The planktonic community consists of low concentrations of many species of well-represented microorganisms (e.g., bacteria, blue-green algae, chrysophyceans, cryptomonads, diatoms, dinoflagellates, crustaceans, and protozoa; see references 19 and 20 for lists and pictures of organisms at the different salinity ranges) that aid evaporation and furnish nutrients for the entire salina. In biological systems favorable to salt production, concentrations and composition of species remain unchanged over time, and water clarity allows sufficient light to reach the pond floors and maintain the benthic community in a functioning condition.

In biological systems unfavorable to salt production, the planktonic community may become dominated by a single species of algae, for example, *Ochromonas*, *Synechococcus*, *Gymnodinium*, or nanosize blue-green algae. When highly concentrated, these organisms deplete dissolved oxygen at night, decimate the small animals and protozoa, and exclude light from the benthic community.

The several-layered benthic community, interspersed with attached seaweeds, seagrasses, and scattered tufts of filamentous green algae (*Cladophora*), completely covers the pond floors. The upper layer (1 to 5 mm, yellow to orange) contains microorganisms similar to those of the plankton as well as unicellular, colonial, and filamentous blue-green algae (e.g., *Synechocystis*, *Gomphosphaeria*, *Microcoleus chthonoplastes*, *Oscillatoria*, *Phormidium*), unicellular green algae, protozoa, dinoflagellates, small animals (copepods, molluscs, nematodes, ostracods), bacteria, loose flocculents of organic matter and fecal pellets. The second layer (1 to 2 mm, green) consists largely of unicellular and filamentous blue-green algae, diatoms, nematodes, protozoa, and bacteria. The third layer (1 to 2 mm, pink to bright red), is dominated by photosynthetic bacteria. The lower layers (20- to 50-mm thick or more, black) include filamentous and photosynthetic bacteria (*Beggiatoa, Chromatium*) and organic matter. Small animals, protozoa, and bacteria — above and within the upper layers — oxidize important quantities of organic materials, contribute flocculents (mainly fecal pellet fragments) to the water and help maintain the benthic community at desired biomass. During strong winds, part of the uppermost layer becomes suspended and imparts additional color to the water.

In biological systems favorable to salt production, the benthic community maintains desired thickness and controls seepage, permanently sequesters important quantities of combined nitrogen and phosphate from the water and locks them in the black lower layers (17,19,21), remains firmly attached to pond floors, and sustains a diverse assemblage of well-represented organisms. In unfavorable systems, the community may grow excessively to decrease pond surface areas and volumes or become dominated by a few species, detach from floors, and float downstream. In these systems, *Cladophora* may grow from tufts to floating rafts that completely cover the surface of ponds, decrease evaporation, and exclude light from the benthic community.

When inorganic and organic substances, organisms, and floating segments of detached benthic communities are exported into the intermediate salinity ponds, they disintegrate and become nutrients for the biota in the more saline environment. Exports from favorable systems power the downstream biota at desired levels; those from unfavorable systems result in communities unfavorable to salt production and gradual silting up of ponds.

Characteristics of Biological Systems in Intermediate Salinity Ponds

Planktonic organisms produced in these ponds (S.G. 1.075 to S.G. 1.160) include blue-green algae (*A. halophytica*, *Dactylococcopsis*, *Synechococcus*), green algae (*Dunaliella salina*, *Dunaliella viridis*, *Tetraselmis*), diatoms (*Amphora*, *Mastogloia*, *Navicula*, *Nitzschia*), brine fly larvae (*Ephydra*), brine shrimp (*Artemia*), dinoflagellates (e.g., *Amphidinium*, *Gymnodinium*), several ciliate and flagellate protozoans (e.g., *Fabrea*), and numerous bacteria. Because fish and crustacean predators are largely excluded by salinity, *Artemia* may establish large populations. In biological systems favorable to salt production, the microplankton consists of many well-represented species, most of which are food for *Artemia*. The plankton color the brine and aid evaporation, but grazing by *Artemia* maintains suspended organisms and particulates produced in these ponds and imported from the low salinity system at levels that allow light to reach the pond floors. Appropriate concentrations of nutrients in the water, proper management of depths and flows, and competition for resources among the species prevents excessive growth of *A. halophytica*, *D. salina*, and *F. salina*. The composition and concentration of nutrients and plankton flowing out of the intermediate salinity ponds maintain downstream systems at desired conditions.

In unfavorable systems of intermediate salinity ponds, development of large populations of *A. halophytica*, *D. salina*, and *F. salina*, and associated mucilage increase brine viscosity, decimate the *Artemia* population, and shade out the benthic community. Exports of large populations of these organisms and organic substances create systems unfavorable to salt production in the downstream system.

The benthic community is a several-layered mat whose uppermost layer (1- to 3-mm thick, orange-brown) includes fecal pellets, sun-bleached blue-green algae and green algae, protozoa, and bacteria. The second layer (2- to 3-mm thick, green) contains blue-green algae and green algae (*A. halophytica*, *D. salina*, *D. viridis*, *Oscillatoria*, *Phormidium*, *Spirulina*), diatoms, protozoa, and bacteria. A middle layer (1-mm thick, red) is dominated by *Chromatium*. The lowermost layer (5 to 10-mm or more, black) consists primarily of *Beggiatoa*, *Chromatium*, *Thiovulum*, and other bacteria situated above and within organic deposits. In the most saline ponds of the intermediate salinity range, the uppermost layers of the benthic community may be interspersed with calcium sulfate crystals.

In benthic systems favorable to salt production, the communities completely cover pond floors, maintain desired thicknesses, house a diverse group of well-represented microorganisms, remain permanently attached to pond floors, and lock away in their lowermost layers important quantities of combined nitrogen and

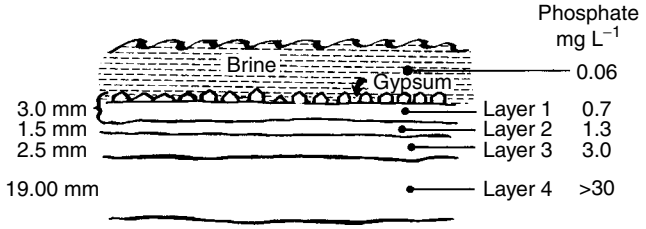

Figure 3. Diagram showing a mat segment with phosphate concentrations of each layer. (*International Journal of Salt Lake Research*, Vol 4, 1996, p. 338, Biological and physical events involved in the origin, effects, and control of organic matter in solar saltworks, Joseph S. Davis and Mario Giordano, Fig. 1, Copyright 1996 Kluwer Academic Publishers, with kind permission from Kluwer Academic Publishers.)

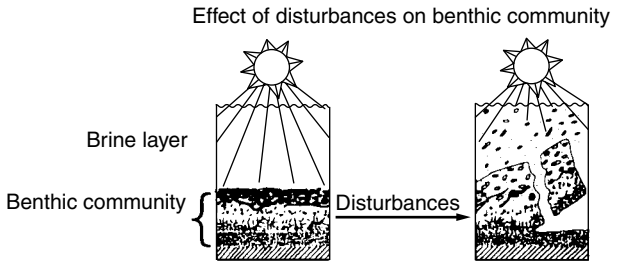

Figure 4. Diagram showing detachment of mat from floor in unfavorable conditions. (With permission of Dampier Salt Limited.)

phosphate from the overlying water (Fig. 3). In systems of intermediate salinity ponds unfavorable to salt production, benthic communities become dominated by *A. halophytica* and associated mucilage, and they accumulate excessively to decrease pond volumes and surface areas; in severe situations large segments (10 to 1,000 mm^2, 50- to 100-mm thick) break free of the bottom and float (Fig. 4) to the surface (21). As the mucilage in the rafts dissolves, the brine becomes viscous, many organisms are liberated into the brine, and the massive flow of organic substances becomes highly damaging to salt production in the downstream ponds.

Characteristics of Biological Systems in High Salinity Ponds

These ponds include the most saline concentrating ponds (S.G. 1.161 to S.G. 1.214) and the crystallizers (S.G. 1.215 to S.G. 1.260); their surface areas, volumes, and variety of living organisms are the smallest in the circuit of ponds. Most of the organic matter that provides food for the communities is imported from upstream. Planktonic organisms produced in these ponds include the aerobic red halophilic bacteria (*Halobacterium salinarium*), anaerobic bacteria, protozoans, and *D. salina*. In biological systems favorable to salt production, the red halophilic bacteria dominate the planktonic community, and concentrations of *D. salina* remain low. The red halophilic bacteria population oxidizes (permanently removes) much of the imported organic matter and multiplies to provide red colors that aid solar energy absorption and brine evaporation. In systems unfavorable to salt production, excessive imports from upstream and subsequent release of organic substances by large populations of *D. salina* create anaerobic conditions during darkness, color the brine black, decrease concentrations of the red halophilic bacteria, deteriorate salt quality and quantity, and lessen the integrity of the crop and salt floors (22).

At floor areas of concentrating ponds without gypsum, a benthic community develops whose upper layer (1 to 2 mm thick, yellow-green) contains filamentous and unicellular blue-green algae, green algae, protozoa, and bacteria, and whose lower layer (5- to 30-mm thick, black) contains bacteria and organic substances. At floor areas covered with gypsum, blue-green algae and bacteria live within the deposit, and organic substances form a lowermost black layer (5- to 20-mm thick) on the native bottom soils. At areas covered with salt, filamentous blue-green algae, bacteria, and organic substances accumulate below the sodium chloride.

In systems favorable to salt production, the benthic community controls seepage, maintains desired thickness, and sequesters nutrients from the overlying brine. Mat microorganisms may control gypsum accumulation by converting the lowermost crystals to fine particles (23), part of which is volatilized to sulfide (24). In crystallizers, the salt floors and/or the current crop remain firm and able to support heavy machinery; and most of the harvested crystals are large and solid. In the wash process, about 12 to 15% of the salt is lost.

In the concentrating ponds of systems unfavorable to salt production, benthic communities may grow excessively and decrease surface areas and volumes, and *A. halophytica* above the gypsum develops mucilaginous mats which break free and float downstream (Fig. 4). In deeper areas of the ponds, mucilage results in viscous brine and causes gypsum to precipitate as microscopic, single crystals rather than in firm, compact deposits. Pond floors become slimy and white with mucilage and gypsum, and the viscous brine transports the single crystals to the downstream ponds. In the crystallizer ponds of unfavorable systems, excessive organic substances interfere with crystal formation and cause salt floors and the crop to lose their structural integrity and become unable to support heavy machinery. The harvested crystals are mostly small, hollow, pyramidal "hoppers" that retain contaminants in their cavities, between layers, and on their surfaces (25,26). When washed, losses of salt are considerably more than 20%.

Characteristics and Management of Key Organisms

Artemia. The largest populations of these crustaceans occur in intermediate salinities; however, when sufficient nutrition is available, low concentrations of brine shrimp may survive throughout the high-salinity concentrating ponds. The well-known essentiality of *Artemia* to salt production lies in the ability of the animals to ingest suspended particles up to 50 micrometers (27), consume large quantities of organic matter (e.g., particulates, algae, bacteria, protozoa), sufficiently clear the brine and enable light to reach the benthic community, and deposit wastes in compact fecal pellets (28) that drop to the pond floors and become incorporated in the benthic community. When

most *Artemia* reach the high salinity ponds, they die and furnish highly suitable food for the aerobic red halophilic bacteria (29) in the downstream ponds. In many saltworks, the local *Artemia* strain is self maintaining, sufficiently vigorous to sustain suspended particles and organisms at desired levels, and able to quickly develop functioning populations. However, reintroduction of *Artemia* may be required when numbers of the animals are too small to control the plankton and to remove suspended organic substances. New introductions are necessary when numbers of the local strain remain too small or are unable to adequately clear the brine (30).

Fast establishment and maintenance of functioning *Artemia* populations can be aided by introducing cysts, freshly hatched nauplii, and adults of the animals at the lowest densities in the brine circuit where salinity excludes predation by copepods and fish (30). Further practices to aid *Artemia* populations include increasing brine depths in the intermediate salinity ponds for higher plankton production and prevention of brine temperatures from exceeding 35 °C (30), maintaining salinities within and between ponds in narrow ranges, modifying ponds to suppress wave formation and eliminate large accumulations of the animals and their cysts in windward corners, and restraining excessive growth of planktonic microorganisms in ponds of low salinity.

Aphanothece halophytica. These algae exist as individual planktonic cells that release dissolved mucilage into the water, as colonies of loosely aggregated cells within mucilage suspended in the water (Fig. 5), or as densely packed cells embedded within firm mucilage on pond floors or adherent to the top of the gypsum deposits. Colors of the algae range from bright green to blue-green or golden yellow to pale yellow. Although *A. halophytica* reproduce best in intermediate salinities, the algae survive and continue to produce mucilage well into high salinities (e.g., S.G. 1.180). When part of diverse planktonic and benthic communities, *A. halophytica* are not harmful to the biological system. However, with fluctuating salinities and/or high concentrations of nutrients, the organisms grow, dominate their communities, and release mucilage. Growth of *A. halophytica* can be suppressed by maintaining communities favorable to salt production in the upstream ponds, by management practices and design features that favor growth of benthic communities (shallow brine depths, "finger dikes" that partially traverse ponds to decrease wave fetch, and appropriate numbers and sizes of ponds) (21), by reintroduction of *Artemia*, and by devices and procedures that keep salinities within and between each concentrating pond in narrow and unchanging ranges.

Dunaliella salina. These motile algae reproduce best in intermediate salinities, but they survive and divide slowly in the high salinity and crystallizer ponds (Fig. 6). Colors of the algae range from green to orange to red. With fluctuating salinities and/or high concentrations of nutrients (21), large populations of the organisms develop, which color the brine bright green to yellow-orange to brick red, release organic substances (31), increase costs of harvest and washing, and decrease the quality of salt. In addition to the management procedures listed to control *A. halophytica*, *D. salina* populations and the released organic substances can be decreased by allowing salt to precipitate on floors of the high salinity concentrating ponds.

Fabrea salina. These ciliate protozoa, confined almost entirely to the intermediate salinities, are too large to be consumed by *Artemia*. In fluctuating salinities and in high concentrations of combined nitrogen and phosphate, the ciliates develop dense populations, consume almost all the plankton, and starve the *Artemia* population. The ciliates can be controlled by maintaining specific gravities in narrow and unchanging ranges within each pond of the low and intermediate salinity ranges.

Halobacterium salinarium. At high concentrations (10^7 to 10^9 per ml), these red halophilic bacteria color the high salinity brines pink to red and maintain organic substances at safe levels. These motile bacteria are highly sensitive to petroleum spills (32) and to ionic concentrations of the brine; with sufficient dilution, the bacteria burst and die (33). Desired concentrations of these

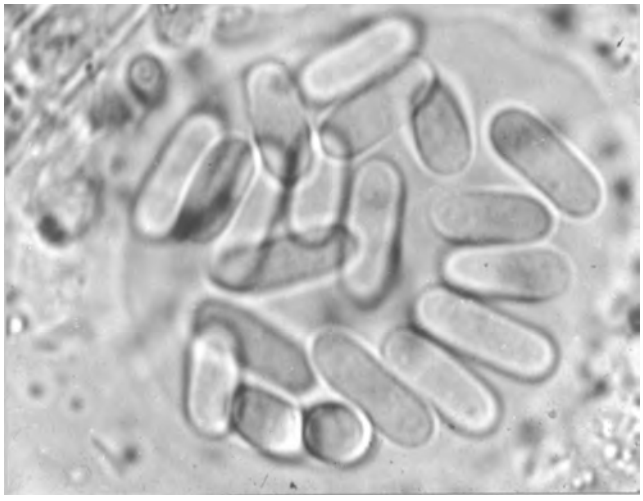

Figure 5. *A. halophytica* within its mucilagenous envelope.

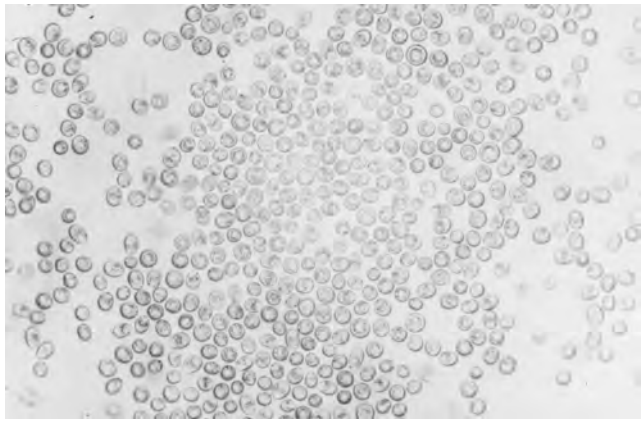

Figure 6. *D. salina* dominant in high salinity brine.

bacteria can be obtained by maintaining in the upstream ponds a diverse assemblage of microorganisms (e.g., *Dunaliella*, *Artemia*, *Dactylococcopsis*, *Synechococcus*, protozoa, brine fly larvae, bacteria) and by maintaining brine largely free of mucilage and cells of *A. halophytica*. Conditions that maximize the bacteria include shallow depths (21), long residence of the brine in the high salinity concentrating ponds, and deposition of salt on the floors of concentrating ponds to stabilize salinities.

PROACTIVE MANAGEMENT

Effects of high velocity winds, excessive rainfall, nutrient-poor or nutrient-rich intake water, and spills of petroleum or other deleterious substances into the water can be minimized with appropriate planning, special construction details, and proper brine management. Data gathering, data interpretation, and periodic inspections can indicate the development of undesirable conditions and allow adjustments and timely repairs before disasters occur.

High Velocity Winds and Rainfall. Saltworks at hurricane- and cyclone-prone locations require reinforced dikes armored with rip-rap, ponds whose long dimensions dampen wave effects of the prevailing winds, and "finger" dikes to decrease wave fetch and prevent back-mixing of brines of differing salinities within ponds. After rainfall, restoration of desired salinities can be aided by decanters at appropriate locations, canals, gates, and pumps for increased salinity control and to channel decanted water away from the ponds, and by appropriate adjustment of flow rates until the desired salinity gradient is restored (21).

Insufficient Nutrients in the Intake Water. This condition results in clear water in all ponds, insufficient evaporation, and leakage of water through pond floors and dikes. Davis (1978) applied several kinds of fertilizers to the most-downstream ponds of a new saltworks with nutrient-poor intake water until desired planktonic and benthic systems developed. Fertilization was then moved upstream until the entire system of ponds developed benthic systems that completely covered pond floors and controlled leakage. Small amounts of fertilizers were periodically placed in the intake water to maintain the system at desired levels (20). Other methods for controlling leakage include transfer of concentrated brines to ponds that leak (34), mixing "leaky" soil with clay (35), and construction of ponds on relatively impervious soil (5).

Excessive Nutrients in the Intake Water. Effects of high concentrations (18) of nutrients in the intake water and from other sources (birds, land runoff) are insidious, and they result in gradually developing unfavorable biological systems, often unobserved during the tenure of a single management official. The paucity of published data precludes meaningful assignment of values to the category labelled excessive nutrients.

Excessive concentrations of nutrients in the intake water (as combined nitrogen and phosphate) can be lowered to safe levels by use of a biofilter (36), harvest of biological products, and by appropriate pond design (21). For small saltworks, a biofilter 3 m by 12 m containing water at 10- to 20-cm depth removed about 60% of the combined nitrogen and phosphorus from the intake seawater (36).

Salinas may be designed for increased efficiency of nutrient sequestration and removal. Davis (1993) recommended five or more ponds in each salinity range (21), ability to operate the saltworks at depths that allow light to reach pond floors, harvest of biological products (*Artemia*, *D. salina*, fish, shellfish), and periodic removal of gypsum, bottom muds, and sediments. Although accumulated organic substances on the floors of crystallizers of seasonal saltworks are removed with the salt during harvest, periodic removal and replacement of salt floors are essential to control accumulations of organic substances in continuously operated saltworks.

Large numbers of birds may roost or nest on the dikes, feed in the water, contribute damaging quantities of nutrients to the brine, and predate excessively on *Artemia*. Control measures include use of noise cannons, bird-scaring devices, and adjustment of pond depths to exclude wading birds.

Release of Petroleum Products and Maintenance of Dikes and Equipment. Detrimental effects of petroleum products to the red halophilic bacteria (32) can be minimized by careful inspection of pumps and harvest vehicles, routine replacement of hoses carrying hydraulic fluids, and removal of all vehicles from crystallizers at night are essential. Immediate removal of spills of petroleum in crystallizers during harvest or postharvest grading minimize damage to marl or soil floors, the crop, and salt floors.

Proactive care includes periodic surveilance and fast repair of damaged dikes, proper maintenance of pumps, gates and weirs; and observations on the condition, careful inspection, and repair of salt floors. Appropriate inventory of spare parts and availability of portable pumps and other machinery are particularly important during harvest times.

Data Gathering and Utilization

Data routinely obtained by most saltworks (evaporation rate, salinity, rainfall, depths and flow rates, concentrations of contaminants in raw and washed salt, range of crystal sizes in representative salt samples, efficiency of the salt harvest and wash processes) appropriately displayed over time provide valuable information on the physical systems and indirectly indicate the effectiveness of the biological system. Value of this information for management of biological systems can be increased by routinely determining and displaying concentrations of combined nitrogen and phosphorus, organic content of the intake water, condition and composition of the benthic communities, and concentrations and conditions of key organisms in the water.

CONCLUSION

Production of high-quality sea salt at the design capacity of a solar saltworks requires integration of biological and

physical processes in the ponds. Proper management of the processes enables salt production under both favorable and unfavorable conditions. The latter include high concentrations of nutrients in the water, excessive rainfall and high velocity winds, and damage to the brine shrimp and red halophilic bacteria populations.

SAMPLING TECHNIQUES FOR ENVIRONMENTAL MICROBIOLOGY

YVETTE M. PICENO
GREG A. DAVIS
Rockford, Tennessee

Sample collection methodology is an important consideration for any microbiology endeavor because the data obtained is directly related to the way samples are collected and handled before analysis. The precise strategy used will be dictated to some extent by the analytical method chosen, but general guidelines can be stated for several environmental matrices. This review will present currently used sampling techniques for water, soil or sediment, and air samples, emphasizing considerations for molecular or chemical analyses rather than activity or culture-based analyses, in part to conserve space. Activity measurements and culture-based analyses are important (1) in combination with community structure information, but sampling issues for such analysis can be involved and may need to be tailored to each environment. Clinical (tissue) specimen sampling and food sampling will not be covered in this article. Where sampling strategies may deviate substantially for a matrix within each of the general categories covered, the methods will be presented separately. Given the breadth of the topic at

hand, the descriptions will be necessarily brief. For more detailed information, consult the appropriate sections of this Encyclopedia and the references cited herein.

SAMPLING STRATEGY

The project or study goals will determine the sampling strategy, especially regarding sample distribution across a site or matrix and subsampling or pooling samples before analysis. Surveys of new areas should take into consideration the natural variability of environmental parameters, allowing patterns to be assessed. Preliminary studies to assess variability of a variety of factors across boundaries or gradients expected to influence microbes are a necessity for designing meaningful studies and experiments. The spatial resolution necessary to accurately characterize microbial assemblages and communities will be determined by physical, chemical, and biological factors. Reviewing basic principles of geostatistics as discussed in References 2 and 3 will improve sampling designs for a variety of environments.

Often, it is not feasible or even possible to sample at a resolution truly meaningful to the microbes of interest. In this respect, biofilms provide a valuable opportunity to study microbial growth patterns and the chemical parameters that both influence them and are influenced by them. Microelectrode and scanning confocal laser microscopy studies of biofilms provide the closest approximation to relevant physicochemical measures currently available. Unfortunately for many important environmental matrices, physical structures, such as coarse soil particles, can preclude or severely restrict the use of microelectrodes or microscopic techniques. Also, even when a variety of approaches are possible for an environmental matrix, time and monetary constraints may necessitate a circumscribed sampling approach.

When sampling, it is important to either sample in a truly random manner or to sample in such a manner as to accommodate the established structure, such as environmental gradients or macroscale environmental patchiness. If the purpose of an experiment is to assess the effect of a treatment, then minimizing natural variability as much as possible is advisable. When sampling in an environment where unavoidable patches are much larger than the sampling unit, a randomized block design may be most useful. When sampling in an environment where the patches are much smaller than the sampling unit, a simple random sampling strategy may be sufficient. In this context, a simple (or completely) randomized design would be the equivalent of placing a sectioned grid over a sampling area, assigning each section a number, and using a random number generator to assign each treatment (including all replicates) to each numbered section. Conversely, a randomized block design would section an area by physicochemical boundaries and then assign equal numbers of replicates of each treatment to each section. Of course, the placement of each replicate within a section could be assigned randomly. Several design schemes are depicted in Figure 1 (as taken from Ref. 4) and also are depicted in Ref. 2. Regardless of the sampling design, it should go without saying that a nonmanipulated (i.e., control) sample should be included in every experiment.

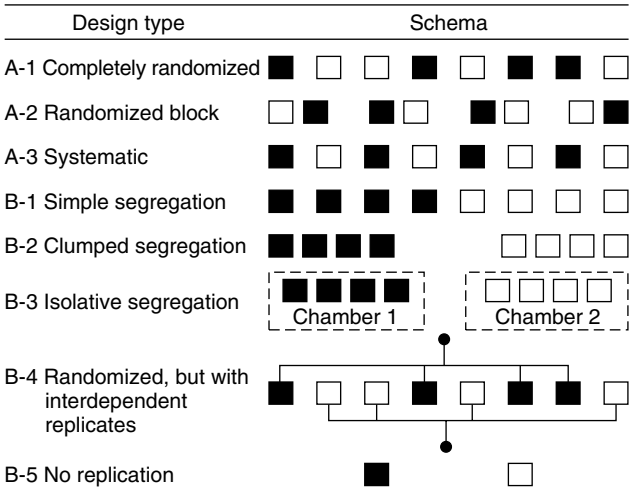

Figure 1. Schematic representation of various acceptable sampling designs (A) of interspersed replicates of two treatments (shaded, unshaded) and various ways (B) in which the principle of interspersion can be violated. Figure 2. Go-Flo sample bottle with closed top valve. Ball valves at each end are opened when the bottle reaches 1 atm pressure (about 30 ft) and are closed by a messenger (or electronically) when the bottle reaches the desired depth. Bottles typically range from 2.5 to 30 L (**a**) but can be made as large as 200 L (**b**). Images and information generously provided by General Oceanics, Inc. (*http://www.GeneralOceanics.com*). See color insert.

It is always advisable to know how the data will be analyzed statistically prior to sampling. Several texts can be consulted (4–6), and consulting a statistician can be an excellent way to assure the method chosen makes sense. van Elsas and Smalla (2) discussed sampling strategies and presented a table of questions to help guide soil sampling, and these considerations are equally applicable to other matrices. Krebs (4) provided more detailed explanations and examples of sampling strategies, using ecological data to familiarize the reader with equations.

Once the basic statistical parameters are understood, one can consult more recent literature to investigate methods for analyzing complex data (e.g., phospholipid fatty acid or denaturing gradient gel electrophoresis profiles) (7–11).

As with most sampling issues, whether to pool (or composite) samples will depend on the question being addressed (12). Pooling samples will probably cause one to lose information (13), which, if it was known, might affect future experimental designs or even direct testable hypotheses. On the other hand, pooling samples for surveys of large areas may be the only feasible way to characterize communities. For homogeneous environments, using a sample taken from a composite sample may be sufficient (13). However, in other environments, maintaining spatial resolution may be very important (14). Riemann and coworkers (15) collected depth-integrated samples from the deep sea and discussed how this may have affected the apparent diversity of DNA sequences retrieved. The decision to pool samples also may be directed by practical considerations, such as labor or equipment availability. van Elsas and Smalla discussed these issues in greater detail (2).

SAMPLE QUANTITY

The amount of sample that is required will depend on the type and number of analyses performed. Thirty grams of soil or sediment commonly are extracted for phospholipid fatty acid (PLFA) analysis, and 10 to 20 g of material is usually more than sufficient for nucleic acid extractions. As one example of a culture-based analysis, Fredrickson and Balkwill (16) suggested using 10 g soil in 95 ml buffer (e.g., 0.1% sodium pyrophosphate, pH 7.0) with subsequent 1 : 10 dilutions for MPN assessments of (sub-) surface soils. Therefore, collecting 75 to 100 g of material per sample location is generally sufficient to conduct several analyses.

The amount of water required for these same analyses will depend on the concentration of biomass present. One to two liters of water is required for PLFA analysis of moderately clear water (low biomass), whereas the amount of water analyzed may be restricted to a few hundred milliliters or less in very turbid water samples. For other analyses, several hundred to 1000 liters may be needed [e.g., for viral or pathogenic cyst detection from natural waters (17)]. However, if a full chemical constituent analysis is required and numerous analyses (macromolecular, culturing, etc.) are to be performed on a sample, then larger amounts of sample or numerous representative samples may need to be collected. Several chemical and routine culturing analyses are detailed in the Standard Methods for the Examination of Water and Wastewater (12) (e.g., Table 1060:I summarizes information for sample volume, container matrix, preservation, and storage recommendation for several measurable physical and chemical water parameters).

An important point to consider when collecting sample material is the limit of detection (LOD) or quantitation (LOQ) for the analyses being performed. Sufficient material must be collected to yield detectable or quantifiable product. For PLFA, at least 10^5 cells are required for detection and 10^{7-9} cells (*Escherichia coli* cell equivalents) or a total of approximately 200 pmol PLFA per sample are required for meaningful data analysis of pure cultures and complex communities, respectively (18). For nucleic acid-based analyses, the limit of detection is harder to define because of the uncertainties in DNA extraction and coextraction of inhibitors for various analyses, many of which are PCR-based analyses (see RIBOTYPING METHODS FOR ASSESSMENT OF IN SITU MICROBIAL COMMUNITY STRUCTURE). Felske and Akkermans (13) demonstrated that one gram of soil was sufficient to characterize the dominant bacteria in grassland surface soils over a fairly large area using nucleic acid techniques. For several matrices, this quantity of material is sufficient for nucleic acid extractions when samples are well mixed or composited. This observation will probably not hold true in other environments, particularly for low biomass environments (19).

SAMPLE SIZE (NUMBER OF SAMPLES)

The number of samples required to accurately define a parameter for a system will depend on the natural variability of that parameter. For a "quick and dirty" microbial community characterization survey, a minimum of three to four samples from a relatively homogeneous matrix may suffice. However, in spatially heterogeneous environments, a greater number of samples may be required to gain a representative perspective (19). Some investigators pool samples to reduce the number of samples processed in surveys but this should be done only with good reason (as discussed previously) because of the potential loss of useful information. It is beyond the scope of this article to discuss whether subsampling from a very large sample is pseudoreplication or an acceptable form of replication, given the physical scale of influential parameters on microbes. It is, however, a point to consider before sampling, and Krebs (4) discussed three kinds of pseudoreplication (including temporal pseudoreplication that could be analyzed as a repeated measures analysis of variance) to help differentiate them from truly replicated sampling designs.

Determining an adequate sample size for experiments is trickier than that for surveys and may require data from a pilot study. Motulsky (5), in *Intuitive Biostatistics*, explained simply the important parameters for testing hypotheses, including α, β, and power indices. Krebs (4) provided a more detailed explanation of these parameters and the equations required to estimate sample size in relation to a desired level of power.

SAMPLE TRANSPORT AND STORAGE

The most common practice is to transport samples on ice (or blue ice) if cell components (e.g., lipids or DNA) will be analyzed within a few days. If samples must be stored (see the following text), then it is common practice to freeze the samples immediately (e.g., putting soil or filtered samples on dry ice) and transport them frozen

until they can be transferred to a freezer, preferably stored at −80 °C. When collected for culturing or physiological measurements, samples can be kept as close to in situ temperature as possible if they will be processed quickly (within a few hours); otherwise, it is better to keep samples cool than to let them become too warm before culturing. Generally, samples should not be stored unless it is absolutely necessary. There can be remarkable increases in culturable heterotrophs during storage (19,20), even when stored below 10 °C, and changes in phospholipids have been documented as soon as several hours after disturbance (21). van Elsas and Smalla (2) noted that storing samples for up to three weeks at 4 °C in the dark may be acceptable for some analyses but that control measures or assessments should be included whenever possible to check for changes.

Maintaining in situ aerobic or anaerobic conditions after sampling also is important when activity or culture-based analyses will be performed. Collecting and transporting samples under anaerobic conditions is discussed in References 16 and 22. Cragg and coworkers described an inexpensive, field-portable bag for anaerobic sample transport and storage. Wine bags, consisting of nylon, aluminum, and polyethylene material, were used in conjunction with an activated Anaerocult-A sachet and a heat sealer to generate and maintain anaerobic (CO_2) conditions for at least three years. The bags were sterilizable by autoclaving or gamma irradiation and can accommodate moderately large samples. If these or similar containers are not used, then samples should be collected in containers that are not readily gas permeable and should be transported under N_2 or Ar when possible.

Water can be transported and stored in presterilized containers or filtered, even in the field, and placed in presterilized filter holders (e.g., Petri dishes). Several filter materials are used for molecular analyses [e.g., polycarbonate (23,24), Durapore (25), Sterivex (26)]. Anodized aluminum filters (Anodiscs, manufactured by Whatman) are used routinely for collecting material from water samples for subsequent lipid or DNA extraction. An advantage of using Anodiscs for DNA extraction is that they can be crushed after filtration and placed into 2-ml screw cap tubes for subsequent bead-beating cell lysis. Alternatively, once filtered, samples can be stored at 4 °C for several days or at −80 °C for long-term storage (23,26). If RNA instead of DNA will be extracted, it is best to freeze the filters immediately. Filtering material onto Anodiscs is useful for medium to high biomass samples, but other filter materials may be needed for low or very low biomass samples. Fuhrman and Davis (25) used Durapore filters for analyzing deep-sea samples, whereas Riemann and coworkers (15) used capsule filters.

Basic handling criteria for soils are similar to those for water. It is best to process soils as soon as possible, given that microbial community changes can occur rapidly (27). Soils can be stored at 2 to 4 °C for short periods (several days) for certain analyses but freezing is commonly used for long-term storage. Freezing for some matrices may adversely affect some cellular components, potentially reducing DNA recovery because freezing happens slowly in soils and sediments. If long-term storage is the only option prior to analysis, then freezing at −80 °C, often after shaking or sieving, is the option that is most widely used currently (28). Air-drying may severely decrease or alter the cellular component to be analyzed and should be avoided (2,3,29). Lyophilization, however, is used successfully for long-term sample storage for lipid analysis (18) and may also be acceptable for ergosterol analysis (29).

Obviously, samples collected for physiological measurements (especially activity measurements) should be held at a temperature close to in situ temperature and processed as soon as possible; this has been discussed further by van Elsas and Smalla (2). Freezer packs should be used to keep samples cool during sample transport unless tightly sealed (and, for shipping, preferably plastic) containers are used. If regular ice is used to keep samples cool before processing, the ice should be double-bagged. It is very important that soil or sediment samples are not subjected to excessive wetting during transport, which can result from leaking ice containers or damaged sample containers. Presterilized 50-ml screw-cap tubes are excellent short-term storage containers, especially for small soil cores, when wet ice is used for sample transport. Self-sealing (30) or Whirl-pak® plastic bags also are very handy.

Gessner and Newell addressed sample storage issues for determining fungal biomass in plant litter via ergosterol analysis (29). The storage methods presented may be useful for soil analysis too, although this was not stated explicitly. The authors emphasized the importance of not air-drying the samples and suggested that methanol immersion followed by storage at 4 °C is the best procedure for preserving ergosterol content. Freezing followed by lyophilization (just prior to sample analysis) and homogenization may be acceptable, but preliminary studies should compare ergosterol content from such samples to those that have been methanol-preserved.

Caron (31) briefly discussed sample preservation for various protozoa, including algae. Because various protozoa require different preservation solutions [e.g., an alkaline preservative must be used for foraminifera so as not to dissolve the tests, whereas acidic Lugol's solution is used for ciliates (31)], multiple aliquots of a sample may need to be preserved in these various ways to provide the most complete assessment possible. Several detailed procedures are presented in Reference 32; these procedures allow simultaneous sample fixation and preparation for later microscopic examination for activated sludge, freshwater, and marine water samples.

FURTHER CONSIDERATIONS BY SAMPLE MATRIX

Water (Fresh and Marine)

Grab samples are used commonly for collecting surface water samples. Grab samples are collected by immersing a bottle or bag into the water to a desired depth (33) or drawing water from a specified depth using a pipette (34) or tubing (35). A device designed to sample subsurface water is described in Reference 12, Section 9060 A.g. Other samplers to note for shallow- or moderate-depth water environments are those discussed in References 36 and

37. The flow-through samplers (e.g., the Friedinger bottle or the Go-Flo Niskin bottle; Fig. 2) are particularly good samplers for both their simplicity and ability to collect moderate to large amounts of sample (>250 ml to 60 L, General Oceanics has even made a 200-L sampler) (36,37). Several of these samplers also are used for deep-water sampling (see the following text).

Usually, samples are transported in bottles and then processed after returning to a lab (23); although, for very large samples, the water may be passed through filters in the field (see the following text). Sometimes, glass fiber filters or other large pore filters are used to remove large particulate material from samples before filtering onto a 0.45 or 0.22-μm pore size filter (24–26) for sample analysis. Prefiltering should be done only when necessary because it may affect the results, given that microbes are known to attach to particles.

For some analyses, very large amounts (several hundred liters) of sample are required and so water is filtered in the field (38–40). This is often the case when the goal is to detect pathogens or viruses from surface water, particularly for viable assays. Payment and coworkers (40) described a cartridge filtration and backflushing method [modified by Kaucner and Stinear (39)] for detecting several pathogens [*Giardia*, *Legionella*, and *Clostridium* (and *Cryptosporidium* by Kaucner and Steiner)], and Hurst (17) discussed cartridge filtration for viral collection. Hurst also detailed sampling and retrieval protocols for sampling viruses from drinking waters and wastewaters. Sampling flow rates ranged from 4 to 40 L/min for the various large-volume investigations.

As a special area of surface waters, the air–water interface is an important component, and several devices have been used to collect surface films. Several samplers were discussed in References 36 and 37. Screen samplers are widely applicable, and Nucleopore membrane filters are used commonly to sample the neuston. Screens can be made of stainless steel or Nytex mesh, are inserted into a water column vertically, and then are withdrawn horizontally (parallel to the air–water interface) for sample collection. Surface material from approximately 150 to 300 μm is collected. For additional information concerning air–water interfaces, see NEUSTON MICROBIOLOGY: LIFE AT THE AIR–WATER INTERFACE, this Encyclopedia.

When sampling water columns for protozoa (including algae), water can be passed through a series of sieves as described in Reference 37. Delicate organisms may be damaged when collected by sieving or by filtration (31). Alternatively, one of the several types of plankton nets (Fig. 3) or the Hardy Plankton Recorder (a continuous-flow apparatus) can be used (36,37). Samples collected by the Hardy Plankton Recorder are automatically formalin-fixed as the sample is collected.

Drinking water treatment and distribution systems and wastewater treatment facilities are other commonly sampled aqueous environments. Grab samples and biofilm samples are used to assess microbiological parameters in various parts of drinking water treatment and distribution systems (12,41). Grab samples are collected after flushing pipes thoroughly and then collecting samples in bottles or by lowering bottles into open reservoirs (12, Section 9,060 A.3). The samples are kept cool until analyzed (within 24 hours for culturing analyses) (12, Sections 9,060 B). For large-volume water sampling, Hurst noted that cartridge filters could be stored at −70 °C when the samples could not be processed for viral elution within two days but that some viruses lost viability when they were frozen (17). The effect of long-term or frozen storage on other organisms was not mentioned, although Schaefer (42) stated that filtered samples should not be frozen if they will be assessed for *Giardia* or *Cryptosporidium* because ice crystals disrupt the cysts and oocysts, thereby affecting detection. Also, when the water is chlorinated, it is necessary to dechlorinate the water before sample transport and storage. Sodium thiosulfate should be added to a final concentration of 100 mg/L (12, Section 9,060 A.2.). Dechlorination is especially important when samples are concentrated (17,42). A sampling apparatus design and detailed sampling protocol are presented in Reference 42.

Microbiol.* **59** (7), 2,293–2,298. Copyright © 1993 by ASM Journals. Reprinted by permission of American Society for Microbiology Journals.

Given that organisms in drinking water may well come from bacteria released from biofilms, it is important to analyze biofilms as well as bulk water samples from these sources. An excellent way to monitor biofilms in pipes is to use a Robbins device (43,44) [or a modification thereof (41,45)]. This device has slides (or "coupons") attached to screws or bolts that are positioned around the circumference of a pipe or material housing (Fig. 4). Water flows across the coupons and exits the device without stagnating around the coupons. The coupons can be made from any material of interest that can be attached to the holders or painted onto a suitable substrate. Various configurations for Robbins devices are depicted in the aforementioned articles.

Biofilms are of concern in many other places too, such as industrial processes and wastewater treatment facilities, where characterizing the organisms present can help solve problems. Biofilms collected from such facilities may well be amenable to microscopic analysis if debris is not much of a problem. Scanning confocal laser microscopy (SCLM) is widely used in conjunction with fluorescent dyes and labeled probes to study biofilms (46). Ladd and Costerton (44) gave detailed procedures for studying biofilms (e.g., measuring activity) and briefly stated ways to grow and collect biofilms. Kalmbach and coworkers (45) also described planktonic cell collection via filtration and biofilm handling for in situ hybridization. For culture-based assessments (e.g., sulfate-reducing bacteria in oil-production facilities), recovered biofilms should be mechanically disrupted, for example, by shaking them with glass beads in a buffer containing a nontoxic, nonionic detergent to facilitate quantitation (46,47).

Biofilms can be obtained by suspending coupons in an environment and then retrieving the coupon for analysis (as described previously) or by using biofilms produced in situ if the support material is amenable to handling (48). In either case, biofilms can be transported in sterile liquid [e.g., buffer or water drawn from the collection site (47)] or fixed immediately in buffered formalin (43,48). Immediate fixation in formalin or another fixative is especially useful when microscopic examination is planned. If destructive analytical methods are used (e.g., PLFA or nucleic acid extraction), then scrapping and collecting the biofilm into bags or bottles may be sufficient. Standard collection and transportation recommendations then apply. However, glass or metal coupons resistant to the chemicals used in an analysis can be processed directly (i.e., without removing the biofilm first).

The deep sea is being studied more frequently as better sampling equipment is designed and as more nonculture-based analytical methods become available. While culture-dependent studies were still the primary means of studying this environment, several sampling devices were developed (and are still being developed) to maintain in situ conditions during sampling. One such device was described and illustrated in Reference 49 and a diagram of a similar multisampler is presented in Figure 5. This sampler allows up to 12 samples to be collected, either in high-pressure sampling units or in Niskin bottles. The high-pressure sampling unit [designed by Bianchi and coworkers (49; Fig. 6)] allowed subsample collection without sample decompression and had an insulating coat to alleviate temperature changes until the unit could be properly incubated after retrieval (49). In addition, the entire high-pressure sampling unit could be autoclaved. Bianchi and coworkers demonstrated the importance of maintaining in situ pressures during activity measurements using this device (49). Another example of equipment used to maintain high hydrostatic pressures for ex situ experiments was illustrated elsewhere (50).

The importance of maintaining in situ conditions will depend on the use of collected material and the organisms themselves. Activity-based analyses provide the greatest challenge; sampling for other analyses is less demanding. Deming stated that maintaining in situ temperature was more important than maintaining hydrostatic pressure for recovering culturable psychrophiles (50). It was also noted that the temperature sensitivity seemed less important for recovering hyperthermophiles than for recovering psychrophiles. For molecular studies, Niskin bottles (15) on Rosette samplers (25) have been used for sampling deep-sea environments. It was not necessary to maintain in situ temperatures or pressures for these studies.

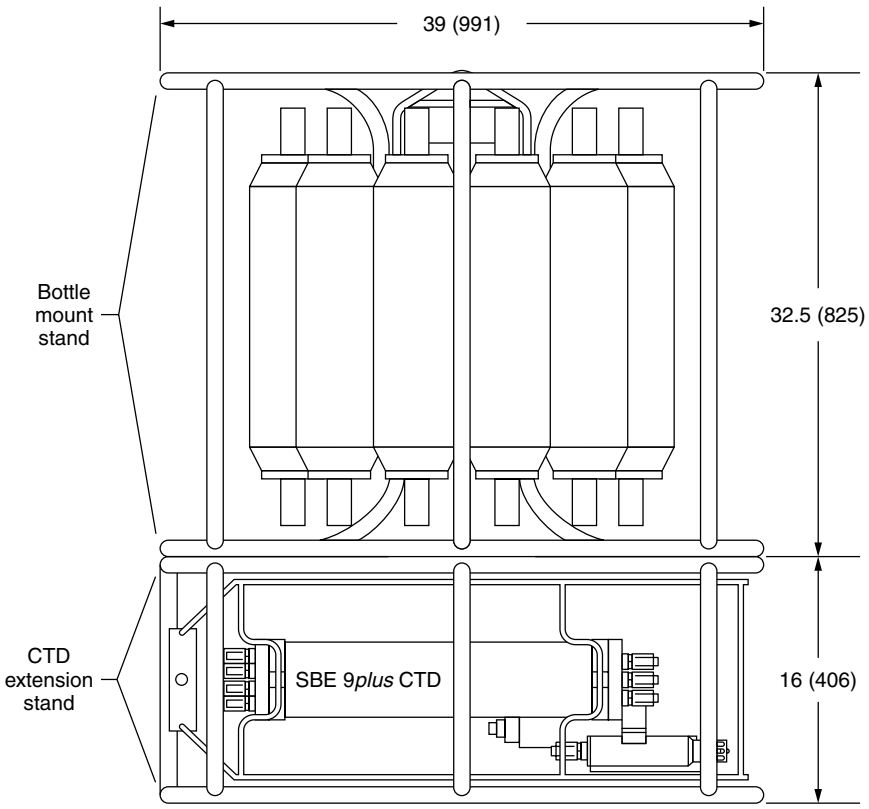

Figure 5. Diagram of a multibottle water sampler (SBE 32 Carousel Water Sampler) showing bottle stand and an optional 9*plus* CTD unit used to close bottles at preprogramed depths. Additional equipment, such as a data logger, can be mounted as well. Diagram and information kindly provided by Sea-Bird Electronics, Inc. (*http://www.seabird.com*).

The one aqueous environment other than the deep sea that poses significant sampling challenges is groundwater. Thankfully, there is an extensive literature base from which to draw advice. In particular, sampling considerations for remediation sites are presented in great detail in Reference 51. Details about samplers and monitoring wells for soil water and groundwater sampling are provided in Reference 52. Briefly, soil water or groundwater collections from the vadose zone (generally 15 m or less in depth) can be made with pressure or vacuum water samplers. Vacuum samplers from permanently installed samplers collect interstitial water and water from adjacent macropores. When using permanent samplers, it is best not to sample within one year of well installation. Various problems are associated with vacuum samplers, a very important one being that it may be difficult to obtain sufficient sample for analysis (52). Pan or wick-type samplers collect water from macropores, especially following wetting events (precipitation or irrigation) (52). The amount of water collected will depend on the system, although the samplers should generally be emptied after each wetting (e.g., rain) event to prevent cross-contamination.

Bailers or various kinds of pumps can be used to collect water from groundwater monitoring wells (16,52). This equipment and any tubing should be sterilized or disinfected before samplers are deployed. Bailers equipped with check valves are the least expensive samplers but may yield the least representative sample because of mixing and aeration commonly experienced with these samplers (52). Bladder or submersible pumps that can be used to collect water from depth are described in Reference 52 and are best when used as dedicated pumps (i.e., one pump per well). Whenever possible, groundwater should be pumped until a stable chemical (Eh, pH) composition is measured before a sample is collected (53,54). Pumping or purging at least two to three well volumes is common.

When the groundwater is known or suspected to be anaerobic, precautions should be taken to maintain the anaerobicity, at least until the physicochemical parameters are measured. This can be a problem with tubing material, such as that used with a peristaltic pump, because some of the tubing is gas-permeable. Low or non–gas-permeable tubing should be used for everything except the area around the pump head, where flexible tubing is necessary. A compromise between low gas permeability and flexibility around a pump head is C-Flex™ tubing (Consolidated Polymer Technologies, Cole-Parmer), which can be sterilized and which works under vacuum. A relatively new sampler, presented in Reference 55 and shown below in Figure 7, was designed to minimize pressure differences during groundwater sampling. This sampler purportedly maintains in situ gas concentrations better than other samplers, thereby yielding more representative groundwater samples.

Soils and Sediments

Collecting intact cores is the best method for sampling soils or sediments. Shovels, trowels, or other scoops are

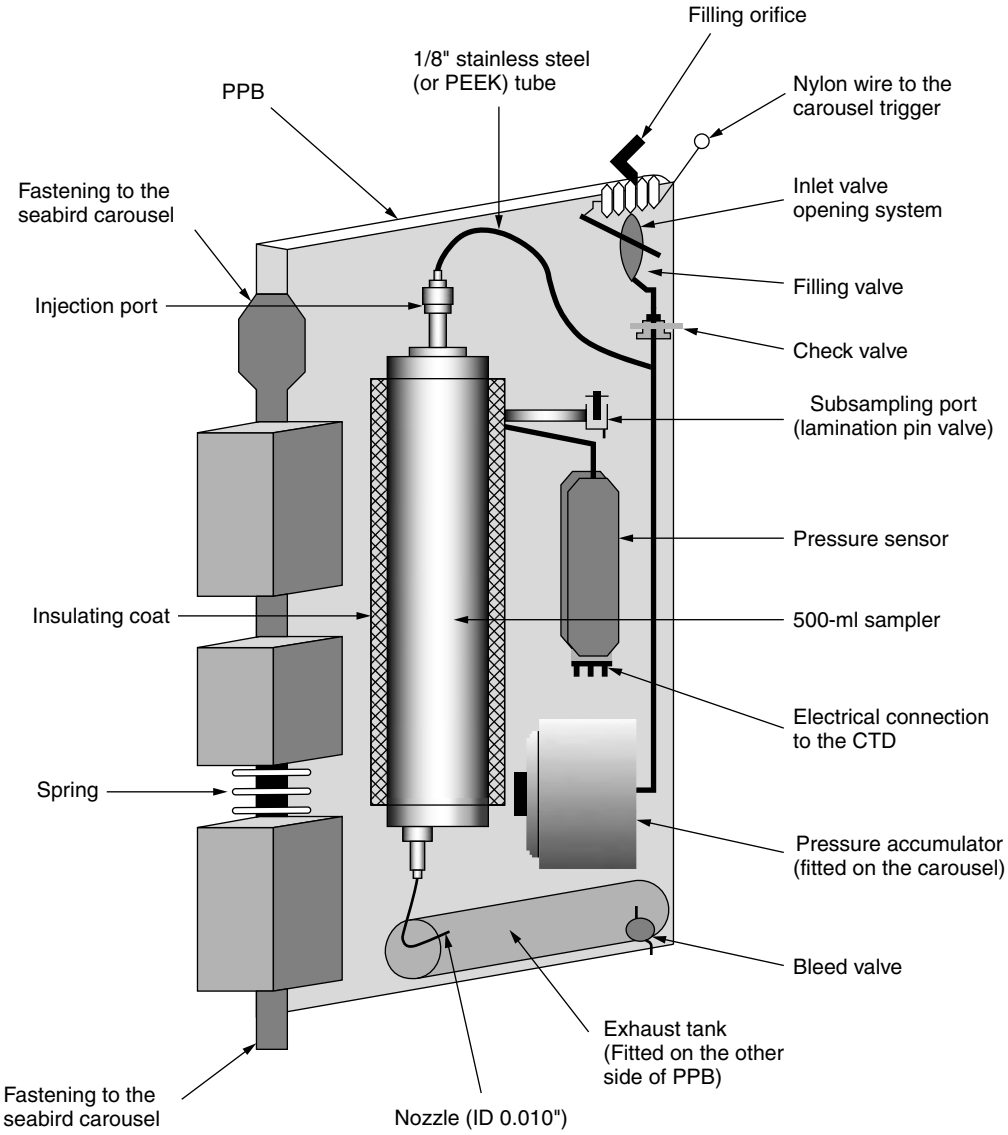

Figure 6. Diagrammatic representation of the high-pressure sampler unit (HPSU) designed by Bianchi and coworkers that was mounted onto an SBE 32 Carousel Water Sampler. The exhaust tank is fitted on the hidden side of the polypropylene board (PPB). The sampling unit's specifications and operating information are detailed in Bianchi and coworkers, 1999 (49). Redrawn and reprinted from A. Bianchi, J. Garcin, and O. Tholosan, *Deep-Sea Research, Part 1* **46**, 2,129–2,142 (Fig. 2, p. 2,132), Copyright © 1999, with permission from Elsevier Science.

easy to use, but may overestimate the contribution of surface inhabitants in relation to the deeper residents unless one is careful to sample to a predetermined depth. Coring provides an even representation of organisms at various depths and causes the least disturbance before sample processing. Shallow surface samples can be collected by hand using cut-off syringes (50) or hand augers (2). Additionally, cores with silicon-sealed injection ports (Fig. 8) can be used for activity measurements of various types (56) but have disadvantages (e.g., diffusion limitations) as well as advantages (e.g., minimal disturbance of natural physicochemical properties) as discussed by Deming (50).

Submerged surface sediments have been sampled with dredges, trawls, and box corers (36,37). Diagrams of various grab samplers and corers are presented in References 36 and 37 along with discussions of the advantages and disadvantages of each. The Jenkins, Craib, and Barnett frame-mounted corers provide the least disturbance, regarding both vertical core compression and water-sediment surface layer disturbance, of the samplers discussed (36). These corers have hydraulic pistons to slowly drive cores into the sediment, and the last two have ball valve end seals to better retain sandy sediments. Additionally, the Barnett sampler has a 12-core sampling capacity. Examples of a box corer and a multicorer are shown in Figure 9. Herbert (36) also discussed several ways to remove cores with minimal disturbance.

Terrestrial subsurface coring requires more sophisticated devices (coring tools), a variety of which are described

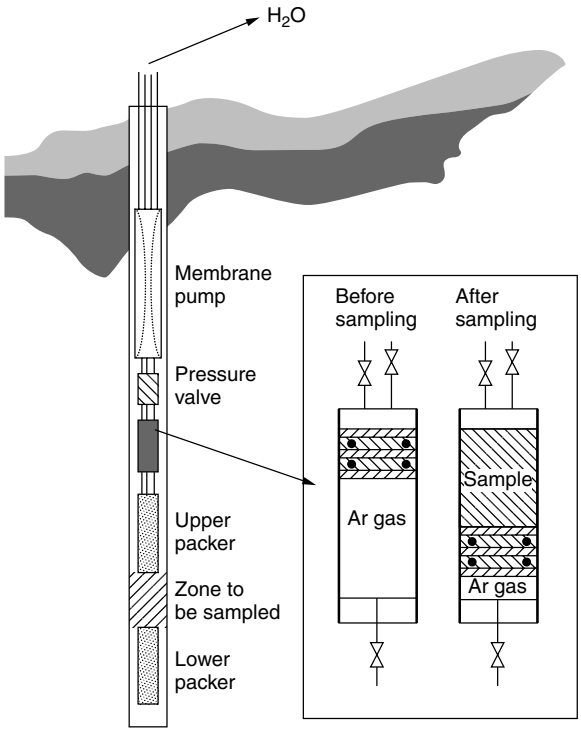

Figure 7. Diagram showing a pressurized groundwater sampling system (called PAVE) deployed in a borehole. The sampler can be opened and closed from the surface, and multiple sample vessels can be used simultaneously. in References 53 and 57. This topic is presented in greater detail in a subsurface drilling and sampling chapter in this Encyclopedia. A brief presentation of the most basic considerations follows. Presterilized (foil wrapped and autoclaved) liners can be used with some subsurface corers to aid with short-term storage and transport (19,53). Such liners are used for coring unconsolidated subsurface soils (53). Liner material should be selected carefully regarding the soil matrix and the possibility that bacteria could use the material as substrate (e.g., acetate liners), particularly if long-term storage is necessary. When sampling subsurface sediments that may be anaerobic, it is important to minimize oxygen exposure. Coy (Ann Arbor, MI) anaerobic chambers can be set up at makeshift field labs and samples can be processed as described in Reference 53. Cragg and coworkers (22) also described a method for maintaining anaerobic conditions in bags for years. As stated previously, retrieved cores can be capped immediately (16) and sealed with bee's wax or, when the sediment is not flush with the core liner, the sediment can be sealed with wax and then capped before being transported. This precaution is important to prohibit sloughing or mixing of unconsolidated sediments during transport and can help maintain field sediment moisture content. When sampling the subsurface, it is also necessary to decontaminate (e.g., steam clean) all the equipment that might contact a sample (16,58).

A detailed procedure for subsurface coring is described in Reference 16. Briefly, clean and disinfect all equipment that will come in contact with sampling material. Prepare the borehole or corer with tracers (such as by placing a plastic bag of tracer compound in the shoe of the core barrel so that it ruptures on impact, see Fig. 10), place an appropriate core liner (e.g., Lexan, PVC, stainless steel) into the core barrel, collect the sample, cap the core liner ends, and place the liner in a glove bag containing Ar or N_2 for transportation. When removing material for analysis, outer core material should be pared (53,59) to reduce the chance of including contaminated material and inner and outer material should be examined by tracer analysis (16). A variety of tracers can be used to account for possible contamination from drilling muds or circulating fluids, for example, chemical tracers (Br) (58) or (pseudo-) biological tracers [fluorescent microspheres (58) or nonindigenous bacteria (60)]. Chemical tracers can be added to drilling muds but microspheres are often too costly for this and so usually they are used only as described above. Detailed procedures for handling samples and sampling equipment are presented in References 19,57,58, and 61.

The last soil habitat discussed will be the rhizosphere. This is a cursory treatment; a more detailed examination is presented in RHIZOSPHERE MICROBIOLOGY, this Encyclopedia. The rhizosphere is loosely defined as the area of soil or sediment influenced by plant roots (3), mainly root exudates or cell lysates. Rhizosphere studies, therefore, vary in the distance from the plant from which material is collected. Whipps and Lynch (1990) differentiated the endorhizosphere, ectorhizosphere, rhizoplane, and rhizosphere from one another; thus, one can envision different ways of studying these zones: TEM or other microscopy for the endorhizosphere (62), SCLM for the ectorhizoplane or rhizoplane (63), culturing (64,65), or direct extraction (11,66,67) for some or all locations. Campbell and Greaves (68) reviewed a variety of methods for studying rhizospheres, including sampling considerations for culture-based investigations. Several examples of culture-based sampling methods are presented in the literature. For example, Smit and coworkers (69) plated serial dilutions of slurries consisting of 10 g of soil in 100 ml $MgSO_4$ (10 mM) to recover culturable soil fungi. Fredrickson and Balkwill (16) suggested using 0.1% sodium pyrophosphate to recover culturable bacteria from soils or sediments. Bagwell and coworkers (70) and McClung and coworkers (71) used a "rhizoplane" inoculant method to retrieve culturable organisms by rinsing (sterile buffer is probably best for this purpose) soil from the root and inserting the root into semisolid nutrient agar. This culture method recovered both aerophiles and microaerophiles (70).

Slightly different sampling and processing methods are used for molecular-based studies than for culture-based studies. Smit and coworkers (69) presented a method for sampling rhizosphere fungi. The material adhering to the roots after gentle shaking was transferred to tubes containing gravel and phosphate buffer (120 mM, pH 8). Samples were vortexed for 30 s and then DNA was extracted from the supernatant via bead-beating. This method and others (67) work well for molecular studies.

Air

Air sampling is usually conducted to determine if a health risk is likely given the number and/or types of bacteria or fungi present in a specified environment. There is growing concern about health risks associated

with organisms in indoor air, but the best sampling and analytical methods have not been established. Various samplers are used routinely to recover culturable bacteria and fungi (via impingement, impaction onto agar, swabbing, or settling), but culture-based analyses are known to greatly underestimate the number of organisms present (72,73). Furthermore, viable (or culture-based) analyses are expected to be as biased in assessing species composition as the methods that have been used for soil and water samples (74). One must keep in mind, however, that the purpose for air sampling must guide the sampling protocol used and that culture-based analyses may be the most appropriate choice in some instances. Other analytical methods are being pursued, however, to address the suspected shortcomings of current sampling methods in the majority of indoor environments. Nonviable or direct analytical methods are gaining popularity as a result of their success in numerous other settings (75–79), although much work is needed in this area before the findings are rendered meaningful and useful. The most appropriate bioaerosol sampling method for molecular analyses is still being developed.

It is also important to consider a more complete sampling strategy for indoor air quality assessments than merely sampling the air. It may be important to sample possible source material (HVAC units, carpeting, wall board, ceiling tiles, humidifiers, etc.). Sampling considerations and guidelines for such investigations are presented elsewhere (80–84). Of course, consulting a certified industrial hygienist to assist with sampling strategies is advisable if one does not have expertise himself. Additionally, the reader is directed to BIOAEROSOL SAMPLING AND ANALYSIS, this Encyclopedia, for a more extensive discussion of most of the topics addressed herein and for further information concerning bioaerosol assessments.

There are a variety of samplers available for bioaerosol assessment (85,86). Willeke and Macher (87) compiled a table listing the most widely used air samplers and their pertinent information for sample collection (an abbreviated list is presented in Reference 77). It is important to choose a sampler with a d_{50} cut point [the point at which 50% of the particles of that size are retained by the sampler (87)] sufficient to sample the organisms of interest. A table of calculated and reported d_{50} values for various samplers is presented in Reference 77 and in BIOAEROSOL SAMPLING AND ANALYSIS. No one sampler will provide a complete assessment of all components of indoor air, but several samplers are used routinely for culturable microorganisms. The most commonly used collection methods for sampling biological agents (including allergens, bacteria, fungi, dust mites, viruses, and volatile compounds) are compiled in Reference 88, Table 6.1, and readers are referred to this table for specific comparative information. It is important to familiarize yourself with basic air sampling concerns before sampling. For instance, samplers need to be calibrated before and after sample collection, and they need to be oriented correctly when sampling in air streams (87,89,90).

Although there are no safety threshold limit values (TLVs) for bacterial or fungal concentrations in air currently (80), it is important to determine the concentration of these organisms in indoor and outdoor air samples to determine if the cells are multiplying indoors. Usually, colony-forming units are counted from plated samples and the total CFUs are compared among indoor and outdoor locations. In this instance, the comparison yields the important information. If accuracy is more important, then a nonculture-based assessment tool may be necessary. Macnaughton and coworkers (72) demonstrated that phospholipid fatty acid analysis gives more accurate biomass measurements than do culture-based methods. Regardless of the sampling method, sampling equipment needs to be calibrated against a primary standard before and after a sampling event for the data to be meaningful. If the calibration measurements differ by more than 10%, the samples should not be used (77,80). Equipment calibration is discussed in greater detail elsewhere (87,91).

Bioaerosol counts differ throughout a 24-hour period and can be affected by the number of building occupants, occupant activity, ventilation operation, and other factors. Unfortunately, the number of samples needed to thoroughly characterize a building would probably be cost-prohibitive for a fully replicated sampling scheme. A good guideline is to collect at least duplicate plates from each site (i.e., each place in a building) at least twice in a 24-hour period (with the first set of duplicate samples taken at least two hours before the second set of samples) on the basis of guidelines in Reference 80, Chapter 5. A recent suggestion (80) is to collect duplicate samples at least three times a day on three consecutive days (representative of standard building conditions) to estimate average inhalation exposure. Guidelines for times of the day to sample, length of sample collection, sample location within a room, and other considerations are given in Reference 80.

Agar impactors are easy to use and require the least amount of processing after sample collection (see Fig. 2 in BIOAEROSOL SAMPLING AND ANALYSIS). Slit-to-agar and multiple-hole impactors are used often for culturable microbes, although they are expensive. Many labs offering bacterial and fungal counts from such plates also rent these units precalibrated, thus making sampling even easier. For sampling both bacteria and fungi, the culture media used will depend on the organisms one expects to recover. Media used for culturing bacteria can be trypticase soy agar (TSA) or blood agar (incubated at 35–37 °C) when culturing human commensal bacteria or R2A (incubated between 20 and 30 °C) when culturing general environmental organisms. Fungal media are generally malt extract agar (MEA) or 2% MEA, which lacks glucose and peptone (incubated at 18–22 °C), but DG-18 and rose bengal (MEA base) also are used. Wu and coworkers found that DG-18 yielded a greater number of taxa and organisms (colony-forming units) than MEA in a hospital study, ostensibly because of the slower growth of normally rapidly growing fungi, thus allowing growth of less competitive organisms (92). It is important to note also that rose bengal becomes fungicidal when exposed to light (93). In general, media plates should not be exposed to temperature extremes.

Liquid impingers also are used to collect culturable microorganisms (see Fig. 4 in BIOAEROSOL SAMPLING AND ANALYSIS). The collection fluid can be sterile water, buffer, or media, and should be chosen to optimize recovery of the target organisms. Mineral oil is a suitable collection fluid and is less problematic than buffer or water for long collection times because it is less prone to evaporative losses. The fluid used should be compatible with sample processing and minimize added stress on collected microbes. Liquid impingers can be useful for sampling in environments where the microbial concentration is unknown because the liquid can be serially diluted to optimize colony counts. Also, several analytical methods can be used to examine one sample from a liquid impinger. The sample can be used for particle counting methods, concentrated and used for microscopy, or plated onto a variety of media for culturing different microbes. Biochemical and immunological assays (e.g., of endotoxins or fungal toxins) are also possible from collection fluid. Liquid impinger samples also can be used for PCR-based analyses, although they may have to be filtered to concentrate the organisms of interest. For pros, cons, and caveats associated with impinger samplers, and especially for information about particle bounce and reaerosolization with improper use, see BIOAEROSOL SAMPLING AND ANALYSIS (87).

Molecular-based detection methods for bioaerosols have proven successful in various settings (75,76,79,94,95), and sampling procedures often rely on membrane filtration. Indeed, the greatest benefit of using a PCR detection approach is that viability is not a concern and therefore filtering becomes a reasonable collection method. Teflon (PTFE) (76) and polyethersulfone (dissolvable in chloroform) (95) membranes have been used to collect bioaerosols, as have glass fiber filters (for PLFA analysis) (72,73).

Samples should be analyzed within 24 hours for viable analyses. When samples are collected for chemical and molecular analyses but will not be processed within a few days, the samples can be stored frozen (such as samples collected onto filters or filtered liquids). For example, samples collected on glass fiber filters for PLFA analysis should be stored frozen, preferably at $-80\,^{\circ}C$, for long-term storage. One exception to this generalization is endotoxin analysis. Endotoxin is a component of interest in indoor air quality assessment because it is produced as the lipid-A portion of the lipopolysaccharide (LPS) component of the outer membrane of gram-negative bacteria. The bacteria do not have to be viable, nor does the cell wall have to be intact for this allergen to cause problems. There is a discrepancy about the best sample storage method for endotoxin analysis (96). However, it appears that dry samples can be frozen or held desiccated at $4\,^{\circ}C$, whereas bulk liquid samples should not be frozen. Formaldehyde preservation is not recommended if endotoxin concentrations are expected to be low (96).

CONCLUSION

As should be evident at this point, no one sampling method or unit (equipment) will serve even one environmental matrix completely. The best sampling design will accommodate not only the environmental matrix but also the analysis (analyses) to be performed. The foregoing information serves only as a guideline for sampling issues, and the readers are referred to the material referenced herein for more detailed information required before sampling in any environment. Additionally, a vast amount of information about many samplers is available through websites, and readers are strongly encouraged to take advantage of this information when appropriate. Viable analyses require the greatest effort in maintaining sample integrity (especially regarding temperature and O_2/gas concentrations), whereas molecular and/or chemical analyses may require one to "freeze" the sample to reduce losses and great changes over time. The preservation method depends on the parameters measured.

Acknowledgments

The authors gratefully acknowledge Pamela Kerr for reproducing all the figures that had to be redrawn for this publication. This task could not have been completed without her. We also thank the various companies noted in the figure legends for supplying images of some of the sampling equipment they manufacture. The authors thank C. R. Lovell and two anonymous reviewers for comments on a previous draft of this text.

SEAGRASSES COMMUNITIES

CAROLYN CURRIN
NOAA National Ocean Service Center
Beaufort, North Carolina

Seagrasses are a group of rooted aquatic vascular plants with worldwide distribution (1). Seagrasses form productive ecosystems in coastal and estuarine environments, and are valued for several ecosystem functions, including filtering of nutrients and suspended sediments, erosion control, providing food and refuge for fish, and habitat for several endangered species of turtles and marine mammals (2,3). Microorganisms play a key role in several of these processes, including nutrient cycling and the trophic transfer of seagrass primary production. Microbially mediated processes are of vital importance to the carbon and nitrogen cycles supporting seagrass production and ecosystem function (4). In particular, microbes may enhance seagrass growth via nitrogen fixation, and are responsible for the decomposition and remineralization of seagrass detritus (5–7). Autotrophic and heterotrophic bacteria, cyanobacteria, fungi, and eukaryotic microalgae are all found in association with seagrasses. This article will review the distribution of microorganisms within the components of the seagrass ecosystem and describe the most important microbially mediated processes within those systems.

SEAGRASS ECOLOGY

Seagrasses occur in temperate and tropical environments along a depth gradient from the intertidal to approximately 50-m depth (1). The lower depth limit is controlled either by the penetration of light through the water column or by hydrostatic pressure. Seagrasses can grow in low

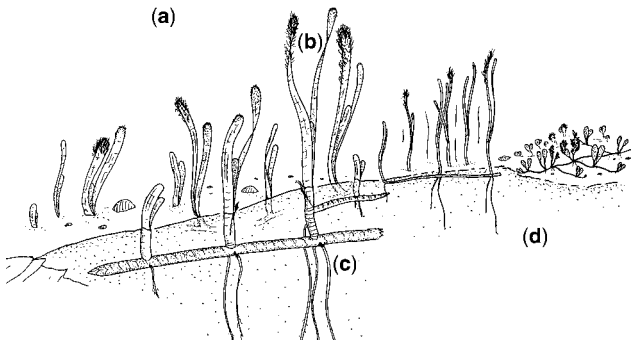

Figure 1. A mixed-species seagrass bed, illustrating placement of the (**a**) water column, including leaf canopy, (**b**) phyllopshere, (**c**) rhizosphere, and (**d**) sediments. From left to right, the growth forms of *Thalassia testudinum*, *Halodule wrightii*, and *Halophila decipiens* are shown.

Table 1. Distribution and Physical Characteristics of Several Common Seagrass Species (1,9)

Species	Geographic Distribution	Average Aboveground Biomass ($gdw\,m^{-2}$)	Average Belowground Biomass ($gdw\,m^{-2}$)
Zostera marina	North Atlantic and Pacific	298.4	159.7
Zostera noltii	Northeast Atlantic, Mediterranean, Black Sea	82.5	66.1
Zostera capricornii	Australia	191.4	176.0
Halodule wrightii	Caribbean, Gulf of Mexico, Indo-Pacific	253.5	193.3
Thalassia testudinum	Caribbean, Gulf of Mexico, Western Atlantic	519.0	582.5
Thalassia hemprichii	Indo-Pacific	86.9	209.9
Posidonia oceanica	Mediterranean	501.0	1,610.7
Cymodocea nodosa	Mediterranean, east Atlantic	146.7	285.0
Enhalus acoroides	Indo-west Pacific	72.0	392.4
Halophila decipiens	Pantropical	77.5	66.0
Halophila ovalis	Indo-west Pacific, Australia	54.8	21.1
Halophila stipulacea	Western Indian Ocean	2.3	2.6

organic–matter siliceous or carbonate sands, and in high organic–matter content muds (8). They can form extensive meadows in quiescent lagoons and embayments, or occur in smaller patches in high-energy environments with strong currents or wave action (8). The structure and life history of seagrasses is also variable, and affects associated microbial populations. Long-lived seagrasses (e.g., *Thalassia testudinum*, *Posidonia* sp.) have a higher percentage of structural carbohydrates and fiber and a greater proportion of belowground root/rhizome biomass extending deeper into the sediment than do seagrass species that are smaller in stature and shorter-lived (9) (see Fig. 1). A list of seagrass species mentioned in this article, along with their geographic distribution and average aboveground and belowground biomass, is provided in Table 1.

Seagrasses are in decline in many developed coastal regions because of shoreline development, fishing activities, and increased water column turbidity and nutrient concentration (10). A marine protist, *Labyrinthula*, has been implicated as being responsible for the seagrass wasting disease that decimated *Zostera marina* populations in the 1930s and 1940s and may have contributed to a seagrass die-off documented in Florida Bay in the 1990s (11,12).

DISTRIBUTION OF MICROORGANSIMS IN SEAGRASS ECOSYSTEMS

Four distinct microhabitats supporting microbial populations and activities can be identified within a seagrass ecosystem: (*1*) water column overlying the seagrass bed, including water in the seagrass canopy; (*2*) phyllosphere containing epibiota on seagrass leaves; (*3*) rhizosphere in sediments, including microorganisms intimately associated with seagrass roots and rhizomes; and (*4*) aerobic surficial and anaerobic subsurface sediments in the seagrass bed (see Fig. 1).

Water Column

The water column overlying seagrass beds contains heterotrophic and autotrophic bacteria, cyanobacteria, and eukaryotic microalgae. The bacterial population is about evenly divided between free-living and particle-attached forms, though the per-cell activity of the latter is usually greater (13). Studies in both temperate and tropical systems have found a positive correlation between measures of seagrass productivity and the water column bacterial community, suggesting a direct utilization of seagrass production by heterotrophic bacteria in the overlying water. Examples include a positive correlation between the diel rates of seagrass photosynthesis and water column bacterial production, increased bacterial abundance and production in the water column over seagrass beds than over adjacent unvegetated sediments (13,14), and evidence for the microbial utilization of dissolved organic carbon (DOC) excreted by seagrasses into the water column (15). Calculations of carbon needed to support bacterial production in the water column have also indicated that

Table 2. Abundance and Growth Parameters of Bacteria in Three Microhabitats (Water Column, Phyllosphere, Sediments) within the Seagrass Ecosystem

Habitat and Seagrass Species	Location	Bacterial Cell Density	Bacterial (Carbon) Production	Doubling Time	Reference
Water column					
Thalassia testudinum	Texas	0.9 to 2.7 $\times 10^9$ L^{-1}	22 to 109 mg $C m^{-2} day^{-1}$		(15)
T. hemprichii	Australia	1.6 to 2.5 $\times 10^9$ L^{-1}	18 mg $C m^{-2} day^{-1}$	8 to 14 hours	(13)
Zostera capricornii	Australia	1.1 to 1.7 $\times 10^9$ L^{-1}	13 to 32 mg $C m^{-2} day^{-1}$	1 to 8 days	(14)

seagrass production plays an important role in supporting the production of heterotrophic bacteria in the water column (15–17).

Bacterial density in the water column overlying seagrass beds exhibits a range over several orders of magnitude (Table 2). Estimates of bacterial production in the water column range from 13 to 95 mg C $m^{-2} day^{-1}$. These growth rates indicate that bacteria in the water column can process a substantial portion of seagrass primary production, with estimates for specific seagrass systems ranging from 7 to over 50% (15–17). Bacterial production in the water column can be an effective means of transferring seagrass primary production into marine food webs, as bacteria are grazed by a variety of zooplankton and filter feeders, which in turn become prey to larger organisms.

Much less is known about the relationship between seagrasses and photosynthetic microalgae or cyanobacteria in the water column. Phytoplankton are competitors with seagrasses for water column nutrients, and when water column nutrients increase, phytoplankton biomass increases (25). Increased phytoplankton biomass leads to decreased penetration of light through the water column, and seagrass growth can become light-limited. A frequent result of estuarine eutrophication is the replacement of benthic seagrass production with water column phytoplankton production (10,26).

Seagrass canopies reduce water current and turbulence, and can create a gradient within the water column in living and detrital particles, with greater particle and microbial abundance within the canopy (26,27). In a *Posidonia oceanica* bed, bacteria dominate the water column heterotrophic biomass, whereas picoplankton (cyanobacteria *Synechococcus*) dominate the autotrophic biomass (26). Living and nonliving particles are of approximately equal biomass in the water column over the seagrass canopy, whereas detrital particles are fourfold greater than living particles within the seagrass canopy.

Phyllosphere

Seagrass leaves support a diverse and abundant epibiota, including autotrophic and heterotrophic bacteria, cyanobacteria, fungi, and eukaryotic algae, in addition to a diverse group of macroalgal epiphytes and epifauna (20,28,29). Seagrasses with a longer leaf turnover time generally have larger leaves and support a greater epibiota than those with short (<12 days) turnover times. A gradient in abundance of microorganisms can be found along a single leaf, and among leaves in a seagrass shoot. Outer leaves, and the tips of leaves, are relatively older and harbor a denser microbial assemblage than younger leaves and the basal portions of leaves (19,29).

Production by heterotrophic bacterial populations on seagrass leaves has been linked to the utilization of organic carbon, phosphorus, and nitrogenous compounds excreted by the leaves (19,30,31). An estimated 1 to 30% of daily seagrass net productivity may be incorporated into bacterial biomass on leaves, and the amount of organic carbon excreted by seagrass may be sufficient to provide nearly all the carbon required for epibacterial growth (19,23).

Colonization of seagrass leaves by organisms follows a successional pattern, which can be seen along a single leaf or in a gradient from youngest to oldest leaf on a shoot. Heterotrophic bacteria are abundant early in the succession of

the epibiotic community, with homogenous patches of rod and coccoid-shaped cells occupying the leaf surface (29,32). Diatoms quickly follow bacteria, and often dominate the epiphytic community (32–34). The epiphytic diatom community on co-occurring seagrasses is similar, suggesting that site-specific rather than substrate-specific characteristics dictate the epiphytic diatom community composition (34,35). On long-lived seagrasses, the bacterial-diatom community may be followed by encrusting algae, filamentous macroalgae, and an abundant community of protozoans, nematodes, and copepods (28).

There are several factors that influence the biomass and community composition of microorganisms occupying the seagrass phyllosphere. Seagrasses and microorganisms compete for light and nutrients (33,36), although there may be mutualistic relations as well, with seagrasses providing organic carbon to bacteria and nitrogen-fixing microorganisms providing nitrogen that ultimately gets incorporated by the seagrass (see later section). Seagrasses with longer leaf turnover times, or with higher concentrations of plant sugars, may support higher densities of epibacteria (18). Seagrass leaves also contain phenolic compounds, which can inhibit microbial growth (37), and are at least partially responsible for the frequent observation of increased epiphytic biomass on older leaves, which have a lower concentration of phenolics. Differences in the epiphytic communities found on seagrass leaves and structural mimics have been documented, (38,39) suggesting that there may be a direct interaction between leaf chemistry and development of the epiphytic community.

In several studies, the epiphytic communities have been demonstrated to have no deleterious effect on seagrass carbon fixation or growth (39,40). However, an increase in water column nutrient supply can result in the increased growth of seagrass epiphytes and decrease in seagrass biomass (33,36,41). Shading by increased epiphytic biomass has been suggested as a cause of seagrass decline in eutrophic estuaries (42,43). Nutrient addition does not always result in increased epiphyte growth, however, and other parameters, including water residence time, water column depth and physical mixing properties, as well as the presence of microalgal grazers, affect the relationship between nutrient supply, epiphytic growth, and seagrass production (25,41,44).

Epiphytic photosynthetic bacteria, cyanobacteria, and eukaryotic microalgae, in addition to macroalgae, can account for a significant amount of primary production within the seagrass ecosystem, and may also contribute to the pool of DOC utilized by epibacteria. In tropical and semitropical systems, epiphytic primary production has been estimated to equal or exceed seagrass primary production (40,45,46). In temperate systems, epiphytic primary production is estimated at between 8 and 50% of seagrass primary production (39,47,48). Numerous studies have demonstrated that epiphytes growing on seagrass leaves are the primary food source for many animals utilizing seagrass habitats, particularly in tropical ecosystems (49–53).

Species of the family Labyrinthulaceae, fungus-like protists, have been isolated from the leaves of 11 seagrass species collected from around the world (54). *Labyrinthula* is associated with seagrass "wasting disease," an outbreak of which in the 1930s caused massive destruction of *Z. marina* beds along the Atlantic coasts of Europe and North America (55). In the 1980s, *Labryinthula* was also implicated in a *T. testudinum* seagrass "die-off" which occurred in the Florida Keys (11). Further studies have revealed that *Labyrinthula* is commonly found in the older leaf tissue of many seagrass species, and may play a functional role in natural plant senescence (54) This finding, and the occurrence of *Labyrinthula* in many lush, productive stands of seagrass, suggests that there are causative factors in addition to the presence of *Labyrinthula* that result in outbreaks of wasting disease or seagrass die-offs.

Seagrass Rhizosphere

The seagrass rhizosphere, including rhizomes, roots, root hairs, and associated sediments, harbors an active heterotrophic bacterial population. The diffusion of oxygen from the roots into the rhizosphere and the exudation of organic carbon and amino acids from roots are features of the rhizosphere that differentiate the activity and composition of the rhizospheric microbial community from the sedimentary microbial community (23,56–58). The highest density of microorganisms and highest rates of microbial activity are generally found in two areas of the rhizosphere: the zone of maximal root/rhizome biomass and the root growing tips. The depth of the maximal root/rhizome biomass zone is variable, ranging from 0 to 1 cm in *Halophila* spp. to 20 to 30 cm depth in *T. testudinum* or *P. oceanica* beds (Fig. 1). The dominant microbial processes in the rhizosphere include sulfate reduction and nitrogen fixation. Nitrogen fixation will be discussed in a separate section later. Methanogenesis, nitrification-denitrification, and ferric iron reduction also occur in the rhizosphere. These processes, and the relationship between seagrass photosynthesis and microbial activity in the rhizosphere, are summarized later.

Aquatic plants living in reduced sediments rely on the diffusion of oxygen to root and rhizome tissue to preserve aerobic metabolism in belowground tissue, a necessity for plant survival (58). Oxygen can diffuse out of the plant tissue into the rhizosphere, creating a thin aerobic zone and potentially permitting aerobic microbial activity in the seagrass rhizosphere. Direct measures of the aerobic zone surrounding seagrass root/rhizomes are few, but a thin (<100 μm), oxygenated layer has been documented in several seagrass species (57,59) and a relatively low concentration of sulfide in the rhizosphere can also be attributed to oxidation via O_2 excreted by roots (56,60). Steep oxygen gradients and the excretion of organic carbon from plant tissue create a rhizosphere capable of supporting a diverse population of microorganisms.

Nitrification-denitrification and ferric iron reduction, two processes associated with oxic–anoxic interfaces, occur in the rhizosphere of *Z. marina,* although at much lower rates than are typical for the rhizospheres of freshwater vascular plants (61,62). Ferrous iron accumulates on root/rhizome surfaces, and iron-reducing bacteria have

been isolated from root surfaces, although it is not yet known whether dissimilatory iron reduction or the activity of sulfate-reducing bacteria is responsible for the observed activity (61) The activity of these bacteria may be important in controlling the availability of iron for plant uptake. Similarly, coupled nitrification-denitrification in the rhizosphere could also play an important role in controlling the concentration and speciation of dissolved inorganic nitrogen available for plant uptake. Denitrifying bacteria have been isolated from the rhizosphere of several seagrass species (see later).

A strong link between seagrass photosynthesis and rhizospheric microbial activity is evident in *Zostera capricornii* beds, where 90% of the root/rhizome biomass is located in the 0- to 5 cm-depth layer. Whole plants receiving decreased irradiance support lower rates of sulfate reduction and nitrogen fixation in the rhizosphere, and microbial activity in the surrounding sediment is less than that found in the rhizosphere (Fig. 2). Rates of sulfate reduction in the *Z. capricornii* rhizosphere average between 4.5 and 8.2 μMol SO_4^{2-} gdw^{-1} day^{-1}, and a substantial portion of the daily carbon fixed by *Z. capricornii*, 8 to 18%, is required to fuel the activity of rhizospheric bacteria (63). Nitrogen fixation may be more reliant on the organic carbon substrate available in the rhizosphere than sulfate reduction. Microbial activity in the rhizosphere accounted for only 4% of the total, depth-integrated sulfate-reduction rates measured in *Z. capricornii* beds, whereas rhizospheric microbial activity accounted for 39% of the depth-integrated nitrogen fixation (63). A similar result was reported from intertidal *Z. noltii* beds, where rhizospheric sulfate reduction accounted for 11% or less of the sedimentary total, whereas rhizospheric nitrogen fixation accounted for 31% of the total sedimentary nitrogen fixation (64).

Sulfate-reducing bacteria represent a large component of the bacteria associated with the *Z. marina* rhizosphere, and are primarily associated with the root/rhizome surface (65). Surface sterilization of the roots results in a 80 to 95% decrease in both sulfate-reducing and nitrogen-fixing activity, and it is likely that a substantial number of the sulfate-reducing bacteria in the seagrass rhizosphere are capable of nitrogen fixation. Inhibition of sulfate reduction in the *Z. nolti* rhizosphere results in a significant (50 to 80%) reduction of nitrogen-fixation activity, similar to results obtained in experiments with the rhizospheric microbial community associated with *Z. marina* and *T. testudinum* (64,66–68). The population of sulfate-reducers occupying the *Z. marina* rhizosphere from a seagrass bed in Denmark exhibit a high tolerance to O_2 exposure, which may be an inherent feature of the microorganisms or indicative of a consortial relationship with aerobic bacteria occupying the rhizosphere (65). Sulfate-reduction rates in the rhizosphere are substantially higher than those in adjacent sediments, ranging from 20 to 50 μMol SO_4^{2-} gdw^{-1} day^{-1}. Rhizospheric sulfate reduction in *Z. marina* occurs faster in the light than in the dark, and is enhanced by the addition of organic substrates, again demonstrating the reliance of rhizospheric sulfate-reducing bacteria on the products of seagrass photosynthesis (69).

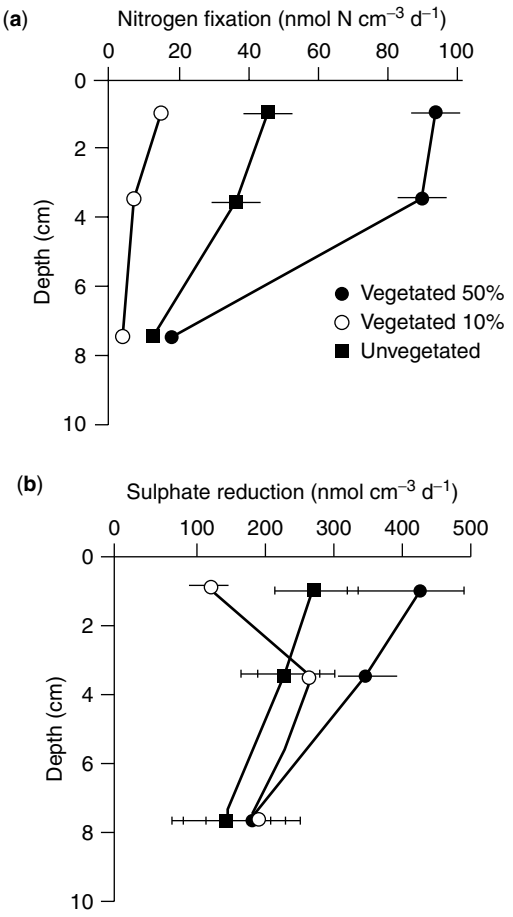

Figure 2. Effect of reduced surface irradiance on rhizospheric (**a**) nitrogen fixation and (**b**) sulfate reduction in a *Z. capricornii* seagrass bed. Depth distribution of nitrogen fixation and sulfate-reduction rates in adjacent seagrass bed sediments are also illustrated. Redrawn from (63).

Utilization of root exudates by the sulfate-reducing community does not always result in a diurnal variation in sulfate-reduction rates, however. In both an intertidal *Z. noltii* bed and mixed-species stands of tropical seagrasses, researchers found no diurnal variation in rates of rhizospheric sulfate reduction (22,70). However, in the tropical seagrass bed in Australia, other measures of microbial activity, including nitrogen fixation and incorporation of tritiated thymidine, did exhibit a diurnal pattern indicative of direct utilization of seagrass photosynthate. This discrepancy may be because sulfate-reducing bacteria do not utilize the photosynthates directly, but rather rely on products resulting from bacterial hydrolytic and fermentative activities (22).

A variety of facultative and strict anaerobes have been isolated from the seagrass rhizosphere. Acetogenic (*Acetobacterium*) and sulfate-reducing (*Desulfovibrio*) bacteria were the primary components of the microbial community occupying both root epidermal and deeper cortex layers of *Halodule wrightii* (71). Bacteria were detected in 100% of the epidermal cells, over 90% of the exterior cortex cells, and up to 60% of the interior cortex cells. Nitrogen-fixing *Klebsiella* species have also been isolated from

intracellular root tissue of *H. wrightii* (72). Many of the bacteria isolated from *H. wrightii* roots are gram-positive clostridia, in contrast to the gram-negative population that typically dominates seagrass bed sediments (71,73). Methanogenic bacteria (Archea) and denitrifying bacteria have also been identified from *Halodule* spp. root samples (71,74).

Seven groups of denitrifying bacteria have been isolated from the rhizosphere and surrounding sediment of *H. universis* and *T. hemprichii*. The isolates are primarily gram-negative rods, and included strains that could be identified as *Pseudomonas*, *Alcaligenes*, and *Vibrio*. Several strains that were halophilic, facultatively anaerobic, and fermentative also demonstrated denitrifying activity (74).

Isolates from *Z. marina* are primarily associated with root/rhizome surfaces, rather than intracellular or root cortex tissue. However, a novel sulfate-reducing bacterium, designated *Desulfovibrio zosterae*, has recently been isolated from surface-sterilized root/rhizome tissue (75). Gram-negative rods capable of exopolymer production and possessing a respiratory metabolism represented the majority of strains isolated from the sediment and rhizosphere of *Z. capricornii*. An *Alternomas* spp. represents 1.5 to 2.0% of the bacterial population in *Z. capricornii* and adjacent sediments, although it is found in highest numbers in association with root/rhizome tissue (76).

Sedimentary Bacteria

Seagrass bed sediments exhibit a broad range in physicochemical parameters, from fine-grained, organic rich sediments to coarse-grained, organic-poor sediments. In temperate areas, sediments are usually a combination of siliceous sands and finer silt-clay particles, whereas in many tropical environments carbonate sands and silts predominate. Regardless of the sediment matrix, however, sediments within seagrass beds are generally finer-grained and have a higher organic matter content than adjacent unvegetated sediments, because of the trapping of particles by the seagrass canopy and the accumulation of seagrass detritus within the sediments (8). Sources of primary production to support microbial activity in seagrass beds are not limited to the seagrasses. Carbon production by phytoplankton, macroalgae, and epibenthic and epiphytic microalgae can equal or exceed seagrass primary production, and all provide organic substrate to support heterotrophic bacterial activity in seagrass bed sediments (21,46,77). Rates of microbial activity in nonrhizospheric seagrass sediments are generally lower than those in the rhizosphere, and higher than microbial activity rates measured in unvegetated sediments. This trend in microbial activity is correlated with the gradient in available organic matter that occurs from the rhizosphere to adjacent sediments.

Seagrass bed sediments are primarily anoxic, although there may be a shallow oxidized zone at the sediment surface and around live seagrass roots. In the aerobic zone, bacteria oxidize organic substrates completely to carbon dioxide. A zone of denitrification may exist at the aerobic–anaerobic interface, and denitrifiers also oxidize organic material to carbon dioxide, converting nitrate to ammonia and N_2 in the process. In the anaerobic zone, fermentative bacteria convert organic matter to short-chained organic molecules and carbon dioxide. These end products are then used by sulfate-reducing and methanogenic bacteria, resulting in the end products of carbon dioxide and methane, respectively. In marine sediments, sulfate reduction rates far exceed rates of methanogenesis. Differences in belowground plant biomass, annual primary production between seagrass species, and differences in nutrient status and temperature between sites, prevent generalizations about the amount of seagrass carbon remineralized by sediment bacteria, and the role of sediment bacteria in nutrient recycling.

The microbial community inhabiting seagrass sediments includes aerobic and photosynthetic microorganisms in surficial sediments. The photic zone in seagrass bed sediments is very shallow because of the fine-grained nature of the sediments and shading by the seagrass canopy. Nonetheless, in some tropical systems the sand microflora can account for a greater proportion of system primary production than the seagrasses themselves (46,78), and algal carbon has been identified as a major source of organic carbon supporting microbial activity in seagrass bed sediments (21,77). The aerobic zone in seagrass sediments is usually shallow, extending from a few millimeters in depth to at most several centimeters.

The abundance of bacteria in seagrass sediments ranges from 10^8 to 10^{10} cells gdw^{-1}, which falls on the upper end of the range for marine sediments (Table 2). The major factors controlling bacterial abundance in marine sediments are particle size (sediment surface area) and organic matter content. These factors, in addition to seasonal changes in the availability of detrital carbon, are likely correlated with bacterial abundance in seagrass bed sediments, although few comparative studies are available (21,79).

A variety of techniques, including tritiated thymidine incorporation, leucine incorporation, and measures of O_2 uptake or CO_2 production, have been utilized to examine factors affecting the activity of bacteria in seagrass sediments. Published estimates of sedimentary bacterial carbon production exhibit a range of over two orders of magnitude (Table 2), and it should be noted that these estimates include the activity of rhizospheric bacteria. It is therefore not surprising that diel variation in the activity of sedimentary bacteria has been observed in several cases, and the utilization of organic carbon from root exudates has been postulated to support a significant fraction of sedimentary bacterial activity (60). The relationship between sedimentary bacterial activity and seagrass production may vary along different spatial and temporal scales, as demonstrated in an examination of *P. oceanica* beds in the Mediterranean. Bacterial activity was positively correlated with annual seagrass production, but on seasonal timescales, bacteria and seagrass production were inversely correlated. This is attributed to competition for inorganic nutrients between the microbial and macrophyte communities (79,80) The role of nutrients in microbial decomposition of detritus is discussed in more detail later.

Microbial communities at the interface between the aerobic and anaerobic sediments resemble those that occur in the seagrass rhizosphere. Depending on the availability of electron donors and organic matter, manganese reduction, dissimilatory nitrate reduction, and ferric iron reduction may occur near the oxic–anoxic interface. Denitrification rates are higher in seagrass than in adjacent unvegetated sediments, and may also exhibit a diel cycle, with peaks at dawn (56,81)

Sulfate reduction is the dominant anaerobic process in seagrass bed sediments, and because of the shallow depth of the aerobic zone in seagrass bed sediments, sulfate-reducing bacteria remineralize the major portion of seagrass productivity, after initial utilization by hydrolytic and fermentative bacteria (4,22). Rates of sulfate reduction in seagrass bed sediments are reportedly 5 to 50% lower than rates associated with the rhizosphere, but generally higher than sulfate-reduction rates in unvegetated sediments (4,60,64,69).

NITROGEN FIXATION IN SEAGRASS ECOSYSTEMS

Nitrogen is often the limiting nutrient for marine primary production, and so there has been considerable interest in measuring rates of nitrogen fixation in marine ecosystems. Nitrogen fixation is a microbially mediated process that converts N_2 into biologically available nitrogen. Some of the highest rates of nitrogen fixation measured in marine environments are associated with seagrasses (82,83). Factors controlling nitrogen-fixation rates and spatial and temporal patterns of nitrogen fixation vary among seagrass systems, and the following discussion will describe nitrogen fixation in several seagrass species. In most studies, the acetylene-reduction technique is used to estimate rates of nitrogen fixation, whereas in a few instances the incorporation of ^{15}N-labeled N_2 has been measured (6,7).

Nitrogen fixation has been measured in the phyllosphere, rhizosphere, and sediments associated with seagrasses of the genus *Zostera*. The highest rates occur in the rhizosphere, are correlated with the zone of highest root/rhizome biomass, and are usually, but not always, associated with roots rather than rhizomes (63,67,84–86). Rhizospheric nitrogen fixation is between 25 and 200% higher in light than in dark incubations, and is stimulated by the addition of organic substrate, suggesting a tight coupling between seagrass photosynthesis and rhizospheric nitrogen fixation (6,63,68,85,87,88). Figure 2a illustrates the depth distribution of nitrogen fixation in the rhizosphere and surrounding sediments of *Z. capricornii*, and the deleterious effect of lower surface irradiance on rhizospheric nitrogen-fixation rates (63). The seasonal pattern of rhizospheric nitrogen fixation in *Zostera* spp. also reflects the dependence of nitrogen-fixing bacteria on seagrass photosynthate, as nitrogen-fixation rates are higher during the plant's major growing season (85,88). The physical location of nitrogen-fixing bacteria associated with *Zostera* spp appears to be on the root/rhizome surface, as opposed to intracellular or cortex tissue (86).

Both dissolved inorganic nitrogen and oxygen concentrations can affect rates of nitrogen fixation in the *Zostera* rhizosphere. Reduction of N_2 by the nitrogenase enzyme is an energetically expensive reaction, and the nitrogenase enzyme is rendered inoperable upon exposure to oxygen. Accordingly, many microorganisms only fix nitrogen under nitrogen-limiting conditions, and must protect the enzyme from oxygen using physiological, spatial, or temporal separation of enzyme activity from oxygen. Rhizospheric nitrogen fixation in a *Z. marina* bed in Denmark showed no inhibition of acetylene-reduction activity with the addition of between 200 and 800 $\mu M\ NH_4$ (84), whereas the addition of 100 to 200 $\mu M\ NH_4$ or NO_3 reduced rhizospheric nitrogen fixation by 20 to 40% in a *Z. marina* bed off Long Island, New York (67), and 10 to 50 $\mu M\ NH_4$ inhibited 50% of the acetylene-reduction activity in a *Z. nolti* rhizosphere (89). These data suggest rhizospheric nitrogen fixation will persist even in sediments with fairly large concentrations of dissolved inorganic nitrogen, as DOC excreted by the seagrass provides ample organic substrate to fuel the process. Although the rhizosphere is generally found in anaerobic sediments, oxygen can diffuse through the rhizomes to the roots, creating microaerobic conditions at the root tips. Results comparing acetylene-reduction rates in aerobic and anaerobic conditions often, but not always, indicate higher rates under anaerobic conditions, particularly for whole-core incubations (63). The deleterious effect of O_2 on rhizospheric nitrogen fixation is consistent with reports that sulfate-reducing bacteria are responsible for between 25 and 80% of rhizospheric nitrogen fixation (64,68,84,85). Over a hundred strains of microaerophilic and facultative anaerobic nitrogen-fixing bacteria have been isolated from *Z. marina* roots collected in Japan (87), all belonging to the family Vibrionaceae. Of these, the majority were in the genus *Vibrio*, and a group of *Photobacterium* were also identified.

Nitrogen-fixation rates in the phyllosphere and adjacent sediments are much lower than those in the rhizosphere of *Zostera* beds. Estimated rates of rhizospheric nitrogen-fixation range from approximately 1 to 7 $mg\,N\,m^{-2}\,day^{-1}$ for *Z. marina* and *Z. noltii* to between 10 and 40 $mg\,N\,m^{-2}\,day^{-1}$ for *Z. capricorni* (6,67,68,85). Nitrogen-fixation rates in the phyllosphere of *Zostera* spp are usually reported as absent or in trace amounts (67,88). The exception is a report of epiphytic cyanobacteria colonizing *Z. marina* leaves in the fall, which exhibited acetylene-reduction rates higher than the rhizosphere (88). Nitrogen fixation associated with *Z. marina* rhizome detritus has been reported from North Carolina, and could contribute another 1.5 $mg\,N\,m^{-2}\,day^{-1}$ (24).

Experiments using ^{15}N-labeled N_2 demonstrate that N_2 fixed in the rhizosphere is taken up by the plant and approximately 50% translocated to the leaves (6). In that experiment it was demonstrated that nitrogen fixation could provide between 33 and more than 50% of the annual nitrogen demands of *Z. capricorni*, similar to estimates based on acetylene-reduction activity (63). Estimates of the contribution nitrogen fixation makes to the annual nitrogen demands of the temperate species *Z. marina* and *Z. noltii* are much lower, ranging from 3 to 28% (67,68,85).

Halodule wrightii, a seagrass species with a wide distribution in subtropical and tropical latitudes, harbors endophytic nitrogen-fixing bacteria in root and rhizome

tissue (72). The bacteria, a *Klebsiella* sp., lines cortical cells intracellularly, particularly in root tips and in actively growing rhizome tissue. The bacteria are able to fix nitrogen under aerobic conditions, presumably by compartmentalizing nitrogenase in the cell and thus protecting it from oxygen inactivation. In addition to the endophytic bacteria, substantial numbers of nitrogen-fixing bacteria are also associated with the root/rhizome surface (72,90). As sometimes observed in *Zostera* spp., rhizospheric acetylene-reduction rates are higher in aerobic than anaerobic incubations in *H. wrightii* (90). Substantial rates of nitrogen fixation are also associated with the microbial community on *H. wrightii* leaves, with much lower rates associated with sediments and the water column (90,91).

In general, measured rates of nitrogen fixation are higher in tropical than in temperate seagrass species. Several species of tropical seagrasses support nitrogen-fixing epiphytic populations, including *H. wrightii*, *T. testudinum*, and *Halophila stipulacea* (82,91,92). In *H. stipulacea* meadows in the Red Sea (Gulf of Elat), phyllospheric nitrogen-fixation rates were 21 times higher in the light than in the dark, and were not affected by treatment with DCMU, a photosystem II inhibitor, suggesting that photosynthetic bacteria or cyanobacteria were the primary nitrogen fixers (92). Phyllospheric nitrogen fixation represents 89% of total nitrogen fixation associated with *H. stipulacea*. In contrast, nitrogen fixation associated with the phyllosphere of *Thalassia* is less than that which occurs in the rhizosphere, and is associated primarily with the colonization of leaves by cyanobacteria (82).

Estimates of rhizospheric nitrogen fixation associated with *T. testudinum* range from 5 to 140 $mg\,N\,m^{-2}\,day^{-1}$, with an average value of about 20 $mg\,N\,m^{-2}\,day^{-1}$ (93,94). Rhizospheric nitrogen fixation rates for other species of tropical seagrasses fall within the same range, and are approximately 10 to 20 times higher than estimates for temperate seagrasses (7,85,95). Tropical seagrasses often exhibit phosphorus limitation, rather than the nitrogen limitation often noted for temperate species (96), but also see Reference (97). Although this is largely caused by the presence of carbonate sediments, which bind phosphorus more tightly than the siliceous or clastic sediments found in temperate areas, the alleviation of nitrogen limitation may also be a result of the higher rates on nitrogen fixation found in tropical seagrasses.

MICROBIAL DECOMPOSITION OF SEAGRASS DETRITUS

There are few grazers that directly consume seagrass plants, so the large majority of seagrass primary production is subject to microbial decomposition prior to entering the food web or ultimately being remineralized. Heterotrophic bacteria are the microorganisms primarily responsible for the decomposition of seagrass detritus, although fungi may play a role in the decomposition of seagrass detritus deposited in the intertidal (98). Bacteria colonize detrital seagrass rapidly, and decomposition is often conceptualized as having three phases: an initial leaching and utilization of soluble material, microbial decomposition of relatively labile particulate detritus, and a slower decomposition of more refractory material. Thus, exponential decay rates are often calculated, although the results of many decomposition experiments can also be fitted with a linear function. The rate and efficiency with which microbes decompose seagrass detritus contribute to the overall extent to which a seagrass ecosystem may support secondary production and/or export organic matter to adjacent ecosystems.

Both free-living and attached microorganisms are able to rapidly utilize the dissolved organic matter released by seagrasses in the initial phase of decomposition. The proportion of detrital carbon released as DOC during a three-day abiotic leaching period has been estimated at between 13 and 27.6% for *T. testudinum*, *Syringodium filiform*, and *Z. marina* leaves and root/rhizomes (99,100). A lower estimate of approximately 2.6% of total detrital carbon was made for the proportion of monomeric carbohydrates leached from *Cymodocea nodosa* leaves over 2 days (101). In flask incubations, heterotrophic bacteria grow quickly on DOC leached from seagrass detritus, and include both free-living and aggregate forms (100,101). Flagellates quickly graze the free-living bacteria and exhibit a sharp increase in density that coincides with a significant reduction in bacterial cell density (100,101). Dissolved organic matter (DOM) is released from detritus both via abiotic leaching and as a result of hydrolysis of particulate organic matter by microbes attached to detrital particles. In the later stages of decomposition, the activity of attached bacteria may be supplemented by DOM released from fresher detritus, in addition to DOM utilized via a coupled hydrolysis uptake (101).

The rate at which seagrass detritus decomposes is dependent on a number of factors, including age and species of origin, temperature, and environmental setting (i.e., buried versus aboveground). Most investigators have utilized litterbags to estimate decay rates for detritus in a variety of settings (Table 3). Decay rates can be calculated as:

$$k = \ln(W_o/W_t)\left(\frac{1}{t}\right) \quad (1)$$

where W_o = original dry weight, W_t = dry weight at end of period, and t = time (101). Decomposition in the initial 3 to 14 days results in the loss of between 25 and 55% dry weight of *Halophila decipiens* plants, *T. testudinum* roots, and *Z. marina* whole plants and rhizomes, and estimated decay rates (k) range between 0.012 and 0.126 day^{-1} (Table 3) (5). Similarly, *H. wrightii* leaves in litterbags suspended in the water column lost 35.5% of the initial ash-free dry weight in 24 days (102). During this initial stage, there is evidence that leaves and roots decompose faster than rhizomes, and *Thalassia* rhizomes in particular are resistant to decay (Table 3) (99). Decomposition rates slow considerably after the first few weeks, and litterbag studies show that over a period of between 120 and 240 days, seagrass detritus decays at rates ranging from 0.003 to 0.018 day^{-1} (Table 3). Very little decay may occur after the first 4 to 6 months of decomposition (101,102). It should also be noted that decay rates as estimated by weight loss in litterbags may be an overestimate, caused by the loss of very fine particulate matter from the litterbag. A direct comparison

Table 3. Decomposition Rate of Several Seagrass Species as Determined by Litterbag Experiments. Incubation Time is Expressed in Days. The Variable k Expresses Weight Loss per Day, and is Calculated as $k = \ln(W_o/W_t)(1/t)$

Seagrass Species and Plant Part	Location	Incubation (Days)	Time % Weight Loss	k	Reference
Halophila decipiens whole plant	Caribbean-surface	6.5	26	0.048	(104)
	Caribbean-buried	6.5	62	0.126	
Zostera marina whole plant	Virginia (mid-Atlantic)	3	25	0.096	(105)
		42	70	0.029

		160	58	0.005	(108)

of *P. oceanica* decomposition rate using O_2 uptake and litterbag weight loss showed that only about 40% of the weight loss from litterbags could be attributed to microbial respiration (103). Others have noted that decomposition in litterbags may be slower than in unconfined detritus because of the exclusion of shredders (5).

Estimates of the efficiency with which bacteria are able to convert detrital carbon into biomass exhibit a wide range, although in general they fall within the 10 to 30% range typical of estimates for bacterial growth on vascular plants. Not surprisingly, the highest estimates are generally associated with the utilization of DOC or the early stages of particulate decomposition, and lower efficiencies occur in the later stages of decomposition (100,101,105,109).

The concentration of lignin, structural carbohydrates, and phenolic compounds varies between species of seagrass, and seagrasses with relatively higher concentrations of these compounds will decompose more slowly (5,99,110). Other factors, including temperature, depth, oxygen concentration, and sediment type, have also been shown to affect seagrass decomposition rates, although not in a consistent matter (5,103). In several instances, studies have noted that anaerobic or buried detritus decomposes faster than detritus suspended in the water column or on the sediment surface, suggesting that an anaerobic microbial community is necessary for the remineralization of the more refractory organic matter (5,99).

Inorganic nutrients, particularly nitrogen and phosphorus, are likely a controlling factor in the microbial decomposition of seagrass detritus. The C/N and C/P ratio of seagrasses is two to five times higher than that of bacteria biomass, and additions of inorganic nitrogen and phosphorus to seagrass sediments result in increases in microbial activity and rates of organic matter loss (111). A correlation between detrital C/N content and decay rate has been found when comparing decomposition of different plant parts (leaves versus rhizomes), and comparing senescent versus detrital material (99,103). However, a broad analysis of published seagrass decomposition data failed to find a positive correlation between C/N ratio and decomposition rate, suggesting that nitrogen content is but one of several factors affecting microbial decomposition rates of seagrass detritus (5). Although microbial decomposition of many vascular plants results in a significant increase in the detrital C/N ratio, this has been rarely observed in studies of seagrass decomposition (5,101,110).

Microscopic examination of the microbial community responsible for the decomposition of seagrasses reveals a diverse community dominated by bacteria. Bacteria quickly colonize surfaces of detrital particles, and initial communities dominated by only a few bacterial types soon give way to diverse communities composed of coccoid, rod-shaped, stalked, and filamentous bacteria (24,32,101,105). Some studies have noted the presence of particularly large bacterial cells, greater than 0.6 μm^3, indicative of a sapotrophic environment (24,105). Rod-shaped and filamentous bacteria have been noted to occupy crevices on leaf surfaces and tunnels within cell walls (101,112). These features are often surrounded by halos, suggesting extracellular lysis of cellular material. Both microscopic observations and biochemical analysis of seagrass detritus suggest that the cuticle is particularly resistant to microbial decay, as is fibrous detrital material (102,112). Filamentous bacteria may be particularly important in the degradation of structural carbohydrates, and the diversity of microbes in close proximity to one another suggests an active microbial consortium, such as has been described for the degradation of organic matter in other aquatic environments (24,112,113).

The role of bacteria in transferring seagrass primary production to grazers has been examined by estimating the amount of seagrass carbon converted into microbial biomass associated with detritus. In each instance, attached bacteria have been found to constitute a minor amount of detrital carbon, and several studies have concluded that bacteria attached to detrital particles are not an important food item for benthic feeding organisms. Moreover, estimates of the amount of detrital carbon converted to microbial biomass are also very low, with most estimates well under 10% (104,105). These estimates do not include microbial growth on DOC released by both living and detrital seagrass, nor do they include an accurate assessment of extracellular microbial production. Most of these calculations are based on carbon, and as noted, bacteria have a lower C/N ratio than detritus and so make a greater contribution to the nitrogen requirements of consumer organisms. Although bacteria attached to detrital particles appear to play a minor role in transferring secondary production to consumer organisms, bacteria are part of other trophic pathways that may transfer seagrass primary production to secondary production (114,115).

CONCLUSION

Seagrasses form productive ecosystems in shallow coastal areas worldwide. The vast majority of this primary production is initially utilized by microorganisms either in the water column, attached to living plant surfaces, on detrital particles, or in adjacent sediments. Aboveground plant surfaces also provide structure for a rich epibiotic community, including bacteria, cyanobacteria, microalgae, and other protists. Members of the *Labyrinthulae* family have been identified to play a role in seagrass senescence, and certain strains are capable of initiating cell death. No other microorganisms have been identified as seagrass pathogens. Because seagrasses are in decline in many parts of the world, due to coastal development and eutrophication, a closer look at the relationship between microbial activity and the productivity associated with seagrass ecosystems is warranted.

Nitrogen-fixing bacteria and cyanobacteria occur throughout the seagrass ecosystem, and nitrogen-fixation rates often show a diel or seasonal pattern consistent with the direct utilization of seagrass photosynthate. Nitrogen-fixing microorganisms can provide a significant amount of the nitrogen required for plant growth, and plant uptake of fixed nitrogen has been documented. However, bacteria can also remove nitrogen from the ecosystem via coupled nitrification-denitrification, which may be facilitated by the organic matter and O_2 excreted by seagrasses. The availability of other essential plant nutrients, including iron and phosphorus, can also be controlled directly via microbial activity. Bacterial sulfate reduction, the dominant process in seagrass bed sediments, produces sulfide, which is deleterious for plant growth. Future efforts should be directed toward understanding how changes in water quality, nutrient concentration, and salinity can alter the relationship between seagrasses and their associated microbial communities.

The degree to which the detrital food chain succeeds in transferring seagrass production to consumers is still poorly understood, and appears to be highly variable. In some instances, highly productive seagrass beds appear to contribute little to the food chain supporting fish and shellfish, whereas other reports document a significant connection. Very little is known about how the composition and activity of the microbial community in seagrass ecosystems may affect the efficiency of this trophic transfer, and how environmental variables may alter this relationship.

SEA ICE MICROORGANISMS

ROLF GRADINGER
University of Alaska
Fairbanks, Alaska

Organisms living in polar regions are exposed to harsh environmental conditions. In contrast to the restricted development of life on the exposed land, enormous biomass of bacteria, protists, and metazoans are found in the more sheltered marine environments of the Arctic and Antarctic. One key factor in the polar marine ecosystems is sea ice. Already during the first expeditions to the poles, scientists observed discoloration of the sea ice that was due to accumulations of millions of unicellular algae per liter of sea ice. Combined efforts in biological, physical, and chemical studies elucidated the processes, allowing for life inside the frozen seawater. This contribution reports on the diversity, biomass, and productivity of algae and bacteria in polar sea ice with a regional focus on the Arctic.

DIFFERENT TYPES OF ICE

Ice occurs in cold climate regions as freshwater and as marine ice that are distinctively different in their physical and chemical properties (1). Freshwater ice is formed on lakes or rivers by freezing of freshwater or by accumulation of snow on glaciers. Icebergs are large floating masses of ice, which detached from coastal glaciers and are transported by wind and currents out to sea. Freshwater ice consists of freshwater ice crystals, incorporated sediment, and gas bubbles. Marine ice, which is formed by the freezing of seawater, is basically a two-phase system consisting of solid ice and liquid brine (plus intrusions of particles and gas bubbles). Three major types of sea ice can be distinguished depending on location and ice age. Fast ice is attached to land and forms ice sheets in coastal areas where it may grow either annually or for several years. Pack ice (annual pack ice or multi-year pack ice) consists of separate ice floes (floating flat pieces of ice with varying sizes ranging from a centimeter to a kilometer scale), drifting on the surface of the ocean with wind and currents. The structure and the dynamics of the sea ice are complex. The seasonal and interannual variation of its extent (Fig. 1) was studied by satellite analysis of passive-microwave data with a spatial resolution of app. 25×25 km grid size (2). On an average (period 1979 to 1987), minimum Arctic ice extent ($9.3 \cdot 10^6$ km^2) is reached in September and maximum in March ($15.7 \cdot 10^6$ km^2). This seasonal change is mainly (86%) caused by ice formation and melt in the marginal Arctic seas on the Eurasian and Canadian shelves (e.g., Barents Sea, East Siberian Sea, Kara Sea, and Laptev Sea), whereas the central Arctic ice cover is rather stable (14% of total variation of ice extent). New ice formation starts (depending on latitude) in August/September and commences throughout the winter until March with little interannual variability of the timing. Snow accumulates on the ice surface during winter to a thickness of about 40 cm (3). In May/June, snow melt starts and low saline ponds form on the surface of the ice floes (4,5).

In winter, sea ice extents from the Antarctic continent up to 2,200 km and covers on average $19 \cdot 10^6$ km^2 in September. From October onward, ice retreats to the coast ending with the minimum average ice extent of $4 \cdot 10^6$ km^2 with an interannual variability of 11% (2). The formation of sea ice occurs over areas of approximately $7 \cdot 10^6$ km^2 in the Arctic, and $16 \cdot 10^6$ km^2 in the Antarctic (1). The physical processes during early ice growth in a wave zone such as an achieving ice edge are basically understood and described as following the "pancake cycle" (6,7): the

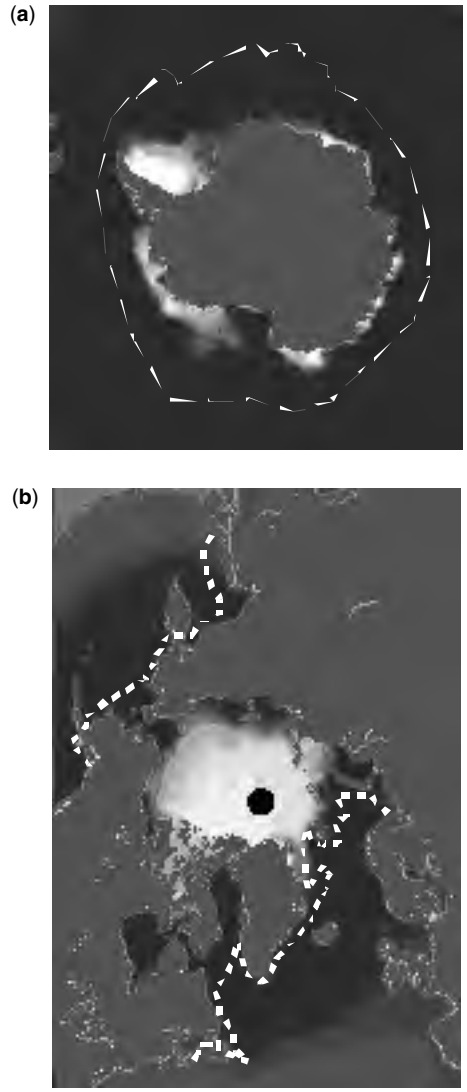

Figure 1. Example for the seasonal variation between minimum and maximum (dashed line) sea ice extent in the Antarctic (**a**) and Arctic (**b**). See color insert.

freezing of seawater leads to an accumulation of ice crystals (frazil ice) in a surface layer a few centimeters thick called grease ice. Further freezing results in the consolidation of the grease ice in the form of either small pancakelike structures or under calm conditions, in uniform ice sheets called nilas ice. During ice formation, a fraction of the incorporated brine solution (high saline water between ice crystals) drains out from the ice, thus transporting salts, dissolved nutrients, and particles from the ice into the water column (8,9). Subsurface formation of very large frazil ice crystals (discs of 10 to 15 cm in diameter and about 0.5 cm thick), so-called platelet ice, caused by upward flow of supercooled water along the floating Antarctic ice shelves, is only known from Antarctica (10,11).

Ice thickness data for the Arctic were compiled from upward looking sonar data of twelve submarine cruises for the period 1958 to 1992 (12). The mean draft of Arctic pack ice varied interannually between 2.8 m (in 1986) and 4.4 m (in 1970) with a mean of 3.6 m over the entire investigation period. Ice thickness increases from areas with mainly first-year ice (e.g., Russian Arctic: thickness <2 m) to areas with multi-year ice cover (central Arctic, region north of Greenland: thickness 7 to 8 m) (13,14). Overall, ice thickness changes seasonally by about 0.5 to 1.0 m (14). The dominant first-year ice in Antarctica reaches maximum thicknesses of 1.5 to 2 m (15).

The sea ice drifts with wind and ocean currents were studied in detail in the Arctic by the Arctic Buoy Program (16). In the Beaufort Sea, ice drifts in a large anticyclonic gyre, the so-called Beaufort Gyre, with speeds from close to 0 in its center to 3 $cm\,s^{-1}$ in the marginal zones. Ice floes need about 5 to 10 years to complete a cycle. Seasonal fluctuations in the wind stress cause reversal of the current and the formation of polynyas (areas of open water surrounded by sea ice). From the Russian shelves, the Transpolar Drift transports pack ice across the central Arctic to the major export area, the Greenland Sea, with speeds of 2 to 10 $cm\,s^{-1}$ (3). The ice movement from the East Siberian Sea to the Fram Strait requires approximately three to four years. About 10% of the sea ice of the central Arctic is exported each year through Fram Strait into the Greenland Sea (1) where it melts.

The three-dimensional structure of the brine system varies with ice texture. In granular ice, an irregular network of brine channels and pockets develops, whereas channels are more vertically oriented in columnar ice (17). In the bottom 1 to 3 cm of growing and stable sea ice, a so-called "skeletal layer" of parallel oriented ice platelets with brine filled spacing of about 0.5 to 1.0 mm within each ice crystal is formed. The brine salinity and the volume of the brine channels are dependent on the temperature and the salt content of the ice (18–20). A decrease in the ice temperature from $-4\,^{\circ}C$ to $-10\,^{\circ}C$, for example, leads to an increase in brine salinity from 70 to 144. The minimum observed temperature of newly formed Arctic sea ice in autumn 1995 ($-6.9\,^{\circ}C$) corresponds to a brine salinity of 110 representing an approximately threefold increase of ambient salinity compared to seawater. Within first-year and multi-year ice floes seasonally fluctuating gradients of temperature, bulk salinity, and brine properties evolve (4,5) and, for example, brine salinity may vary between 0 and above 120 at the ice surface with season, whereas parameters at the ice–water interface are relatively constant.

The seasonality of light is remarkable in polar areas and consequently, organisms experience day lengths from 0 to 24 hours (Fig. 2). Under-ice photon flux is controlled by the thickness and characteristics of the snow and ice, and the enclosed sediment and biota (1). The albedo (= ratio of reflected to incident shortwave radiation) of ice floes covered with cold snow varies between 0.80 and 0.85, decreasing to 0.70–0.75 with the onset of snowmelt. Snow-free multi-year ice floes have albedo values ranging from 0.55 to 0.75 depending on surface temperature. First-year sea ice and melt ponds exhibit lowest values (0.15 to 0.60). The bulk shortwave extinction coefficient k_z varies with depth (21) and has in deeper layers a mean value of 1.5 m^{-1}.

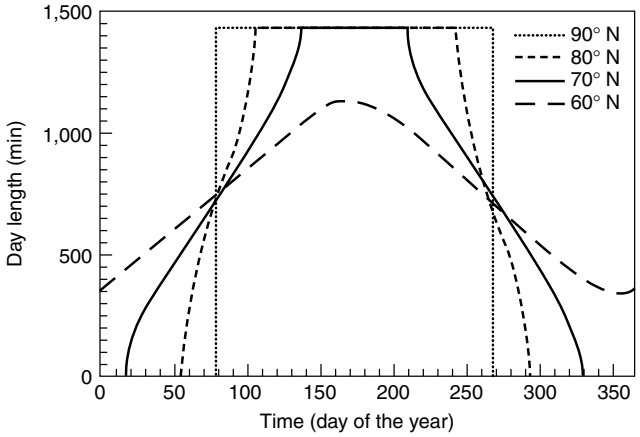

Figure 2. Day length (min) in Arctic latitudes.

The quality of the light is altered by the wavelength dependent spectral absorption coefficient k_λ which has relatively constant values between 400 and 500 nm, and increases for longer wavelengths. Red wavelengths are more quickly absorbed, and the spectrum changes with increasing ice depth with maximum transmission between 450 and 550 nm. Algal accumulations may have considerable impact on the spectrum and absorption of the shortwave radiation (22–25). As a consequence of the above mentioned factors, shortwave radiation intensities are reduced by orders of magnitude under sea ice compared with surface irradiance.

PRIMARY PRODUCERS WITHIN THE ICE

Life at the Surface of Ice Floes

Historically, the snow and melt pond habitats associated with the surface of sea ice received little attention (26,27), although snow and glacial fields on land were known to be colonized by algae, bacteria, fungi, and protozoa (28). There, algae occurring in concentrations of more than $5{\cdot}10^5$ cells ml^{-1} can stain snow and glaciers, as has been shown for many parts of the world (29). Coloration of the surface of Arctic pack ice floes occurs for at least two reasons. Grey to brownish coloration due to lithogenic sediments (so-called "dirty ice") has received increasing interest from marine geologists (30). First evidence for the occurrence of algae on the surface of ice floes was provided in 1828 (31) when red snow patches were seen on sea ice close to Svalbard at 82° N. A detailed study showed that a red snow patch community on an Arctic ice floe belonged to the so-called "nivalis cryobiont"-complex with the chlorophyte *Chlamydomonas nivalis* as the dominant species (32). *Chlamydomonas nivalis* is the typical red snow alga for the northern hemisphere (29) and probably the most common and widely distributed snow algal species of all (33). Several other chlorophytes (*Ancylonema* sp., and *Chlorella* sp.) and one cyanophyte species (*Stigonema ocellatum f. paniformes*) were found in addition to *C. nivalis* during the Russian ice drift studies "North Pole 22" in 1975 and "North Pole 23" in 1979 in the central Arctic Ocean, whereas diatoms were absent (34). The lack of living diatoms is typical for all temporary snowfields (also on land), which are mostly dominated by *Chlamydomonadaceae* such as *C. nivalis* (35). The occurrence of empty diatom frustules on the surface of sea ice (36) is not the result of active growth in the snow–ice interface but from passive accumulation due to ice melt. No observation of surface ice or snow coloration due to typical snow algae have been published for Antarctic sea ice.

Chlamydomonas nivalis is a psychrophilic species and survives temperatures of −35 °C (37), which makes winter survival on ice floes temperature independent. *Chlamydomonas nivalis* is introduced into the central Arctic Ocean from land by northward blowing winds (38,39) like pollutants emitted in North America or Europe (40) Besides growth, high concentrations can be achieved by passive accumulation. The snow melting in spring leads to an increase in particle concentrations at the remaining snow or ice surface (by freshwater flushing) and to particle transport into melt ponds and the upper layers of the sea ice (32). Here, *C. nivalis* is able to grow during the entire Arctic summer, partly because of its protection against ultraviolet (UV) radiation by the red carotenoid pigments (29,41). Primary production estimates for algae on the surface of Arctic ice floes are rather rare but the few obtained rates (e.g., 87 mg C m^{-2} d^{-1}) of a *C. nivalis* patch may even exceed those of bottom ice algae (42). Lower surface algal production rates of 0.2–4 mg C m^{-2} d^{-1} were probably not determined within colored snow patches (34). On the basis of volume specific incorporation rates (43,44) and cell counts (32), potential primary production may range from 3 to 1,200 mg C m^{-3} snow d^{-1} leading to an integrated value of 12 to 480 mg C m^{-2} d^{-1}. The formation of mucilaginous aggregates by snow algae in association with nonliving material (32,38) allows the cells to trap lithogenic material for an improvement of the growth conditions in the vicinity of the cell. The mucilaginous aggregates formed by *C. nivalis* may furthermore provide an agent for fast vertical transport of the generally fine-grained ice sediments, which can occur in extremely high concentrations of up to 51 g l^{-1} (30), after ice melt.

Melt ponds cover up to 60% of the surface of Arctic ice floes (1), however, knowledge on biological properties is rare (5,32,34,45). In the central Arctic two types of melt ponds can be visually distinguished by their color (45). Blue ponds turned out to be freshwater habitats with a medium salinity (Psu) of 0.1. Green ponds had salinities of about 29 and were connected to seawater either by holes in the ice floes or via channels to the leads. Besides differences in pH and nutrient concentrations, the composition of the community also differed. In both types considerable concentrations of bacteria, photo- and heterotrophic protists including *C. nivalis* were described from this habitat (26–47). Besides flagellated algae (e.g., *Chlamydomonas* spp., *Carteria* sp., *Pyramimonas* sp., *Chrysolykos* sp., and *Dinobryon* sp.), heterotrophic protists (e.g., several dinoflagellate species, *Cryothecomonas* sp., and *Lachrymaria* sp.) also live in the ponds (47). Higher concentrations of pennate diatoms (e.g., *Nitzschia frigida* and *Nitzschia grunowii*) occur in the salty green ponds compared to the freshwater ponds (27,46,47), probably inoculated by wave flushing or migration from the sea

ice into the ponds (48–50). The latter process is supported by the development of typical ice algal communities at the bottom of green ponds (47,50). In the freshwater ponds inoculation by wind transport (51), river inflow (52), and by surviving cysts on the ice is likely.

The Bottom and Ice Interior

Distribution of organisms within the Antarctic and Arctic sea ice are very different (Fig. 3; 53). Four major habitats in Antarctic sea ice can be distinguished on the basis of the vertical distribution of sympagic-ice associated organisms in individual ice floes (54). Biomass maxima may occur (*1*) at flooded ice surfaces, (*2*) at the freeboard layer, (*3*) in interior ice parts, and (*4*) in the bottom layer. In Arctic sea ice, distribution patterns seemed to be less complex with only two regions of high algal standing stock, both associated with the bottom of the ice floes: (*1*) bottom communities (53), and (*2*) sub-ice communities (5). Consequently, biological research focused on the bottom centimeters of Arctic sea ice neglecting the biological properties of the inner parts of the ice. However, recent studies on the vertical distribution of bacteria in pack ice floes from the Barents and Laptev Seas and ice algae in the central Arctic have already demonstrated that the paradigm of the dominance of bottom communities in Arctic sea ice has to be revised (55,56).

The algal pigment concentration in Arctic pack ice floes (55) vary vertically over entire ice thicknesses of up to 6.7 m between individual ice segments of about

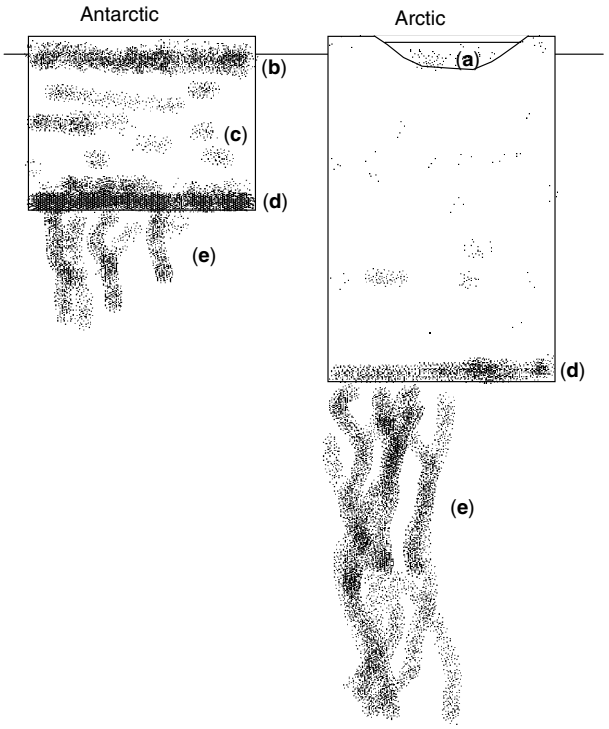

Figure 3. Regions of major algal biomass accumulation in Arctic and Antarctic sea ice: (**a**) melt ponds on Arctic summer ice, (**b**) freeboard and infiltration layers, (**c**) internal layers, (**d**) bottom layers and (**e**) attached under-ice algae. Ice thickness in Antarctica <2 m, in the Arctic 2–4 m.

10 cm thickness between 0.0 and 109.2 μg chl *a* l^{-1} melted ice. In most cores (85%), biomass maxima occur in the bottom 30 cm of the ice floes; only 35% harbor at least one internal maximum. The integrated algal abundances range from 320 to $14,100 \cdot 10^6$ algal cells m^{-2}, with the calculated ice algal carbon (IAC) from 13 to 457 mg C m^{-2} with phototrophic flagellates (including dinoflagellates) contributing on average 48% to total abundance and 20% to IAC. Pennate diatoms contributed 52% of total abundance and 72% of IAC. Although *Synechococcus* -like picocyanobacteria are incorporated into newly forming sea ice (57), they are nearly absent in older first-year and multi-year ice floes. Toward the bottom of the ice floes, the algal abundances increase from about 390 cells ml^{-1} to 3,850 cells ml^{-1}, and the relative composition changes with a decrease in the contribution of phototrophic flagellates from 97 to 32% (median values) and an increasing fraction (from 0% to 68%) of pennate diatoms. The IAC varies between 28 and 2,160 mg C m^{-3} (median = 180 mg C m^{-3}) in the lowermost segments, with a share of 46 to 100% (median = 91%) by pennate diatoms. The seasonal variation (spring to autumn) of integrated algal pigment concentration in Greenland Sea pack ice was negligible. These observations from Arctic pack ice differ from observations from annual coastal fast (58,59) or pack ice (23,60,61). In the coastal areas of Canada, ice algae grow exponentially until the ice melts in May reaching final integrated chl *a* concentrations that are two orders of magnitude higher than the pack ice data (Table 1). Pennate diatoms are the major primary producers in these regions and algal biomass is concentrated in the bottom segments (62,63). Episodically, accumulations of centric diatoms instead of pennate forms were reported (50,64).

So far over 200 diatom species (mainly pennate taxa) and over 70 species of flagellates from Arctic sea ice have been described. Approximately the same amount of diatom species were identified from the southern ocean (79). Although the knowledge about the diatom diversity is rather complete, little information is still available about the diversity of photo- and heterotrophic flagellated taxa, which are susceptible to handling artifacts. The melting process of sea ice samples have a severe impact on the observed communities, and direct ice melt tends to underestimate the diversity and biomass of the more vulnerable flagellates compared to diatoms (55,75).

In the Antarctic sea ice, algal biomass that is indicated by pigment concentration can exceed values of that of the Arctic at the snow–ice interface (infiltration community), in the interior parts and at the bottom (Fig. 3, Table 1). Under coastal fast ice, loose aggregations of platelet ice crystals may accumulate forming a specific habitat allowing for extensive algal growth (11,80). Algal growth in Antarctic sea ice follows the seasonal trend as described for Arctic fast ice (81). Two distinct algal blooms form in the bottom layer of the sea ice of which one forms in autumn after ice formation with maximum values up to 829 mg chl m^{-3}. After decrease during winter, spring bloom values exceed 1,000 mg chl m^{-3}. In the pack ice of the Weddell Sea, biomass seem to be lower with 4.5 mg m^{-3} ice (73). Integrated algal biomass in Antarctic sea ice ranges with season and location from about

1.4 mg chl m^{-2} (74) to above 2,900 mg m^{-2} (82). Beside diatoms, the haptophyte *Phaeocystis antarctica* may contribute a large fraction to the biomass in infiltration and freeboard layers (e.g., Kristiansen and coworkers 1998).

Under-Ice Habitat

In summer, melt of sea ice leads to reduction of salinities of the upper meters of the water column. Apollonio defined the so-called "halocline flora" (83), which is characteristic for the upper 2 m of Arctic waters in summer and occurs at a constant biomass level of 1 to 2 mg Chl *a* m^{-3} for periods of six to eight weeks. The vertical stabilization allows the increased biomass in this layer, which also caused a *Chrysochromulina* bloom under Baltic Sea fast ice near Tvärminne, Finland (84). The halocline flora is dominated by phototrophic flagellates (Chlorophyceae and Chrysophyceae) with *Chlorella* sp., *Oocystis* sp., *Scenedesmus bijugatus* and *Ochromonas* sp. as major taxa (27).

Melt water can also accumulate under the ice floes in depressions and influences the exchange rates between ice and water column by enhanced desalination, sealing, and topographic smoothing of the ice bottom. Such under-ice ponds cover at least 5% of the total ice area of the Arctic (85). Biological activity within such ponds can be high: in one brackish water under-ice pond an algal bloom had formed within an algal pigment concentration of 29.6 mg m^{-3} with *Pyramimonas* sp. (20,320 cells ml^{-1}) as dominant species (86). In addition, phototrophic euglenophytes (<1 cell ml^{-1}), heterotrophic flagellates (4,360 cells ml^{-1}), and bacteria ($2.21 \cdot 10^6$ cells ml^{-1}) were identified.

Certain algae in the Arctic and Antarctic are able to use the underside of ice floes as a suitable surface for attachment. The often meter-long huge bands of diatom *Melosira arctica* hang from Arctic ice into the water column (87), mainly below young ice and first-year ice (70,88). These curtainlike structures consist of drilled chains, wrapped in a mucilaginous envelope. Co-occurring with *M. arctica*, several pennate diatom species (e.g., *Licmophora* sp.), heterotrophic flagellates, dinoflagellates, and ciliates, which were either attached to, gliding on, or moving between the chains were found. In Antarctica certain diatom taxa like *Berkeleya rutilan* form mat strand assemblages, which either float directly below the ice or are also attached to the ice bottom (48,89).

NUTRIENT CONCENTRATIONS

Nutrient concentrations in the ice are generally about one order of magnitude below winter concentrations in

Arctic surface waters. However the accumulated algal biomass in sea ice does not only reflect the initial nutrient concentrations but also the nutrient supply during ice algal growth (69). Initial bulk concentrations of inorganic nutrients in newly formed Arctic sea ice are below surface values because of brine drainage (e.g., nitrate concentrations below 4 mmol m^{-3}; (57) and decrease further with time. In coastal areas, nitrate is accumulated by ice algae and bulk concentrations (4 to 123 mmol NO_3 m^{-3}) in the bottom 3 cm of the ice exceed values of Arctic surface water and concentrations in the brine of pack ice floes by far (90,91). Only during spring brine nutrient concentrations in the bottom ice layer of Arctic sea ice are above typical k_s values (half saturation constant for nutrient uptake) for marine microalgae (92); limitation is likely in summer and autumn (93). However, measurements of nutrient uptake kinetics of Arctic sea ice algae under suboptimum growth conditions are still lacking. Growth limitation by nutrients is also expected for Antarctic ice algae (94,95) although initial concentrations in Antarctic surface waters are among the highest in the ocean of the world.

Resupply of inorganic nutrients may occur by either molecular diffusion across the viscous sublayer (mainly in the skeletal layer) from the water column or by biological regeneration of nutrients (96). The potential contribution of desalination of the ice sheet to the nutrient flux is predicted to be small because internal concentrations are low (69). Several studies in coastal sites pointed out the strong coupling between the strength of tidal currents and the induced supply of nutrients from the water into the ice, and the algal growth (69,91,97,98). In the central Arctic the coupling mechanisms are considerably different (55). Velocity of tidal currents varies regionally with lowest values (<10 cm s^{-1}) in the central Arctic (99), and values >50 cm s^{-1} in the Canadian Arctic or on the Russian shelves. The free drift of ice floes (in comparison to fast ice) and low current velocities can lead to a reduction of the current shear at the ice–water interface and consequently nutrient exchange rates between water and ice. The described pycnocline formation under the sea ice by freshwater accumulation below the pack ice additionally hinders exchange between ice and water in summer.

BACTERIA IN SEA ICE

A large fraction of total biomass in Arctic and Antarctic sea ice is contributed by bacteria (56). With the onset of algal growth, a favorable habitat for bacteria is created within the ice matrix and the increase in bacterial abundance and activity follows the increase in algal biomass (100). In Arctic fast ice, bacterial production is only a minor fraction of the ice-based carbon cycle when compared with primary production estimates (100). For other Arctic and also Antarctic locations, bacterial production can exceed those of algae for certain periods of the year (101,102). Information about the abundance and characteristics of ice bacterial communities of pack ice floes in the Eurasian sector of the Arctic is sparse in comparison with the knowledge on fast-ice systems (103). The volume of individual fast-ice bacteria ranges between 0.47 μm^3 (100,104) and 0.65 μm^3 (105). Those from drifting pack ice were lower with a median value of 0.09 μm^3, which resembles the median for bacterial volume from drifting Antarctic ice floes (0.07 μm^3, (101)). The bacterial cell volume is influenced by environmental parameters like food availability or grazing pressure. Dissolved organic material (DOM) concentrations in the ice are mostly higher than in the underlying water column (105–108) and the bacteria in the DOM-rich fast ice habitat are larger than the pelagic cells (105). A direct relation between DOM concentration and bacterial cell size was also observed in marine benthic habitats (109). The different DOM concentrations in fast ice and pack ice are one factor responsible for the observed bacterial cell size differences also because the algal biomass in Arctic fast ice is significantly higher than in the pack ice floes (110). Grazing processes have been already proposed by (101) as another size-controlling factor. This idea is further supported as heterotrophic flagellates are feeding on bacteria in Arctic fast ice as effectively as in other aquatic environments (104). However, the observed size differences between Arctic and Antarctic ice bacteria may also be because of the different techniques applied (100). The ratio of bacterial to algal biomass is not constant along vertical profiles within sea ice. The algal biomass exceeds the bacterial biomass in Antarctic (111) and Arctic sea ice (56,100) within the algal maxima at the bottom of the ice floes. Comparison based on the integrated values revealed that the integrated bacterial biomass was up to 10 times higher than the algal biomass. The relation of bacterial to algal biomass for Antarctic pack ice decreases from, on average, 55.1% in spring to 21.2% in autumn (112). Real estimates of bacterial abundances and biomass are biased by varying integration depths, ranging from 0.04 m (100) to 2.71 m (56). Vertical patchiness in the distribution of bacteria occurs on different scales inside the ice, with 78% of the bacterial biomass in the lowermost 5 mm of a 4-cm-long bottom section (104). To resolve spatial relationships between ice algae and bacterial biomass, small-scale sampling strategies with vertical resolution below 1 cm must be used, as have been successfully applied to the bottom parts of the fast ice in the Canadian Arctic (104,113).

The dominant heterotrophic bacterial taxa include proteobacteria, many pigmented marine *Cytophaga*-like and *Flavobacterium* rod-shaped and filamentous bacteria (CFG group), and gram-positive micrococci (114). *Archaea* are also known to inhabit Antarctic sea ice (115). A large fraction of bacterial genera and species are yet to be discovered, as demonstrated for Antarctic samples (116,117). The bacteria in the ice are not only exposed to grazing by flagellates but also lysis by bacteriophages, which have been described for Arctic sea ice (113). The mean ratio of viruses to bacteria in ice samples is high compared with the water column data. High virus activity could explain the discrepancy between primary and secondary production in Antarctic ice floes observed by Grossman and Dieckmann (101).

ADAPTION TO THE ENVIRONMENT

The microorganisms living within the sea ice are adapted both morphologically and physiologically to the unique temperature, salinity, light, and spatial characteristics of their habitat.

Temperature

All physiological processes are related to temperature, however, the rate at which metabolism decreases with varying temperatures, varies. Incorporation of radioactive tracers by Antarctic bacteria and algae are significantly higher at temperatures well above the in situ conditions (−1.9 °C) with optima between 2 and 15 °C (118). Both ice algae and bacteria can be called psychrophilic (119) because their growth optimum was below 15 °C. For Arctic cold regions, a higher relative decrease in bacterial versus algal production rate was observed, with decreasing temperature, causing an uncoupling of their activities in cold water conditions, which could explain higher DOC concentrations in these waters (120,121). However, studies from both Arctic and Antarctic provide also contradictory evidence.

Salinity

The salinity in the sea ice brine channels covaries with temperature as described earlier. Sea ice algae have evolved enormous osmoregulation potential, which allows them to grow at salinities (PSU) as high as 100. Four Arctic diatom species, isolated from Chukchi and Beaufort sea ice, were relatively euryhaline and maintained growth rates of 0.6 to 0.8 divisions per day over a salinity range of 10 to 50 (122). The growth of bottom ice algal communities of the Antarctic pack ice was observed at salinities from 11.5 to 34, and growth rates increased with increasing salinity (123). Growth of ice microalgae from the Weddell Sea (Antarctica) occurred down to −5.5 °C and a corresponding salinity of 95 (124). Lower temperatures and higher salinities were also tolerated. Greenland Sea ice algae exhibited positive growth over a salinity range of 4.0 to 74.0, with growth rates of 0.12 to 0.19 day^{-1} of the algal community and 0.32 to 0.39 day^{-1} for individual species (125). Antarctic sea ice algal communities, dominated by *Nitzschia stellate* and *Amphiprora* sp., tolerated higher salinities (30 to 50 PSU) better than lower ones (123,126), whereas assemblages dominated by other species such as *Pleurosigma* sp., *Amphiprora kufferathii*, and *Pinnularia quadratarea* exhibited maximal growth rates at 6 to 10 PSU (127,128). Acclimation to changing salinities is achieved in two ways, either extracellularly and anisoosmotically with inorganic ions, or intracellularly using organic compounds. Arctic and Antarctic unicellular ice algae, for example, are known to synthesize osmolytes like prolin or DMSP

Table 2. Comparison of Photosynthetic Parameters and Growth Rates of Bottom and Interior Ice Algae

Note: Photosynthetic efficiency (Alpha/Alpha*, defined in text) in (μg C μg Chl a^{-1} h^{-1}) (μmol m^{-2} s^{-1})$^{-1}$; maximum photosynthetic rate under light saturation (P^B_m) in (μg C μg Chl a^{-1} h^{-1}); biomass/chlorophyll *a*-specific photosynthetic rate (P^B or P^{Chl}) in (μg C μg Chl a^{-1} h^{-1}); Integrated primary production (mg C m^{-2} d^{-1}); growth rate (d^{-1}). Thickness of bottom and interior layers vary for the different authors; values represent means or ranges.

(dimethylsulfoniopropionate) (129) to remain isoosmotic with the surrounding medium if salinity increases. Similar experiments on salinity tolerance on Antarctic sea ice bacteria revealed upper thresholds for active growth of about 90 (128).

Light or Dark Adaptation

Incident irradiance in polar areas varies primarily with seasons, over diel cycles, and on even shorter timescales with cloud cover. During the polar winter, microalgae faces total darkness for a period of up to six months (130). A natural Arctic pack ice algal community, incubated for a dark period of 161 days, remained at 40% of the initially determined algal concentration and 64% of the initially observed species level (131). Many experimental studies on the impact of the light regime were conducted with cultures of Arctic and Antarctic diatoms (130,132). To survive long periods of darkness, marine microalgae have at least three survival strategies: facultative heterotrophy, storage, and utilization of energy reserves at a reduced metabolic rate, and resting spore formation. These strategies are not exclusive and vary in importance between species (130). Studies on Arctic, temperate, and Antarctic diatoms demonstrated their ability to utilize DOM for nutrition (133–136). Other studies (137) consider this process to be insignificant. The storage of energy in the form of lipid droplets or carbohydrates has been observed in many diatoms (138–140). Analysis of lipid composition of Arctic ice algae showed a predominance of neutral lipids over glycolipids and phospholipids (141,142). The high level of neutral lipids (37 to 94% of total fatty acids), independent of season, points toward the assumption that neutral lipid production is a basic characteristic of ice algae regardless of season (142). The production of other lipids may vary with season (143,144). Production of glycolipids in Arctic ice algal cultures may significantly increase after exhaustion of inorganic nutrients (145). Combined with energy storage, reduction of cellular metabolism (134,146) enables the survival of algal cells during the dark polar winters.

Many algal groups (e.g., diatoms and dinoflagellates) have evolved specific cell types and stages to survive unfavorable environmental conditions (147). In studies on Antarctic (130,146) and Arctic (50,131) ice communities spore formation was however rarely reported. Consequently, resting spores do not play an important role in winter survival of most ice protists except for specialists like dinoflagellates living in the upper part of Antarctic fast ice (148,149).

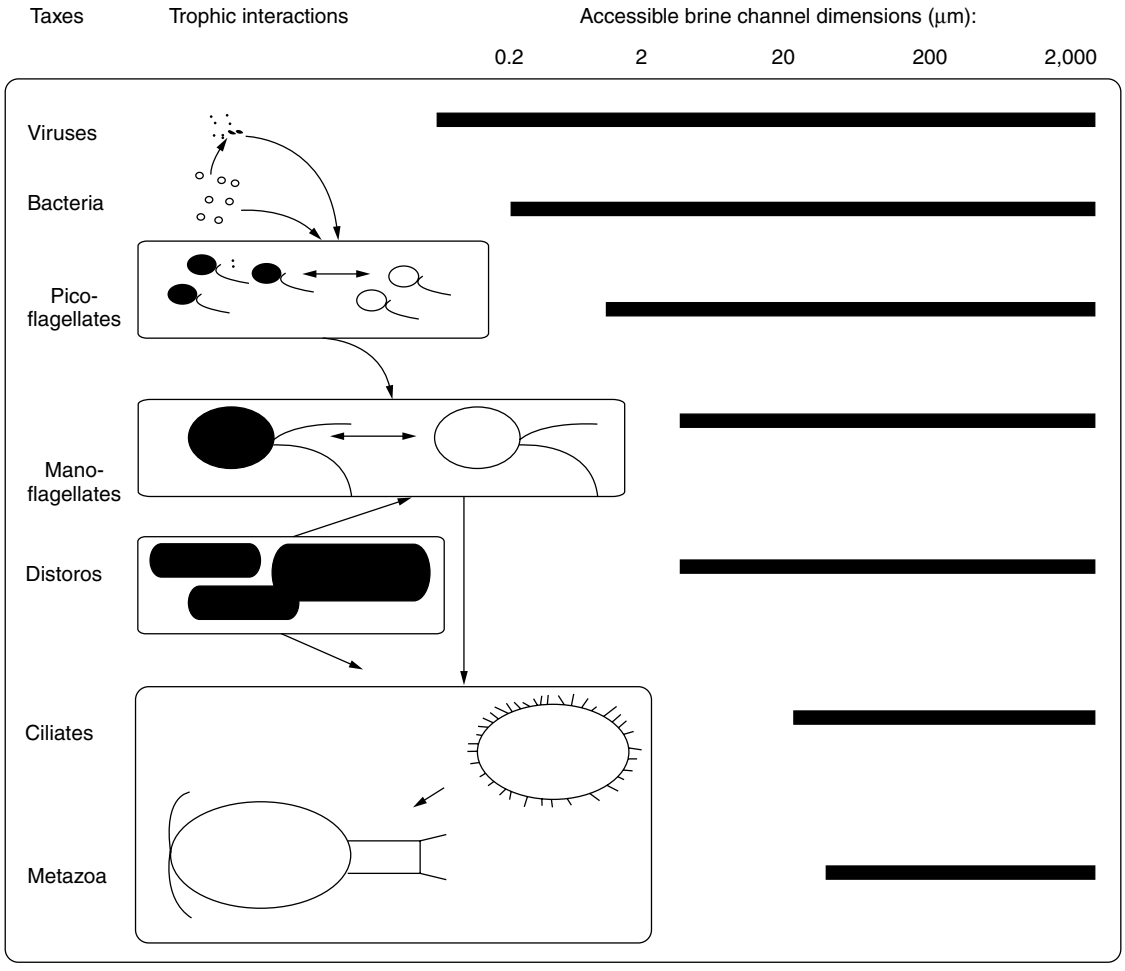

Figure 4. Schematic representation of the influence of brine channel diameter on the structure of the sympagic food web.

The high photoacclimation potential of polar phytoplankton and sea ice algal assemblages allows survival and rapid growth in low-light conditions (150–153). Chlorophyll specific algal production rates (P^{Chl}-ratios) of bottom ice algal communities from Arctic first-year pack ice ranged between 0.04 and 0.31 $\mu g\,C\,\mu g$ Chl $a^{-1}\,h^{-1}$ (93), similar to data from first-year bottom ice algae collected near Resolute (Table 2; 93,154). P^{Chl}-ratios of the interior communities in first-year segments are higher and ranged between 0.05 and 0.90 $\mu g\,C\,\mu g$ Chl $a^{-1}\,h^{-1}$. The P^{Chl}-ratios of 0.02 to 0.05 $\mu g\,C\,\mu g$ Chl $a^{-1}\,h^{-1}$ for bottom communities and 0.01 to 0.13 $\mu g\,C\,\mu g$ Chl $a^{-1}\,h^{-1}$ for interior communities of multi-year sea ice are typical for photosynthetic responses to very low irradiance measured in situ (0.4 to 3.3 $\mu mol\,m^{-2}\,s^{-1}$ (93)) compared with saturation intensities around 5 to 10 $\mu mol\,m^{-2}\,s^{-1}$ (23,130,150,155–157). Positive net photosynthesis of Arctic pack ice algae occurred even at a mean irradiance level of 0.36 ± 0.05 $\mu mol\,m^{-2}\,s^{-1}$ (93), which is well below threshold values from other field observations (1–9.3 $\mu mol\,m^{-2}\,s^{-1}$; (157–160)), but coincide with laboratory values of 0.2–2 $\mu mol\,m^{-2}\,s^{-1}$ (155,161).

Habitat Structure

The diameters of the brine channels span from few micrometers to several centimeters (17). The accessible pore space in sea ice plays a similar role for the geochemical cycling and biological interaction as shown for other marine and terrestrial habitats (177). At least pennate diatoms, many ice flagellates (e.g., *Anisonema* sp., *Thaumatomastix* spp., and *Protaspis* spp.), ciliates, turbellarians, and crustaceans have a behavioral preference for moving and feeding along the ice crystal surfaces, although a quantification of the surface area in relation to the concentration of attached or gliding biota is still missing. Many ice inhabiting organisms (e.g., bacteria, snow algae, diatoms, and metazoans) produce extracellular organic substances (32,48,83) and could alter the ice surface by coating it with transparent exopolymer particles (TEP) or via release of antifreeze chemicals. The spatial and temporal variability of brine channel geometry will cause changes in the structure of the sympagic food web (Fig. 4), excluding larger taxa from narrower brine channels. The brine volume itself is affected by changes of ice temperature and bulk salinity (19,20). Reduction of brine volume by, for example, cooling increases the concentrations of dissolved and particulate matter in the brine network, thereby exposing the biota to higher levels of nutrients, changes osmotic stress and increases grazing pressure as long as grazing is density-dependent.

GRAZING ON THE SEA ICE ALGAL BIOMASS

Precise measurements of ice algal production are difficult because of the type of habitat. Conservative estimates (178) calculated that about 20 to 25% of the entire primary production in polar seas is contributed by ice algae. A certain fraction of ice algal production is ingested by heterotrophic protists (179) and sea ice metazoans (180–182). Additionally, larvae of benthic animals (polychaetes and mollusks) migrate in shallow coastal areas into the brine channel network of first-year ice (183). The knowledge on the potential contribution of algal grazers to the carbon flux within polar sea ice is rudimentary and was partially ignored (184,185). Calculated grazing pressure by ice fauna (181) is by one order of magnitude lower than mean primary production estimates of 57 $mg\,C\,m^{-2}\,d^{-1}$ (70) and 83 $mg\,C\,m^{-2}\,d^{-1}$ (186) of Arctic sympagic algae.

CONCLUSION

Research over the last decades has considerably increased our understanding concerning the diversity, biomass, and activity of microorganisms in the unique sea ice environment. The strong linkages between physical and chemical properties and the seasonal development of the ice microbial communities were studied in detail. New endemic species of ice bacteria and protists were described, and others will be added. Focus of sea ice research will extend the current issues but also proceed to new topics. Many sea ice covered regions like the Canadian Basins in the Arctic and the western Weddell Sea in Antarctica have hardly been studied ever, offering opportunities for future exploration. Future investigations will focus on the ecophysiology of ice-associated organisms and their adaptations to the extreme conditions (e.g., the fluidity of membranes or the activity of enzymes at low temperatures). Additionally, effects of the shrinking ice extent on biological processes in Arctic waters will be an important issue over the next years to decades.

SEDIMENTS: SULFATE REDUCTION IN MARINE SEDIMENTS

Mark E. Hines

Biological sulfate reduction is an important component of the sulfur and carbon cycles in marine sediments. Sulfate-reducing bacteria are anaerobes that are situated at the terminus of the anaerobic food web where they liberate inorganic carbon and sulfide as the primary end products of organic matter mineralization. Dissimilatory sulfate reduction may account for half or more of the total organic carbon mineralization in many sediments, especially those close to shore where sulfate reduction is the dominant anaerobic process (1,2). Oxygen is usually consumed rapidly near the surface in coastal sediments and alternate electron acceptors such as nitrate and metal oxides may be depleted within a few millimeters to centimeters of the surface as well. Because seawater is rich in sulfate, its use in marine sediments as a bacterial terminal electron acceptor during organic matter oxidation can occupy several vertical centimeters. It has been estimated that approximately 5×10^{12} g yr^{-1} of sulfate-(S) is reduced by bacteria globally with greater than 95% occurring in the ocean (3). Most of this sulfate reduction occurs in coastal regions that receive high inputs of organic material. Besides its importance in the degradation of organic compounds, the reduced sulfur produced during sulfate reduction is important geochemically, because it is highly reactive, and involved in the precipitation of highly insoluble metal sulfides and the accumulation of dissolved sulfide. The reduced products can be readily reoxidized under oxidizing conditions and can act as substrates for autotrophic bacteria, thus completing the sulfur cycle.

In this article, the focus is mainly on the role of sulfate reduction in the mineralization of organic matter, including its importance in both vegetated and unvegetated sediments and coastal marshes. In addition, characteristics of sulfate-reducing bacteria, their abundance and diversity, aspects of their biochemistry, interactions with other bacterial groups, and geochemical considerations are addressed.

BIOGEOCHEMICAL CYCLING

Anaerobic Food Web

The anaerobic bacterial food web is more complex than the aerobic web because many anaerobic systems require microbial consortia to supply intermediate compounds via fermentation reactions (Fig. 1). As will be discussed in more detail later, the primary role of sulfate-reducers

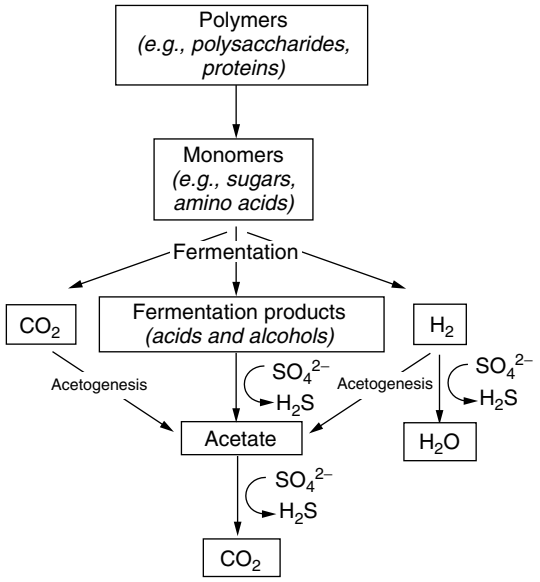

Figure 1. The anaerobic microbial food web displaying the role of sulfate reduction in the utilization of organic fermentation products and hydrogen and the production of acetate.

is to complete degradation by mineralizing relatively small organic substrates to carbon dioxide. Although the group as a whole contains a diverse array of metabolic capabilities, sulfate-reducers are not involved in polymer breakdown and few seem to be capable of degrading compounds more complicated than simple monomers or fermentation products.

Biogeochemical Zonation and Bacterial Competition

Rates of carbon mineralization in sediments generally decrease exponentially with depth and usually display a seasonal cycle that follows temperature changes. The pathway of decomposition depends primarily on which terminal electron acceptors are utilized, with oxygen utilization (aerobic respiration) occurring first, followed by nitrate, manganese, iron, sulfate, and carbon dioxide (methanogenesis). The order of electron acceptor use is governed by thermodynamics (the energy yield), substrate affinity (the ability of a physiological group to lower substrate concentrations to a level which cannot be used by other groups), and aspects of the biochemistry of the respective bacterial groups (e.g., anaerobes restricted to anoxic sediments). In most cases, the terminal processes in each zone are mutually exclusive, although overlaps between zones and the co-occurrence of processes have been noted in certain situations. As can be seen in Fig. 2, sulfate reduction is restricted to near the bottom of biogeochemical hierarchy. However, when organic loading is rapid and/or organic material is relatively labile, rapid use of electron acceptors results is thin vertical zones in which the sulfate-reducing region can be within millimeters to a few centimeters of the surface. Sulfate reduction can also occur within reduced microniches in oxidized sediments (4), especially when these niches are relatively large, that is, $<200\ \mu m$. Because seawater is rich in sulfate, the vertical extent of the sulfate-reduction zone can be several centimeters to tens of centimeters or more. Hence, sulfate reduction can be a dominant process in organic matter mineralization in marine sediments.

The most reliable method to determine the extent of the sulfate-reduction zone is to measure sulfate in sedimentary pore waters (Fig. 2). The vertical profile of sulfate is also an indication of the rate of sulfate reduction and the sedimentation rate; a steeper decline in sulfate signifying a more rapid rate of sulfate reduction (5). However, sulfate profiles can be greatly disrupted by the activities of burrowing benthic fauna or vascular plants; effects that will be addressed further in the following text.

The sulfate concentration in sediments affects sulfate reduction only when concentrations are quite low. The reduction of sulfate in marine sediments appears to be zero-order with respect to sulfate down to concentrations of about 2 mM (5,6). In freshwaters, sulfate concentrations must be much lower before they limit sulfate reduction. Because freshwater contains little sulfate compared with seawater, the importance of sulfate reduction in sediments increases in an estuary as the salinity increases (7). Therefore, the vertical extent of the sulfate-reduction zone increases substantially as more sulfate becomes available, whereas the methanogenic zone is "pushed" deeper into the sediment and its contribution to carbon mineralization decreases in importance.

The competition among terminal bacterial groups is easily demonstrated by amending sediments with alternate electron acceptors and observing changes in bacterial activities. For example, sediments receiving amendments of nitrate or freshly precipitated iron or manganese oxides display a rapid decrease in sulfate-reduction activity that is accompanied by an increase in nitrate reduction or metal oxide reduction, respectively. These changes in electron acceptor use are often accompanied by decreases in the concentrations of substrates used by both physiological groups, underscoring the ability of bacteria within vertically higher zones

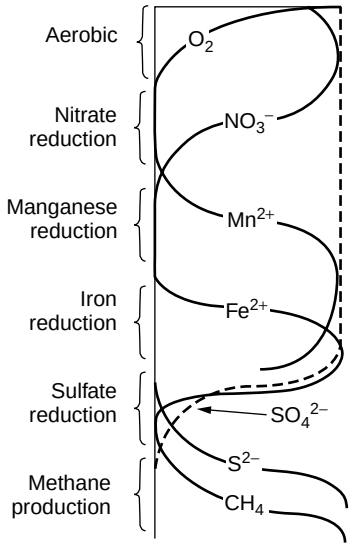

Figure 2. Vertical biogeochemical zones in sediments. Plots on the right represent the chemical profiles most widely used to delineate the vertical extent of each zone.

to lower substrate concentrations to levels below the minimum level required for other groups of bacteria (8,9). The minimum threshold concentrations of hydrogen for nitrate-reducing bacteria, for example, are several fold lower than those required for sulfate-reducers, which in turn are several fold lower than the minimum concentration that can be used by methanogens. Therefore, the terminal bacterial group in each biogeochemical zone can effectively preclude the growth of those from the deeper zone by maintaining low substrate concentrations. In the case of the sulfate-reducing bacteria, they are excluding methanogenic bacteria.

Sulfate Reduction versus Methanogenesis. Considerable controversy exists regarding the interaction between sulfate reduction and the methanogenesis in sediments. Geochemical evidence indicates that methane is consumed within the methanogenic zone suggesting that sulfate-reducing bacteria are capable of utilizing methane that diffuses from below (10,11). Radiotracer studies have shown that labeled methane is oxidized to carbon dioxide at the interface between the zones (12). Early work suggested that a sulfate-reducing isolate was able to oxidize methane, but this was not confirmed. It was suggested that methane oxidation at the interface between the methanogenic and sulfate-reduction zones may be because of a syntrophic relationship in which methanogenic bacteria act in reverse by converting methane to hydrogen and carbon dioxide, while sulfate-reducing bacteria consume hydrogen (13). Further evidence exists that a unique archaeal group is present at this interface (14,15) and biogeochemical and molecular data seem to indicate the presence of a phylogenetically distinct group of sulfate-reducers in this region as well (16).

Some electron donors are more readily metabolized by methanogens than sulfate-reducers and these "noncompetitive" substrates can allow methanogenesis to occur in the presence of active sulfate reduction (17). Examples of these types of substrates include C_1 compounds such as methylated amines, methylated sulfur compounds (e.g., dimethyl sulfide and methane thiol), and methanol. Methylated nitrogen and sulfur compounds are common degradation products of osmoregulating compounds found in certain marine algae and salt marsh grasses, and their use by methanogens partially explains the occurrence of significant concentrations of methane in sulfate–containing estuarine sediments and salt marsh sediments. In fact, the degradation of the osmoregulant glycine betaine in marine sediments produces acetate and trimethylamine, the former of which is consumed by sulfate-reducing bacteria whereas the latter is consumed methanogenically (Fig. 3; 18). Methanol is a degradation product of plant structural components such as pectin.

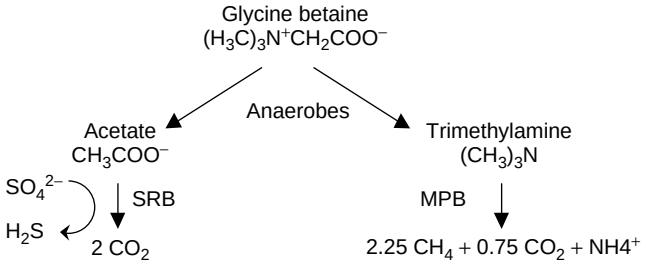

Figure 3. An example of the formation of a "noncompetitive substrate" (trimethylamine). Glycine betaine, an osmoregulant in marine organisms, is degraded to acetate and trimethylamine, which are consumed by sulfate-reducers and methanogens, respectively (18).

Geochemical Considerations

Sulfate reduction greatly influences the biogeochemical cycling of elements in sediments. The cycle of sulfur can be quite complex and involves several diverse groups of bacteria. The sulfide end product is highly reactive chemically and also serves as a significant electron donor for sulfur oxidizing bacteria. The oxidation of sulfide can produce intermediate redox phases of sulfur such as elemental sulfur (S^0) and thiosulfate ($S_2O_3^{2-}$) that can serve as both electron donors and acceptors for various bacteria. Sulfide is also a primary source of sulfur for assimilation by anaerobic bacteria such as methanogens. Sulfide is a strong reductant that easily reduces metals in sediments, and it rapidly precipitates metal ions as highly insoluble metal sulfides, the most notable being iron monosulfide (FeS) that imparts the black color to anoxic sediments. The cycling of iron is controlled to a large extent by sulfate reduction because sulfide can reduce iron oxides and precipitate iron (Fig. 4). The accumulation of precipitated metal sulfides and pyrite in marine sediments has produced a large reservoir of minerals over geologic time. In addition, large mineral deposits like the copper sulfide ores in Germany are thought to have formed from the reaction of bacterially produced sulfide with copper-rich solutions in marine microbial mats. Sulfate-reducers are also capable of producing magnetic minerals (19).

Sulfate-Reduction Activity

Knowledge of the role of sulfate reduction in sediments has increased greatly since the introduction of the use of ^{35}S as a tracer for determining sulfate-reduction rates (20). At first, rates were estimated from the incorporation of ^{35}S into dissolved sulfide (H_2S) and acid volatile sulfides (iron monosulfides, FeS), which were thought to be the only significant products. However, it was determined

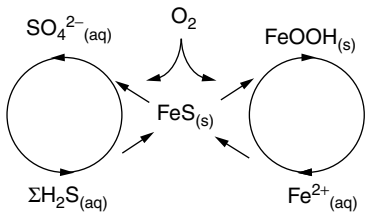

Figure 4. Interactions between the cycles of sulfur and iron in sediments. Processes moving from top to bottom represent reduction reactions whereas those moving from bottom to top are oxidation reactions. Iron monosulfide (FeS) is precipitated from sulfide and reduced iron, and FeS, Fe^{2+} and H_2S are able to be oxidized biologically and chemically. FeOOH reduction can occur biologically and chemically as well, but SO_4^{2-} reduction is only biological.

that in some habitats, such as salt marsh sediments and near the oxic/anoxic boundary, a significant fraction of the reduced sulfur produced during sulfate reduction is rapidly converted to pyrite (FeS_2), a compound that was previously thought to be produced at rates on the order of several years (21). Methods now routinely utilize a reduction step using reduced chromium under acidic conditions to incorporate all major reduced inorganic sulfur species that may form during sulfate reduction (22,23). Sulfate-reduction rates can also be determined from losses of sulfate in incubated sediments and from mathematical models that describe the loss of sulfate with sediment depth in terms of sedimentation and diffusion (24–26). Depth increases in reduced sulfur compounds and the abundance of sulfate-reducing bacteria are useful as comparative indicators of the sulfate-reduction process, but they are poor indicators of actual rates of activity.

The rate of organic matter input (i.e., sedimentation) and the availability of sulfate control the rate of sulfate reduction in sediments. Sulfate is rarely limiting in marine systems except in brackish estuarine waters and within depth in sediments in which sulfate has been depleted. Organic matter deposition is highest nearshore where primary production or sediment transport is high. Sulfate-reduction rates in sediments can span several orders of magnitude, but typical nearshore rates in the upper 5 to 10 cm are often approximately 50 to 500 nmol ml^{-1} day^{-1} (3). Rates in sediment with unusually rapid sedimentation rates can reach 2,000 nmol ml^{-1} day^{-1} (27). Sulfate reduction in salt marshes and microbial mats can reach rates as high as 4,000 and 14,000 nmol ml^{-1} day^{-1}, respectively (28,29).

Stoichiometry

The mineralization of nutrients from marine organic matter during sulfate reduction follows a stoichiometry similar to that present in typical marine organic material. In general, two moles of carbon are mineralized per mole of sulfate reduced. Because marine organic matter exhibits a C:N:P ratio of approximately 106:16:1 (30), the mineralization of nitrogen and phosphorus during sulfate reduction obeys this stoichiometry as follows (31):

$$(CH_2O)_{106}(NH_3)_{16}H_3PO_4 + 53\ SO_4^{2-} \longrightarrow 106\ CO_2 + 16\ NH_3 + H_3PO_4 + 53\ S^{2-} \quad (1)$$

Because sulfate reduction is a relatively inefficient process and the growth of sulfate-reducers per mole of substrate is low, their nitrogen and phosphorus demand is also low and ammonium and phosphate accumulate in sulfate-reducing sediments at ratios like those mentioned in the preceding text (32). Inorganic carbon produced during sulfate reduction is in the form of the bicarbonate ion ($HCO3^-$) rather than as carbon dioxide and this bicarbonate is a major contributor to the ability of sediments to neutralize acid. In addition, using the Richards stoichiometry (eq. 1), it is possible to use rates of sulfate reduction in marine sediments to determine the turnover or residence time of nitrogen and phosphorus in sediments and to predict the flux of nutrients into overlaying waters from sulfate-reducing sediments (33).

Seasonal Effects and Oxygen Consumption

The dissolved and solid phase products of sulfate reduction are responsible for consuming a significant portion of the oxygen that diffuses into sediments, and this oxygen sink can be equal to or greater than the amount of oxygen consumed by aerobic bacterial respiration (34). In typical coastal marine sediments, it is possible that 90% of the reduced sulfur produced during sulfate reduction each year is recycled back to sulfate (Fig. 5). The remaining sulfide is buried as a metal sulfide and eventually transformed into pyrite (FeS_2). The amount of energy that is acquired by bacteria during sulfate reduction is quite low compared with aerobic bacteria, in part because the sulfide end product retains a significant portion of the original energy. However, this sulfide can act as an energy source for other bacteria, especially photoautotrophic and chemoautotrophic bacteria in aerobic surface sediments.

Sulfate reduction activity varies greatly throughout the year, primarily in response to changes in temperature, and this seasonality affects the annual cycling of iron minerals and oxygen. During summer when microbial activities are rapid, alternate electron acceptors including oxygen are consumed near the sediment water interface and maximum rates of sulfate reduction may occur near the sediment surface (Fig. 6). During winter when microbial activity is slow, oxygen diffuses further into sediments and the sulfate-reduction maximum is not only slow, but situated deeper in the sediments (Fig. 6). In addition, any solid phase reduced sulfur (e.g., FeS) that accumulated in surficial sediments from sulfate reduction during summer is gradually oxidized in winter by the deepening front of oxygen. Therefore, a strong seasonal

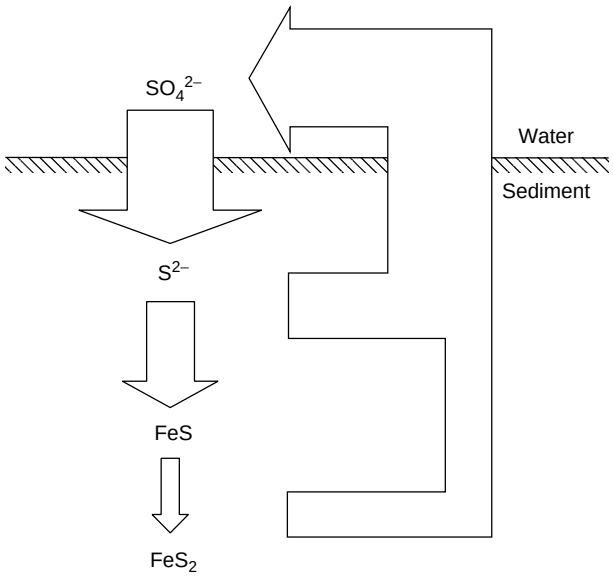

Figure 5. The recycling and reoxidation of reduced sulfur in marine sediments. The bulk of sulfur reduced is recycled back to SO_4^{2-}, including a large portion of the FeS. A small fraction of the FeS is converted to pyrite each year.

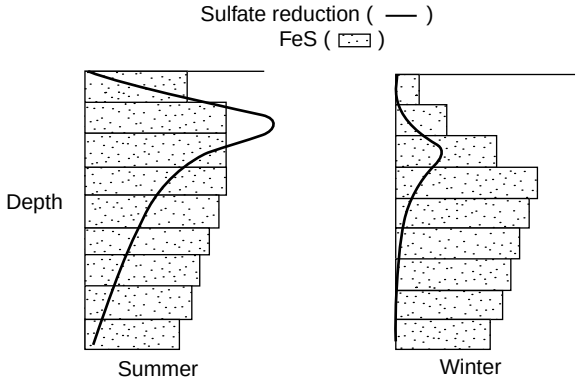

Figure 6. Vertical sulfate-reduction rates and concentrations of iron monosulfide (FeS) in hypothetical marine sediments in summer and winter. Rates in winter are slower with a deeper maximum, and FeS in winter is oxidized back to SO_4^{2-}.

cycle of inorganic sulfur is common in nearshore sediments with net accumulation in summer and net oxidation in winter (33,34). Seasonal sulfate-reduction activity is also influenced by changes in rates of organic matter inputs. For example, periodic plankton blooms are often followed by significant increases in sulfate-reduction activity as planktonic material is degraded. In addition, sulfate-reduction rates increase when the growth of seagrass or salt marsh grasses increase.

METABOLIC DIVERSITY

Unlike their aerobic counterparts, sulfate-reducing bacteria often require microbial consortia to supply appropriate substrates for energy and growth. It is generally accepted that sulfate-reducing bacteria oxidize products of fermentative bacteria such as fatty acids, alcohols, some aromatic acids, selected amino acids, and hydrogen. However, this list is incomplete and is continually growing as new metabolisms are discovered. Sulfate-reducers can also metabolize chemolithotrophically when utilizing hydrogen as an electron donor. Because most of the substrates used by sulfate-reducers are provided by a variety of other bacteria, these compounds represent rapidly recycled intermediates that accumulate quickly when sulfate-reducing bacteria are inhibited (35). Sulfate-reducing activity can be specifically inhibited through the use of sulfate analogs such as group VI oxyanions like molybdate and selenate. Amendments of these inhibitors to sediments results in the accumulation of volatile fatty acids and hydrogen and show that acetate is a primary electron donor utilized by sulfate-reducers (Fig. 7).

Although the reduction of SO_4^{2-} is considered to be the classic role of sulfate-reducing bacteria in the environment, these bacteria are capable of diverse metabolisms, including (*1*) nitrate/nitrite reduction; (*2*) iron and manganese reduction; (*3*) arsenate reduction; (*4*) metal methylation and demethylation; (*5*) organic fermentation; (*6*) use of xenobiotics and petroleum by-products; (*7*) sulfur disproportionation; (*8*) the utilization of various intermediate redox states of sulfur, and; (*9*) the production of intracellular magnetite. Oxygen reduction has been

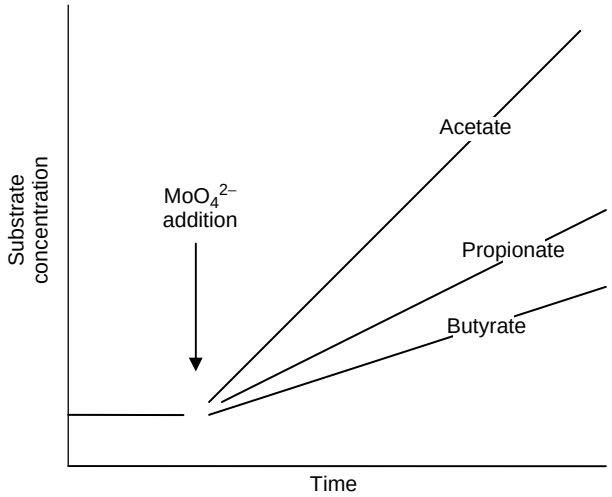

Figure 7. Use of a sulfate-reduction inhibitor (molybdate) to elucidate substrates used by sulfate-reducing bacteria. On inhibitor addition (arrow), those compounds that were being consumed during sulfate reduction accumulate at a rate equal to that at which they were consumed (35).

demonstrated under microaerophilic conditions and can be quite rapid (36). Oxygen-dependent growth has also been determined (37).

Physiologically, sulfate reduction is divided between complete and incomplete oxidation processes. Incomplete oxidizers utilize a variety of substrates, many of which are incompletely degraded to acetate. For example:

$$2\ \text{lactate} + SO_4^{2-} \rightarrow 2\ \text{acetate} + 2\ CO_2 + 2\ H_2O + S^{2-} \quad (2)$$

or

$$4\ \text{propionate} + 3\ SO_4^{2-} \rightarrow 4\ \text{acetate} + 4\ CO_2 + 2\ H_2O + 3\ S^{2-} \quad (3)$$

Some incomplete oxidizers are also capable of fermenting substrates without sulfate respiration, for example:

$$3\ \text{lactate} \rightarrow 2\ \text{propionate} + \text{acetate} + CO_2 \quad (4)$$

However, as will be pointed in the following text, some strains of sulfate-reducers are capable of fermentations that yield hydrogen (H_2) as one of the end products, but this H_2 must be removed quickly by a syntrophic partner. All sulfate-reducers isolated before 1977 were incomplete oxidizers including mostly members of the genus *Desulfovibrio*, the first of which was isolated more than 100 years ago (38). Although no isolates existed before the late seventies, it was postulated for many years that sulfate-reducing bacteria were capable of utilizing acetate as an electron donor.

The first acetate utilizer, and therefore complete oxidizing sulfate-reducer, isolated was a gram-positive sporulating bacterium of the genus *Desulfotomaculum* (39). Since then, several species of acetate-utilizing gram-negative bacteria have been recovered representing a suite of

metabolic capabilities and representing new genera. Complete oxidation entails the production of carbon dioxide as a major end product and includes the use of acetate, for example:

$$\text{acetate} + SO_4^{2-} \rightarrow 2\ CO_2 + H_2O + S^{2-} \quad (5)$$

Although physiologically distinct in many ways, the incomplete and complete oxidizing sulfate-reducing bacteria can coexist with the former supplying acetate to the latter in some instances.

Sulfate-reducing bacteria also can be involved in interspecies hydrogen transfer, in which hydrogen equivalents are transferred to other bacteria in lieu of sulfate respiration, for example:

Desulfovibrio

$$2\ \text{lactate} + 4\ H_2O \rightarrow 2\ \text{acetate} + 2\ CO_2 + 4\ H_2 \quad (6)$$

H_2-utilizing methanogen

$$CO_2 + 4\ H_2 \rightarrow CH_4 + 2\ H_2O \quad (7)$$

In essence, sulfate-reducers act as fermenting bacteria and the path to H_2 formation is favorable because of the maintenance of low H_2 partial pressure by the H_2-consuming methanogen. In addition, methanogenic bacteria can also use the acetate produced.

Disproportionation

During the past 15 years it was demonstrated that sulfate-reducing bacteria have the ability to conduct inorganic fermentation of sulfur compounds, known more correctly as sulfur disproportionation (40). Thiosulfate, sulfite, and elemental sulfur can be disproportionated and this ability has been found in many sulfate-reducing genera (41) and occurs as follows:

Thiosulfate

$$S_2O_3^{2-} + H_2O \rightarrow SO_4^{2-} + HS^- + H^+ \quad (8)$$

Elemental sulfur

$$4\ S^0 + 4\ H_2O \rightarrow SO_4^{2-} + 3\ HS^- + 5H^+ \quad (9)$$

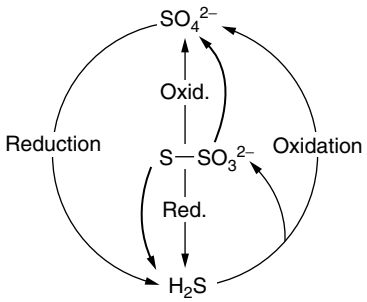

Figure 8. Thiosulfate shunt in marine sediments. Typical oxidation and reduction reactions are labeled. The heavy lines indicate the process of thiosulfate disproportionation (44).

Sulfite

$$4\ SO_3^{2-} + H^+ \rightarrow 3\ SO_4^{2-} + HS^- \quad (10)$$

Pure cultures have been isolated that are capable of all these reactions including an isolate that is an obligate disproportionator that does not reduce sulfate (42).

Disproportionation reactions are important in sediments because they provide a mechanism for anaerobic sulfur cycling (43). Thiosulfate appears to be a key component of the sulfur cycle in sediments because it can be oxidized, reduced, and disproportionated. Sulfate-reducing bacteria are key components of this cycling because they are capable of reducing sulfate and thiosulfate and they are able to disproportionate thiosulfate. A "thiosulfate shunt" seems to exist in sediments in which thiosulfate couples both reductive and oxidative pathways of the sulfur cycle [Fig. 8; (44]. Thiosulfate can be the main product of sulfide oxidation in reducing sediments, and much of this can be disproportionated with the remainder either oxidized to sulfate or reduced to sulfide. Hence, most of the sulfide produced during sulfate reduction can be ultimately oxidized to sulfate after passing through a thiosulfate intermediate. Elemental sulfur disproportionation is not energetically favorable under standard conditions. However, bacteria are able to grow via this process when metal oxides are present to rapidly remove sulfide (45). Although disproportionation is important in the sulfur cycle, it has been argued that it is not a major mode of metabolism in terms of bacterial energetics or growth (46). However, sulfide scavenging by sedimentary metal oxides may allow the process to act as a common metabolic process (42).

DIVERSITY OF SULFATE-REDUCING BACTERIA

Sulfate-reducing bacteria are a complex physiological group and classifying them has traditionally required the consideration of several properties, the most important of which are motility, cell shape, G + C content of DNA, the presence of desulfovirin and cytochromes, growth temperature, use of various electron donors, and the ability to conduct complete or incomplete oxidation of organic substrates. However, the recent analysis of rRNA sequences has allowed for a more thorough organization of the sulfate-reducing bacteria into four major groups: (*1*) gram-negative mesophiles; (*2*) gram-positive spore formers; (*3*) thermophilic *Bacteria* spp.; and (*4*) thermophilic *Archaea* spp. The latter two groups will not be addressed here. The gram-negative mesophilic group of sulfate-reducers is placed within the delta (δ) subdivision of the Proteobacteria and includes two families: the Desulfovibrionaceae and *Desulfobacteriaceae*. The *Desulfovibrionaceae* includes the genera *Desulfovibrio* and *Desulfomicrobium*, and this family appears to be rather phylogenetically distinct. The *Desulfobacteriaceae* family is much less distinct and includes several genera (perhaps > 20) including many of the complete oxidizing species (47). The gram-positive spore-forming sulfate-reducers constitute primarily members of the genus *Desulfotomaculum*.

Before the late 1970s, only two genera of sulfate-reducing bacteria were known, *Desulfovibrio* and *Desulfotomaculum* species. The desulfovibrios have received the most attention, primarily because they are relatively easily isolated from the environment and not difficult to maintain in laboratory culture. They were originally described as gram-negative sulfate-reducing bacteria that are curved rods, do not produce spores, and utilize primarily hydrogen and lactate as electron donors. However, the group has been expanded to include members that are capable of using several other electron donors and electron acceptors, the latter including nitrate, oxygen, and metal oxides. They are the classic examples of sulfate-reducers that conduct incomplete metabolism with acetate as an important end-product. Phylogenetic analyses have shown the desulfovibrios to be sufficiently diverse and distinct to warrant placement within their own family, the *Desulfovibrionaceae* (48). *Desulfovibrio* species are routinely isolated from marine sediments and probably are an important component of sulfate reduction in the sea.

Desulfotomaculum species are gram-positive, rod shaped, spore-forming sulfate-reducing bacteria that as a group display wide phylogenetic diversity. They are also quite phylogenetically distinct from all other sulfate-reducing bacteria. *Desulfotomaculum* species are not considered to be particularly important in marine sediments compared to the nonspore-forming sulfate-reducers. However, they are easily isolated from organic-rich sediments and they possess metabolic capabilities that are known to be important in sediments. Their ability to form spores does give them a competitive advantage in some habitats and they are found to dominate environments like rice paddy sediments that undergo wetting-drying cycles that could harm nonsporing cells. *Dtm. acetoxidans* was the first sulfate-reducer isolated that was capable of acetate oxidation.

Knowledge of the breadth of the sulfate-reducing bacteria has expanding greatly in the past 20 years. Many new lineages of sulfate-reducers have been isolated and described. The phylogeny of sulfate-reducers has expanded to include the family *Desulfobacteriacae* (49), which includes many new genera that are capable of complete and/or incomplete oxidation; the genera *Desulfobacter*, *Desulfobacterium*, and *Desulfococcus* to name a few. Members of the filamentous, gliding sulfate-reducing genus *Desulfonema* also appear to be common inhabitants of organic-rich sediments, especially within redox gradients (50). The recent explosion in information on sulfate-reducing bacteria clearly demonstrates the ability of the group to completely oxidize organic substrates including acetate, and their importance in decomposition processes in sediments. Sulfate-reducers as a whole are phylogenetically distinct from other bacteria, which have lead to the discovery of signature sequences of ribosomal subunit genes that have been used as oligonucleotide probes and PCR primers for the detection, determination of relative abundance, and microscopic visualization of members of the group.

Sulfate-Reducing Populations in Sediments

The population composition of sulfate-reducing bacteria has been investigated using culturing, biochemical, and genetic methods. In general, estimations of abundance using plating or most-probable number (MPN) methods are 10^2-10^5 ml^{-1}, which appear low when considered in terms of the rate of in situ sulfate reduction and culture estimates of rates per cell. This discrepancy is undoubtedly because of the inability of viable counting techniques to recover the majority of bacteria present. MPN techniques yield more realistic estimate of sulfate-reducer abundance (10^6-10^8 ml^{-1}) when applied to marine microbial mats (51) and salt march sediments (28).

Because of the complex nature of the anaerobic bacterial food web, it is generally thought that the sulfate-reducers account for only about 5% of the total bacteria present despite their important role at the end of the food web. In situ hybridization techniques that use fluorescent oligonucleotide probes to visualize individual cells of specific bacteria groups have yielded sulfate-reducing bacteria counts in marine sediments as high as 3×10^7 ml^{-1}, which represented up to 6% of the total *Bacteria* (52). Hybridizations of bulk sedimentary RNA with probes also demonstrated that about 1 to 6% of the total bacteria present in sediments were sulfate-reducing (53). Sulfate-reducers in salt marsh sediments can account for more than 30% of the total (eu)bacteria (28). This high percentage is probably due to the fact that marsh grasses exude organic substrates from roots that can be used directly by sulfate-reducers, thus circumventing the need for fermenting bacteria.

A wide variety of sulfate-reducing bacteria are found within sediments. Enumerations of bacteria using MPNs supplemented with specific substrates for sulfate-reducing groups have shown the presence of bacteria able to use many substrates including lactate, ethanol, acetate, malate, and propionate (54). Lactate and acetate utilizers often outnumber other groups illustrating the importance of both incomplete and complete oxidizing sulfate-reducers in sediments. Additions of various electron donors illustrate the importance of both general types of sulfate-reducers. For example, propionate amendments cause a temporary increase in acetate concentrations, whereas lactate amendments result in a temporary increase in propionate and acetate (55). Sulfate-reducing marine sediments also display an abundance of even chain bacterial phospholipid fatty acids indicative of the presence of acetate-utilizing bacteria of the genus *Desulfobacter* (55). Using MPN methods, acetate-utilizing sulfate-reducers were most abundant in a marine microbial mat (51), whereas ethanol utilizers greatly outnumbered acetate utilizers in salt marsh sediments (28).

Molecular analyses have furthered the description of sulfate-reducing groups in marine sediments. Both whole-cell in situ hybridizations and hybridizations using RNA extracted from sediments have been employed to investigate the diversity of sulfate-reducers. In addition, diversity has been investigated by sequencing rDNA clones and rDNA bands excised from denaturing gradient gel electrophoresis (DGGE). Incomplete oxidizing groups of sulfate-reducers seem to dominate in marine sediments,

primarily members of the *Desulfovibrionaceae*, but also *Desulfobulbus* species are abundant. However, the distribution of groups varies with depth and among habitats. For example, members of the *Desulfobacteriaceae* and *Desulfovibrionaceae* were equally abundant in the upper 2.0 cm of sediments, but the incomplete oxidizers (*Desulfovibrionaceae* species) dominated at depth (53). Complete oxidizers were essentially absent from Arctic Ocean sediments (56), yet they dominated sediments inhabited by salt marsh grasses (28). Complete oxidizers, that is, *Desulfobacteriaceae* species accounted for more than 20% of the total *Bacteria* RNA in some instances in the marsh, whereas *Desulfovibrionaceae* species were a small fraction in all cases. Members of the *Desulfobacteriaceae* are metabolically diverse and may be well-suited for environments that undergo widely changing seasonal redox changes like those encountered in salt marsh sediments and at the sediment surface. The presence high numbers of *Desulfobulbus* species in marsh sediments (28) may reflect the ability of members of the genus to conduct sulfur disproportionation reactions (see the following text), which would be stimulated by plant-mediated redox cycling within the rhizosphere and the production of intermediate redox states of sulfur.

Many desulfovibrios are capable of aerobic respiration, are able to withstand several hours of full aeration, and are common inhabitants of oxic regions of microbial mats (57). Their rapid motility allows them to position themselves in the microaerophilic gradient where they can benefit from organic compounds released by photosynthetic bacteria. The complete oxidizing gliding sulfate-reducer *Desulfonema* is a common inhabitant of the oxic–anoxic interface in microbial mats (50,51,58), and is also abundant within the partially oxygenated rhizosphere of salt marsh plants (59). Filamentous morphology, aggregate formation, and diurnal migration are all adaptations that allow *Desulfonema* species to thrive in the rapidly changing conditions of a microbial mat. Although, conflicting results are apparent, it is clear that sulfate-reducing bacteria populations in marine depositional environments are highly dynamic, metabolically versatile, and important contributors to elemental cycling.

INTERACTIONS WITH MACROORGANISMS

Plants and animals inhabit many sedimentary sites, and their presence greatly affects the distribution and activity of sulfate-reducing bacteria. Although the physiology of plants differs greatly from that of animals, the ultimate effect of their presence is similar such that each is capable of introducing organic matter and oxidants into sulfate-reducing regions. Hence, macroorganisms are responsible for stimulating subsurface redox cycling of elements. Figure 9 is an example of how a salt marsh plant and a deposit-feeding polychaete cause such a subsurface cycle with the plant introducing dissolved organic carbon and oxygen, while the worm introduces particulate organics and iron oxide as the oxidant. Although both organisms stimulate the cycle of sulfur and iron, the plant causes dissolved iron to cycle more rapidly than the dissolved sulfide, whereas the worm causes the opposite to occur.

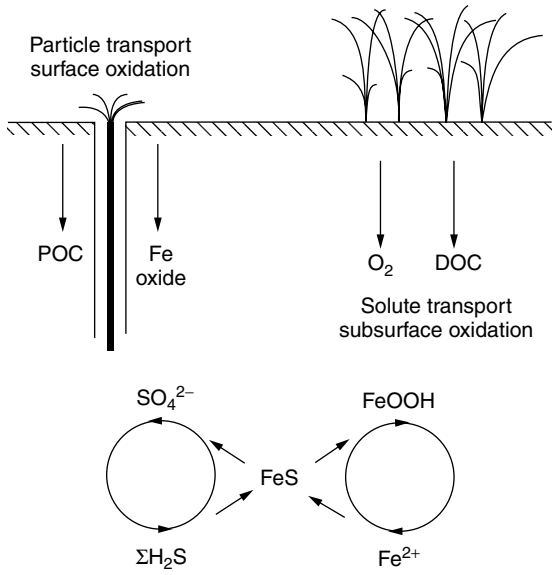

Figure 9. Effect of a deposit-feeding worm (left) and rooted aquatic plants (right) on the sulfur and iron cycles in nearshore marine sediments. Worms transport particulate carbon (POC) and sold phase iron oxides to depth by depositing fecal pellets at the surface. Plants transport oxygen and dissolved organic carbon (DOC) to depth by exuding these materials directly from roots (60).

Salt Marshes

Sulfate reduction is a key component of bacterial metabolism in marine sediments inhabited by vascular plants including salt marsh grasses that inhabit the intertidal zone and submerged sea grasses. Sulfate reduction in marsh sediments can account for most of the decomposition that occurs (61,62). Sulfate-reduction rates are among the highest ever measured in marine sediments and populations of sulfate-reducers are abundant. Vascular plants not only provide particulate organic material to sediments, but they also alter sediments by releasing dissolved organic materials and oxygen from roots. The release of root exudates fuels microbial activity belowground whereas oxygen release stimulates subsurface redox cycling of elements and provides a redox gradient capable of supporting an active bacterial community.

Spartina alterniflora, the common cordgrass prevalent along much of the East Coast of the United States, releases dissolved organic matter and oxygen from roots only when plants are elongating aboveground. Exudation ceases on flowering in midsummer. Sulfate-reduction activity responds to this release by increasing rapidly when exudation begins in the spring and decreasing abruptly at the onset of reproductive growth (62). Roots washed free of sediment support an active sulfate-reducing community that responds to these changes in plant growth stage. For example, the relative abundance of *Desulfobacteriaceae* species increases drastically when plants are growing aboveground, which may be because of the ability of this family to thrive and compete under conditions of rapid changes in redox conditions (28,59). As mentioned previously, members of the *Desulfovibrionaceae* represent only a small portion of the sulfate-reducing community

in these marsh sediments. *Spartina alterniflora* releases ethanol from roots during anaerobic metabolism and it appears that *Desulfobulbus* species, which are abundant in the rhizosphere, consume this material rather than *Desulfovibrionaceae* species

Sea Grasses

The sea grass rhizosphere also supports a sulfate-reducing community that is much more active than in unvegetated sediments nearby. In some plant species, rhizosphere sulfate reduction displays a diel cycle in which activity increases during the day because of photosynthesis-driven exudation of organic matter from roots (63). Similar to salt marshes, many sulfate-reducers are attached to seagrass roots, and these communities are unusually tolerant to oxygen exposure (64). Sulfate-reducing bacteria have been identified as the key group involved in nitrogen fixation in the rhizosphere and they may be responsible for satisfying a significant portion of the plant nitrogen demand (65,66). Hence, sulfate-reducers can have a mutualistic symbiosis with marine plants. Although sulfate-reducers are rather loosely attached to seagrass roots, active *Desulfovibrio* species have been found within roots and even deep within root cortex cells (67), which suggests a highly developed mutualism.

Benthic Fauna

Sedimentary sulfate reduction is also influenced by the presence of burrowing macrofauna. Benthic worms and bivalves pump oxygenated water into reducing sediments and fauna introduce organic matter to depth by reworking and turning over surficial sediments and by stimulating organic accumulation in burrows. Sediments inhabited by reworking fauna support rapid rates of sulfate reduction throughout the reworking zone whereas uninhabited sediments display rapid decreases in rates with depth (33). Sulfate-reducers degrade organic matter originally destined for aerobic decomposition at the sediment surface after it is prematurely buried by infauna. These effects are also influenced by the seasonality of animal activity in which sulfate-reduction activity increases sharply when infaunal reworking activity commences in late spring (68). Walls of oxygenated burrows have steep redox gradients that support complete elemental cycles within the burrow wall, and sulfate reduction is an important component of this cycling (69).

CONCLUSION

Sulfate reduction is the most important anaerobic bacterial process in nearshore marine sediments in terms of the mineralization of carbon and nutrients, the support of autotrophic processes near the sediment surface through recycled sulfur, and the formation of sedimentary minerals. The abundance of sulfate in seawater allows sulfate reduction to occur over wide depth-intervals in sediments and sulfate reduction consumes more oxygen than aerobic bacteria in may instances. During the last 20 years, our knowledge of the phylogenetic and physiological diversity of sulfate-reducing bacteria has increased dramatically and has elucidated the wide impact of these bacteria on marine deposits. Although sulfate-reducers that inhabit marine sediments generally fall into one of three phylogenetic families, the metabolic diversity within each family is great, and it is highly likely that many new members with even more amazing capabilities will be discovered soon. Sulfate-reducers are key players at redox boundaries, are capable of migrating within these boundaries, and demonstrate an ability to interact syntrophically with other aerobic and anaerobic bacteria. They are also important contributors to sediments inhabited by plants and animals and they have acquired the ability to live symbiotically within tissues. As molecular, microelectrode, and high technology methods continue to advance, this important group of bacteria will certainly be shown to be even more important in the biogeochemistry of marine sediments.

SEPTIC TANK SYSTEMS

DAVID BUTLER
STEPHEN R. SMITH
Imperial College
London, United Kingdom

Septic tank systems are the most popular type of small-scale processes for on-site treatment of domestic wastewater in unsewered urban and rural areas, and can provide a practicable and cost-effective solution to wastewater treatment in these situations. In the United States, for example, some 24% of households are connected to tank systems (1). In England and Wales only 4% of properties are unsewered, but this still amounts to more than 750,000 septic tanks in use (2).

Septic tank systems consist of a tank and a drainage field. The tank is a watertight, underground vessel that provides conditions suitable for the settlement, storage, and partial decomposition of sludge (settled waste solids). Raw wastewater is fed to the tank from the dwelling served and the settled wastewater is discharged to the drainage field through the tank outlet. Sludge accumulates at the bottom of the tank and has to be removed periodically.

Three zones are normally present in the septic tank:

1. a scum layer that forms a crust on the surface of the tank liquor,

Table 1. Advantages and Disadvantages of Septic Tank Systems

Advantages	Disadvantages
Low capital cost	High space requirement
Low energy requirement	Tank effluent is unsuitable for open discharge
Low maintenance	Potential for local nuisance and health hazard
Potential for groundwater recharge	Potential for groundwater pollution
Low sludge production	Requires some owner education and participation

2. the wastewater from which solids are deposited, and
3. the bottom sludge layer of deposited material.

The organic matter in the tank may undergo anaerobic digestion, and the extent of stabilization depends on the size of the tank, frequency of sludge removal, and temperature.

The drainage field functions both as an effluent-disposal facility and a treatment zone (see section "Drain Field"), typically consisting of a system of subsurface irrigation pipes or a soakaway, which drains the effluent into the surrounding soil. Proper design and installation of both the tank and drainage field are essential for the efficient operation of the system as a method of wastewater treatment.

The main advantages and disadvantages of septic tank systems for on-site treatment of wastewater are summarized in Table 1.

DESIGN

Tank Size

The main function of a septic tank is to provide primary treatment by separating and retaining solids from the incoming flow. Tanks should be designed to maximize retention, because high levels of solids in the outlet flow block soil pores and reduce the life of the drainage field. The principal factors to be considered in deciding on tank capacity are

- average daily flow of wastewater,
- adequate hydraulic retention time, and
- adequate sludge- and scum-storage space.

The average daily flow of wastewater to the tank depends on the average water consumption and the number of people served. Per capita water consumption depends on a number of factors including climate, demography, and socioeconomic levels (3,4).

An appropriate period of time is required for the retention of wastewater in the tank to allow the settlement of heavier solids and flotation of lighter material, such as fats and grease, present in the wastewater. Hydraulic retention times (HRT) recommended by the United States Public Health Service, for example, range from 12 to 24 hours (5).

The size of tank should provide sufficient capacity for solids capture, and space is also needed for solids retention. The amount of storage required depends on the planned frequency of sludge removal from the tank and the expected rate of anaerobic decomposition of the sludge.

Sludge (septage) is usually removed from the tank at predetermined intervals ranging from six months to three years. Longer desludging intervals are appropriate in warm climates because of the greater extent of sludge stabilization and volatile solids (VS) loss that occurs at high ambient temperatures. Typically, cleaning is necessary when sludge and scum occupy more than one quarter of the tank volume or exceed approximately 500-mm depth (6).

As an example, these two design requirements are brought together in the relevant British Standard (7). The minimum total capacity of a septic tank, where desludging is carried out at not more than 12-monthly intervals, is given by:

$$C = 180P + 2{,}000 \quad (1)$$

where

C = capacity of the tank (liters)
P = the design population with a minimum of 4

The value of 180 in Equation (1) is based on the required storage capacity for wastewater and solids and provides for proportionately higher retention times at lower populations to allow for surges in flow expected from small systems (8).

Tank Configuration

Septic tanks can be of various shapes, the most common being rectangular, square, and circular in plan (Fig. 1). Single- or two-chamber tanks are in common use. Where two-chamber tanks are used, it is recommended that the main sludge-retention chamber should contain at least two-thirds of the total tank capacity (7).

The design and location of inlets, outlets, and inter-compartment connections can have considerable influence on tank operation (9). The main design requirement is to minimize turbulence as the wastewater enters the tank to avoid the disturbance of settled sludge. Short-circuiting can be minimized by providing small baffle walls at the tank inlet and outlet.

Tanks are ventilated to allow digestion gases to escape. This is usually by the house drain vent stack, provided the incoming house drain is not trapped before entry to the tank. Alternatively, ventilation may be provided at the

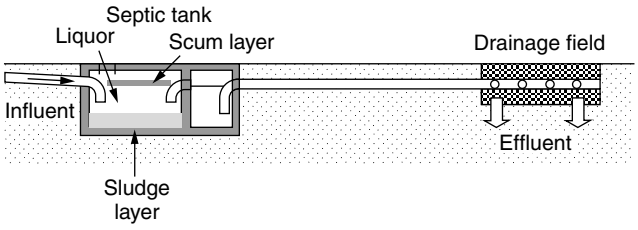

Figure 1. Typical septic tank system.

tank itself, either by special vent pipes or by ventilating manhole covers.

Prefabricated septic tanks are widely available constructed from glass fiber, thermoplastics or precast concrete sections. The main design requirements are that they must be watertight, structurally sound, and durable. Inspection manholes reach up to ground level and precautions are normally taken to prevent the entrance of storm runoff into the tank.

Tank Location

A septic tank is located so as to permit straightforward collection of wastewater from the dwelling and discharge to the drainage field. Standard "setback" distances have been commonly applied to various structures or natural features to minimize potential problems from leakage, particularly around the inlet and outlet pipes (Table 2).

Risk assessment and geostatistical investigations by the U.S. EPA (11) suggest that septic tank systems should be located at distances of 80–325 m away from abstraction wells, depending on aquifer and source characteristics, based on allowing natural inactivation of viruses to take place (i.e., an 11-order magnitude reduction in virus concentrations in groundwater compared with the source). However, the U.S. EPA does not currently advocate a specific setback or reliance on natural viral inactivation to protect groundwater sources. Current proposals are for on-site inspections for all groundwater systems supplemented by microbial monitoring at priority sites to identify high-risk facilities that are required to take corrective action. This aspect will be further explored in the section on pathogen removal and potential health implications.

Size of the Drain Field

The effluent of a properly designed and efficient septic tank is slightly turbid, owing to finely divided solids in suspension, and has a relatively low biochemical oxygen demand (BOD). However, it remains offensive and malodorous and contains almost no dissolved oxygen. In addition, the effluent is potentially harmful to health, because it may contain enteric pathogenic bacteria and viruses, as well as cysts and eggs of parasitic protozoa and helminths that pass through the tank (3). It is not normally suitable for direct discharge to a watercourse or other open channels or for irrigation of crops. A secondary-treatment stage is required to remove much of the dissolved polluting matter and the disease-causing agents, and this is usually provided by the drainage field. The objectives of the drainage field are thus to

- absorb the tank effluent,
- provide aerobic treatment to the effluent, and
- protect water resources and prevent nuisance.

A number of drainage field options are available and the selection and design will depend particularly on the outcome of a site assessment, based on factors such as (2)

- subsoil (nature, depth, percolation value),
- location of water table and watercourses,
- site (size, location, slope),
- adjacent habitats,
- surrounding topography, and
- number and effectiveness of other septic tank systems in the area.

Table 2. Setback Requirements for Septic Tanks and Drainage Fields (10)

Minimum Distance from (m)	Septic Tank	Drainage Field
Buildings	1.5	3.0
Property boundaries	1.5	1.5
Wells	30	30
Streams	7.5	30
Embankments	7.5	30
Pools	3.0	7.5
Water pipes	3.0	3.0
Paths	1.5	1.5
Large trees	3.0	3.0

Subsurface Irrigation

Subsurface irrigation systems are the preferred method of field drainage in most situations. They consist of a network of perforated pipes laid in trenches filled with gravel (12). They allow the effluent to be widely distributed through a large volume of soil and minimize the risk of soil saturation. The pipes are laid with a slight gradient (typically 1 in 200) at a depth not exceeding 750 mm. A typical subsurface irrigation system is shown in Figure 1. The drainage field is located downslope of the tank and property, and away from stormwater soakaways, wells, and the site boundary (Table 2).

There are three key aspects to consider in the rational design of subsurface irrigation systems (13):

- *Soil Hydraulic Characteristics*. The permeability of the receiving soil will influence the size of irrigation system required and this can be measured on site. For low-permeability soils (coefficient of permeability $<5 \times 10^{-5}$ cm s^{-1}), this may be the limiting factor in design.
- *Biological Mat*. The permeability of biological mat (biocrust) that forms at the trench–soil interface may become limiting in permeable soil. Higher loading rate systems can be designed by increasing the HRT in the septic tank to improve solids/BOD removal.
- *Protecting Groundwater Quality*. The principal factor is the type of subsurface soil and distance to the water table from the subsurface irrigation system.

Water-infiltration rate after partial clogging determines the length of pipe required for subsurface irrigation. For practical purposes the infiltration rate is regarded as being broadly similar for most soil types and is conservatively taken as 10 l m^{-2} d^{-1} (13). The required length of trench, L, can be estimated from the following equation:

$$L = \frac{Pw}{2di} \qquad (2)$$

where

P = design population
w = water used (l capita^{-1} d^{-1})
d = effective depth (m)
i = infiltration rate (l m^{-2} d^{-1})

A factor of two is used in the denominator of Equation (2) to account for the dispersion of effluent on both sides of the trench. The effective depth is measured from the base of the trench to the water table. The design can be adapted to local site and soil conditions using information obtained from in situ percolation tests (14,15).

Subsurface irrigation is not appropriate for sites with low soil permeability, high groundwater conditions, shallow depth to bedrock, or excessive land slope (16).

Soakaways

A soakaway is a point drainage field consisting of a gravel-filled pit excavated to a depth of 2 to 5 m and with a diameter of 1 to 2.5 m. The soakaway should be as large as practicable, and never smaller than the tank itself (16). Soakaways take up less space than subsurface irrigation systems, but distribute the effluent less efficiently and are only appropriate in areas of low groundwater level.

Other Methods

Alternative "ground-based" options for effluent treatment are possible on sites with high groundwater or low-permeability soils. One approach, for example, is a mound system in which tank effluent is pumped into a gravel bed or trench over a sandy soil mound. The wastewater is treated as it percolates into the indigenous soil (5).

Evapotranspiration systems utilize rapid-growing grass species to reduce the water content of the effluent by transpiration to the atmosphere. Effluent is distributed in open joint pipes below the evapotranspiration bed, which is constructed from a layer of gravel, 200–500-mm deep, underlying topsoil (100 mm) and is planted with an appropriate high biomass production grass species. A retaining earth bank is usually constructed around the bed. Nutrients supplied in the effluent act as a fertilizer and are taken up into the plant biomass that is periodically cut and removed. A disadvantage with evapotranspiration systems is that they require intensive management input to operate efficiently (5).

OPERATION

Tank Performance

Treatment Efficiency. The five-day biochemical oxygen demand (BOD_5) and total suspended solids (TSS) removal efficiencies of septic tanks in temperate climates are typically in the range 25 to 45% and 50 to 70%, respectively (17–19). These are similar to values usually achieved by plain sedimentation. Approximately 20% of the total nitrogen (TN) and 30% of the total phosphorus (TP) is removed in the retained sludge (20). Septic tank effluent typically contains 75 mg/l TSS, 140 mg l^{-1} BOD_5, 300 mg l^{-1} chemical oxygen demand (COD), 40 mg l^{-1} TN, and 15 mg l^{-1} TP (21), although larger TN concentrations of 100 mg l^{-1} have also been reported (22). The N and P contained in the effluent are predominantly in soluble inorganic forms.

A comparison of septic tank installations showing high and low rates of sludge accumulation (23), reflecting the effectiveness of anaerobic digestion in the tank, shows that TS, VS, COD, and concentrations of volatile fatty acids are significantly greater in sludge from systems with high sludge production and low rates of microbial activity (Table 3). Accumulation rates greater than 0.225 l capita^{-1} d (82 l capita^{-1} y) may be indicative of septic tank failure in terms of microbial activity and organic matter stabilization.

The major processes influencing pathogen removal from wastewater in septic tanks are settlement of solids and hydraulic retention time. Bacteria and viruses attached to the solids settle to the sludge layer, and eggs of helminths and protozoa will also settle if sufficiently dense (24). Pathogens that do not settle to the sludge layer remain suspended and will pass out of the septic tank in the effluent. For these organisms, hydraulic retention time is the key parameter that controls the loss of viability because many pathogens are susceptible to environmental stress outside the host environment and naturally decay

Table 3. Physicochemical Properties of Sludge from Septic Tanks with Low or High Sludge Accumulation Rates (23)

Parameter	Low Rate (<0.18 l capita^{-1} d^{-1})	High Rate (>0.225 l capita^{-1} d^{-1})
pH	6.7	6.6
Eh (mV)	−310	−339
TS (g l^{-1})	37	46
VS (g l^{-1})	26	32
CH_4 (ml l^{-1} d^{-1})	26	16
COD (mg l^{-1})	2502	3873
Acetic (mg l^{-1})	194	340
Propionic (mg l^{-1})	300	547
Isobutyric (mg l^{-1})	22	46
Butyric (mg l^{-1})	42	36
Isovaleric (mg l^{-1})	45	92
Valeric (mg l^{-1})	15	24

with time. Septic tanks, by virtue of their limited retention capacity and operation at ambient temperature, do not significantly stabilize the sludge and provide little or no reduction in the infectivity of enteric pathogens or parasites discharged to them (24). The accumulation of sludge in the tank reduces retention times and the benefit of this operational feature in pathogen elimination is severely compromised when desludging is not carried out on a regular basis or when the tank capacity is inadequate.

The maximum removal achieved by septic tanks is of the order of a 2-log decrease in the pathogen content of the effluent compared with the influent and, as a consequence, significant concentrations of all the pathogen types remain. Typical decreases in fecal coliform (FC) bacteria of about 1 to 2 times 106 FC 100 ml^{-1} are usually observed in efficient septic tank systems (25). However, 7 to 27 times 106 FC 100 ml^{-1} were detected in the effluent from overloaded septic tanks in Cyprus, whereas untreated household wastewater contained approximately 30 times 106 FC 100 ml^{-1} (26). These data emphasize the potentially significant passage of enteric pathogens through septic tanks that are inappropriately designed and managed in terms of capacity and desludging regime. Other research (27) shows that the numbers of indicator bacteria may increase as wastewater passes through the tank. Viruses are not significantly removed by settlement in the tank. However, viral counts and numbers of other enteric pathogens in tank effluents are usually high only if infections have occurred (21).

Hydraulic Retention Time (HRT). HRT is the volume of the available space between the settled sludge and scum divided by the design flow rate. This is a key design parameter influencing tank performance and the extent of wastewater stabilization and pathogen removal. For example, TSS removal was increased by a further 28% in a study in which the HRT was extended from 20 to 35 hours (28). An increase in HRT from 22.5 to 90 hours resulted in increases of BOD and TSS removal from 60 and 53% to 85 and 91%, respectively, as well as small increases in nutrient removal (29).

Shape and Compartmentalization. Tank shape influences the velocity of the wastewater through the septic tank, the depth of sludge accumulation, and the possible development of stagnant zones. If the tank is too deep, then the reduction in surface area lowers the efficiency of sedimentation. Conversely, a tank that is too shallow has inadequate space available for sludge and scum storage (30). However, shape has relatively little effect on overall treatment efficiency for tanks of comparable volume. For example, a comparison of circular and rectangular tanks showed that both forms achieved similar average BOD_5 removals of 43 and 47%, respectively (31). Generally, a rectangular shape is considered to be the most efficient form of single-compartment tank with an optimum length that is three times the width and the recommended depth of the tank is in the range 1.2–1.8 m (31).

A two-compartment arrangement may improve the removal of BOD and suspended solids compared with a single compartment of similar total capacity (6,14), due principally to the capture in the second compartment of solids that pass through the first compartment. No additional improvement in performance is gained from more than two compartments.

Effect of Temperature. Ambient temperature conditions have an important effect on the performance and biological processes within the tank including sludge-accumulation rate, which is indicative of the extent of microbial activity and stabilization in a septic tank (23). Increasing temperature has little overall effect on TSS, but significantly improves BOD_5 removal, and a high degree of wastewater stabilization is possible in warm climates. For example, BOD_5 and TSS removal efficiencies in excess of 80% were obtained in a septic tank system in Bombay, India (32). In northeastern Brazil, an overall retention time of 11 h was sufficient to remove 67 and 78% of the influent BOD_5 and SS, respectively, entering a communal septic tank (33). This level of performance is comparable to that achieved by anaerobic ponds in warm climates, which effectively remove 60 to 80% of influent BOD_5 and TSS, respectively (34,35). Little reduction in BOD_5 occurs below 10 °C in anaerobic ponds, but, as temperature increases the BOD_5 is typically reduced by 40 to 60% at 20 °C and by more than 80% at $\geq$25 °C (36).

Anaerobic digestion of organic matter proceeds slowly at temperatures below 15 °C (Table 4). The production of methane gas (CH_4), which is indicative of active anaerobic digestion, usually only occurs at temperatures of $\geq$15 °C (17) and the observed increase in sludge VS content also reflects a reduction in the extent of microbial degradation and stabilization of organic matter as ambient temperatures decline (Table 5). Consequently, appreciable solids accumulation occurs in cool climates and must be accommodated by the provision of greater tank capacities. In cold climates twice the tank volume is required compared with regions where wastewater temperatures are atleast 12 to 15 °C (37) for sludge storage. The HRT also becomes more critical as ambient temperatures decline (38) and longer retention times are required at low temperatures to achieve even a modest-level organic matter stabilization by anaerobic digestion processes.

Sludge (Septage) Production. The volume of sludge (or septage) produced in a septic tank depends on the following criteria:

- concentration of suspended solids in the influent,

Table 4. Effect of Temperature on Anaerobic Treatment (37)

Temperature (°C)	[a]Rate of Methane Formation Relative to That at 35 °C	[a]Retention Time Required for Treatment Relative to That at 35 °C (days)
5	0.1	10.0
15	0.4	2.5
25	0.8	1.2

[a]35 °C = 1.0.

Table 5. Effect of Septic Tank Liquid Temperature on Sludge Volatile Solids (VS) Content (33)

Tank Liquid Temperature (°C)	VS in Sludge (%)
0.6	79.0
4.4	77.4
15.0	74.6
26.0	52.7
28.5	37–47

- concentration of suspended solids in the effluent,
- extent to which the solids are liquefied or converted into gas, and
- moisture content of the sludge after differing periods of retention.

However, these factors are potentially highly variable so that sludge-accumulation rates are difficult to predict in practice. In the United States, sludge-accumulation rates are typically in the range 0.82–1.6 l capita^{-1} d^{-1} (300–600 l capita^{-1} y^{-1}) (3) and in Europe a value of 0.25 l capita^{-1} d^{-1} (93 l capita^{-1} y^{-1}) is reported (39). However, much lower accumulation rates are possible in warmer climates because of the greater extent of sludge stabilization. In Zambia, for example, sludge-accumulation rates are as low as 0.08 to 0.11 l capita^{-1} d^{-1} (30–40 l capita^{-1} y^{-1}) and an average value reported for South Africa is 0.09 l capita^{-1} d^{-1} (32 l capita^{-1} y^{-1}) (40).

Septage represents a mixture of aged solids combined with fresh material and contains potentially significant numbers of pathogenic bacteria, viruses, protozoal cysts, and helminth eggs that settle from the liquid phase (3). It is only partially stabilized, is potentially malodorous, and is 50 times stronger than municipal wastewater in relation to its BOD_5 and COD content (41). Therefore, sludge from septic tanks presents a significant microbiological and environmental risk and requires careful and responsible disposal. Septage may be disposed of by discharging to wastewater treatment works, where conventional wastewater and sludge-treatment processes reduce the risk of infectivity and the residual biosolids are disposed of by landfilling, incineration, or are reused on land as a fertilizer-replacement and soil-conditioning product. Aerobic digestion of septage and mesophilic anaerobic codigestion with landfill leachate also has potential in mitigating environmental problems caused by the disposal of poorly treated septic tank sludges (42,43). However, the sludge may be recycled directly on land, where it is managed in the same way as untreated urban wastewater biosolids by the provision of barriers to disease transmission and minimization of odor nuisance. These measures have a well-founded scientific basis (44) and include incorporation of the sludge into the soil by cultivation immediately after application, or subsurface injection, coupled with restrictions on the sowing, harvesting, and types of crops that can be grown (45,46). There are no reported cases of disease outbreak where these practices have been followed for untreated sludge (47). Nevertheless, in some countries, direct land application of untreated wastewater sludge, including the sludge from septic tanks, is not considered favorably because of uncertainty over the potential risks of disease transmission.

Drainage Field Performance

Biocrust/Biological Mat. The biological mat or biocrust that develops at the trench–soil interface penetrates the soil to a limited extent but it forms predominantly near the soil surface to a thickness of 5–30 mm (48). The crust consists of captured wastewater solids, mineral precipitates, and a high concentration of microorganisms consisting mainly of aerobic bacteria but also some protozoa and nematodes. The extent of the crust layer is also linked with the accumulation of microbial polysaccharides (49). A mature crust is regarded as an essential feature for efficient biological treatment and is also potentially an effective barrier to bacteria and viruses (3,41)

Treatment Efficiency. The efficiency of wastewater treatment by the drainage field is often assessed in terms of the improvements in water-quality parameters achieved between the tank outlet relative to various depths in the soil profile below the drainage field. For example, BOD, COD, and TSS removals of 75 to 95%, a decrease in ammonium-N content of 80 to 90%, and reductions in phosphate concentration of 25 to 50% were recorded at a depth of 1.5 m for a drainage field on sandy clay soil and treatment efficiency increased with the depth of unsaturated soil (50). The degree of bacterial removal is also strongly influenced by the extent of soil saturation (41) (the transport and attenuation of microbial pathogens in septic tank systems are discussed in more detail later). In another example (51), more than 90% removal of BOD and COD and more than 99% removal of coliform bacteria were reported for septic tank effluent flowing through 2 m of chalk and, again, treatment efficiency was shown to increase with depth (51).

Operational Problems

Septic tank systems fail to operate efficiently owing to a number of common faults. The problems are mainly associated with backing-up or surface-flooding with wastewater, and with pollution of surface or ground waters. Most operational problems are related to poor location or lack of maintenance (2). Inadequate design and installation are also important factors exacerbating the poor performance of septic tank systems.

In North America, septic systems contribute the largest volume and most numerous sources of all effluents discharged to groundwater, representing approximately 20 million potential point sources of groundwater pollution (52). During the period 1971 to 1978, overflow or seepage of wastewater primarily from septic tanks or cesspools was responsible for 41% of the outbreaks of disease and 665 of the illnesses caused by contaminated untreated groundwater in the United States (53). This aspect is discussed again later in the chapter.

PROCESS MICROBIOLOGY

As discussed, there are two physically separate steps in the treatment of wastewater by septic tank systems including

1. a primary stage for the settlement of solids accompanied by varying degrees of anaerobic digestion in the tank and
2. a secondary stage consisting (normally) of aerobic oxidation and (occasionally) anoxic denitrification in the drain field/soil.

Both stages have important roles in the attenuation and transformation of pollutants and for reducing enteric pathogens and parasites. The stabilization of organic matter and transformations of soluble mineral N, which is the principal inorganic environmental contaminant of concern in domestic wastewater, are mediated by microbial processes in the tank and drain field. These processes have been well researched and are summarized below. The biogeochemical evolution of domestic wastewater in conventional on-site septic tank systems can be described by simple, microbially catalyzed redox reactions involving organic C and N in wastewater in three different redox zones in the system (52). Anaerobic digestion of organic matter and production of CO_2, CH_4, and NH_4^+ predominate in the first zone (tank). In the second zone, gaseous diffusion through the unsaturated soil of the drain field supplies O_2 for aerobic oxidation of organic C and NH_4^+. It is also possible for a third redox zone to occur in which NO_3^- is reduced to N_2 gas by anaerobic denitrification. More details of the specific microbial activities involved are outlined in the following text.

Tank

Retained solids in a septic tank are digested anaerobically by bacteria reducing the volume of accumulated sludge. The dissolved and suspended colloidal organic components of the wastewater are also degraded by microbial action. Together, these processes remove the settleable matter from the wastewater and reduce its BOD. Anaerobic bacteria have slow growth rates so that although a small proportion of the BOD is removed by conversion to cellular material, the contribution to sludge production is minimal and the predominant mechanism of biodegradation is fermentation to CH_4 (54).

Drain Field

Sites of Microbial Activity and Mineralization. The secondary treatment of septic tank effluent is based on microbial activity in the biocrust and the upper layers of soil in the drainage field. Soluble and colloidal organic compounds and simple inorganic nutrient salts, particularly ammoniacal N and phosphate compounds including detergent residues, are applied to the soil in the effluent. Biodegradable organic constituents are mineralized by many types of aerobic soil bacteria to simple end products. Nitrogen in septic tank effluent is typically in the ratio 80% NH_4–N and 20% organic N and there is virtually no NO_3–N present (55). Inorganic NH_4–N ions are liberated during the mineralization of organically bound N in the septic tank and drainage field (56).

Importance of Gas Exchange for Microbial Activity. Biochemical nutrient transformations occur within the top 500 mm of soil in the drainage field where diffusion processes maintain adequate gas exchange and the oxygen status of the soil atmosphere to sustain aerobic biological activities (52). If O_2 supply is limiting in the drainage field, however, aerobic mineralization and nitrification processes are arrested and the accumulation of organic matter carried by the effluent will block the soil pores causing failure of the septic system. Soil porosity controls permeability and gas exchange processes and is critical for the correct biological functioning of the drainage field. A continuum of air-filled pore space is essential for effective gas diffusion and this requires an air-filled porosity of approximately 10% in soil (52). Soil types with the textural characteristics similar to fine-grained sand provide the optimum physical environment for maximizing gas exchange in the drainage field. By contrast, impervious or clay soils are unsuitable as a drainage field for purification of septic tank effluents (5).

Nitrification. Active nitrification (57) processes have been recorded in drainage fields with an average atmospheric composition of 19.6% O_2, some 5 cm from the clogged or crust zone (55). In sandy soils, however, nitrification of NH_4–N to NO_3–N is essentially complete within about 2 cm of the biocrust (55). Nitrification activity is most prevalent in the zone of aeration between the drainage field and the capillary zone, but is suppressed by anaerobic conditions where groundwater is near the base of the field. Under these circumstances, NH_4^+ can leach to the groundwater, although concentrations decline with distance from the drain system as a result of absorption to soil colloids (3,55).

Nitrate formation by NH_4^+ oxidation in the drainage field and leaching to groundwater is one of the primary impacts of septic systems at most sites and is generally an unavoidable consequence of the proper functioning of conventional septic systems (52,58). Estimated average N-loadings to the drainage field and inputs to groundwater in septic tank effluent are in the range 4–8 kg N capita^{-1} y^{-1} (22,59). Complete nitrification in the soil may contribute approximately 33 kg NO_3–N to the groundwater per year for an average family of four persons (59). Consequently there is a significant risk of NO_3^- concentrations exceeding drinking water standards in the effluent plume generated from septic tank systems (60). Nitrate may be transported significant distances from the site before physical dilution and dispersion processes reduce concentrations in groundwater to a level that may be acceptable for potable abstraction. The potential environmental significance and extent of N-loadings from septic tanks have been demonstrated in a modeling study of N-flows in a 360-ha mixed land use catchment in north-central Connecticut (61). In that example, septic tanks represented 25% of the N exported from the catchment.

Denitrification. Denitrification reduces NO_3^- principally to N_2 gas under anoxic soil conditions and is performed by a range of bacteria (57) that are commonly found in the subsurface environment. Organic carbon is usually the principal electron donor in denitrification reactions and 70–75% of the NO_3^- lost from a septic tank plume in an unconfined medium sand aquifer was due to carbon oxidation (62). The remainder was associated with sulfide oxidation, which also plays an important role. Oxygen is the preferred electron acceptor to NO_3^- in metabolism and oxic conditions are thought to inhibit denitrification activity. However, denitrification increases when gas exchange to the atmosphere is restricted and may be observed in alluvial soil as the air-filled porosity decreases below 11–14% (63). In practice, denitrification is rarely observed in the drainage field of septic tank systems because the availability of organic carbon (OC) is limited because of microbial mineralization processes. The reported cases of significant denitrification activity are associated with certain localized and site-specific factors and can be generally regarded as exceptional rather than the rule. For example, NO_3^- attenuation from septic systems by heterotrophic denitrification occurs in certain aquifers (62,64) with elevated OC concentrations (0.15% by weight; the OC content is more usually approximately 0.03% by weight). Denitrification is also possible where hydrogeological conditions in the drainage field cause partial anaerobiosis of the soil. In one case (65), more than 80% of the NO_3^- in recharge from a drainage field was lost by denitrification caused by a fluctuating water table and relatively warm soil temperatures (18 °C).

Phosphate. The extensive use of phosphate builders in detergent products in industrialized countries means that significant amounts of polyphosphate are transferred to the wastewater from clothes' washing and bathing. Nevertheless, approximately half the P-loading of septic tank effluents is derived from urine and feces (22). Typically, the P-loading to the drainage field in septic tank effluent is 0.6 kg capita^{-1} y^{-1}. The hydrolysis of polyphosphate compounds to potentially labile orthophosphate is enhanced by bacterial activity in soil and residual organic forms of P present in septic tank effluent are also mineralized to this inorganic form. However, P in septic tank effluent is almost entirely present as orthophosphate (22). Conventional opinion has been that orthophosphate ions are bound in immobile minerals in soil and little significance was attached to the potential consequences of P-accumulation. However, this view has changed in the light of recent research demonstrating that soils eventually reach P-saturation, causing leaching losses that contribute to diffuse pollution of surface waters and subsequent eutrophication (66). Soils attenuate septic system phosphate through mineral-precipitation reactions (67), but this capacity also becomes saturated with time, allowing phosphate to advance at a slow but potentially significant rate (60). Phosphate migration in the saturated zone appears to be controlled by chemical adsorption processes that allow slow but progressive movement. Consequently, the gradual accumulation of P in the vadose zone of the drainage field and the mobility of the phosphate plume in groundwater indicate that septic tank systems can be significant contributors of phosphate to nearby surface waters with potentially long-term implications for surface water eutrophication.

Biodegradation of Household Chemicals

Detergents, solvent cleaners, disinfectants, and other types of chemical products are widely used in households in developed, industrialized countries and are discharged in the wastewater. The fate and attenuation of household chemicals in septic tank systems have important implications for the environment and in particular for groundwater contamination particularly in countries such as the United States, where both household chemicals and septic tanks are commonly used (1). Chemicals present in laundry detergents represent the largest proportion of substances discharged in wastewater from households.

Studies of the chemical fate and transport of detergent residues in septic tank systems emphasize the importance of biodegradation and chemical-sorption processes in attenuating these household chemicals. Some biodegradation is possible in the septic tank itself, although the main process is associated with sorption onto the settling solids and partitioning into the sludge that is retained in the tank (68). Organic chemicals can be categorized according to three principal types of behavior when applied to soil in waste (69):

1. volatile compounds that are quickly lost to the atmosphere,
2. compounds that are rapidly mineralized by microorganisms and have little or no persistence, and
3. persistent compounds that are strongly adsorbed onto organic matter in waste and soil.

The main types of household chemicals fall within the first two categories. The use of persistent potentially toxic organic compounds has largely been phased out and they are not likely to be significant constituents of modern household products.

The fate and attenuation of detergent residues is of primary interest in assessing the potential environmental implications of domestic wastewater disposal by septic tanks. For example, linear alkyl benzene sulfonate (LAS) and nitrilotracetric acid (NTA) are important by-products from detergent use, but these chemicals are quickly biodegraded with mineralization half-lives in soil and groundwater of 9 to 17 days and 1 to 3 days, respectively (70). The maximum average LAS concentration measured in domestic septic tank effluents was 6.5 mg/l (22). Degradation rates are most rapid in soil of the drainage field and proceed at a slower rate in soil sampled further away from the discharge, emphasizing the importance of acclimation by the microbial community to the types of chemical present. Properly functioning septic tank systems are effective at removing synthetic organic chemicals from domestic wastewater and this is principally achieved through biodegradation processes (70). However, physico-chemical attenuation may also play a role. For example, the sorption of LAS by the soil matrix is controlled by a hydrophobic

mechanism and is enhanced with increasing organic matter and clay contents in soil (71).

Bleaching agents and organic solvents are potentially more potent environmental chemicals than those originating from detergents and are also discharged to septic tanks. The processes influencing the attenuation and transport of dichlorobenzene (DCB) in a septic tank groundwater plume have been examined by injecting the chemical and a tracer (NaBr) into the septic system (72). The tracer arrived at the groundwater table after 10 days, whereas DCB arrived after 57 days, indicating significant attenuation and retardation during migration through the aerobic unsaturated zone at the test site. There was evidence of significant biodegradation of DCB and the estimated half-life was 15 days. Increased attenuation was observed after a 7-day lag period for biological acclimation, further substantiating the importance of biodegradation processes.

The formation of adsorbable organic halid (AOX) from the use of bleaching agents containing sodium hypochlorite contributes significantly to the discharge of these potentially toxic organic compounds in domestic wastewater. Adsorbable organo-halogens may be removed in the septic tank by sorption onto the sludge solids and biodegradation when there are only background traces of AOX present in the domestic wastewater (0.1–0.2 mg l^{-1}) (73). However, significant removal rates of 87–94% are also reported (73) when AOX concentrations are elevated from the use of sodium hypochlorite in bleached laundry water. Approximately 30% of the generated AOX may be removed in the tank and the remainder is attenuated by the drainage field. Adsorbable organo-halogen compounds have minimal persistence and do not accumulate in the sludge or in the soil, and are rapidly degraded in the septic system. Biodegradation is probably the main mechanism of attenuation because the performance of the drainage field at removing AOX is enhanced by the use of hypochlorite, triggering the possible microbial adaptation to the presence of AOX.

These examples illustrate that household chemicals are usually effectively removed by properly functioning septic tank systems by sorption and biodegradation processes in the tank and drainage field. There are no reported examples in the scientific literature in which significant groundwater contamination has occurred with anthropogenic organic chemicals originating from domestic septic tank systems. The attenuation processes operating within the septic system and the intrinsic biodegradability of household chemicals minimize the potential risk to groundwater.

Pathogen Removal and Potential Health Implications

Septic tank effluents are unlikely to achieve the microbiological quality required for re-use as irrigation water (74) and are unsuitable for this purpose without further treatment. It is also inadvisable to grow vegetables or other food crops on or adjacent to the drainage field because of the risk of infection from consuming contaminated produce. The closure of water and nutrient cycles by reusing domestic sewage is advocated for reasons of community sustainability, but this depends on providing appropriate posttreatment for the removal of pathogens (75–77). Under most circumstances the effluent is not recycled and disposal to a drainage field is the usual method of treating the effluent to inactivate the pathogen load. The processes responsible for pathogen removal in the drainage field include death rate, flow rate, filtration, adsorption, microbial competition and antagonism, moisture, pH, sunlight, and temperature (78,79).

With proper hydraulic functioning of the drainage field, the populations of total coliforms, fecal coliforms, and enterococci are reduced to background levels within relatively short distances (60 cm) below the percolation trench in unsaturated soil (79). The most abrupt reductions in bacterial populations occur in the biocrust at the interface of the drainage field trench and the soil. The biocrust zone is only several centimeters in thickness but is effective in trapping and retaining bacteria. It is critical to the purifying action of the septic tank drainage field and represents the primary barrier to subsurface escape of fecal microorganisms (79). A soil-transition zone is usually observed from a high bacterial population in the biocrust region, that may be equal to or greater than the levels found in the effluent, to reduced populations in deeper zones equivalent to uncontaminated soil. Usually, 30–90 cm of permeable soil beneath the base of the drain field trench is adequate for complete bacterial removal and a more restrictive region is necessary to form the clogged biocrust zone. This is in line with the recommended practice for the installation of septic tank systems in the United States that require 120 to 150 cm of "suitable" soil as an adequate zone for the protection of groundwater (79). However, the transition zone may not effectively retain all pathogen types. In particular, owing to their small size, viruses can travel significant distances from the drainage field into the subsurface rock (51).

There are many reports of environmental problems caused by the contamination of ground and surface waters with enteric pathogens from septic tank installations. The potential risk of disease transmission from potable or recreational use of water contaminated by septic tank systems is a major concern in many different regions of the world (80–85).

The contamination of water used for drinking from private supplies is often the main cause of human exposure to enteric pathogens originating from septic tanks (81). Bacteria can migrate long distances of up to 600 m in certain aquifer types such as sandy subsurface rock, placing nearby potable abstractions potentially at risk (86). In a cohort study of 181 rural families (87) the numbers of *Escherichia coli* indicator bacteria in well water were significantly associated with gastrointestinal illness as a direct consequence of groundwater contamination with enteric pathogens from septic tanks. Increasing the distance between the septic tank system (i.e., the drainage field) and abstraction well above 20 m significantly reduced the likelihood and extent of contamination with the fecal indicator bacteria. Although these results provide assurance that risks to health can be mitigated by adopting appropriate setback distances, bacteria are poor indicators of other enteric diseases, including viruses (84) or parasites, such as Giardia oocysts (82). To assess the potential for infections

from these organisms requires the direct quantification of protozoan oocysts and the isolation of an appropriate indicator virus. A recent investigation (84) of the survival and transport of an enterovirus indicator and fecal coliform bacteria from septic systems located on sandy soil types showed that the main issues relating to viral and bacterial contamination of groundwater from septic tanks were that

- system design is less important than soil properties and the depth of the vadose zone,
- under suboptimal conditions, septic tank systems on sandy soils with seasonally high water tables can cause groundwater contamination with enteric pathogens,
- risks of viral contamination are highest in coarse textured (sand) soils when water tables are shallow (e.g., small vadose zone or saturated soil conditions) and in winter when temperatures are low, and
- large reductions in enteric pathogens are possible if the clay content of the drainage field is at least 15%, if the vadose zone is at least 1 m deep and if the drainage field distribution lines do not become submerged in the groundwater.

Although retention of enteric microorganisms by drainage fields may be effective in unsaturated soil conditions, a common fault is the siting of tank installations on land that has a shallow water table or where the soil may be seasonally waterlogged. Under saturated flow conditions, transport of microorganisms is markedly increased compared to unsaturated flow. In particular, the small size and surface electrical properties of viruses facilitate transport over potentially long distances by saturated flow and migrations of 1,000 to 1,600 m in channeled limestones, and 250 to 410 m in glacial silt-sand aquifers have been recorded (11). For example, enteroviruses were detected in a shallow, sandy soil aquifer receiving tank effluent (87), and poliovirus or bacterial phage tracers were also isolated in the vicinity of a septic tank (88). However, other research (89), using coliphages as indicators of pathogenic human viruses, showed that coliphage concentrations in groundwater in an unconfined sand and gravel aquifer were close to the limit of detection (1 coliphage per 1,000 l) at a typical setback distance of 30.5 m.

The oocysts of parasitic protozoa, Cryptosporidium and Giardia are more than 100 times larger than viruses, which restricts their movement by intergranular flow. Oocysts of these parasites are rarely detected in groundwater. However, their occasional presence (90) indicates that removal by filtration in the unsaturated and saturated zones may not necessarily guarantee the protection of water quality from contamination with these types of organism, particularly in fractured or channeled aquifer systems or in very coarse gravel aquifers.

PERFORMANCE ENHANCEMENT

The problems associated with the discharge of pollutants from septic tank systems and the subsequent contamination of ground and surface water resources' nutrients has prompted the development of a variety of methods that improve performance to mitigate the environmental impacts. Most of the alternative approaches or enhancements are microbiologically mediated, as discussed in the following sections.

Seeding

The benefits of seeding an active population of anaerobic bacteria are well known for enhancing the treatment efficiency of anaerobic wastewater stabilization ponds and improving effluent quality (34). For example, consistently higher BOD_5 removals are observed from the enhanced seeding of supernatant in ponds that retain a layer (e.g., 400 mm) of aged (2 y) sludge compared to ponds where all the sludge is periodically removed (34). The provision of an inoculum source of anaerobic bacteria to accelerate the establishment of effective anaerobic digestion can also markedly improve the efficiency of septic tank systems for wastewater stabilization. This is done by collecting sludge from an existing tank, with an established anaerobic microbial population, and adding this material to a new installation or by leaving a small amount of sludge (e.g., equivalent to 20% of the tank volume (8) behind in the tank after routine desludging operations.

Microbial Additives

There is a growing market in products that aim at improving the extent of biodegradation in septic tanks and reduce sludge accumulation, odor, and drainage field blockage. These products are usually in the form of dried bacterial cultures and may also include enzymes. The general consensus, however, is that such products are ineffective (15). Additives based on hydrolytic yeasts, enzymes, and bacteria are ineffective because the rate-limiting step in sludge stabilization in septic tanks is usually CH_4 formation (23). The microorganisms responsible for biotransformation and stabilization processes in septic tanks and the drain field are ubiquitous and well adapted to the environment, and inoculated bacteria are usually ineffective competitors compared to indigenous groups. However, there is some evidence supporting the use of additives to improve biodegradation efficiency of septic tank systems (23). For example, a formulation of "mineral insoluble additives" stimulated the different stages of anaerobic digestion and reduced sludge production in septic tanks by as much as 60%, reducing the frequency of desludging up to 15 to 20 years (23). There are also claims that additive formulations could be developed to ultimately reduce the amount of sludge produced by as much as 90%.

External Organic Carbon Substrate

The introduction of a carbon source to support heterotrophic denitrification in the drainage field as solid phase substrate or by liquid injection is highly effective for NO_3^- removal. In the injection system, for example, methanol is introduced at the base of a specially constructed drainage field above an impermeable layer to intercept and denitrify the NO_3–N (91). Demonstration

trials showed that this technique significantly reduced the inorganic N-content of drainage to 0.1 mg N l^{-1} within 1 m of travel through the impermeable pan beneath the drain field from an initial value of 41 mg N l^{-1} (as NH_4^+) in the effluent (91). An arguably more innovative approach is to install porous barriers constructed from reactive solid organic carbon material (sawdust) to intercept water flow within the drainage field for passive in situ NO_3^- attenuation (92). Reactive porous media barriers in field trials have achieved significant attenuation of NO_3–N of 60–100% of input concentrations up to 125 mg N l^{-1}.

CONCLUSION

Septic tank systems provide a relatively simple and practicable method of treating wastewater from dwellings in unsewered, remote, or rural locations, and they can be effective in reducing the risk of enteric disease transmission when properly functioning. The basic engineering principles for designing a suitable tank are well defined and there is also general guidance for constructing the drainage field. However, it is the operation of the drainage field where most potential environmental problems arise because of the wide variability in soil conditions and subsurface hydrogeology that affects system performance. A conflict emerges between the basic requirement for a porous soil structure to facilitate aerobic biodegradation and nitrification processes, whereas pathogen retention is more effective in fine-textured soils.

Nitrate production is an inevitable consequence of a correctly operating septic system and this is probably the most significant contaminant of groundwater impacted by septic tank discharge. Biological denitrification is rarely present in drainage fields. Phosphate is also a major constituent of septic tank effluent and presents a potential risk of surface water eutrophication. However, P is usually effectively retained in the drainage field by chemical precipitation reactions in most types of soil. Common household chemicals rapidly biodegrade in the drainage field and there is no evidence for their accumulation in soil or sludge.

Very little pathogen removal occurs during sedimentation of solids in the septic tank and the majority of the pathogen load is eliminated from the wastewater by the drainage field. The occurrence of pathogenic organisms in the wastewater depends on the extent of infections in the individuals using the septic system. Although the drainage field can be effective at reducing pathogens, there are many examples in which this barrier breaks down and significant groundwater contamination is reported with important implications for human health.

SHIGELLA

ALFREDO G. TORRES
University of Maryland School of Medicine
Baltimore, Maryland

Shigella are gram-negative, non-spore-forming, facultative anaerobic bacilli closely related biochemically and antigenically to *Escherichia coli*. Most fail to ferment lactose or to produce gas when fermenting glucose, and all are nonmotile (1). They cause a disease called dysentery (bacillary dysentery or shigellosis), an infection of the large bowel characterized by abdominal cramps, diarrhea, and fever. Initially, the diarrhea may be copious and the liquid stools often contain blood and mucous. It is sometimes accompanied by other symptoms such as vomiting and headache, and the infection rarely involves other parts of the body (2).

Shigella spp. are usually acquired by drinking water that is contaminated with human feces or by eating food washed with contaminated water. The organisms invade the cells lining the colonic mucosa and multiply there, killing the cell; this is the cause of the symptoms produced. However, it occasionally invades the bowel beyond the surface lining. At least one species, *Shigella dysenteriae*, also secretes a toxin that most likely plays a role in tissue destruction and more serious systemic disease.

Shigella spp. continue to have an important global impact, causing an estimated one million deaths and 163 million cases of dysentery annually. The organisms have demonstrated extraordinary competence for acquiring plasmid-encoded multiantibiotic resistance previously used as first-line therapy (4). This finding, in addition to the low infectivity and potential complications with complex or often unexplained pathogenesis, have led several laboratories to try to understand the pathogenesis of shigellosis, with the aim of developing a vaccine against the disease.

Complete overviews on the pathogenesis, epidemiology, clinical significance, detection, and diagnosis of *Shigella* strains have been published elsewhere (3,5–8). This article focuses on the recent progress made to understand the genetic and molecular basis of shigellosis.

THE GENUS *SHIGELLA*

There are four different species of *Shigella*, divided on the basis of differences in O-antigen of their lipopolysaccharide and differences in some biochemical reactions. These are named *Shigella dysenteriae* (13 serotypes), *Shigella flexneri* (15 serotypes), *Shigella boydii* (18 serotypes), and *Shigella sonnei* (1 serotype) (1). In general, *S. dysenteriae* accounts for deadly epidemics in developing countries, *S. flexneri* and *S. sonnei* are responsible for endemic disease, the former being prevalent in the developing world, the latter in developed countries, and *S. boydii* accounts for most cases of infection in India and neighboring countries. From these species, the most extensively studied is *S. flexneri*.

OVERVIEW OF PATHOGENESIS

The fundamental event in the pathogenesis of *Shigella* is the ability to invade and colonize the human intestinal epithelium. This triggers an intense acute inflammatory response with infiltration by polymorphonuclear leukocytes. The pathogenesis of *Shigella* is a multistep process that depends on the capacity of the bacteria to cross the colonic mucosa via M cells associated with gastrointestinal-associated lymphoid tissue (GALT). The bacteria then invade epithelial cells resulting in an inflammatory response caused by cellular components, which facilitate further bacterial invasion. Most of the virulence determinants responsible for invasion of epithelial cells are encoded on a large plasmid that is unique to virulent *Shigella* and enteroinvasive *E. coli* (EIEC) strains.

Virulence Plasmid

The initial observation that established the essential role of plasmids in *Shigella* virulence was done in *S. sonnei* and shortly thereafter in *S. flexneri* (9,10). Noninvasive *S. sonnei* isolates obtained on subculture in the laboratory recovered their invasive abilities when a large plasmid, normally found in clinical isolates of *Shigella*, was reintroduced (9). Since this initial observation, the so-called virulence plasmid (Fig. 1) has been shown to encode genes for (*1*) the production of invasion plasmid antigens (Ipas); (*2*) the synthesis of a type III secretion apparatus, a flagella-like structure able to deliver *Shigella* effector proteins into the eukaryotic cell; (*3*) the induction of endocytic uptake of the bacteria and disruption of endocytic vacuoles; (*4*) the intra- and intercellular spreading phenotype, and (*5*) the regulation of plasmid-encoded virulence genes.

Two independent groups have recently reported the complete sequence analysis of the large virulence plasmid in *S. flexneri* serotype 5a (11,12). The DNA sequence indicated that the genes necessary for entry of bacteria into epithelial cells are clustered within a 31 kilobases (kb) region of the 213-kb plasmid. The genes within this region have been extensively characterized (13). The entry region

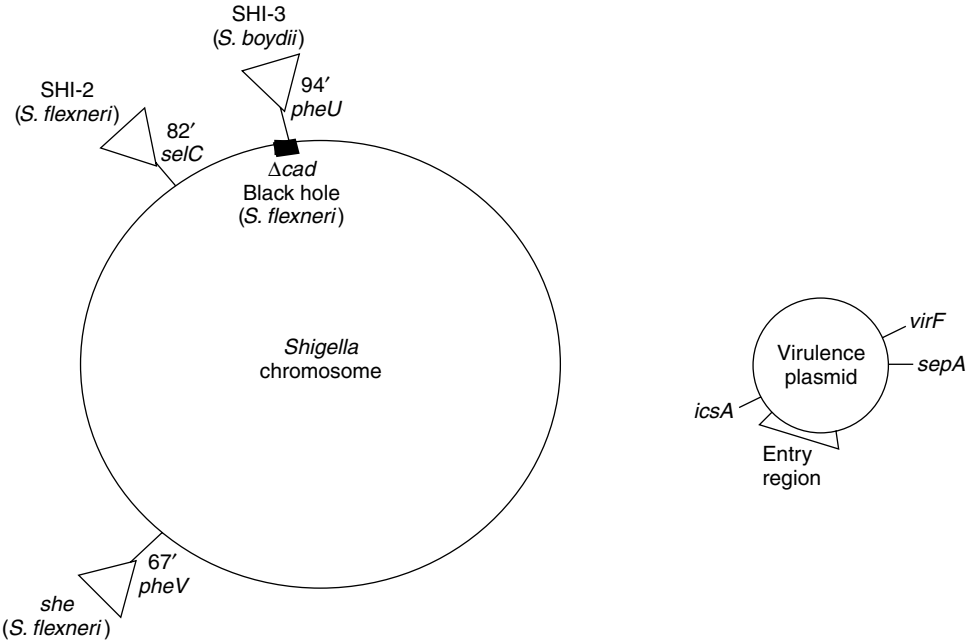

Figure 1. Location of selected pathogenicity islands and selected plasmid-encoded genes of *Shigella*. The location in the chromosome of the pathogenicity islands (PAIs) is indicated by minutes on the basis of the chromosomal map of *E. coli* K-12, and the genes adjacent or disrupted by the insertion of the PAI. The approximate location of the black hole is indicated with a closed square. The region implicated in the entry into epithelial cells and genes associated with pathogenesis are indicated in the virulence plasmid.

is a pathogenicity island-like cluster (see later) that contains (*1*) the *mxi* and *spa* genes encoding components of a type III secretion apparatus; (*2*) the *ipaA*, *B*, *C*, and *D* and *ipgD* genes encoding proteins secreted by this machinery; (*3*) the *ipgC* and *ipgE* genes encoding cytoplasmic chaperones required for stability of IpaB and IpaC, and IpgD, respectively; (*4*) the *virB* gene encoding a protein required for transcription of the *mxi*, *spa* and *ipa* genes; and (*5*) additional genes of unknown function.

Outside of the entry region, other genes associated with virulence have been identified. They include (*1*) the *icsA* (*virG*) gene encoding an outer membrane protein that is directly responsible for the ability of the bacteria to move within the cytoplasm of infected cells; (*2*) the *virF* gene encoding a transcriptional activator that controls expression of *icsA* and *virB*; and (*3*) the *sepA* gene, which encodes a secreted serine protease of the autotransporter family.

In addition, the virulence plasmid contains two copies of the *shet2* gene encoding a putative enterotoxin, and genes encoding several secreted proteins, which include *virA*, *ipaH4.5*, *ipaH7.8*, *ipaH9.8* and six uncharacterized genes designated (outer *Shigella* proteins): *ospB*, *ospC1*, *ospD1*, *ospE1*, *ospF*, and *ospG*. The proteins encoded in this plasmid are directly involved in the entry into epithelial cells and invasive phenotypes observed in the pathogenesis of *Shigella* strains.

Entry into Epithelial Cells and Type III Secretion System. In order for *Shigella* to enter an epithelial cell, the bacterium must adhere to its target cell. Entry into the host cell appears to be receptor-mediated, but the specific adherence factor has not been defined (3). The bacterium crosses the epithelium in selected areas corresponding to M cells of the follicle-associated epithelium (FAE) (Fig. 2; 14). More than 25 different genes are essential for *Shigella* entry and most of them are located in two adjacent operons located in an area called the entry region (Fig. 1; 7). One of these operons, the *mxi-spa* operon encodes a type III secretion apparatus that allows bacterial proteins to be secreted or translocated into the host cell cytosol (6). There are at least 25 proteins secreted through the Mxi-Spa secretion apparatus (11). The Ipa proteins (IpaA-D), which are encoded in the adjacent operon, are critical for *Shigella* entry and are among the major products secreted through the type III secretion apparatus (6). The secretion of Ipa proteins is induced by the epithelial cell and controlled by IpaB and IpaD, which prevent secretion of proteins before the bacterium-host cell contact occurs. The type III secretion apparatus allows the insertion of a pore into the host epithelial cell membrane. This pore contains a complex of the IpaB and IpaC proteins that induce a cascade of cellular signals, which result in actin polymerization and internalization of the bacterium. Among the other secreted proteins, IpaA and IpgD are required for the formation of a focal adhesion–like structure at the bacterium-cell membrane contact site (15), whereas the function of the other secreted proteins is unknown. *Shigella* are then internalized by a process caused by the formation of fingerlike extensions of the plasma membrane known as filopods that are quickly remodeled in lamellipods, resulting in an endocytic vacuole that entraps the microorganism (7).

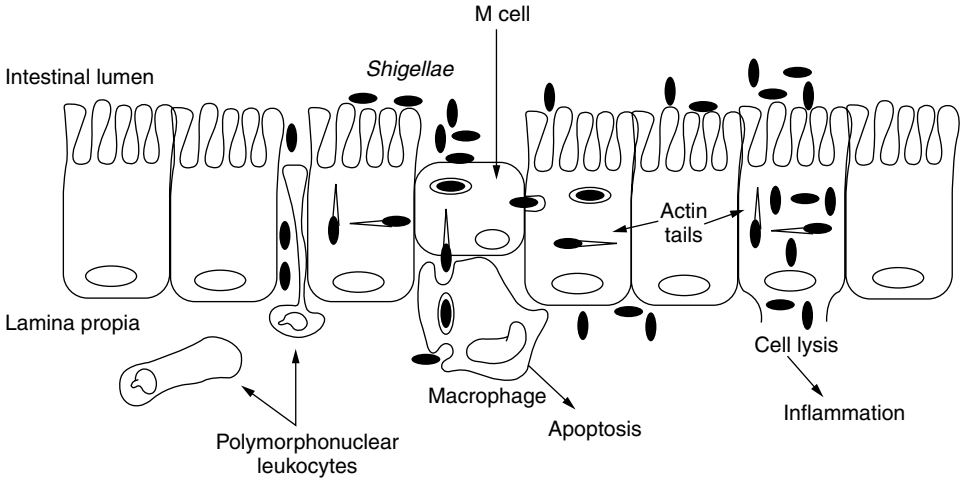

Figure 2. Entry and dissemination of *Shigella* in epithelial cells. The bacteria do not invade the intestinal epithelium directly. Instead, *Shigella* enter the M cells by inducing their own endocytosis (see text for details). *Shigella* escapes the endocytic vacuole and uses the cell cytoskeleton actin to spread from cell to cell. Then, they invade the epithelial cells and macrophages. *Shigella* invasion induced programmed cell death in macrophages, which triggers the initial stages of inflammation. *Shigella* multiply in the cytoplasm and cause the subsequent death of the infected epithelial cell inducing an intense response of inflammatory cells (polymorphonuclear leukocytes), bleeding, and abscess formation.

Intercellular and Intracellular Spread. After engulfment, *Shigella* is surrounded by a membrane-bound vacuole within the host cell (Fig. 2). *Shigella* rapidly lyses the surrounding vacuole and is released into the cytosol, where it grows and divides. Once the microorganism has escaped from the vacuole, it quickly becomes coated with filamentous actin and ultimately forms an actin tail at one pole of the bacterium (16). *Shigella* actin-based motility is mediated exclusively by the IcsA/VirG outer membrane protein (17). IcsA/VirG recruits host cytosolic components to induce actin nucleation. The neural Wiskoff-Aldrich syndrome protein (N-WASP), vinculin, the Arp 2/3 complex and several other host cytoskeletal proteins interact directly or indirectly with IcsA/VirG to cause actin tail formation, which propels the bacterium through the cytoplasm (7). When the pathogen reaches the plasma membrane of the cell, it forms a fingerlike projection from the surface of an infected cell to the surface of an uninfected cell. The tip of the protrusion penetrates the surface membrane of the adjacent cell with the subsequent internalization of the microbe. *Shigella* break out of the double membrane of the vacuole and are released into the cytoplasm, thereby starting a new cycle of infection in a new host cell.

Following host cell invasion and penetration, degeneration of the epithelium and inflammation of the lamina propia characterize *Shigella* infection. After crossing M cells, *Shigella* are found in an area essentially populated by macrophages and dendritic cells. *Shigella* expressing the invasion phenotype have another useful role, which is to cause the death of phagocytic macrophages by activating normal programmed cell death (apoptosis) (18). Macrophage apoptosis caused by the bacterial IpaB protein not only permits bacterial survival following the crossing of the FAE but is also central to the early triggering of inflammation (19). It is likely that this apoptotic process participates in the inflammatory rupture of the epithelial barrier and facilitation of bacterial dissemination.

Invasion of epithelial cells by *Shigella* stimulates the release of proinflammatory cytokines and chemokines, such as IL-8. This event accounts for the recruitment of polymorphonuclear leukocytes (PMN) to the site of infection and their transmigration through the epithelium, which causes major tissue destruction (13). It has been shown that IL-8 production by invaded epithelial cell results in the containment of *Shigella* infection at the epithelial level, but at the cost of massive epithelial destruction, particularly by PMNs (20).

Shiga Toxin

Shigella dysenteriae serotype 1 is unique among *Shigella* species in the production of a potent toxin known as the Shiga toxin (Stx) (21,22). Stx is a bipartite molecule composed of a single enzymatic A-subunit and a pentamer of receptor-binding B-subunits. The toxin binds to a glycolipid receptor found in target cells, globotriaosylceramide (Gb_3: Galα1–4-Galβ1–4-glucosylceramide), and it is internalized by endocytosis. The A-subunit is proteolytically cleaved and reduced, generating A_1 and A_2 peptides. The A_1 peptide inhibits mammalian protein synthesis by cleaving the N-glycosidic bond at adenine residue 4,324 in the 28S RNA of the 60S host cell ribosome. The importance of this toxin is that infections with Stx-producing bacteria may lead to hemolytic uremic syndrome (HUS), an often fatal kidney failure condition, particularly in children. In addition to *S. dysenteriae* type 1, related Shiga toxins are secreted by enterohemorrhagic *E. coli* (EHEC) strains and other bacteria that are associated with cases of HUS on a worldwide basis.

Pathogenicity Islands and "Black Holes"

In general, pathogenicity islands (PAIs) are large and unstable genetic elements, acquired by lateral gene transfer, with different G + C content, often associated with tRNA genes, which contribute to the virulence of bacterial pathogens. The concept of PAIs was developed on the basis of data on genome structure and pathogenicity of enteric organisms, especially pathogenic *E. coli*. However, this concept is now used broadly in other gram-negative and gram-positive pathogens. In this section, the recent progress in the identification and characterization of different PAIs in *Shigella* species will be discussed and the new concept known as "black holes" introduced.

Pathogenicity Islands. In *Shigella* spp. four distinct PAIs have been identified (Fig. 1). These include the plasmid-encoded *ipa/mxi-spa* locus described previously; the *she* PAI, encoding an enterotoxin and several autotransporter proteins; and the SHI-2 and SHI-3 PAIs, encoding aerobactin iron-uptake systems.

The *she* PAI is 46-kb unstable chromosomal locus inserted next to the *pheV* tRNA gene in *S. flexneri* serotype 2a (23,24). This PAI carries the *set1A* and *set1B* genes encoding the two subunits of ShET1 enterotoxin and the genes encoding the autotransporter proteins SigA, Pic, and Sap. In addition, this PAI includes genes commonly found in PAIs of pathogenic *E. coli* strains, and several open reading frames (ORFs) of unknown function. ShET1 production results in fluid accumulation in a rabbit ileal loop model. Pic, is a secreted protease implicated in mucinase activity, serum resistance, and hemagglutination. Finally, SigA, is a cytopathic protease that contributes to intestinal fluid accumulation. The precise contribution in pathogenesis and epidemiology of the *she* PAI is under further investigation.

The siderophore aerobactin is a low molecular weight iron chelator with high affinity for iron frequently found among *Shigella* and enteroinvasive *E. coli* (EIEC) strains that has been associated with increased virulence (25). The genes involved in synthesis and transport of aerobactin, which are often plasmid-encoded, were recently found within a pathogenicity island in two *S. flexneri* strains from serotypes 2a and 5 (26,27). This island, designated SHI-2 (*Shigella* pathogenicity island 2), is located downstream of *selC*, and occupy 23.8-kb in *S. flexneri* serotype 5 and 30-kb in *S. flexneri* serotype 2a. The G+C content of the island is slightly lower than that of the rest of the *Shigella* chromosome (51%) and varies from 48.5% in serotype 5 to 46% in serotype 2. In addition to the aerobactin transport and synthesis genes, SHI-2 encodes other genes found in the PAI of enterohemorrhagic *E. coli* O157 : H7, and genes encoding proteins, which confer immunity to colicins I and V.

A fourth island has been recently characterized in *S. boydii* strain O-1392 (28). SHI-3 is located within a 21-kb region between the *lysU* and *pheU* genes. The island contains the aerobactin operon flanked by genes found in mobile genetic elements. The fact that SHI-3 was found in other locations among closely related species, suggests that this PAI is an unstable and mobile genetic element associated with virulent *Shigella* species, although its role in virulence has not been established.

Black Holes. One common biochemical property of *Shigella* and EIEC strains is their lack of lysine decarboxylase (LDC) activity. The LDC^- phenotype has been proposed to be associated with virulence and Maurelli and coworkers found that introduction of *cadA* (the gene for LDC) in *S. flexneri* 2a causes attenuation in the virulence and inhibition of enterotoxin production (29). Failure to transduce *cadA* into the chromosome of *Shigella* led to the analysis of the chromosomal region flanking this gene in *S. flexneri* and EIEC. Comparison of the chromosomal region flanking *cadA* in *S. flexneri* and EIEC with *E. coli* K-12 revealed a large chromosomal deletion up to 90 kb in the vicinity of the *cadA* gene (Fig. 1). This novel concept called "black holes" suggests that deleting genes that are detrimental to the pathogenesis of the organism, provides an evolutionary advantage that enables *S. flexneri* and EIEC to enhance virulence.

Other Potential Virulence Factors

Several chromosomal genes have been implicated in *Shigella* virulence. These include the *sodB* gene, the lipopolysaccharide (LPS) synthesis genes and in *S. dysenteriae*, the *shu* locus (3,30). *sodB* encodes the superoxide dismutase protein, and $sodB^+$ *Shigella* are resistant to cell-mediated bactericidal activity, which seems to be a decisive factor in the development of colitis (31).

The O-specific polysaccharide domain of LPS is both an essential virulence factor and a serotype-specific protective antigen (32). Its importance in virulence was initially inferred from the avirulence phenotype of rough *Shigella* in animal models and the inability of these strains to spread from cell to cell in tissue culture monolayers (3,33). Recently, it has been shown that both the length distribution and the number of LPS O-antigen molecules on cell surface are important for *S. flexneri* invasion and full virulence (34,35).

Finally, in *S. dysenteriae* type 1, genes encoding the heme iron transport system are contained on a region found in two distantly related lineage of pathogenic *E. coli* and *S. dysenteriae* strains, but not in other *Shigell*a species, suggesting acquisition by horizontal gene transfer. In *S. dysenteriae*, however, a mutation in the heme uptake system did not reduce the virulence, suggesting that the presence of additional iron transport systems in *S. dysenteriae* complement the function of the heme uptake system (36). The role of the multiple *S. dysenteriae* iron transport systems in virulence is currently under investigation.

SHIGELLA AND THE ENVIRONMENT

Regulation of *Shigella* virulence is subject to tight control by several mechanisms involving many proteins and an array of environmental signals (Fig. 3). It is thought that the tight control by environmental factors prevents inappropriate expression of the virulence genes in or

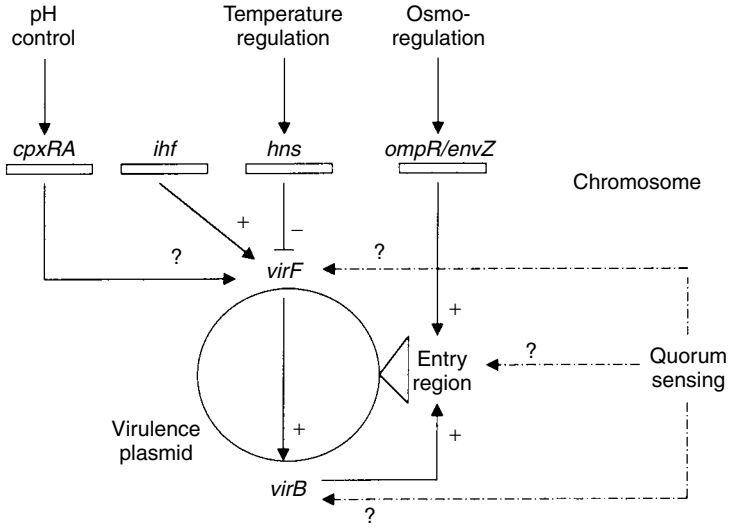

Figure 3. Schematic representation of the key elements in the *Shigella* virulence gene regulatory cascade. For simplicity, only the entry region is shown in this figure as target of regulation. The environmental factors are shown controlling the expression of chromosomal genes. The proteins encoded in these genes activated or repressed the plasmid-encoded virulence genes. The question marks refer to those mechanisms of regulation of virulence genes that has not been totally defined (+, positive regulation; –, negative regulation).

outside the host. The expression of *S. flexneri* virulence genes is activated when bacteria are shifted from 30 to 37 °C, in medium of moderate level of osmotic stress (similar to that of physiological saline) and a pH of 7.4 (37). Temperature is a key environmental cue exploited by *S. flexneri* to sense passage into the human gut (38). The factors controlling the thermal regulation have been identified and include chromosomally encoded H-NS, which repress virulence gene expression at 30 °C, and the virulence plasmid-encoded VirF and VirB proteins, which are transcription factors required for the expression of the invasive phenotype at 37 °C (37).

A second global regulator, the integration host factor (IHF), also contributes to the expression of virulence genes of *S. flexneri*. IHF is required for the positive activation of *virF* in both exponential and stationary phase cultures and for the activation of *virB* in stationary phase (37).

Transcription of *virF* is also under pH control. In *S. sonnei*, the pH control is dependent on the chromosomally located *cpxRA* genes, a member of the two-component regulatory system (39). The control by *cpxRA* can be overruled by thermal regulation and so far, the direct binding of CpxR to the promoter region of *virF* has not been demonstrated. A second two-component regulatory system has been implicated in the control of *S. flexneri* virulence (40). The osmotic stress sensor protein EnvZ and the response regulator OmpR have been shown to control the expression of plasmid-located virulence genes, but direct evidence of this regulation has not been obtained.

It has been proposed that an additional environmental factor, the cell density, is also involved in the control of virulence gene expression in *Shigella* (41). Bahrani and coworkers showed that the expression and secretion of Ipa proteins is increased with cell density, peaking in stationary phase cultures. This data suggests that the quorum sensing molecules present in stationary phase cultures (known as autoinducers), influence *Shigella* virulence gene expression. Recently, Day and coworkers demonstrated that the expression of *ipa*, *mxi*, and *spa* invasion operons is maximum in stationary phase bacteria and that conditioned media derived from stationary phase cultures enhance the expression of these loci (42). This report also showed that expression of *virB*, a gene encoding the transcriptional factor essential for the expression of the invasion loci, peaks in late log phase. Their data showed that the quorum sensing autoinducer molecule active in late log phase, does not influence the expression of the invasion operon and is not required for *Shigella* virulence (42). More data is required to define the role of quorum sensing in the expression of virulence factors in *Shigella* strains.

Epidemiology

Shigella are highly host-specific, causing natural infections in humans and only occasionally in other higher primates. The target susceptible populations are infants, the elderly, and the very ill that suffer the most severe symptoms of the disease, but all humans are susceptible to the disease to some degree. *Shigella* are not easily killed by stomach acid, so an infectious dose of as few as 10 organisms can cause the infection. Since production of shigellosis requires ingestion of such small numbers of the organism, it is extremely difficult to control the spread of the disease. Transmission occurs most quickly in overcrowded populations with poor sanitation where it more easily spreads from person to person. Although transmission via food is less common, contamination of food with human sewage (either directly or via contaminated water) has led to outbreaks, especially with cold, uncooked foods such as salads and raw vegetables.

In developing countries, *Shigella* is a common endemic infection because of inadequate sewage disposal and lack of effectively treated water supplies. Ninety-nine percent of the estimated *Shigella* cases worldwide occur in developing countries (163.2 million from 164.7 million total) (4). The majority of *Shigella* isolates in developing countries correspond to *S. flexneri*, with *S. sonnei* being the next most prevalent. However, when pandemic dysentery caused by *S. dysenteriae* serotype 1 appears, the rate of infection increases and often becomes a leading cause of

death. In developed countries, most cases of shigellosis are seen in young children with *S. sonnei* as the predominant serotype (4). In addition, family members frequently acquire infection from infected individuals in the same household, so that infection can spread from children to adults and vice versa.

Outbreaks of infection have been described in other groups of people in close contact, such as in military bases, refugee camps, among cruise ship passengers or following natural disasters. Severe forms of infection can occur, particularly in travellers to developing countries. In these cases, the patient may become very ill and dehydrated, and in the absence of medical treatment, dysentery can be fatal.

VACCINE DEVELOPMENT

Although *Shigella* species are important agents of diarrheal epidemics worldwide, causing an estimated 164.7 million cases of dysentery and approximately 1.5 million deaths annually (4), there is no current licensed vaccine to prevent shigellosis. There are three factors that have restricted the development of such a vaccine, including (*1*) the inability to raise serum antibodies, which confer immunity after parentally injected inactivated whole-cell vaccines; (*2*) the lack of a good animal model; and (*3*) only indirect evidence of the immune mechanism(s) in humans activated after infection (43).

Despite these factors, a new generation of candidate vaccines had shown great promise for the prevention of shigellosis (44–46). The primary role of a *Shigella* vaccine would be to protect against clinical disease. An additional benefit would be to interfere with infection and colonization. The most important *Shigella* strains to be targeted for vaccine development are *S. flexneri 2a*, *S. dysenteriae* type 1, and *S. sonnei*. However, the possible emergence of new serotypes has been emphasized. The emergence of *S. flexneri* serotypes 1, 3, 4, and 6 in several countries and a switch toward a predominance of *S. sonnei* in developing countries has been observed (4).

Several approaches to the development of *Shigella* vaccines have been tested. Two of the most promising approaches in development of candidate vaccines include the use of live attenuated strains and acellular vaccines based on lipopolysaccharide/polysaccharide antigens. Several attenuated vaccine candidates have been derived from *S. flexneri* 2a. Recently, CVD 1207, a derivative from the wild-type *S. flexneri* 2a strain, was tested in a phase one clinical human trial. This live attenuated vaccine candidate retains the ability to invade epithelial cells but cannot effectively spread intercellularly after invasion, does not produce enterotoxin, and has limited proliferation in vivo. CVD 1207 was shown to be highly attenuated and well tolerated at dosage levels that were markedly reactogenic with earlier invasive *S. flexneri* 2a vaccine candidates, but showed modest serum antibody responses and was insufficiently immunogenic after a single dose (46). Another attenuated *S. flexneri* 2a vaccine candidate has been successfully tested in human trials. Strain SC602 carries deletions of the plasmid-borne virulence gene *icsA* and the chromosomal aerobactin locus *iuc*, which resulted in a double attenuation of its capacity to move intra- and intercellularly, and of its survival within tissues. Double-blind, placebo-controlled studies on the safety and the immunogenicity of this candidate vaccine indicated that SC602 is the first attenuated candidate vaccine that provides protection against shigellosis in a stringent, challenge model (45).

Shigella polysaccharide-protein conjugates are vaccine candidates consisting of proteins that elicit enhanced antibody responses against the poorly immunogenic polysaccharide (47). A phase II (double-blind, randomized, and vaccine-controlled) study of a conjugate vaccine composed of *S. sonnei* O-specific polysaccharide bound to *Pseudomonas aeruginosa* recombinant exoprotein A (*S. sonnei*-rEPA) has been conducted in Israel (44). The study revealed that the vaccine was safe and highly immunogenic and indicated that one injection of *S. sonnei*-rEPA confers type-specific protection against *S. sonnei* shigellosis (44). Recently, the safety and immunogenicity of *S. sonnei and S. flexneri* 2a conjugates were evaluated in a clinical trial using different carrier proteins (43). The data suggested that these conjugates were safe and immunogenic and they can be used to induce a more complete and long-lasting immunity against shigellosis (43).

The essential requirement for the development of a *Shigella* vaccine in the near future is the clear understanding of the host innate immune response to the organism and how this affects the adaptive immune response throughout the disease. An ideal vaccine should be easy to administer, preferably orally, although parental vaccines should not be discarded if all the following requirements are met: well-tolerated; able to induce a high-level, long-term protection after a single dose; multivalent, and easy to manufacture. In addition, it is essential that the new strategies for vaccine development take into consideration most of the antigenically distinct serotypes of *Shigella* causing endemic and epidemic infections. It has been estimated by Kotloff and coworkers that if a vaccine had 70% efficacy, up to 91 million cases and more than half million deaths might be prevented each year (4).

CONCLUSION

Recent progress to better understand *Shigella* infection has been possible by establishing the interactions between the bacterial secreted products and their target host cellular components. The completion of the *S. flexneri* virulence plasmid sequence and the fast progress in the elucidation of the genomes of other intestinal pathogenic strains, including the sequence of the *Shigella* chromosome, will allow the analysis and identification of other putative virulence genes implicated in the pathogenesis of the microorganism. This approach has become particularly important in determining the real contribution of other chromosomal-encoded proteins in addition to the already identified virulence factors. More studies are needed to determine, for example, the regulatory networks controlling the expression of the genes in the chromosomal PAIs, and to define the

global scheme of signaling pathways at the bacterial or the cellular level that coordinate the expression of the full range of virulence factors implicated in the disease.

The global understanding at the molecular and cellular levels of the pathogenesis of *Shigella* will enable the development of the ideal vaccine that covers most of the major *Shigella* serotypes and effectively provides protection against the disease. This vaccine is obviously needed since there is a high disease burden mostly in developing countries and a tendency of resistance to current antibiotics, but the major challenge to overcome in the assessment of *Shigella* vaccine efficacy is the absence of previous candidate vaccines that develop full protection.

SNOW AND ICE ENVIRONMENTS

CHRISTIAN H. FRITSEN
Desert Research Institute
Reno, Nevada

Average present-day temperatures at Earth's poles are well below 0 °C and water is readily found in its solid form as ice and snow within both the terrestrial and marine environments throughout the year. At lower latitudes, ice and snow are also prevalent features of terrestrial and aquatic systems at high elevations (e.g., alpine environments) and at lower elevations during winter. Ice and snow are only present at extremely high altitudes near the equator. Hence, the distribution of ice and snow environments is discontinuous, yet ubiquitous in time throughout the globe. The physical binding of H_2O into a solid hexagonal matrix has profound affects on the physical and chemical habitats of organisms (microbial or otherwise) to the extent that the abilities of organisms to persist are tested. As a result, there is a general trend for decreasing biological diversity along the gradient of environments with ice and snow persistence (1). At the extreme end of the spectrum, where ice and snow persist at temperatures that are continually below 0 °C, prokaryotic microbiota are the primary life forms present (2,3), although spores and pollen of higher plants may persist (4).

Microbiota within ice and snow experience a heterogeneous microenvironment in which the transition of water between the liquid and solid phases determines the activity of liquid H_2O, the transport of life-sustaining solutes, and the transfer of radiant, thermal, and chemical energy. All of these processes critically influence the ability of microbes to remain viable, adjust their metabolic processes, and generate macromolecules and cells. How ice environments have been manifested during the evolution of Earth's climate and biosphere (5) and whether or not these environments have helped determine the evolution of life throughout Earth's dynamic ecosystems are highly speculative at this time (6,7). However, it is apparent that an array of microbes possesses the ability to survive freezing conditions, to grow, and form functioning microbial communities throughout a range of ice and snow environments. Noteworthy are the microbial communities in (*1*) temperate snow fields, (*2*) sea ice, (*3*) ponds and holes on glaciers, and (*4*) ice covers on lakes. These communities, nominally consisting of autotrophic primary producers and heterotrophic bacteria, function to provide the basis for new energy acquisition and internal material cycling that support ice-based ecosystems. Ice environments such as permafrost (4), the snow and ice in the polar ice caps (3), and accretion ice formed from lakes covered by the Antarctic ice cap (2,8,9) are still being investigated to determine if these environments support microbial aggregates to the extent that they can be considered ice communities/ecosystems or whether these ice and snow environments merely provide a cold refuge for cells capable of survival therein.

The major freshwater ice and snow microbial habitats are reviewed within this contribution to provide information regarding the physical and chemical attributes of ice and snow microenvironments that either allow or preclude microbial colonization, survival, growth, succession, and adaptation. That is, the environments reviewed within this article are those within (*1*) snow (including snowfields in temperate alpine regions and on polar ice caps), (*2*) glacial ice (including polar ice sheets and temperate glaciers), and (*3*) accretion ice on lakes. In many instances, the fundamental characteristics of the microhabitats may be similar, yet the formation processes, dynamics, and microbial populations therein can differ greatly. Sea ice and permafrost are the two additional extensive ice biomes, yet present knowledge regarding these environments as ecosystems warrants full and separate discourses that are presented in other contributions within this Encyclopedia (see sections on Permafrost and Sea Ice). Similarities and contrasts between the aforementioned ice environments and the attributes of the microbiota within ice and snow environments are discussed throughout this article.

SNOW

The availability, timing, and duration of liquid water are primary determinants of when and where microbial communities develop in snow and ice environments. Within snow fields in temperate regions, the development of microbial communities is determined primarily by the balance between seasonal warming and melting that allows liquid water to become available within the snow's ice matrices. A cool climate is required that allows snow fields to accumulate enough mass to allow sufficient time during the melting seasons for microbial excystment, microbial migration, and growth processes that are integral parts of the life histories

of snow microbiota. Because of the "race" between a snowbank's dissipation and biological growth and succession processes, not all snow fields are capable of developing productive communities of snow-ice microbes. Snowfields in high alpine environments or in areas with high winter precipitation are more likely to meet this "window" and develop dense blooms of microalgae. Snow banks that are transient or are only saturated with liquid water for a few days before they completely melt are not likely to provide a viable habitat for microalgal growth or microbial succession. On the other extreme, snowfields that continually remain below the freezing point of water do not generate measurable liquid contents, and luxuriant growth of both heterotrophic and autotrophic microbiota can be extremely inhibited (3).

Snow communities have been known since the time of Aristotle (10) and early work and reviews have emphasized the taxonomy and the physiology of snow microalgae (11–13). More recently, studies have advanced to include investigations of the relationships between algae, bacteria, protists, and metazoans in temperate snowfields to the extent that these environments are now being studied as distinct microbial ecosystems inhabiting transient snow environments (14,15).

Pink snow or red snow is often caused by *Chlamydomonas nivalis* and is perhaps the most commonly recognized of the snow algae. The red coloration is caused by the carotenoid pigmentation of aplanospores (nonmotile algal spores; 16). Although this life-stage of *C. nivalis* may be the most recognized and *C. nivalis* is the most studied of microbiota in temperate snowfields, it is by no means the only photoautotroph present in snow. Many additional species of green algae (Chlorophyta, e.g., *Chloromonas*, 17), diatoms (18), and Cyanobacteria (13,19) are also commonly found in temperate and polar snow environments, although diatoms are only reported on occasion (19). The life histories of the diatoms and Cyanobacteria that may be coupled to snow dynamics are relatively unknown compared to those of the Chlorophyte algae, namely, *Chlamydomonas* (20) and *Chloromonas* (17) species.

The life history of *Chlamydomonas* and *Chloromonas* in snow environments includes the processes of (*1*) deposition of spore or zygotes on the soil surface in the summer, (*2*) spore burial by cold-dry snow during the winter, (*3*) excystment when snow banks begin melting in the spring, (*4*) migration of the excysted flagellated stages up to the snow surface where mating may or may not occur (5), and (*5*) spore or zygote formation induced by environmental cues such as UV radiation or nitrogen deficiency (14,16).

The in situ production of reduced carbon compounds and growth of snow algae is supported by nutrients deposited with the snow as dissolved matter, atmospheric dust, and forest litter (21). The forest litter and atmospheric dust also provide energy for heterotrophic bacteria such that a microbial-based food web often develops during a snowbank's melting period consisting of heterotrophic flagellates, ciliates, fungi, tartigrades, and worms (10,21). The energy supporting the transient food web is derived from both allochthonous materials and that from resident photoautotrophs. Sattler and coworkers (85) have reported evidence of microbial growth within cloud droplets below 0 °C, which implies that the microbial cycling of materials in snowfields may actually begin before snow crystals are deposited.

Bacteria associated with snow algal blooms are often attached to the aplanopsores and algae, suggesting the microenvironments surrounding these cells are probable zones of enriched organic matter and nutrition (21). Similar biofilms with polysaccharide matrices may confer freezing protection (22,23) through the depression of the freezing temperature of water and the stabilization of macromolecules (proteins and lipids) during desiccation that is induced by freezing (23).

Microbial survival and production within permanently cold snow (i.e., less than 0 °C) such as that found at the South Pole or at extremely high altitudes do not have substantial periods when liquid water is available. Hence, snow algae are not typically present in such environments; rather, desiccant resistant strains of bacteria (e.g., *Deinoccous*, *Bacillus*) and fungi are more typically reported (2,3). Carpenter and coworkers (3) reported significant uptake of tritiated thymidine in South Pole snow at temperatures below −12 °C during a 24-hour incubation. If active in situ, these bacterial populations must rely on allochthonous input of reduced organic matter because photoautotrophic populations are virtually nonexistent (3).

GLACIAL ICE

Glaciers and ice sheets contain several distinct environments in which microbes can colonize, grow, and develop extensive communities (Fig. 1). The accumulation zones of glaciers and ice sheets are areas where the mass balance leads to the net accumulation ice mass due to precipitation in the form of snow. Air temperatures average below 0 °C and liquid water availability in the snow is limited to short seasonal melting periods or along ice crystal boundaries. The stratigraphy of the glaciers and polar ice sheets in accumulation zones consists of fresh snow, compacted snow or firn, glacial ice with visible air inclusions, and ice with no visible air inclusions. The thickness of the snow and firn layers is determined by the weight of the snow compressing the ice and melding the ice crystals through recrystallization processes. Below a depth of approximately 1,000 meters, the weight of the overlying ice provides sufficient pressure to convert the air in the bubbles into gas clathrates. Hence, ice below approximately 1,000 meters appears clear because gas clathrates have similar refractive indices as ice water. Because alpine glaciers are typically less than 1,000-m thick, they rarely contain clear ice formed from pressure recrystallization processes.

Liquid water available to support metabolism within the glacial ice of polar ice caps is held to be a primary constraint on microbial processes. With average and maximum air temperatures well below freezing point throughout the year in accumulation zones, bulk liquid water is not created through thermally induced melting processes. Rather, liquid water availability is more likely limited to microhabitats at snow crystal boundaries and

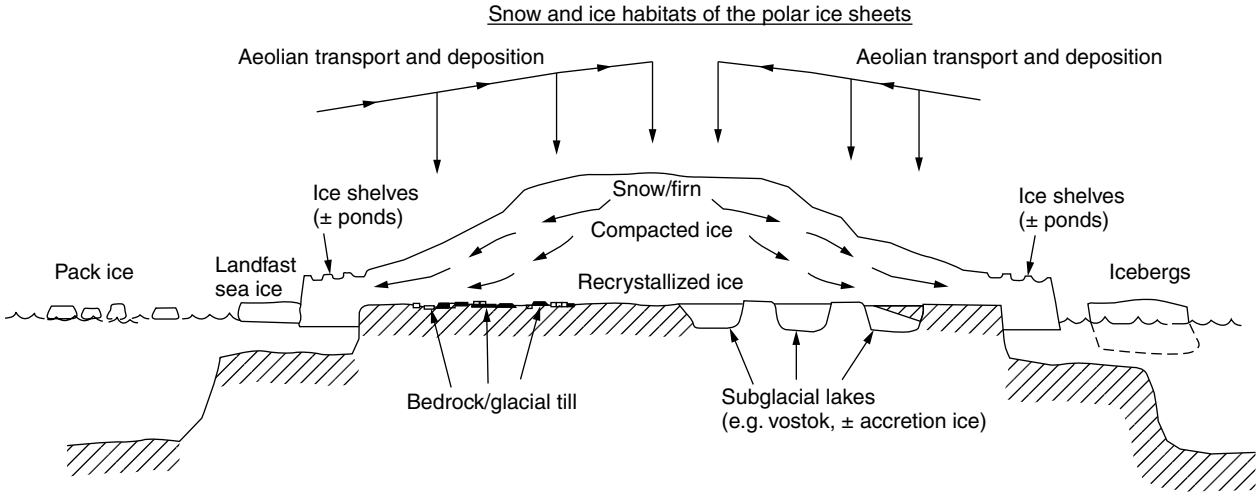

Figure 1. Schematic of snow and ice environments in Antarctic and Greenland ice caps. Arrows denote the movement of materials (ice/snow, particulates, etc.).

in microhabitats with high solute concentrations created through reprocessing of the ice habit (25). Trophic structures that would include primary (either photoautotrophic or chemoautotrophic), heterotrophic secondary production and material cycling within these ice sheets have yet to be demonstrated. Rather, studies thus far have indicated more of an abundance of heterotrophic microbes (spore-forming and non-spore-forming bacteria, and fungi), although at low concentrations ($>10^4$ cells ml^{-1}; 24) relative to concentrations (10^5 cells ml^{-1}) typically found in aquatic ecosystems. Because of the apparent lack of active autotrophs, metabolism of allochthonous materials deposited during the ice sheet accrual appears to be the primary source of energy for these systems (3,25). The extent to which in situ processing of these materials occurs remains to be determined.

Surveys of polar ice cores and snow indicate that desiccation-resistant strains of microbiota appear to be most prevalent in these environments. Specifically, gram-positive non-spore-forming bacteria, spore-forming bacteria, planctomycetes, fungi, and the radiation/desiccation resistant *Dineococcus* (3) are common among the microbes recovered from ice cores and polar snow. Christner and coworkers (24), in surveys of polar ice and temperate glacial ice (e.g., Taylor Dome of Antarctica, Guliya ice cap, Sajama ice), also found more cultivable bacteria in nonpolar ice cores and implied that the distance to source materials was a primary factor controlling the abundance of biota in these settings. Taken a step further, their work further implies that the production of cells in ice sheets is not substantial, relative to the mass of cells initially colonizing these ice habitats; rather, cell abundance is more a function of transport and deposition processes. Diatom frustules, unicellular algae, and dust are also found within the Antarctic ice cap, and bacterial cell have been higher in sections of ice with dust (2). Higher bacterial numbers associated with dust particles implies either increased deposition of microbes along with the dust or microbial proliferation in the microenvironment associated with the dust. Existing information on cell identities and abundances alone does not provide evidence that the accumulation zones of polar ice sheets provides an environment whereby in situ growth or cell proliferation occurs. The observations that microbiota can be recovered from glacial ice aged more than 10,000 years and that measurable metabolic activity is rapid implies that in situ basal metabolic activity should be occurring to preserve viability against lethal processes such as cold denaturation of proteins, amino acid racemization, and radiation-induced destruction of macromolecules.

The ablation zones of glaciers and ice sheets are the zones where sublimation, evaporation, and direct liquid water runoff lead to the net loss of ice mass. The surfaces of glaciers and ice sheets in these zones are often riddled with pockets of sedimentary material and organic matter that have melted and formed cylindrical holes in the ice surface (26–28). Such cryoconites holes, once started, enhance the localized collection of particulate materials, which creates positive-feedback processes, leading to further augmentation of the deepening and widening of the cryoconite holes. However, the opacity of the surrounding glacial ice (which attenuates radiation penetration into these holes), in conjunction with the seasonal freezing of the melt water and surface sublimation, provides a negative feedback that prevents cryoconite holes from deepening much beyond a half of a meter in depth (29,30). Bulk liquid water becomes available in cryoconite holes during the summer melting periods and allows these cryoconite microenvironments to support biota including diatoms (31), desmids (29), Cyanobacteria (29), bacteria (31), protists, and metazoans such as tartigrades (32). Although it is now known that cryoconites support microbial populations, relatively little is known about the structure and dynamics of the bacteria therein. The primary emphasis of studies thus far has been on the physical properties of the habitat (30,33,34) and the identities of the resident photoautotrophs and protists (31,32). Studies having a bacteriological emphasis on these cryo environments seem highly warranted.

Bedrock, mud, or subglacial lakes lie below the glacial ice of major ice caps or glaciers. The extent of the subglacial liquid water throughout the polar regions is still being explored. However, several subglacial lakes lying beneath the Antarctic ice cap have been detected (35). Studies on the origin and dynamics of these lakes are in their infancy because they were only discovered in the past decade. One of the largest of these lakes, Lake Vostok, lies beneath 3,700 meters of ice in East Antarctica. The overlying ice on this lake contains snow and glacial ice and accretion ice that formed from freezing of lake water onto the base of the overlying glacial ice (36). Both the glacial ice and the accretion ice in the Vostok ice core contain heterotrophic microbial cells (2,37,38). The cells in the accretion ice, however, are most likely to have originated from the subglacial lake rather than via direct deposition in the overlying snow and subsequent burial, which is the presumed source of the materials and cells in the glacial ice (24). Algae or protists have not been recovered from either ice type.

Extensive floating and grounded ice shelves form where glacial ice sheets float over the coastal ocean along continental or island margins (Fig. 1). The major ice shelves of the Antarctic are the Filschner-Ronne, which flows into the Weddell sea, and the Ross ice shelf, which flows into the Ross sea although lesser ice shelves (e.g., Amery, Larsson, etc.) are found throughout the coastal margin. In a few coastal areas of the Antarctic (most notably McMurdo Sound near Ross Island), coastal ice shelves exist in a climate in which the average summer air temperatures in conjunction with sediment laden glacial ice allow the formation of surface melt features (ponds and cryoconites). Glacially derived ice shelves are also present along the margins of Greenland and northern islands in the Arctic (39). Lesser Arctic ice shelves are also found in regions surrounding northern islands (e.g., Ellsmer and Ward Hunt) that have formed by the formation and persistence of land-fast sea ice that may reach thicknesses exceeding 5 to 10 meters (e.g., the Ward Hunt ice shelf) (39,40). The origin and dynamics of these ice shelves differ from those derived from glacial ice such that sea ice accretes on the bottom of the ice shelf whereas the upper surface experiences ablation and evaporative losses. In this regard these sea ice derived-ice shelves are similar to perennial ice covers on polar lakes (see following text), whereby an "ice-conveyor" is created by adding "new" ice on the bottom and ablating "old" ice from the upper surface.

The surfaces of ablating Arctic and Antarctic ice shelves appear similar, both having undulating surfaces consisting of ridges and troughs running approximately parallel (39,40). Within the troughs, extensive ponds and streams form that undergo annual melting and freezing. It is within these annual melt features that viable, productive, and extensive microbial systems are found (40–42). Ice shelf microbial ecosystems have been studied most extensively in the McMurdo Sound region of Antarctica, yet recent studies in the Arctic indicate the microbiota are similar in that they too are primarily composed of mat-forming Cyanobacterial consortia. Ice shelf mat-forming microbial consortia are most often dominated by filamentous Cyanobacteria (Oscillatoriales and Nostocales) that form the cohesive macroscopic structure that also harbors viruses, bacteria, diatoms, and protists (41,43). Microbial mats on ice shelves may develop distinct vertical zones with changes in pigmentation and biota induced by strong vertical gradients in radiant energy and oxidation-reduction potentials (43,44). Although these mats may become vertically deliminated, the continual movement and freeze-thaw cycles of the ice environment probably precludes the layering to the extent of those on the benthos of ice-covered lakes that have been termed modern-stromatolites (45). Although anaerobic sediments can develop below Cyanobacterial mats in the Antarctic ice shelves and sulfate reduction and methanogenesis has been demonstrated (46), the uniqueness of these ice-anerobic environments that are caused by ice movement and freezing and thawing are not understood at this time. Most probably annual disruptions of the chemical and physical gradients often necessary to develop layered microbial communities have large effects on the microbial dynamics within the distinct zones of sulfate oxidation/reduction, nitrate oxidation/reduction, carbon dioxide oxidation/reduction typical of mats, and associated anaerobic sediments.

ICE COVERS ON LAKES

Sea ice supports active microbial communities and their composition, productivity, dynamics, and role in polar ecosystems have been studied in the Arctic (47) and Antarctic oceans for many decades (48–51). During the 1990s, researchers have also realized that ice covers on freshwater lakes around the world also support active microbial communities/consortia (52–54). Specifically, it is now known that perennial ice covers on Antarctic lakes and seasonal ice covers on high mountain lakes contain active microbial communities that produce and cycle materials within the interior of the ice matrices.

A common feature of lake ice covers that develop and support microbial communities is the presence of substantial liquid water (>10% by volume) within the ice interior — either transiently or during prolonged summer melting. The same can be said of sea ice, yet a liquid water environment on the order of 5% by volume is maintained throughout the year within sea ice in brine pockets (55). Freshwater ice covers are unlike sea ice in that they do not contain enough dissolved salts to create brine pockets and channel networks that would provide a substantial volume of liquid water within the ice sheet year-round. Rather, liquid water within freshwater ice covers is present as films of water along ice crystal or particle boundaries when temperatures are below 0 °C or in bulk quantities in association with melting or dynamic flooding processes.

Flooding and infiltration of liquid water within the snow cover occurs when the weight of the snow cover depresses the surface of the ice below the hydrostatic water level and is the primary mechanism creating a liquid water environment in the ice covers on high mountain lakes. When flooding occurs during colder winter months, the layer of flooded snow can refreeze (or at least partially refreeze), which creates a layered structure to the ice

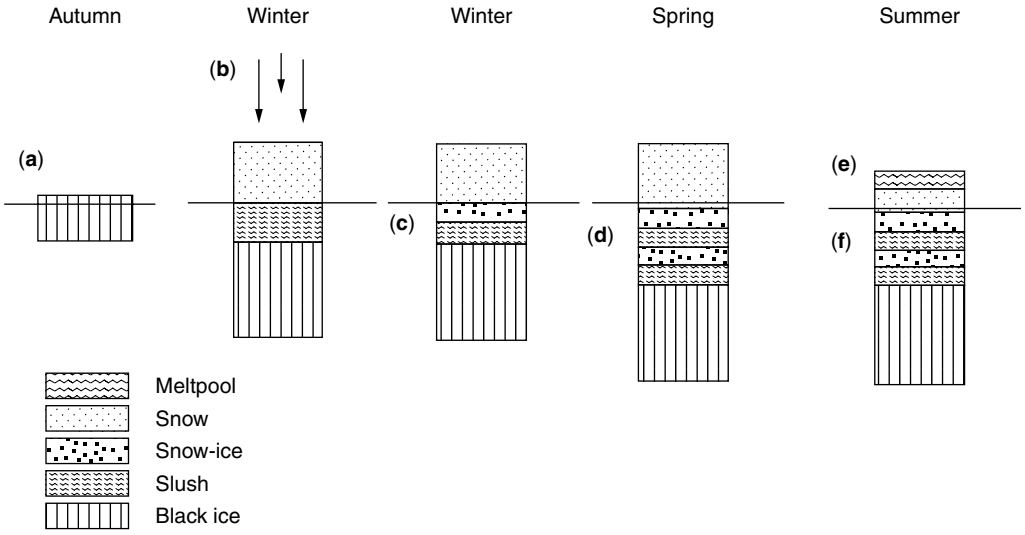

Figure 2. Dynamics of temperate ice covers. (**a**) Black ice forms from freezing the lake water during the autumn. (**b**) Snowfall and accumulation on black ice. When the accumulating snow cannot be supported by the buoyancy force of the black ice, the surface of the consolidated ice is depressed below the surface of the lake and the ice floods with lake water, creating slush (lake water mixed with snow crystals). (**c**) During winter the slush may entirely or partially refreeze, thus creating a layered ice stratigraphy with liquid water between consolidated snow ice and black ice layers. (**d**) Through multiple flood and freeze cycles high mountain lake ice covers can generate several layers of slush and consolidated ice. In these slush layers, bacterial activity and growth occurs through the winter (58). (**e**) Meltponds form during the summer melting. (**f**) Slush layers remain during melting phase. Both the meltponds and the slush layers in the spring and summer are "hotspots" for bacterial production and protist activity that is linked to new growth of photoautotrophs (54).

cover consisting of dry snow, consolidated ice, slush (snow crystals plus lake water) and consolidated ice (Fig. 2). Growth of microbiota and succession stages consisting of autotrophic algae, bacteria, heterotrophic flagellates, and ciliates have been documented within slush layers in ice covers in the Austrian Alps and the Pyrenees Mountains of Spain (53,54). The slush habitats created through flooding and the subsequent growth and succession in these lakes is not unlike the processes that create near-surface habitats in sea ice in the Antarctic pack ice (50,52,56,57). Similar microbial successions are likely to occur in high mountain lakés throughout the world, yet documentation of their distribution is limited.

Snow algae (*Chlamydomonas* sp.) inhabit surface melt pools (Fig. 2) that develop late in the melt cycle of high mountain lake's ice covers (53). Within the ice cover's layered structure, autotrophic species can be similar to those in the underlying water column, yet in some years the slush layers develop distinct autotrophic community compositions (53,54). Bacterial populations within the ice covers have been shown to be distinct from those in the under ice water column when comparing the relative percentages of α-, β- and γ-subclasses in these environments (58). The activity of bacteria in slush habitats covers the range from that of oligotrophic to eutrophic production rates (53) and are probably responsible for observed nitrate and nitrite chemistries indicative of denitrification (59,60). The growth and succession and release of microbes in the melting ice covers affect the lake's water column dynamics in a manner similar to that proposed for marginal ice edge zones within the Arctic and the Antarctic (61).

Liquid water habitats are generated through surface and internal melting during the austral summer within several perennial ice covers on freshwater lakes in the Antarctic (Fig. 3; 62). Local microscale (micrometers to meters) melting is facilitated by the absorption of solar radiation by dark material (sediments, pigmented algae, organic matter) during the periods when the ice covers warm to 0 °C and remain isothermal (Fig. 3; 62). Because there is no temperature gradient in the ice covers during summer, the absorbed radiant energy is not conducted away from the place where it is absorbed. Hence, local melting ensues and creates pockets of liquid water that facilitate the accumulation of particles and creates aggregates of materials that melt and migrate downward through the ice covers (63). Several lakes in the McMurdo Dry Valleys of the Antarctic (e.g., Hoare, Fryxell, Miers, Bonney, Vida) have the sediment accumulations at 0.5 to 3 meters depth (63,64) and it is within these sediment-aggregates that microbial communities, nominally consisting of Cyanobacteria and heterotrophic bacteria, have been found to persist and grow (52,64).

Microbial communities in perennial Antarctic ice covers contain microbiota similar to those found in surrounding terrestrial environments (65). Cyanobacteria of the genus *Phormidium, Nostoc* and *Leptolyngbya* are common within the mats or flakes of matlike aggregates in these ice covers (52,64,65). Similar Cyanobacteria dominants are

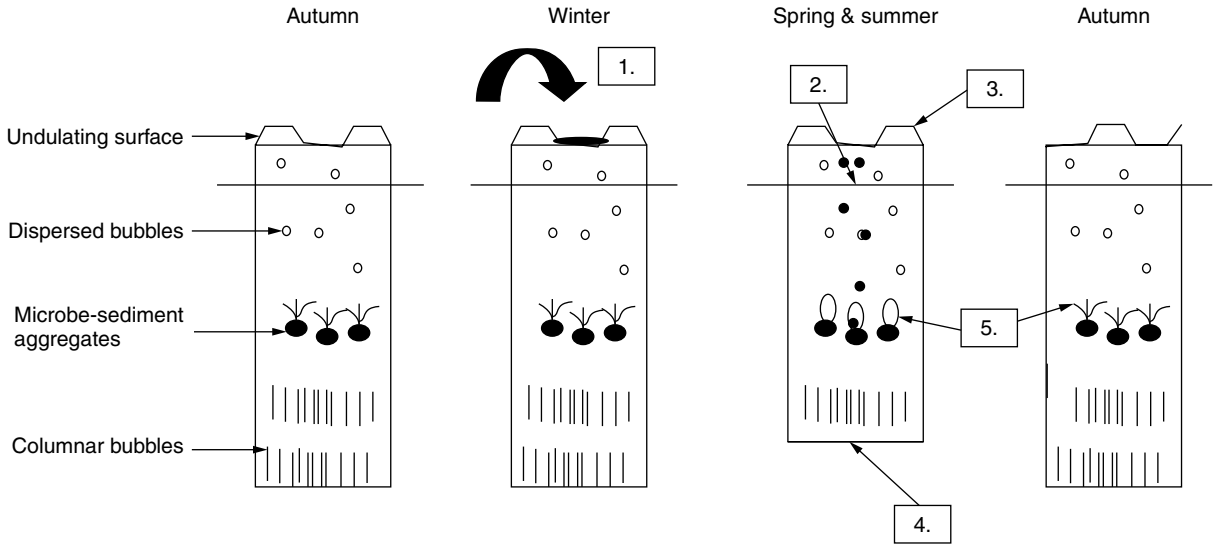

Figure 3. Dynamics of temperate perennial ice covers. Microbe sediment aggregates are located within the ice covers interior in a frozen state during the autumn. 1. Sediment and microbial aeolian deposition on the ice surface — primarily during winter storm events, basal freezing occurs during this time as well. 2. Surface deposited sediments migrate downward during spring and summer because of absorption of solar radiation and localized melting. 3. Sublimation of ice evaporation of meltwater from the upper surface. 4. Basal melting reduces thickness of ice cover during summer. 5. Cyanobacterial consortia in sediment aggregates exposed to liquid water grow during summer (64), additional migrating materials collect onto aggregates during this time as well. During autumn and winter these habitats refreeze, producing arched bubbles indicative of remnant water pockets (63).

found in the soils (65), streams (66,67), glaciers (29), and benthic mats in the lakes (68). The genera of Cyanobacteria in ice or the aforementioned habitats are not typical dominants of phytoplankton in lakes. Rather the lake's phytoplankton are more typically composed of autotrophic eukaryotic algae, although populations of Oscillatorian Cyanobacteria have been found in the plankton of some Dry Valley lakes (69). Bacterial 16S rRNA recovered from the ice-sediment aggregates included clusters grouping with the *Planctomycetales*, *Roseococcus*, and *Rhodoferax* species.

Oligonucleotide probe hybridization assays indicate that these sequences are also found in the McMurdo Dry Valley soils (65). Bud-forming bacteria (e.g., *Planctomycetales*) are common members of soil environments, and their presence in the ice-sediment environment may suggest that this habitat is most readily colonized by terrestrial microbiota rather than truly aquatic forms.

Bacterial and algal cells present below the sediment layers in perennial ice covers have been shown to be active in ice meltwater. These cells are present at relatively low concentrations (bacteria, 2-9e 11 cells m^{-3}) compared with concentrations in association with sediment aggregates (bacteria, 2e12 to 3e13 cells m^{-3}). The composition of these bacterial and algal populations has not been determined via molecular techniques or compared with the sediment aggregates or the water column biota. However, it is probable that they are derived solely from the water column because the sediment aggregates reside above this ice, and the ice structure is not indicative of any ice-sediment interactions that would be evident as melt features (63). Because these microbial cells are active and most probably move upward with the ice on an annual basis they encounter the sediment aggregate zones. When these water column derived biota mix with the sediment-aggregate communities it is unknown if they grow, survive, and contribute to the cycling of material in this new environment. The similarities between the 16S rRNA in the sediment aggregates and those within the terrestrial habitats and the dominant algae comprising mat-forming algae suggest that the terrestrial biota dominate within these perennial ice environments, and the water column derived microbiota are either outcompeted by the terrestrial microbiota in this solid-liquid environment or supplied at a much lower flux than the flux of biota from terrestrial habitats. The distinction between these two possibilities is not known at this time, and it is probable that the community structure in these habitats is determined by a balance of these two processes.

A diverse assemblage of diazatrophs, detected via recovery, amplification, and sequencing of *nifH*, resides within the sediment aggregates in the perennial ice (70), and low rates of N-fixation have been demonstrated (71,72). Hence, diazatrophic bacteria and Cyanobacteria may help these communities meet a portion of their annual nutrient demands, although the flux of nutrients via the flux of new ice from below supplies some nutrients as well. However, the autotrophic growth rates and production compared to the supply of nutrients from the flux of ice meltwater and diazatrophy are not likely to maintain new production by photoautotrophs throughout the year (64). Hence,

the ratio of new production to that based on recycled materials is likely to be low, and net biomass accumulation within the microbial community is also likely to be slow. Because these habitats are extremely heterogeneous over small scales (10- to 1,000-fold variations in sediment concentrations over 1–20 centimeters), relative to the instruments used to sample them (typically 7-cm diameter SIPRE core barrels), and biomass accumulation is slow, it will be difficult to document seasonal or annual changes in biomass within these environments. New techniques for monitoring microscale (<1 centimeter) changes in biomass within ice are perhaps ways of monitoring such processes. Viewing of microscale environments within sea ice has been accomplished on samples brought back into cold rooms using standard brightfield, phase, and epifluorescence microscopy (73). Yet, the application of microscale imaging has yet to be accomplished in situ. New probes being developed for surveying ice environments down boreholes (74) offer the potential for in situ microbiota detection and monitoring.

ECOPHYSIOLOGY OF ICE AND SNOW ENVIRONMENTS

The apparent dominance of microbes from glacial and ice sheet habitats desiccation-tolerant (see discussion in the preceding text) suggests these phenotypes confer a capacity for survival in the frozen condition and proliferation in ice. However, because aeolian deposition is the primary transport process into glaciers and ice sheets, it follows that the organisms surviving the dehydration process associated with aerosol transport are most likely to be the ones that are recovered from these ice environments regardless of their ability to survive once in ice. Hence, atmospheric transport may serve as a physiological barrier to colonization of glaciers and ice sheets.

Once in ice sheets, the ability of organisms to tolerate removal of water from cells and rewetting is likely to be a trait that predisposes the organisms to survive the rigors of a snow or ice environment in which freezing of liquid water leads to the concentration of extracellular solutes and lowering of extracellular water activity. The production of compatible solutes as osmoprotectants under such conditions also offers cryoprotection during freeze thawing (23,75). Hence, the snow and ice environments in which freezing of water is a prominent process (as opposed to melting) are likely to promote the preferential growth of desiccation-tolerant microbiota. These environments include the glacial ice of glaciers and polar ice caps, cryoconite holes, the perennial ice covers of lakes, and snowfields that experience freeze-thaw cycles. The slush habitats of ice covers on alpine lakes and the snowfields experiencing the melting process are environments that would not be expected to impose a requirement for surviving desiccation or freeze-thaw cycles. Specifically, these environments can be colonized by biota that may never experience a freezing environment. Interestingly, these environments are those that contain an abundance of eukaryotic algae, protists, and metazoa with life stages that are not generally considered to be desiccation-resistant or desiccation-tolerant. Many of the microhabitats in sea ice (e.g., the ice water interface, summer slush habitats; 56,57) are also examples of ice and snow environments in which freeze-thaw resistance may not be critical for colonization and proliferation.

Besides the production of compatible solutes, which leads to desiccation and protection against intercellular ice crystal formation (23), microbes are known to possess the ability to synthesize macromolecules affecting the ice crystal habit (76). Such molecules, broadly defined as Ice Active Substances (IASs) may nucleate ice crystal growth, depress the freezing point of water, or inhibit crystal growth or recrystallization. All of these actions may act as cryoprotection because they directly or indirectly deter the intercellular ice crystal formation that leads to mechanical loss of membrane potential and cellular mortality.

Knowledge regarding IASs comes primarily from studies on cultured microbes or microbial consortia in association with agriculture. IAS production by microbes within the ice and snow environments discussed in this review are highly limited. IASs have been detected in association with photosynthetic freshwater and terrestrial consortia in habitats experiencing partial freezing and partial dehydration (77). Interestingly, IASs have not yet been detected within the major freshwater ice or snow ice habitats, yet they have been found in bacterial isolates from polar aquatic environments (78).

Besides having to cope with changes in water between solid and liquid form, snow and ice communities continually experience temperatures of 0 °C or below. In accordance with evolutionary dogma, such environments may be expected to contain psychrophilic microbes. Surprisingly, many of the ice and snow environments reviewed herein lack the characteristics of psychrophilic microbiota (43,79). Notably, the dominance of Cyanobacteria exhibiting slow maximum growth rates and optimum growth rates above 15 °C in the Antarctic's perennial ice covers (64), cryconites, streams, and ice shelf ecosystems (43) suggest that other environmental parameters besides low temperatures provide the selection criteria for survival within these environments. Furthermore, the residence time of biota in these continually cold environments may not be of a sufficient time relative to mutation and growth rates for selective processes to be effective in producing microbes optimally adapted to low temperatures.

Environments containing communities of biota that are not specifically adapted for growth and persistence therein have been called "absolute extreme environments" (E. I. Friedmann) to delineate them from environments that may seem extreme from an anthropocentric point-of-view and yet are occupied by microbiota that are extremely well adapted to live therein. The perennial ice environments, ice shelves, glaciers, and the polar ice caps may indeed be absolute extreme environments whereby the proliferation of microbes occurs and yet may be approaching the limits to which life can persist and function.

CONCLUSION

It would be remiss not to mention that the studies of these extreme environments (absolute and not-so-absolute) and

the abilities of microbiota to survive, grow, and form microbial consortia capable of synergistic survival and growth have direct and indirect implications on assessing the possibility of microbial growth and survival in space and on other planets. Most pertinent to the studies of ice and snow environments on Earth as extraterrestrial analogs are the potential microbial habitats on the surface of Mars that are thought to have existed over 3.5 billion years ago (80), the polar ice caps of Mars of the present (81), and the *contemporaneous* ice habitats existing on Europa (82–84). In our present-day search for habitats on other worlds, we are indeed learning about the distribution and characteristics of life in the snow and ice environments on Earth. It is hoped that we will understand these cold environments on Earth to the extent necessary to define their role in the origin and evolution of life on Earth and their responses to changes in global environments in the past and in the future.

SOIL ARCHAEA.

See ARCHAEA IN SOIL HABITATS

SOIL BACTERIA

DAVID B. ALEXANDER
University of Portland
Portland, Oregon

Bacteria are small, predominantly single-celled, prokaryotic microbes that inhabit soils throughout the world (Fig. 1). Population sizes vary with nutrient availability, temperature, aeration, and other abiotic and biotic factors, but bacteria are generally the most numerous of all soil microbes, often attaining populations of 10^8 to 10^9 colony-forming units (CFU) per gram of soil (1). Microbial growth in soils is usually limited by the availability of organic carbon, so bacterial populations are typically highest in the organic-rich surface layers of soils and in the immediate vicinity of plant roots (a distinctive habitat known as the rhizosphere). Most species grow optimally at moderate temperatures and neutral pH, but collectively, bacteria tolerate a greater range of environmental conditions than any other group of soil microbes. Bacteria also metabolize a greater variety of organic and inorganic substrates than any other group of soil organisms. Through their diverse metabolic activities, bacteria play crucial roles in soil formation, organic matter decomposition, remediation of contaminated soils, biological transformations of mineral nutrients, mutualistic interactions with plants, animals, and other soil microbes, municipal waste treatment, and plant and animal diseases.

BACTERIAL CELL STRUCTURE AND FUNCTION

Phylogenetic schemes based on 16S ribosomal RNA (rRNA) sequences distinguish three major domains of life — Bacteria, Archaea, and Eucarya (2,3). Bacteria and Archaea are single-celled prokaryotic microbes, whereas the domain Eucarya includes single-celled and multicellular organisms with a eukaryotic cell structure. Although Bacteria and Archaea resemble one another

morphologically, they differ significantly in biochemical composition and in certain aspects of their physiology and genetics.

Prokaryotic cells are distinguished by their small size and simple intracellular organization. Most bacterial cells range from 0.2 to 2 μm in diameter and from 1 to 10 μm in length. The small size of bacterial cells enables these microbes to grow and adapt to changing environmental conditions much more rapidly than larger, more complex eukaryotic organisms (Fig. 2). Small cells have a relatively large surface-to-volume ratio, which enables bacteria to rapidly absorb and distribute nutrients throughout the cytoplasm, while minimizing the amount of cellular material that they must synthesize.

Bacterial cells are composed of cytoplasm enclosed within a cell envelope, which, in most species, includes a rigid cell wall (Fig. 3). Many species produce surface appendages that function in movement or attachment to surfaces, and some form characteristic intracellular structures that serve to store nutrients or enhance survival under adverse conditions. The nuclear material of the cell consists of a single DNA molecule (and associated proteins), which is not separated from the cytoplasm by a nuclear envelope.

Cell Envelope

The envelope of a bacterial cell consists of one to three layers — the cytoplasmic membrane, cell wall, and outer membrane. The cytoplasmic membrane is the innermost layer of the cell envelope and is present in all bacteria. In most species, the cytoplasmic membrane is enclosed by a cell wall composed of a rigid, meshlike polymer known as *murein* or *peptidoglycan*. Many soil bacteria have an additional membrane, known as the outer membrane, which lies outside the cell wall. Microbiologists often refer to the combination of the peptidoglycan layer and the outer membrane as the cell wall of these bacteria.

Four groups of bacteria are distinguished by the composition and complexity of the cell envelope (Fig. 4):

- Gram-positive bacteria have a thick cell wall and no outer membrane
- Gram-negative bacteria have a thin cell wall surrounded by an outer membrane composed of phospholipids and lipopolysaccharide
- Acid-fast bacteria have a thin cell wall surrounded by an outer membrane composed of long-chain fatty acids known as *mycolic acids* (4)
- Mycoplasmas have no cell wall or outer membrane

Gram-negative and gram-positive bacteria are the most common types of bacteria in most soil habitats. Only two genera of bacteria, *Mycobacterium* and *Nocardia*, are known to have an acid-fast envelope (5). *Mycobacterium* and *Nocardia* are present in many soils, and several species are pathogenic to animals or humans. Both groups are classified with the actinomycetes, a distinctive group of soil bacteria that are discussed in more detail later in this chapter. Mycoplasmas occur strictly as plant, animal, or human parasites.

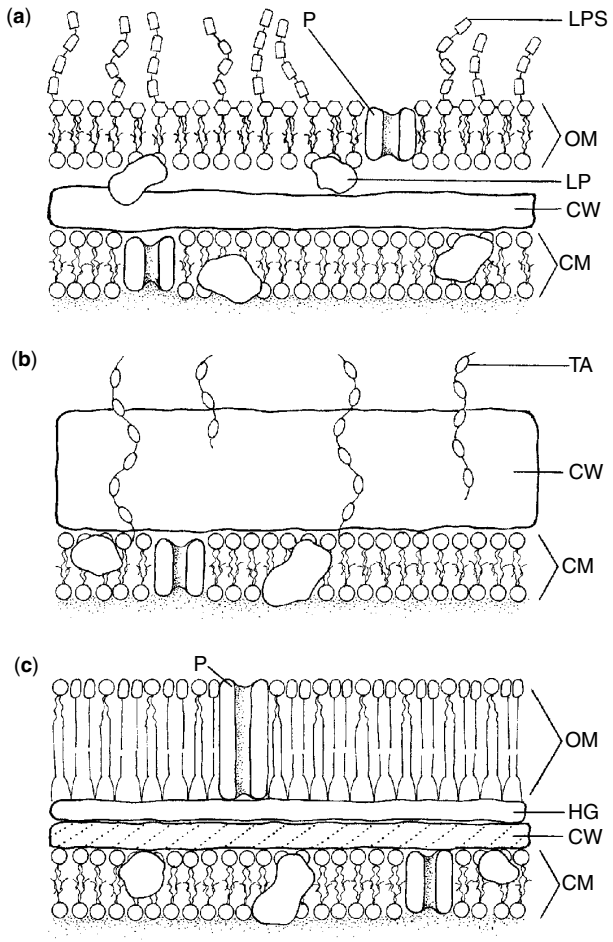

Figure 4. Structure of (**a**) gram-negative, (**b**) gram-positive, and (**c**) acid-fast bacterial cell envelopes. Cell Wall. The cell wall is the most distinctive structure of bacterial cells. Virtually all bacteria are enclosed by a wall composed of peptidoglycan, a polymer that is not found in any other type of organism. Peptidoglycan consists of long strands of alternating amino sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid, with tetrapeptide side chains covalently linked to each *N*-acetylmuramic acid residue. The side chains in adjacent strands are cross-linked by short peptide chains, forming a strong, meshlike framework that encloses the cell.

The thick cell walls of gram-positive bacteria are composed of multiple layers of peptidoglycan. Gram-positive cell walls also contain teichoic acids (anionic polysaccharides composed of repeating subunits of glycerol phosphate, ribitol phosphate, or glucosyl phosphate) and lipoteichoic acids, which extend outward from the cell surface into the surrounding medium. The functions of teichoic acids and lipoteichoic acids are uncertain, but they may serve as recognition and binding sites in gram-positive bacteria and provide a negatively charged cell surface for binding cationic nutrients (6,7).

The thin cell walls of gram-negative bacteria consist of fewer layers of peptidoglycan, in some cases only a single layer, and they do not contain teichoic acids. With fewer layers of peptidoglycan and less extensive cross-linkage than typically occurs in gram-positive walls, gram-negative cell walls are generally more flexible than gram-positive cell walls.

In both gram-positive and gram-negative bacteria, the primary functions of the cell wall are to protect the cell from osmotic lysis and to determine the shape of the cell (8). The solute concentration in the cytoplasm of a bacterial cell is usually much higher than the solute concentration outside the cell. As a result, water diffuses into the cells, generating internal pressure (turgor) that would cause the cells to burst if they were not enclosed by a rigid wall. Gram-negative cells can withstand turgor pressures of up to 0.3 MPa, and gram-positive cells can withstand pressures 5 to 10 times higher (9,10).

The shape and arrangement of cells are important morphological characteristics of soil bacteria. Bacterial cells exhibit a wide variety of shapes (Fig. 5), but the shapes most commonly observed among soil bacteria are rod-shaped cells, called *rods* or *bacilli* (singular, bacillus); spherical cells, called *cocci* (singular, coccus); spiral-shaped cells, called *spirilla* (singular, spirillum); and long, branching filamentous forms, called *actinomycetes*. Some species are intermediate in shape. The more common among these are short rods, called *coccobacilli*, and short, comma-shaped spirilla, called *vibrios*.

In some species of bacteria, particularly among the cocci, individual cells often do not separate after undergoing cell division. Instead, the cells remain attached in characteristic arrangements. Cocci that divide longitudinally form chains of cells called *streptococci* (singular, streptococcus). Those that divide randomly form irregular clusters of cells called *staphylococci* (singular, staphylococcus). A few species of cocci form planar packets of four cells or cuboidal packets of eight or more cells. Rods that remain attached end-to-end following cell division form chains of cells called *streptobacilli* (singular, streptobacillus), whereas those that align side-by-side, rather than end-to-end, form an arrangement called *palisade*.

Outer Membrane. The outer membrane of gram-negative bacteria is a bilayer composed of two different types of lipid molecules. The outer layer is composed primarily of lipopolysaccharide (LPS), interspersed with phospholipid, whereas the inner layer is composed almost entirely of phospholipid. The polysaccharide portion of the LPS extends outward from the surface of the cell and is highly anionic at neutral pH. The negatively charged surface of gram-negative cells interacts strongly with cations in the surrounding solution and may facilitate the development of soil minerals (11). LPS may also play an important role in the colonization of plant roots by gram-negative bacteria (12), and the lipid portion of the polymer is toxic to animals and humans when gram-negative pathogens are attacked by host cells (13).

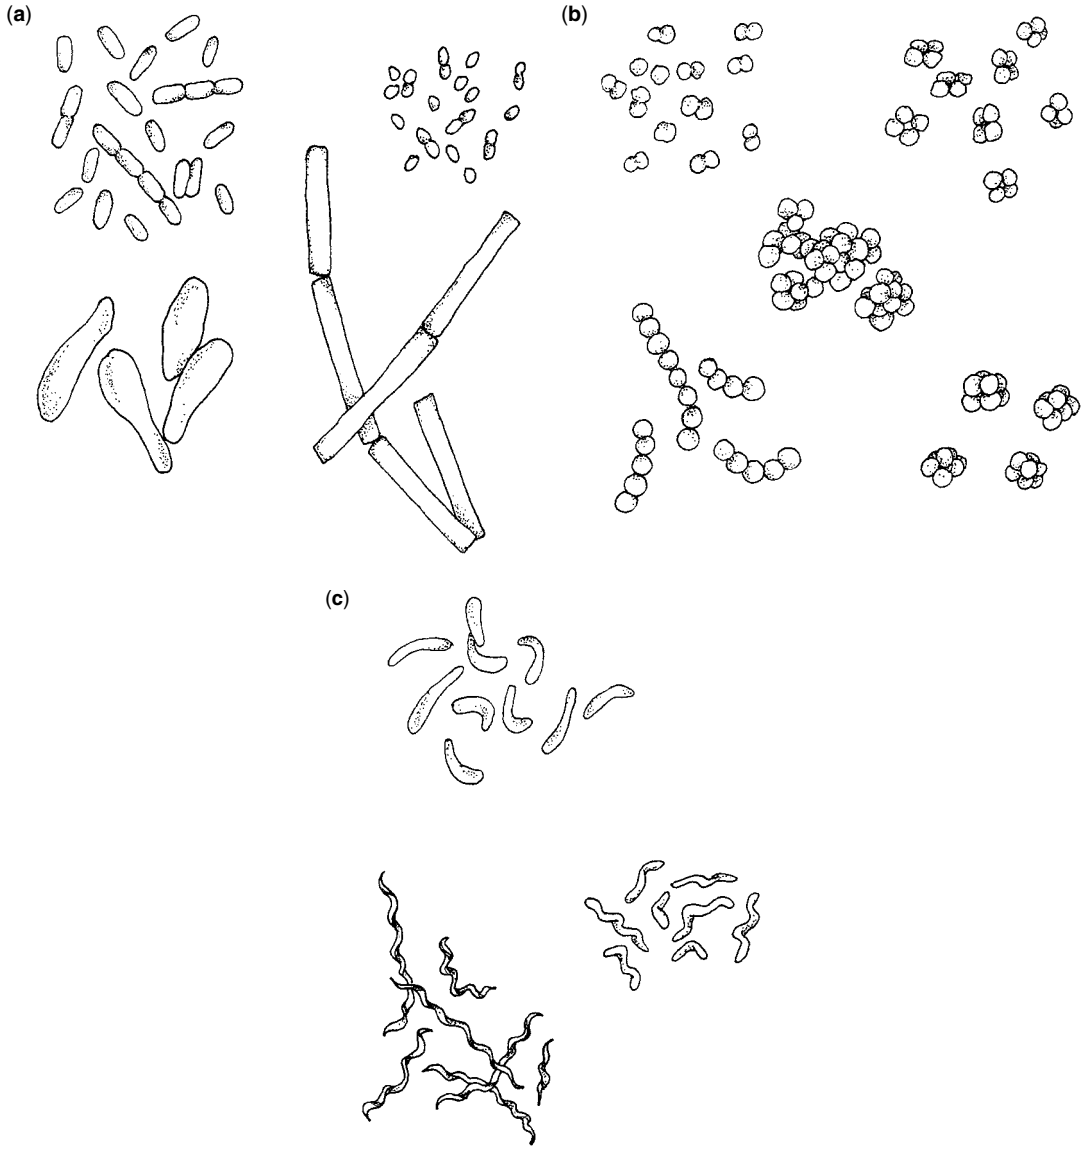

Figure 5. Common morphologies of soil bacteria. (**a**) bacilli, occurring as single rods, coccobacilli (short rods), pleomorphic (irregularly shaped) rods, and streptobacilli (chains); (**b**) cocci, occurring as diplococci (pairs), streptococci (chains), staphylococci (irregular clusters), tetrads, and sarcina (cuboidal packets); (**c**) spirilla, vibrios (comma-shaped), and spirochetes (corkscrew shaped). *Source:* Original drawing by Kim Luoma. Used with permission.

The outer membrane also contains numerous protein channels, called *porins*, which allow water and small dissolved molecules and ions to pass through the outer membrane and the porous cell wall to the cytoplasmic membrane. Larger molecules cannot pass through the porin channels and, therefore, gram-negative bacteria tend to be more resistant than gram-positive bacteria to toxic substances in the environment. Lipoproteins covalently link the outer membrane to the cell wall.

Cytoplasmic Membrane. The cytoplasmic membrane is a phospholipid bilayer studded with numerous *transmembrane* and *peripheral* proteins. Transmembrane proteins extend through the lipid bilayer and have distinct domains on either side of the membrane. Peripheral proteins attach to the inner or outer surface of the membrane by associating with the membrane lipids or by binding to the internal or external domains of the transmembrane proteins.

The phospholipid bilayer forms an effective barrier between the interior of the cell and the external environment. Only water and a few small, nonpolar molecules, such as O_2, CO_2, and N_2, can diffuse directly through this portion of the membrane. The movement of other substances into or out of the cell is mediated by transport proteins in the membrane. Some of these proteins, known as *permeases*, transport substances passively (without expending metabolic energy) in response to energetically favorable electrochemical gradients. Other proteins actively transport substances across the membrane by coupling transport with the hydrolysis of ATP (ATPases)

or by coupling the movement of one substance down an electrochemical gradient with the movement of another substance against an electrochemical gradient (cotransporters).

Electron transport proteins and quinones in the cytoplasmic membrane catalyze oxidative phosphorylation, the final stage of respiration during which bacteria synthesize most of the ATP required for growth and generate the proton (H^+) gradient, which provides energy for the uptake of many essential nutrients. Similar proteins and lipids in the membranes of photosynthetic bacteria catalyze photophosphorylation, the light-activated process by which these bacteria synthesize the ATP and reduced coenzymes needed to assimilate carbon dioxide into carbohydrates.

Sensor proteins in the cytoplasmic membrane play a key role in two-component regulatory systems, which enable bacteria to respond rapidly to changing conditions in their environment (14). When activated by changes in temperature, pH, or reduction potential, binding of external signal molecules, or other environmental stimuli, sensor proteins activate regulatory proteins in the cytoplasm (the second component of the two-component system), which control a variety of cellular activities including cellular movement, metabolism, osmoregulation, transport, competence (the ability to take up DNA from solution and become genetically transformed), and sporulation (15).

Periplasm. The portion of a gram-negative cell that lies between the cytoplasmic membrane and the outer membrane is known as the periplasm. This unique compartment, which is present only in gram-negative bacteria, contains many proteins that perform essential functions for the cell (16). Included among these are hydrolytic enzymes, which catalyze the initial steps in catabolism; detoxifying enzymes, binding proteins that facilitate the movement of substances from porin channels to specific transporters in the cytoplasmic membrane; and some enzymes involved in peptidoglycan synthesis.

Capsules. Many soil bacteria secrete polysaccharides or glycoproteins that form a distinct layer covering the surface of the cell (17). The consistency of this material varies from a thin slime layer to a thick, gelatinous capsule, depending on the species of bacteria and the type and availability of organic nutrients in the soil. The capsule or slime layer enables the bacteria to avoid desiccation as the soil dries and protects them from phagocytosis by larger soil microbes. Thick, sticky capsules may also play a role in the attachment of bacterial cells to surfaces and in the formation of biofilms. These and other extracellular polysaccharides also play an important role, along with fungal and actinomycete hyphae, in cementing sand, silt, and clay particles into stable aggregates that improve soil structure.

Cytoplasm

Nucleoid. The cytoplasm of a bacterial cell does not contain the extensive array of membrane-bound organelles that permeate the cytoplasm of larger, more complex eukaryotic cells. The most distinctive structure visible within the cytoplasm of a bacterial cell is the nucleoid (Fig. 3). This is the region within the cytoplasm that contains the bacterial chromosome, a large, double-stranded DNA molecule that contains most or all of the genetic information of the cell. The chromosomal DNA of a bacterial cell is usually circular and is closely associated with structural proteins and catalytic proteins involved in DNA replication, repair, and transcription (18). Unlike the nucleus of a eukaryotic cell, the nucleoid is not enclosed by a nuclear envelope.

The bacterial chromosome contains all of the information needed for cell growth and reproduction. Most bacteria also contain one or more additional DNA molecules, known as *plasmids*. Plasmids are usually circular, like chromosomal DNA, but they are much smaller and contain much less information. Most contain only a few genes that confer specific, nonessential functions, such as resistance to an antibiotic or toxic substance, or the ability to break down a specific substrate. Plasmids are dispersed throughout the cytoplasm and can replicate independently. As a result, bacterial cells often contain multiple copies of one or more plasmids. Plasmids are passed from generation to generation as a population of cells grow, and some contain genes that enable them to transfer copies of themselves from cell to cell, sometimes between different species of bacteria, by a process known as conjugation. Although conjugative transfer of plasmids has been shown to occur in soils (19), the extent to which this type of genetic transfer occurs in native soil populations remains uncertain.

Ribosomes. The cytoplasm surrounding the nucleoid has a uniform, grainy appearance, largely due to the presence of thousands of ribosomes actively engaged in protein synthesis (20). Bacterial ribosomes are smaller than eukaryotic ribosomes, and they are sensitive to different chemical agents; this property makes ribosomes a common target for antibacterial drugs. The difference in size is expressed in Svedburg (S) units based on the rate at which the particles sediment when centrifuged. Bacteria contain 70S ribosomes, whereas eukaryotic cells contain larger 80S ribosomes in the cytoplasm and 70S ribosomes in mitochondria and chloroplasts. Prokaryotic (70S) and eukaryotic (80S) ribosomes consist of two subunits, a small subunit (30S in prokaryotes, 40S in eukaryotes) and a large subunit (50S in prokaryotes, 60S in eukaryotes), both of which are composed of rRNA and protein. Current phylogenetic schemes designed to represent the evolutionary relatedness among living organisms are based on the degree of similarity in the nucleotide sequences of the rRNA in the small subunits of prokaryotic ribosomes (16S rRNA) and eukaryotic ribosomes (18S rRNA).

Inclusions. Other visible structures within the cytoplasm are collectively referred to as *inclusions*. The most common types of inclusions are storage granules, which are produced when an excess supply of certain nutrients is available in the soil environment. Several species of bacteria store excess carbon in the form of poly-β-hydroxybutyrate, a lipidlike substance, or glycogen, a glucose polymer. Some store excess phosphorus as polyphosphate granules, also known as metachromatic

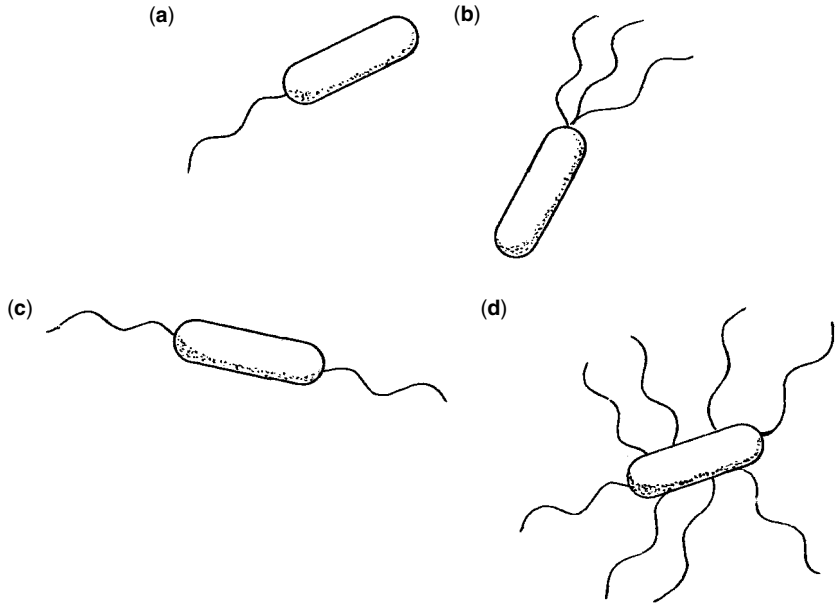

Figure 6. Common arrangements of bacterial flagella. (**a**) monotrichous (single flagellum at one pole of the cell), (**b**) lophotrichous (tuft of flagella at one or both poles of the cell), (**c**) amphitrichous (single flagellum or tuft of flagella at both poles of a cell), (**d**) peritrichous (flagella all around the cell surface). *Source:* Original drawing by Kim Luoma. Used with permission.

granules because they appear red under a light microscope when stained with methylene blue. Some sulfur-oxidizing bacteria produce elemental sulfur granules, which they can use as a source of energy when external supplies of reduced sulfur become depleted.

Appendages

Many bacteria produce slender, hairlike appendages that are anchored in the cell envelope and extend outward from the surface of the cell. The two most common types of appendages — pili (singular, pilus) and flagella (singular, flagellum) — have important functions in the soil environment.

Pili. Survival in soil often depends on the ability of bacterial species to adhere to soil particles, attach to plant roots or to other soil organisms with which they form a symbiotic association, or to form biofilms (aggregates of microbial cells attached to one another, encased in extracellular secretions, and bound to a surface) on pipelines, pilings, or other objects buried in soil. These types of attachment are mediated by pili (also known as *fimbriae*)–short, hairlike appendages that cover the surface of the cell (21,22). Many gram-positive bacteria and virtually all gram-negative bacteria are capable of producing pili. Some plasmids encode a special type of pilus, known as a *sex pilus*, which enables a host cell to attach to a recipient cell and transfer a copy of the plasmid to the recipient by conjugation.

Flagella. Many soil bacteria produce longer appendages, called *flagella*, which enable them to swim in the soil solution when the moisture content of a soil is sufficiently high. Some species form a single flagellum, whereas others produce two or more flagella arranged in characteristic ways (Fig. 6). Reversible motor proteins associated with the cytoplasmic membrane rotate the flagella to generate movement (23). Some microbiologists have questioned whether the moisture content of soils is generally high enough for this to be an important type of motility (24), but it seems unlikely that many species would have retained the complex machinery and regulatory mechanisms involved in flagellar movement if it did not provide a useful function. Flagellar motility depends largely on the thickness of water films on soil particles and on the corresponding matric potential of the soil solution. Motility is negligible at matric potentials lower than -0.1 MPa, but flagellar movement can be significant when continuous water films larger than the size of the bacterial cells are present in the soil (25).

A unique group of gram-negative bacteria known as *spirochetes* have flagella that do not extend outward from the cell envelope. In these bacteria, the flagella are arranged in a bundle, known as an *axial filament*, which wraps around the cell in the space between the cell wall and the outer membrane. Rotation of the axial filament produces a corkscrew type of movement that enables spirochetes to swim through viscous liquids, such as the aquatic sediments that they typically inhabit.

Other types of motility enable bacteria to move on surfaces, such as soil particles or aggregates that are covered by a thin film of moisture. Some species produce lateral flagella, which enable them to swarm on these surfaces, whereas others exhibit alternate forms of motility described as gliding or twitching. Several models have been proposed to explain these types of movement, but none has been established conclusively (24). It is likely that many different mechanisms operate in bacterial motility.

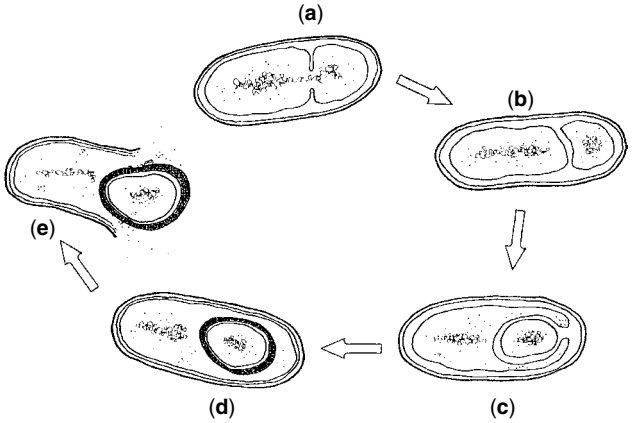

Figure 7. Formation of a bacterial endospore. (**a**) A sporulating cell replicates its nucleoid and undergoes unequal division of the cytoplasm, (**b**) a forespore (FS) develops at one pole of the cell, (**c**) the remainder of the cytoplasm surrounds the forespore, enclosing it within a double layer of membrane, (**d**) the forespore matures into an endospore by synthesizing a thick, multilayered wall around a dehydrated core, (**e**) the cell lyses and releases the mature endospore. *Source:* Original drawing by Kim Luoma. Used with permission.

Endospores

A few soil bacteria, including members of the gram-positive genera *Bacillus* and *Clostridium*, produce *endospores* in response to nutrient depletion or other environmental stresses (26). Endospores are highly resistant survival structures that enable a bacterial population to withstand high temperatures, desiccation, radiation, and exposure to toxic chemicals. As nutrients become depleted, or when cell density reaches a critical level, vegetative (actively growing) cells transform themselves into metabolically inert endospores (Fig. 7). When favorable conditions for growth return, the endospores germinate to form a new population of vegetative cells. Unlike the reproductive spores produced by fungi and actinomycetes, the primary function of bacterial endospores is to enhance survival under unfavorable conditions, rather than increasing the number of individuals in a population. Each bacterial cell in a population of sporeformers transforms itself into a single endospore, which subsequently germinates to form a single vegetative cell, so there is no increase in the number of individuals as a result of sporulation.

Endospores are among the most resistant forms of life known, and the bacteria that produce them are ubiquitous. Any method designed to sterilize materials must be sufficiently harsh to destroy these structures to ensure sterility. Standard conditions to destroy endospores in small volumes of materials with moist heat are 121 °C at 15 psi for 15 to 20 minutes. Larger volumes or dense materials, such as soil samples, require much longer exposure times.

ARCHAEA

Archaea resemble bacteria in many respects. They are prokaryotic, predominantly single-celled microbes, which display a similar variety of cellular morphologies and a similar range of metabolic capabilities. Despite these similarities, archaea appear to be distantly related to bacteria phylogenetically (2,27). Archaeal cells have a strikingly different biochemical composition, they exhibit unique metabolic capabilities not found in bacteria or eukaryotes, and they often inhabit extreme environments that are lethal to other types of organisms.

One of the major differences between archaea and bacteria is the structure and composition of the cell wall. Archaea are classified as gram-positive or gram-negative based on staining properties that parallel those observed in bacteria, but neither group of archaea contains peptidoglycan in its cell wall (28,29). Gram-positive archaea have a thick, homogeneous cell wall composed of *pseudomurein* or heteropolysaccharides. Pseudomurein resembles the peptidoglycan in bacterial cell walls, but does not contain muramic acid or the D-amino acids found in the bacterial polymer. Gram-negative archaea have a thin wall composed of protein or glycoprotein. There is no outer membrane or periplasm in these archaea, unlike their bacterial counterparts.

The unique feature of archaeal cells is the chemical nature of their membrane lipids (30). The lipids in archaeal membranes consist of branched-chain hydrocarbons linked to glycerol by ether bonds, whereas the phospholipids in bacterial and eukaryotic membranes are composed of straight-chain fatty acids linked to glycerol by ester bonds. In some archaea, diether lipids form a bilayer similar to that found in other organisms. In others, long hydrocarbon chains linked to glycerol at both ends (tetraethers) form a less-fluid monolayer membrane. The unique structure and composition of archaeal membranes is thought to play a key role in their ability to survive in extreme environments (31).

Archaea have circular chromosomes like bacteria; but a different class of structural proteins maintain archaeal chromosomes in a different physical conformation that more closely resembles the structure of eukaryotic chromosomes (32). Several key enzymes, including archaeal RNA and DNA polymerases, are also more similar to their eukaryotic counterparts than they are to the corresponding bacterial enzymes (33,34). Archaea are sensitive to many of the same antimicrobial agents as eukaryotic microbes, and are resistant to many antibacterial agents. These observations support the hypothesis based on 16S rRNA sequence analysis, that archaea share a more recent common ancestor with eukaryotes than with bacteria (2).

Archaea are often regarded as remnants of ancient microbes whose range of habitats is limited to extreme environments that are inhospitable to other types of organisms. Archaea are frequently isolated from hypersaline terrestrial or aquatic habitats, and from hot or acidic environments such as hydrothermal vents, hot springs, and anaerobic bioreactors. Recent observations indicate, however, that archaea may constitute as much as one-third of oceanic plankton (35,36). As microbiologists learn more about these microbes, perceptions regarding the distribution and ecological niches of archaea may change.

PHYSIOLOGICAL ECOLOGY OF SOIL BACTERIA

Soils teem with diverse populations of bacteria engaged in a multitude of chemical transformations that are crucial to soil fertility and soil structure, and for maintaining the intricate web of life in terrestrial ecosystems. The primary niche of soil bacteria is to function as decomposers. By feeding on nonliving organic matter in soils, saprophytic bacteria convert the complex organic compounds in plant and animal residues to carbon dioxide, water, NH_4^+, phosphate, and other simple inorganic nutrients, thereby returning these nutrients to the soil in a form that plants and other soil microbes can use. Bacteria abound in a limitless variety of habitats, play major roles in soil formation and in the cycling of several key inorganic nutrients, and participate in a broad range of interactions with one another, with other soil microbes, and with higher organisms.

Nutritional Requirements

Macronutrients. The nutrients that bacteria require in the greatest amounts are carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur. These elements are structural components of the biological molecules (carbohydrates, proteins, lipids, and nucleic acids) that constitute most of the dry mass of bacterial cells. Potassium, sodium, calcium, and magnesium are also required in substantial amounts. These "secondary" macronutrients function as cofactors for cytoplasmic enzymes and maintain ionic balance in bacterial cells.

Soil organic matter and water are the primary sources of carbon, hydrogen, and oxygen for most soil bacteria. Some species obtain carbon and oxygen from carbon dioxide. Nitrogen and sulfur may be obtained from soil organic matter or assimilated from soluble ions (NO_3^-, NH_4^+, or SO_4^{2-}) in the soil solution. Some bacteria can use N_2 as a source of nitrogen when other forms are not available. These bacteria reduce N_2 to NH_3 by a process known as *nitrogen fixation*, sometimes in symbiotic associations with plants. Phosphorus is almost always taken up in the form of phosphate ions because bacteria are unable to transport most phosphorylated organic compounds.

The large, diverse populations of bacteria and other microbes in soils rapidly convert organic substrates into microbial biomass. Competition for these substrates is intense, and the availability of organic carbon often limits microbial growth. The availability of other macronutrients for plants and higher trophic levels depends, in part, on the concentration of these nutrients in organic residues relative to the amount of carbon that is available for microbial growth. When the concentration of nitrogen, phosphorus, or sulfur in soil organic matter exceeds that which is needed for microbial growth using the available carbon, the excess is released into the soil in a form that plants can take up. This process is termed *mineralization*. When the concentration of these nutrients is at or below the levels needed for microbial growth, the nutrients are assimilated into microbial biomass and rendered unavailable to plants, a phenomenon known as *immobilization*.

Micronutrients. Several nutrients are required in lesser amounts. These elements often serve as structural components or activators of specific enzymes in bacterial cells. Iron is the micronutrient that is usually required in the greatest amount. Others include cobalt, zinc, molybdenum, copper, and manganese.

Iron is required as a cofactor for many bacterial enzymes, including several of the electron transport proteins that function in bacterial energy metabolism. Although it is one of the most abundant elements in Earth's crust, iron often exists primarily in the form of insoluble ferric hydroxides that bacteria cannot take up. As a result, most soil bacteria produce siderophores to scavenge trace iron from the soil solution. Siderophores are low molecular weight organic chelators that have a very high affinity for Fe^{3+} ions (37). Bacteria take up the chelated iron through specific receptors in the cytoplasmic membrane. Competition for iron plays a significant role in the interactions among rhizosphere bacteria, and the production of siderophores by some pseudomonads has been suggested as a potential mechanism for the suppression of plant pathogens by these bacteria (38).

Sources of Carbon, Energy, and Reducing Power

Like all living organisms, bacteria require carbon in greater amounts than any other nutrient, and they obtain it from a variety of sources. Heterotrophic bacteria obtain carbon from soil organic matter. Most are saprophytes that feed on nonliving plant and animal residues or humus. Several species are symbionts or pathogens that invade the tissues of other living organisms. Autotrophic bacteria obtain most or all of their carbon from carbon dioxide. These bacteria assimilate carbon dioxide into carbohydrates or other organic compounds that can be metabolized to support cell growth.

In addition to carbon and other essential nutrients, bacteria must obtain energy from their surroundings and generate reduced coenzymes to fuel the biosynthetic pathways that sustain cell growth. Chemotrophic bacteria obtain energy by oxidizing organic or inorganic compounds. Phototrophic bacteria obtain energy from sunlight (or other sources of light energy). Both types of bacteria generate reducing power by coupling the oxidation of an organic or inorganic substrate with the reduction of coenzymes such as NAD^+ (nicotinamide adenine dinucleotide) or $NADP^+$ (nicotinamide adenine dinucleotide phosphate), small organic molecules that function as soluble electron carriers in bacterial cells. Those that oxidize an organic substrate are classified as organotrophs, whereas those that oxidize inorganic compounds are classified as lithotrophs. Table 1 lists the most common nutritional classes of soil bacteria, based on sources of carbon, energy, and reducing power.

Oxygen Requirements

Oxygen (O_2) concentrations vary widely in the infinite variety of microsites in soils. Large pore spaces filled with air provide a relatively high concentration of O_2, which favors aerobic metabolism, whereas smaller pore spaces filled with water can lead to the formation of strictly

Table 1. Common Nutritional Classes of Soil Bacteria

Nutritional Class	Source of Carbon	Source of Energy (ATP Synthesis)	Source of Reducing Power
Chemoorganotrophic heterotrophs[a]	Organic compounds	Chemical oxidation	Organic compounds
Photoorganotrophic heterotrophs[b]	Organic compounds	Light energy	Organic compounds
Chemolithotrophic autotrophs[c]	CO_2	Chemical oxidation	Inorganic compounds
Photolithotrophic autotrophs[d]	CO_2	Light energy	Inorganic compounds

[a] Commonly referred to simply as heterotrophs, with the understanding that organic substrates provide energy and reducing power as well as carbon.
[b] Commonly referred to as photoheterotrophs.
[c] Commonly referred to as chemoautotrophs or chemolithotrophs.
[d] Commonly referred to as photoautotrophs.

Table 2. Oxygen Requirements and Energy Metabolism of Bacteria and Archaea

Oxygen Requirement	Type of Energy Metabolism	Final Electron Acceptor	Reduced Product of Energy Metabolism
Aerobes	Aerobic respiration	O_2	H_2O
Facultative anaerobes	Anaerobic respiration[a]	Nitrate (NO_3^-) or Nitrite (NO_2^-)	N_2, N_2O, NO[b]
		Nitrate (NO_3^-)	Nitrite (NO_2^-)[c]
		Nitrate (NO_3^-)	Ammonium (NH_4^+)[d]
		Fumarate	Succinate
	Fermentation	Organic compound	Organic acids, alcohols
Obligate anaerobes	Anaerobic respiration	Sulfate (SO_4^{2-})	Hydrogen sulfide (H_2S)[e]
		CO_2	Acetic acid (CH_3COOH)[f]
		CO_2	Methane (CH_4)[g]
	Fermentation	Organic compound	Organic acids, alcohols
Aerotolerant anaerobes	Fermentation[h]	Organic compound	Organic acids, alcohols

[a] Facultative anaerobes respire aerobically when O_2 is available.
[b] Denitrifying bacteria.
[c] Nitrate-respiring bacteria.
[d] Dissimilatory nitrate reduction to ammonium.
[e] Sulfate-reducing bacteria.
[f] Acetogenic bacteria.
[g] Methanogenic archaea.
[h] Aerotolerant anaerobes are incapable of respiring aerobically or anaerobically.

anaerobic microenvironments. Oxygen concentrations can also vary widely with time, as soils undergo periods of saturation with water, which may lead to temporary hypoxic or anoxic conditions, and periods of dryness. It is not surprising then that soil bacteria exhibit a full range of adaptation to different O_2 concentrations. Table 2 summarizes the oxygen requirements of soil bacteria and the types of energy metabolism exhibited within each group.

Many soil bacteria are obligate aerobes that grow only in microsites containing relatively high concentrations of O_2. These bacteria obtain energy exclusively by aerobic respiration, so they cannot grow in the absence of O_2. Obligate anaerobes cannot survive in aerobic microsites because they lack the enzymes needed to eliminate the toxic products (hydrogen peroxide and superoxide) that are formed when O_2 serves as an electron acceptor. These bacteria reside in anaerobic microsites and generate energy by fermentation (using pyruvate or a derivative of pyruvate as final electron acceptor) or by anaerobic respiration (using an inorganic compound as final electron acceptor).

Many soil bacteria can grow in the presence or absence of O_2. Facultative anaerobes respire aerobically when O_2 is available, but can alter their metabolism to grow anaerobically in the absence of O_2. Some facultative anaerobes shift to fermentative metabolism under anaerobic conditions, whereas others shift to anaerobic respiration. In either case, aerobic respiration is the preferred mode of metabolism because the high reduction potential of O_2 makes this type of metabolism more energy efficient than fermentation or anaerobic respiration.

Habitats

Bacteria thrive in a virtually limitless variety of habitats. They are abundant in aerobic and anaerobic environments, and they tolerate an exceptionally wide range of temperatures. Most soil bacteria are mesophiles,which grow optimally at temperatures in the range of 15–35 °C. Several species, known as *thermophiles*, grow at temperatures of 45 to 80 °C, and some extreme thermophiles can grow at temperatures approaching 100 °*C*. Thermophilic bacteria typically produce heat-stable proteins that do not denature at elevated temperatures and incorporate increased amounts of saturated fatty acids in their membranes (39).

Other species of bacteria have adapted to grow at temperatures below 15 °C. Psychrophilic bacteria grow optimally at these temperatures, whereas psychrotrophic bacteria are capable of growing at 15 °C or below, but grow optimally at slightly higher temperatures. These cold-tolerant bacteria produce "cold-active" enzymes and synthesize large quantities of unsaturated fatty acids to maintain the fluidity of the cytoplasmic membrane at low temperatures (39).

Many bacteria have adapted to the acidic soils characteristic of regions with high precipitation, and some can tolerate the extremely low pH of acid springs or other specialized habitats. Acidophilic bacteria grow optimally at pH below 5, and extreme acidophiles (such as *Thiobacillus thiooxidans*, a sulfur-oxidizing bacterium) can grow at pH as low as 1. Acidophiles often incorporate acid-resistant fatty acids into their cytoplasmic membranes and maintain a neutral pH in the cytoplasm by actively transporting H^+ out of the cell (40). Alkalophilic bacteria grow at pH as high as 10.5 in arid and semiarid regions.

Poor drainage and rapid surface evaporation in arid regions often results in the formation of salt-affected or saline soils. Many bacteria have adapted to the high salt concentrations (saturation extract electrical conductivity >4 dS m^{-1}) of these soils by producing membranes and enzymes that function in solutions of high ionic strength or by accumulating solutes in the cytoplasm to compensate for the high solute concentration of the soil solution (41). Bacteria that tolerate high salt concentrations are said to be osmotolerant. Some archaea have adapted so completely to saline environments that they cannot grow without high concentrations of sodium. These salt-dependent archaea are called *halophiles*. Bacteria and archaea that tolerate dry habitats, but not necessarily high salt concentrations, are called *xerophiles*. In most soils, matric potential has a much greater influence on the availability of water for plants and soil microbes than osmotic potential.

Aerobic Habitats

Heterotrophic Bacteria. Heterotrophic bacteria play a major role in organic matter decomposition and bioremediation of soils contaminated with organic wastes. The primary products of organic matter decomposition are carbon dioxide, microbial biomass, and complex organic compounds that resist further decomposition. Aerobic or facultatively anaerobic bacteria degrade organic substrates most efficiently when a soil, compost heap, or bioreactor is well aerated. Under these conditions, the bacteria respire aerobically and a major portion of the carbon is oxidized to carbon dioxide or assimilated into microbial biomass. Carbon dioxide generated by aerobic respiration serves as a source of carbon and oxygen for autotrophic microbes and plants.

Bacteria rapidly metabolize the carbohydrates, proteins, fats, and nucleic acids in soil organic matter, but decompose other substances, such as the lignins, waxes, oils, and resins in plant residues, much more slowly. The unaltered remains of plant and animal residues, along with polyaromatic compounds that are formed during decomposition, become part of the stable organic fraction of soils known as *humus* (42). Humus improves soil structure by binding clay particles together to form stable aggregates and enhances soil fertility by improving the retention of nutrient ions and water. Nutrients are slowly released from this fraction of soil organic matter as specific groups of bacteria gradually break down its complex constituents.

Actinomycetes. A unique group of aerobic, heterotrophic bacteria known as actinomycetes deserve particular attention because of its distinctive morphology and metabolic capabilities. Actinomycetes resemble fungi morphologically. They form long, slender, branching filaments called *hyphae* and produce asexual reproductive spores, called *sporangiospores* when enclosed within a sac or *conidia* when not enclosed in a sac. They are distinguished from fungi by their small size, prokaryotic cell structure (including a gram-positive cell wall, 70S ribosomes, and the absence of a nuclear envelope), and sensitivity to antibacterial agents. Actinomycete hyphae are similar in diameter to rod-shaped bacterial cells (1–2 μm), and are considerably smaller than fungal hyphae (10 to 50 μm diameter).

Actinomycetes grow slowly and compete poorly with other soil microbes for readily available organic substrates, but they fill an important niche in soil communities by breaking down an enormous variety of organic compounds (43). Actinomycetes break down chitin, lignin, hemicelluloses, keratin, and other plant, fungal, and animal polymers that many other soil microbes do not decompose. They also tolerate alkalinity and moisture stress better than other soil microbes, which gives them a competitive advantage in arid soils.

Another distinguishing characteristic of actinomycetes is their ability to produce antibiotics. The ecological significance of antibiosis in the soil environment remains largely unknown, but the impact on human health has been enormous. More than 50 of the antibiotics currently in use are produced by actinomycetes of the genus *Streptomyces* (39). Streptomycetes are also notable for the production of *geosmins*, sesquiterpenoid compounds that give soils their characteristic earthy odor.

Chemoautotrophic Bacteria. Chemoautotrophic bacteria generate energy and reducing power by oxidizing inorganic nitrogen or sulfur compounds, iron, or hydrogen (H_2) (Table 3). The ATP and reduced coenzymes derived from these chemical oxidations are used to assimilate carbon dioxide into simple organic compounds that serve as precursors for cell growth. Synthesis of ATP is coupled to electron transport, with O_2 as the sole or preferred final electron acceptor, as in aerobic respiration of organic substrates.

Nitrifying Bacteria. Two groups of chemoautotrophs, collectively referred to as *nitrifying bacteria*, function synergistically in soils by oxidizing different forms of inorganic nitrogen (44). The ammonia-oxidizing bacteria (*Nitrosomonas* and related genera) oxidize ammonia (NH_3) to nitrite (NO_2^-), whereas the nitrite-oxidizing bacteria

Table 3. Energy Sources of Chemoautotrophic Soil Bacteria

Chemoautotrophs	Substance Oxidized to Generate ATP	Oxidized Product of Energy Metabolism	Representative Genera
Ammonia-oxidizing bacteria	Ammonia (NH_3)	Nitrite (NO_2^-)	*Nitrosomonas*
Nitrite-oxidizing bacteria	Nitrite (NO_2^-)	Nitrate (NO_3^-)	*Nitrobacter*
Sulfur-oxidizing bacteria	Hydrogen sulfide (H_2S), metal sulfides, elemental sulfur (S^0), thiosulfate ($S_2O_3^{2-}$)	Sulfate (SO_4^{2-})	*Thiobacillus*
Hydrogen-oxidizing bacteria	Hydrogen gas (H_2)	Hydrogen ions (H^+)	*Pseudomonas*, *Alcaligenes*
Iron-oxidizing bacteria	Ferrous iron (Fe^{2+})	Ferric iron (Fe^{3+})	*Thiobacillus ferrooxidans*

(*Nitrobacter* and related genera) oxidize nitrite to nitrate (NO_3^-). Both groups of nitrifying bacteria consist almost exclusively of obligate aerobes.

In well-aerated soils at neutral to alkaline pH, the NH_3 released by mineralization of organic nitrogen is rapidly converted to NO_3^-, the primary form of inorganic nitrogen used by plants. Nitrate is very soluble in water and does not adsorb to clay particles, which makes it highly susceptible to losses by leaching, runoff, and denitrification. These processes reduce soil fertility and contaminate ground and surface water. Excess NO_3^- in drinking water is harmful to wildlife and humans, especially infants.

Sulfur-Oxidizing Bacteria. Several genera of soil bacteria oxidize sulfides (H_2S or metal sulfides), elemental sulfur, or thiosulfate ($S_2O_3^{2-}$) (45). Complete oxidation of these substrates yields sulfate (SO_4^{2-}), the form of sulfur that is most commonly used as a nutrient by plants and soil microbes. Most sulfur-oxidizing bacteria are obligate aerobes or microaerophiles (aerobic organisms that grow best at low concentrations of O_2), though at least one species (*Thiobacillus denitrificans*) is a facultative anaerobe that can use nitrate as a final electron acceptor. Many are also obligate chemoautotrophs. Some sulfur-oxidizing bacteria are facultative autotrophs that oxidize organic substrates when they are available.

Sulfur-oxidizing bacteria are widely distributed in nature and highly active in well-aerated soils. Mineralization of sulfur-containing organic compounds in soils provides a large portion of the H_2S and metal sulfides that these bacteria oxidize. Sulfides may also be produced by sulfate-reducing bacteria in anaerobic microsites.

Complete oxidation of reduced sulfur compounds yields substantial amounts of H^+, in addition to sulfate, which significantly lowers the pH of the microenvironments where sulfur-oxidizing bacteria reside. Acidification of the soil solubilizes phosphates and other mineral nutrients, which generally enhances soil fertility. Several sulfur-oxidizing bacteria are obligate acidophiles that not only tolerate the acid that they produce, but grow optimally at pH less than 4. Some species are less acid-tolerant and deposit elemental sulfur rather than oxidizing sulfides to sulfate.

Surface mining operations may unearth large deposits of metal sulfides, such as iron pyrite, creating a situation that can lead to large-scale acid production by sulfur-oxidizing bacteria (46). Acid runoff from surface mines kills aquatic plants and animals and renders polluted waterways unusable as a source of water for human consumption or for industrial purposes. Microbial oxidation of metal sulfides, especially in copper and uranium ores, can also be used beneficially in mining. Sulfur-oxidizing bacteria can be used to solubilize metals when the metal content of an ore is too low for recovery by smelting by a process known as *microbial leaching* (47).

Iron-Oxidizing Bacteria. A few species of soil bacteria can obtain energy for growth by oxidizing ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}). The energy yield from this oxidation is low, so these bacteria grow slowly when using iron as a source of energy. Ferrous iron spontaneously oxidizes to Fe^{3+} under aerobic conditions at neutral or alkaline pH, but it is relatively stable at acidic pH. As a result, Fe^{2+} is most abundant in acidic or waterlogged soils and aquatic sediments. Favorable conditions for iron oxidation occur when an acidic soil is well aerated or when groundwater containing substantial amounts of dissolved Fe^{2+} seeps into an aerobic zone. The Fe^{3+} produced by microbial or chemical oxidation of iron is much less soluble than Fe^{2+}, and generally precipitates in the form of ferric hydroxides with characteristic reddish-orange colors.

Hydrogen-Oxidizing Bacteria. The chemoautotrophic bacteria that oxidize H_2 are facultative lithotrophs that normally grow heterotrophically when organic substrates are available in the soil. In the absence of an oxidizable organic substrate, they can oxidize H_2 for energy and use carbon dioxide as their source of carbon. All hydrogen-oxidizing bacteria have hydrogenases associated with the cytoplasmic membrane. Some species also have cytoplasmic hydrogenases that directly couple the oxidation of H_2 with the reduction of NAD^+.

Photoautotrophic Bacteria. Many soil and aquatic bacteria, collectively known as *cyanobacteria*, grow photoautotrophically in aerobic environments. The metabolism of these bacteria is very similar to that of eukaryotic algae and plants. Their photosynthetic pigments and electron transport proteins are organized into two photosystems, and their primary photosynthetic pigment is chlorophyll *a*. Cyanobacteria use water as the primary electron donor for

photophosphorylation and generate O_2 as a product of their metabolism. Carbon dioxide is assimilated by the Calvin-Benson cycle, as in most autotrophic organisms.

This large and diverse group of prokaryotes derives its name from the blue-green pigmentation produced by the combination of the green chlorophyll a and the blue accessory pigment phycocyanin. Some species produce phycoerythrin as an accessory pigment and, as a result, are red or brown in color. All cyanobacteria are gram-negative, but they vary widely in microscopic morphology. They may be single-celled or colonial, or form branched or unbranched filaments. Many of the filamentous cyanobacteria fix atmospheric nitrogen (N_2), usually within specialized cells called *heterocysts* which protect nitrogenase (the oxygen-sensitive enzyme that catalyzes N_2 fixation) from O_2.

Cyanobacteria thrive in many different types of soils and aquatic habitats. They are often among the most abundant primary producers in marine and freshwater environments, and in hot or saline soils. After periods of rainfall, they may form crusts on the surface of desert soils that help to retain moisture and add organic matter to the soil. Several species form symbiotic associations, known as *lichens*, with fungi on rock surfaces, and some form symbiotic associations with ferns, liverworts, or other nonvascular plants.

Anaerobic Habitats

Heterotrophic Bacteria. Organic matter decomposes slowly in anaerobic soils or sediments because anaerobic metabolism is less energy efficient than aerobic respiration. Anaerobic bacteria must oxidize more substrate to obtain comparable amounts of energy, so less is available for cell growth. Less organic carbon is converted to carbon dioxide and microbial biomass, and more accumulates as foul-smelling, acidic waste products. Carbohydrates and lipids are converted to organic acids and alcohols, whereas proteins are converted to organic acids, polyamines, and mercaptans.

In the absence of oxygen, bacteria obtain energy for growth by respiring anaerobically or by fermenting organic substrates. Anaerobic respiration involves many of the same metabolic pathways as aerobic respiration, but with different final electron acceptors. Bacteria can respire anaerobically using nitrate, sulfate, carbon dioxide, fumarate, or other inorganic or organic compounds as the final electron acceptor. Energy yields vary widely depending on the reduction potential of the final electron acceptor. Electron acceptors with higher (more positive) reduction potentials yield more energy than those with lower reduction potentials.

Table 4. Products of Common Bacterial Fermentations

Type of Fermentation	Products of Fermentative Metabolism
Ethanolic	Ethanol + CO_2
Homolactic	Lactic acid
Heterolactic	Lactic acid + ethanol + CO_2
Mixed acid	Ethanol + succinic acid + lactic acid + acetic acid + formic acid + H_2 + CO_2
Propionic acid	Propionic acid + acetic acid + CO_2
Butyric acid	Butyric acid + Acetic acid + H_2 + CO_2
Butanediol	2,3-Butanediol + lactic acid + acetic acid+ formic acid + H_2 + CO_2
Homoacetogenic	Acetic acid
Methanogenic	Methane

Fermentation involves a variety of metabolic pathways that convert pyruvate, a key intermediate in several catabolic processes, or other metabolites to various organic acids and alcohols. The energy yields of these pathways are lower than those obtained with aerobic or anaerobic respiration. Fermentative bacteria are often grouped on the basis of the products that they form under anaerobic conditions (Table 4).

Denitrifying Bacteria. Many soil bacteria can respire anaerobically using nitrate as their final electron acceptor. Most are facultative anaerobes that reduce nitrate only when O_2 is not available for aerobic respiration. In the absence of O_2, or at low O_2 concentrations, these bacteria reduce nitrate or nitrite to dinitrogen gas (N_2). Variable amounts of nitrous oxide (N_2O) and nitric oxide (NO), intermediates in the reduction pathway, are also produced depending on the pH and the concentrations of O_2 and nitrate in the soil (48). The resulting loss of available nitrogen from the soil is termed *denitrification*.

Denitrifying bacteria fill an essential niche in the nitrogen cycle, but their activity is often viewed as harmful because of its consequences in agriculture. Substantial portions of the nitrogen in fertilizers applied to agricultural crops can be lost through denitrification (42), and the nitrous oxide released into the atmosphere harms the environment by contributing to global warming and ozone depletion (49). On the other hand, denitrification is beneficial in municipal water treatment because it provides an inexpensive means to remove nitrate from wastewater and possibly even groundwater.

Sulfate-Reducing Bacteria. The ability to respire anaerobically using sulfate as the final electron acceptor is limited to a few genera of obligately anaerobic bacteria, but these bacteria are widely distributed in nature (50). Sulfate-reducing bacteria convert sulfate to hydrogen sulfide (H_2S), a gaseous end product, but H_2S is not lost from the soil to the same extent as the gaseous products of denitrification. Hydrogen sulfide reacts with metals in the soil to form insoluble metal sulfides, and it can be reoxidized to sulfate or elemental sulfur by chemoautotrophic or photoautotrophic bacteria.

Chemoautotrophic Bacteria. Two groups of prokaryotic microbes use carbon dioxide as their final electron acceptor for anaerobic respiration. Both are obligately anaerobic and both can grow chemoautotrophically, using H_2 as an electron donor, or heterotrophically. The two groups also use the same pathway to assimilate carbon dioxide when growing autotrophically; despite these similarities, they are distantly related phylogenetically and they reduce carbon dioxide to different end products.

Acetogens. Acetogens are bacteria that reduce carbon dioxide to acetate when they use carbon dioxide as the final electron acceptor for anaerobic respiration (51). When growing chemoautotrophically, they obtain energy by oxidizing H_2 and use CO_2 as the final electron acceptor for respiration and as the source of carbon. Unlike most autotrophic organisms, which assimilate carbon dioxide into sugars by the Calvin-Benson cycle, acetogenic bacteria assimilate carbon dioxide into acetyl-CoA by the acetyl-CoA pathway. Acetyl-CoA is then used as a precursor for the biosynthesis of cellular materials. Acetogens can also grow heterotrophically in anaerobic habitats, using carbon dioxide as the final electron acceptor for anaerobic respiration, and they can ferment a variety of organic substrates. Acetate is excreted as a waste product of fermentative metabolism.

Acetogenic metabolism is not associated with a particular phylogenetic group of bacteria, but is scattered among several different groups which commonly inhabit anaerobic environments. Some maintain a symbiotic association with termites. Acetogens live in the hindgut of the insect, where they covert the CO_2 and H_2 produced by cellulose fermentation into acetate, which can be absorbed and oxidized by termites (52).

Methanogens. Methanogens are archaea that reduce carbon dioxide to methane when they use carbon dioxide as the final electron acceptor for anaerobic respiration (53). Like the acetogenic bacteria, these archaea often grow chemoautotrophically, using H_2 as an electron donor and CO_2 as an electron acceptor and carbon source, and they assimilate CO_2 by the acetyl-CoA pathway. Methanogens can also produce methane heterotrophically from a few simple organic substrates, including acetate, methanol, and formate.

Methanogens thrive in anaerobic soil microsites and aquatic sediments, and in the rumen of cattle and other ruminant animals. Since they metabolize only a few simple organic substrates, they typically are members of a complex food web in these environments. Methanogens feed on the H_2, CO_2, acetate, and other products of anaerobic metabolism generated by microbes that decompose more complex organic materials. For many years, sewage treatment facilities have taken advantage of these microbial communities in anaerobic digesters, using the methane produced by methanogenic archaea as a source of energy for heat and electricity (46).

Photoautotrophic Bacteria. Two types of photosynthetic bacteria commonly inhabit anaerobic environments that have sufficient light to support phototrophic metabolism. The two groups, known as *green bacteria* and *purple bacteria*, produce different photosynthetic pigments, assimilate carbon dioxide by different biosynthetic pathways, and differ in the arrangement of photosynthetic membranes inside the cell (54). They are usually found in riparian soils, mud flats, shallow lakes or ponds, or deep, clear lakes in which light can penetrate to anaerobic depths. Unlike the cyanobacteria, they do not use water as an electron donor for photophosphorylation and they do not evolve O_2. As a result, the green bacteria and purple bacteria are often described as *anoxygenic* photoautotrophs.

Green bacteria and purple bacteria grow photoautotrophically only under anaerobic conditions, and most species in both groups are obligately anaerobic. Most purple nonsulfur bacteria, and some of the green bacteria, can grow as photoheterotrophs under anaerobic conditions, using light energy to synthesize ATP while assimilating organic compounds as their primary source of carbon. Most purple nonsulfur bacteria and some green bacteria can also grow heterotrophically under aerobic conditions. Most of the purple bacteria can also fix N_2, and thereby play an important role in the nitrogen cycle in the environments that they inhabit. Table 5 contrasts some of the distinguishing characteristics of the major groups of photosynthetic bacteria.

Green Bacteria. The primary photosynthetic pigments of the green bacteria are bacteriochlorophylls c, d, and e, and a variety of carotenoid pigments that give the bacteria a green to greenish brown color. These pigments are concentrated in cytoplasmic vesicles called *chlorosomes*.

Table 5. Characteristics of Photosynthetic Bacteria

Group	Oxygen Requirement	Photosynthetic Electron Donors	Oxidized Products	CO_2 Fixation Pathway
Cyanobacteria	Aerobes	H_2O	O_2	Calvin-Benson cycle
Green sulfur bacteria	Obligate anaerobes	H_2S, S^0, H_2	S^0, SO_4^{2-}, H^+	Reverse TCA cycle
Green nonsulfur bacteria	Usually anaerobic[a]	Usually organic compounds[b]; can use H_2 or H_2S	H^+, SO_4^{2-}[c]	Hydroxy-propionate pathway
Purple sulfur bacteria	Obligate anaerobes	H_2S, S^0, H_2	S^0, SO_4^{2-}, H^+	Calvin-Benson cycle
Purple nonsulfur bacteria	Usually anaerobic[a]	Usually organic compounds[b]; can use H_2 or H_2S	H^+, SO_4^{2-}[c]	Calvin-Benson cycle

[a] Green nonsulfur and purple nonsulfur bacteria can grow chemoheterotrophically under aerobic conditions in the dark.
[b] Green nonsulfur and purple nonsulfur bacteria preferably grow photoheterotrophically under anaerobic conditions.
[c] Products of photoautotrophic growth with H_2 or H_2S as electron donors.

Chlorosomes are cylindrical or ellipsoidal in shape and are closely associated with the inner surface of the cytoplasmic membrane. The electron transport proteins and reaction center pigments that catalyze photophosphorylation are organized into a single type of photosystem in the cytoplasmic membrane. Green bacteria use reduced sulfur compounds (H_2S, thiosulfate, or elemental sulfur) or H_2 as electron donors for photoautotrophic growth, and assimilate carbon dioxide by the reverse tricarboxylic acid (TCA) cycle or by the hydroxypropionate pathway. They generally oxidize reduced sulfides to sulfate, but in environments containing excess sulfide they form sulfur-storage granules. Interestingly, the sulfur granules are formed outside the cell, but they often remain bound to the cell surface where they can still be oxidized when needed.

Purple Bacteria. Purple bacteria produce bacteriochlorophylls a and b and various carotenoid pigments which give different species an array of different of colors — red purple, purple-violet, brown, orange, rust, or pink. They typically have an extensive system of photosynthetic membranes in the cytoplasm containing a single type of photosystem. In some species, the photosynthetic membranes form layers of flattened sheets called *lamellae*, whereas in others they form spherical vesicles. In either case, the photosynthetic membranes are closely associated with the cytoplasmic membrane.

Two types of purple bacteria are distinguished by the electron donors used for photophosphorylation. Purple sulfur bacteria oxidize reduced sulfur compounds (H_2S, thiosulfate, or elemental sulfur) or H_2, whereas purple nonsulfur bacteria oxidize organic compounds or H_2. Purple nonsulfur bacteria are capable of oxidizing reduced sulfur compounds, but the concentrations of these substrates that support vigorous growth of purple sulfur bacteria are toxic to the nonsulfur bacteria (39). Both groups assimilate carbon dioxide by the Calvin-Benson pathway (the same pathway used by cyanobacteria, algae, and plants). Purple sulfur bacteria form cytoplasmic granules of elemental sulfur when excess sulfide is available in the environment.

CONCLUSION

Bacteria are among the most numerous and ubiquitous of all soil organisms. They are single-celled, prokaryotic microbes whose small size and simple cell structure enable them to grow and adapt rapidly to changing environmental conditions. Bacterial cells consist of a cytoplasmic membrane, nucleoid, ribosomes, and a cell envelope that usually includes a cell wall composed of peptidoglycan. Two major groups of bacteria (gram-negative and gram-positive) and two smaller groups (acid-fast and mycoplasmas) are distinguished by the structure and composition of the cell envelope. Most bacteria may also produce a variety of other structures, such as capsules, pili, flagella, plasmids, inclusions, or endospores, which perform specialized functions and enhance their survival in soils.

Bacteria thrive in all types of environments and derive nutrients and energy from many different sources. Most soil bacteria are heterotrophs that feed on nonliving organic matter in soils or form symbiotic associations with plants, insects, or other soil microbes. Many are autotrophs that use carbon dioxide as their sole or primary source of carbon. Some autotrophic bacteria use light energy to synthesize the ATP and reduced coenzymes needed for carbon dioxide fixation, whereas others oxidize inorganic compounds such as ammonia, nitrite, sulfides, or H_2. Bacteria flourish in aerobic and anaerobic habitats, and many species can shift their metabolism from aerobic respiration to anaerobic respiration or fermentation in response to changing O_2 concentrations. Collectively, they tolerate exceptionally wide ranges of temperature, pH, and soil moisture (water activity).

Through their diverse metabolic activities, bacteria play major roles in soil formation, organic matter decomposition, and remediation of contaminated soils. They mineralize and immobilize inorganic nutrients, mediate all of the oxidative and reductive transformations of nitrogen and sulfur in the biogeochemical cycles of these elements, and form commensal, mutualistic, and parasitic interactions with plants, animals, humans, and other soil microbes. No other group of soil organisms has a greater impact on soil fertility, water and air quality, and on the quality of plant, animal, and human life.

SOIL DISTRIBUTION OF MICROORGANISMS

THOMAS B. MOORMAN
USDA Agricultural Research Service
National Soil Tilth Laboratory
Ames, Iowa

Microorganisms have significant roles in the processes of biodegradation and nutrient transformation in terrestrial ecosystems. Microorganisms are abundant in soil and sediments, and active populations are even found in geologic materials far below the earth's surface. In general, population distributions are controlled by substrate inputs. Thus, substrate-rich environments such as the plant rhizosphere or the forest-litter layer have higher population densities than do root-free surface soil. Surface

soil have far larger populations of microorganisms than deeper sediments, which receive organic substrates only through leaching of materials from the surface.

The distribution and activity of microorganisms is rarely uniformly distributed in soil and sediments. Microbial activities are often localized in "hot spots" and, conversely, greatly reduced in other areas (1). Quantification of these heterogeneous distributions can provide insights into the ecological controls that govern microbial population. Techniques for quantifying spatial variability of populations or processes that have been used in the fields of plant ecology, geology, and soil sciences are now being applied to microbiological investigations (2–4). Spatial variability or spatial distribution is the variation in a population or process across a defined space, which is, generally, defined by the context of the investigation. Variation in space may arise from gradients in environmental variables, such as temperature or substrate concentrations, or from unknown factors. A major objective of microbial ecologists working with soil, plant roots, or sediments is to estimate microbial population densities or process rates. This article briefly describes several types of random and geostatistical sampling methods, and respective data analysis procedures. These descriptions are conceptual in nature, and the reader should consult the cited literature for more in-depth descriptions.

DISTRIBUTIONS AT DIFFERENT SCALES

Selection of appropriate techniques and sampling strategy is dependent on the scale of variation. The potentially overwhelming number of different scales relevant to microbial ecology can be simplified to include the microscale, the stratum scale, and the regional or ecosystem scale (1,2). Regional or ecosystem scale studies covers the quantity and distribution of microorganisms within one or more large geographic units. The definition of a region or ecosystem is often based on criteria with little immediate meaning for the microbiologist, such as geographic or edaphic areas, agronomic-use areas, vegetation zones, or political boundaries. Sampling techniques at these scales generally use volumetric sampling and extraction of cells or their components to estimate population or processes. Total microbial biomass in surface soil is estimated to range between 110 to 1,940 kg C ha^{-1} in arable soil, 500 to 2,100 kg C ha^{-1} in forest soil, and 280 to 2,200 kg C ha^{-1} in grassland soil across a wide variety of regions (5). Even within a geographic region, microbial biomass can vary significantly, as shown in Table 1, with much of the variation attributable to different land uses.

In the Central and Southern High Plains (MLRA 67 and samples shown in Table 1), only a single soil series was sampled, but multiple soil series were sampled in the Northern Mississippi Valley Loess Hills and the Palouse Prairie MLRA. However, variability, as estimated by the standard deviation, was as great within the two MLRAs where sampling was restricted to a single soil series as in the two MLRAs where different soils were sampled as well.

The particular scale addressed in this study estimates the microbial biomass for different land uses within a region, but does not provide an estimate of the spatial distribution of the total biomass within the region or specific land uses.

An example of an assessment of spatial variational scale is the mapping of downy mildew (*Bremia lactuca* Regel) disease incidence in lettuce fields of the Salinas Valley of California (9). Surveys of 32 to 55 fields were conducted during the growing season to determine the mildew severity (by measuring the percentage of infected plants). Global positioning systems (GPS) and geographic information systems (GIS) were used to construct maps showing the spread of disease across the valley during the growing season. It should be recognized that results are often scale-dependent. Although spatial patterns present across small areas are inherently included in studies encompassing larger areas, small-area patterns may be obscured or averaged by the lower resolution required by large-area studies or by large-area patterns.

Table 1. Effect of Land Use on Mean Microbial Biomass (mg C kg^{-1} Soil) in Four Major Land Resource Areas (MLRA) in the United States. Adapted from J. J. Brejda and coworkers, *Soil Sci. Soc. Am. J.* 64, 974–982 (2000); J. J. Brejda, T. B. Moorman, D. L. Karlen, and T. H. Dao, *Soil Sci. Soc. Am. J.* 64, 2,115–2,124 (2000); and J. J. Brejda, D. L. Karlen, J. L. Smith, and D. L. Allan, *Soil Sci. Soc. Am. J.* 64, 2,125–2,135 (2000)

MLRA	All[a]	Land Use			
		Cropland	CRP[b]	Forage Pasture	Forest or Range[c]
Central High Plains	450 ± 410	310	420	560	740
Southern High Plains	180 ± 150	170	160	NA	220
Northern Mississippi Valley Loess Hills	600 ± 430	370	450	750	840
Palouse Prairie	380 ± 335	280	330	440	700

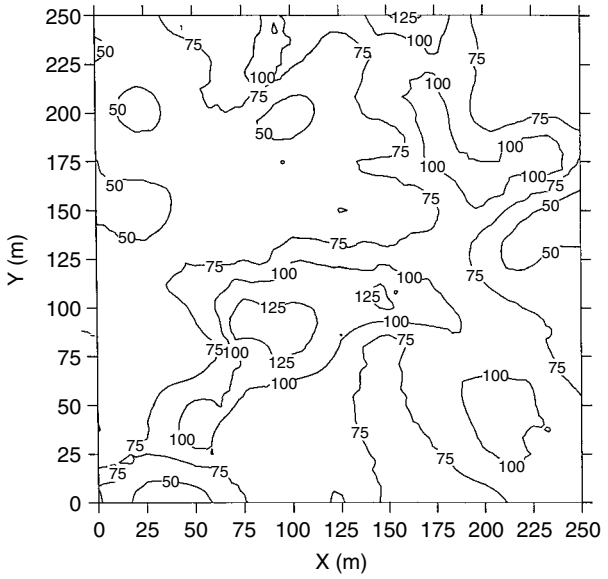

Figure 1. Microbial biomass ($g\,C/m^2$) at a 15 cm depth from the surface in an agricultural soil in central Iowa (3) estimated by kriging.

Spatial variability at the stratum scale considers variation within a single natural body, such as a particular unit of soil or sediment, a layer of water, or a plant canopy; the distributions of total microbial biomass, microbial activities (e.g., methane production); or of individual metabolic groups (e.g., cellulose degraders) in soils, subsurface sediments, or water (10,11). These studies were accomplished using a variety of sampling and enumeration methods and they address variability at the scale of a few meters to hundreds of meters in distance. The distribution of the total microbial biomass at the field scale is mapped in Figure 1.

The microscale encompasses spatial distances ranging from microns to centimeters. Direct microscopic counts of bacteria on root surfaces showed that the distribution of cells was aggregated (12). In this study, the distribution of bacteria was measured using techniques that visualize bacterial cells in situ with minimal disturbance of their natural position on the root surface. In contrast, another study followed the colonization of root systems by an *Enterobacter* strain containing *lux* genes at the centimeter scale (13). Individual cells were not counted, but the light generated by the *lux* gene was used as an indicator of *Enterobacter* colonization.

SAMPLING FOR SPATIAL DISTRIBUTIONS

Understanding the distribution of a parameter (microbial population or process) in space requires a sampling design that relates to units of soil or sediment that can be described in space. Two fundamental considerations that apply after the scale of the study is defined are estimation of the mean and the variability associated with the estimation at different points within the study space. Conventional and geostatistical sampling strategies and their respective statistical analyses of the data allow the estimation of means and variances in space, but the assumptions associated with these approaches differ sharply.

Three types of random sampling are most often used in environmental microbiology. The objective of the study may be to compare populations of microorganisms in the soil that have different histories or treatments imposed on them by an experiment, or different natural histories or gradients. The first approach is random sampling of defined areas or depths of soils at one or more locations. Microbial populations in the different areas of soil or sediment can be compared statistically. This approach assumes that rational criteria can be provided to define the sampling areas. For example, microbial populations in soils under different vegetation types could be compared. An assumption in random sampling is that the individual samples are independent of each other. An example of this approach is the measurement of population and diversity of cellulolytic bacteria in different landscape positions in an 8-ha agricultural field (11). Three soil cores were taken from each landscape position and microbiological analyses were performed. The results were reported as mean densities of culturable cellulolytic bacteria with standard errors.

Random sampling can also be applied to transect sampling, random sampling within blocks, and to stratified random sampling. Stratified sampling refers to the random sampling of individual strata (units of soil, roots, water). Individual means for each strata can be calculated, and then combined to estimate the population of a larger area, with the grand mean weighted by area, strata variance, or other appropriate factors (14). Stratified random sampling was used [Brejda and coworkers (6–8)] to measure the effects of land use on total microbial biomass in the surface soil (Table 1). Sample sites were stratified according to land use and geographic distribution within each MLRA to assure that the sampling strategy would produce accurate, unbiased measurements of microbial biomass in each land use. Morris and Boerner (15) used stratification to obtain samples from different moisture regimes in forested watersheds.

There are often situations in which effective criteria for stratification or other delineation of sampling areas are not known at the start of the investigation. Sampling of soil, sediment, or water using grids or transects can be effective in providing information on the spatial distribution of the microbial community under these circumstances. Quantitative information about the spatial distribution is often displayed through a graph or map. An example of this is the result of Cambardella and coworkers (3) shown in Figure 1. Samples were taken at 25 m intervals in a 250 ± 250 m grid, with additional sampling points at 2, 5, and 10 m intervals for a total of 241 sampling points.

ANALYSIS AND INTERPRETATION OF SPATIAL DATA

Campbell and Noe (16) described three steps in the analysis of spatial data, that is, mapping of populations, analysis of data distributions to determine randomness

or aggregation, and statistical analysis of dispersion and/or autocorrelation. There are a variety of procedures that can produce maps from spatially distributed data, irrespective of whether the data are produced from grid sampling or random sampling. Mapping requires interpolation of measured values to unmeasured areas. Contour mapping typically uses inverse distance weighted average of the nearest four to eight data points (nearest-neighbor interpolation) to estimate the value of a parameter, but alternative methods (minimum curvature, natural neighbors, kriging, radial basis function) are also available in commercially available software. These procedures produce estimated values in a defined space (a distribution), but do not estimate the variability associated with the estimate, except for kriging. An initial map of the data will help guide the course of statistical analyses.

Microbiological data are often abnormal in their statistical distribution (3,11,17), but many data are approximately log-normal in their distribution (15,16,18). Conventional statistics calculated using log-transformed data often analyzed log-normal data sets, but bias can be introduced through this approach. For instance, the geometric mean (mean of log-transformed data) is actually an estimator of the population median. Additional information on statistical procedures for abnormal distributions, including log-normal tests and nonparametric tests, are provided in References 14 and 18. Although log-normal distributions are often encountered, other distributions, such as the Weibull, gamma, and beta, should also be considered if log-transformation provides only marginal improvement in normality. The beta-binomial distribution has been applied to the data on plant disease, and the parameters derived from this distribution can be used to test the aggregation or dispersion of the pathogen's incidence in a plot or field. These tests were used in conjunction with geostatistical procedures by Xaio and coworkers (19) in their study of the soilborne pathogen, *Verticillium dahliae*, causing the wilting of cauliflower. Still, analyses based on statistical distributions generally assume that the data are independent from one another and not correlated in space.

Geostatistical sampling and analysis provide a method for estimating the distribution of a parameter over a space with an estimate of the variance associated with the estimates that describe the distribution. Geostatistical procedures are particularly useful for determining if data are autocorrelated in space and for the analysis of such data. Autocorrelation is simply the tendency of samples located near each other to be more similar than samples taken farther apart. The semivariogram relates variance in a parameter (z) to the distance between the samples (h):

$$\gamma(h) = \left[\frac{1}{2N(h)}\right] \sum_{(i=1\ldots N)} [z(x_i) - z(x_i + h)]^2$$

where $\gamma(h)$ is the summation of the semivariance in z between points $(x_i, x_i + h)$ separated by the lag distance (h). The lag distance (h) is often called the *separation distance*. N(h) is the number of pairs of sampling points separated by the separation distance (20). The semivariance $\gamma(h)$ is calculated for all combinations of x_i and $x_i + h$, as the lag distance between pairs of points (h) increases. Geostatistical sampling may be accomplished using a systematic grid sampling, random sampling, or randomized sampling within blocks or grid cells. Care must be taken to create a sampling design that leads to more than 25 pairs of points in each lag distance class (h), if the information about the variance structure is to be obtained at that distance. After the semivariance is calculated, the semivariogram is fitted to a model by nonlinear least-squares regression procedures (20). In some data sets, a single semivariogram may describe the semivariance pattern in all directions, which is termed an *isotropic semivariance*. In other data sets, there is a directional bias to the data and different semivariograms will be required for different directions (anisotropic semivariance). Directional bias may be caused by external factors, such as plant rows, or by unknown intrinsic factors. In practice, the computation of semivariance and model fitting is performed using one of a variety of software packages.

The semivariogram provides information on the variability in space. The example of a semivariogram shown in Figure 2 was produced from the 241 measurements of microbial biomass described by Cambardella and coworkers (3). The data was log-transformed before analysis and the semivariance (γ) was described by an isotropic, spherical semivariogram. The general formula for a spherical semivariogram is illustrated in Figure 2.

$$\gamma(h) = C_0 + C\left[1.5\left(\frac{h}{A_0}\right) - 0.5\left(\frac{h}{A_0}\right)^3\right] \quad \text{for } h \le A_0$$

$$\gamma(h) = C_0 + C \quad \text{for } h \ge A_0$$

where (h) is the lag distance, C_0 is the nugget variance, C is the structural variance, and A_0 is the range. In this example, the semivariance increases from a minimum value (the nugget, C_0) of approximately 0.05 to a maximum, called the *sill* ($C_0 + C$), of 0.15. The nugget accounts for approximately 31% of the total semivariance. The nugget variance represents the variation in microbial biomass that is present at the lowest value of (h), that is, 2.5 m in this study, and infers

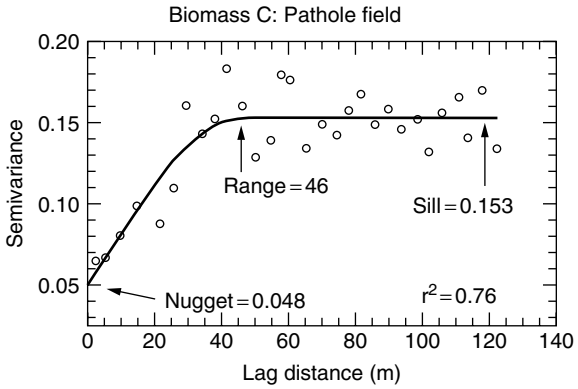

Figure 2. Spherical semivariogram for microbial biomass in a central Iowa agricultural soil.

Table 2. Range (A_0), Nugget (C_0) and Sill ($C_0 + C$) for Selected Semivariograms Describing Spatial Variability of Microorganisms in Soil. Adapted from C. A. Cambardella and coworkers, *Soil Sci. Soc. Am. J.* 58, 1,501–1,511 (1994); G. P. Roberton and coworkers, *Ecol. Appl.* 7, 158–170 (1997); L. M. Dandurand, D. J. Schotzko, and G. R. Knudsen, *Appl. Environ. Microbiol.* 63, 3,211–3,217 (1997); M. Möttönen and coworkers, *Soil Biol. Biochem.* 31, 503–516 (1999); S. J. Morris, *Soil Biol. Biochem.* 31, 1,375–1,386 (1999)

Parameter	Matrix	Semivariogram	A_0, h_{max}(m)[a]	C_0(%)[b]	$C_0 + C$
Ergosterol[c]	Forest soil	Spherical, isotropic	4, 10	0.037 (4)	0.90
Total microbial biomass	Arable soil	Exponential, isotropic	21, 200	0.067 (46)	0.146
Total microbial biomass (PHF)[d]	Arable soil	Spherical, isotropic	46, 125	0.048 (31)	0.153
Total microbial biomass (NT)[d]	Arable soil	Spherical, isotropic	190, 200	0.032 (27)	0.119
Pseudomonas fluorescens	Root surface	Spherical, anisotropic (90°)	10 to 41 $\times 10^{-6}$, 60	0.18–0.92	0.88–1.05
Fungal biomass	Forest soil	Linear sill	0.36, 2.0	2.0 (66)	3.01
Bacterial biomass	Forest soil	Linear sill	1.96, 2.0	1.88 (63)	3.04

[a] h_{max} indicates the maximum separation distance reported.
[b] Value in parentheses is the nugget expressed as a percentage of the sill.
[c] Ergosterol is a biochemical measure of fungal biomass.
[d] PHF and NT indicate two nearby fields described in Reference 4.

that substantial variation is present at smaller scales. In some semivariograms, the nugget accounts for nearly all the semivariance, which indicates that the data are randomly distributed. The range in this example is the lag distance (h = 46 m) where the semivariance reaches the sill (maximum semivariance). Samples separated by distances exceeding the range are truly independent, whereas samples separated by distances smaller than the range will tend to be increasingly autocorrelated as h becomes smaller. The data in this example were described by a spherical semivariogram, but linear, exponential, or Gaussian models may describe other data sets. Most of the commercially available softwares offer a variety of fitting options.

Although the semivariogram provides information on the variability in relation to scale (distance), it provides no information on the distribution of the measured parameter in space. Kriging is a nearest-neighbor interpolation procedure that also estimates the standard error of the kriged mean using the semiovariogram. The kriged map of microbial biomass in Figure 1 was produced using the semivariogram described in Figure 2. Kriging is an interpolation procedure, which is applicable to spatial data that is autocorrelated, which distinguishes kriging from other interpolation procedures, and which makes no assumptions about the spatial relatedness of the data.

A summary of different results obtained from studies of spatial variability of microorganisms in soil is presented in Table 2. These few data reveal several key points. First, the estimates of range (A_0) are scale dependent, which probably reflects the hierarchical nature of spatial data for microorganisms. The range of the maximum lag distance (h_{max}) in these different studies was from 60 μm to 200 m. Second, even across the different scales, the nugget accounts for a large proportion of the total variability, indicating that these measures are not strongly autocorrelated in space. Finally, even when similar measurements are made in closely adjoining physical areas, such as the two fields studied by Cambardella and coworkers (3), the parameters from the semivariograms describing the spatial variability vary considerably.

Spatial information on biological processes can provide clues about environmental controls and the interrelation of microorganisms to other organisms in the ecosystem. Rossi and coworkers (20) provide an interesting account of the application of geostatistics and other techniques to a wide variety of ecological data. Clearly, establishing some quantitative estimate of the parameter of interest (usually a mean or median) and mapping by kriging or other techniques establishes the nature of spatial distribution. The next step is interpretation, and although there are no clear guidelines to the interpretation of spatial data, the work of previous investigators offers some insights into the potential uses of spatial data.

Spatial data are often used in combination with other data obtained at the site of study. The microbial biomass distribution in Figure 1 provides an example. Although organic carbon and microbial biomass are correlated, the points deviating from this correlation trend line shows patterns. For instance, the area of the field with high biomass in the area around the coordinates of (X = 100, Y = 100) is well above the biomass predicted by regression against the organic carbon content of the soil. The relationship between two variables can be approached by conventional regression or geostatistical techniques (covariograms, correlograms), which are described in detail by Rossi and coworkers (20). The difference between conventional regression and geostatistical procedures resides in the assumptions of independence of samples, or in the autocorrelation of samples in space. Finally, geostatistics can be combined with more complex measures of the microbial community, such as the index describing genetic diversity of *Pseudomonas* strains in relation to the spatial scale reported by Cho and Tiedje (23).

SOIL ENZYMES

M. Ali Tabatabai
Iowa State University
Ames, Iowa

Soil may be looked upon as a biological entity (i.e, a living tissue with complex biochemical reactions). Soil contains free enzymes; immobilized extracellular enzymes stabilized by a three-dimensional network of macromolecules and enzyme proteins within microbial cells (1). Each of the organic and mineral fractions in both bulk soil and rhizosphere has a special influence on the total enzymatic activity of that soil (Fig. 1) (2).

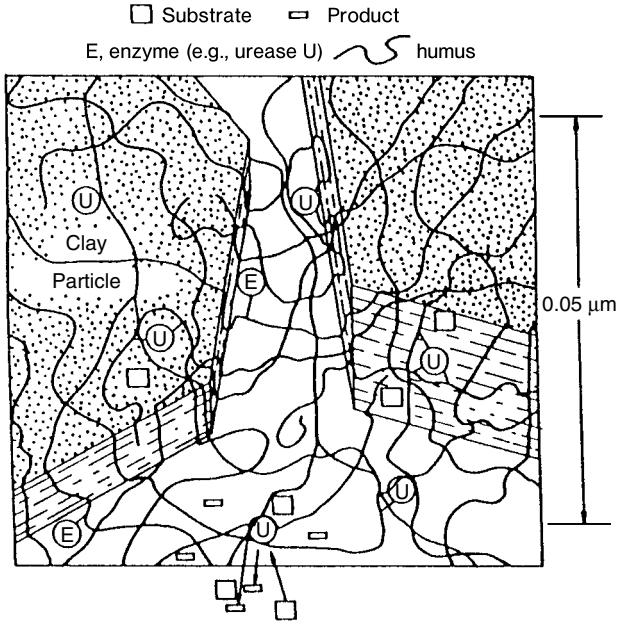

Figure 1. This model for soil enzyme location and activity consists of enzyme embedded in, and perhaps chemically attached to, a humus polymer network in contact with clay particles. Substrates, such as urea, can reach the enzyme by diffusion through pores too small for enzyme to penetrate (2).

Reactions in the soil environment involve chemical, biochemical, and physical processes. Soil contains a large number of biochemical reactions mediated by enzymes, especially those involved in nutrient (e.g., carbon, nitrogen, sulfur, and phosphorus) cycling. Most biochemical reactions are catalyzed by enzymes, which are proteins with catalytic properties. Catalysts are substances that, without undergoing permanent alteration, cause chemical reactions to proceed at faster rates. The reaction is expressed by the following equation:

$$[\mathrm{E}] + [\mathrm{S}] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [\mathrm{ES}] \xrightarrow{k_3} [\mathrm{E}] + [\mathrm{P}] \qquad (1)$$

where E refers to enzyme, S to substrate, ES is the enzyme-substrate complex, P is the product released, [] indicates concentration, and k_1, k_2, and k_3 are the rate constants.

In addition, most enzymes are specific for the type of chemical reactions in which they participate. Enzyme specificity is often dictated by the nature of the groups attached to the susceptible bonds. For example, α-chymotrypsin and trypsin are proteolytic enzymes capable of hydrolyzing certain peptide bonds in protein. α-Chymotrypsin will hydrolyze peptide bonds in which the carbonyl group (−C=O) of that bond is supplied by the amino acid L-tyrosin, L-phenylalanine, or L-tryptophan. Trypsin will hydrolyze peptide bonds in which the carbonyl group of the peptide bonds is supplied by the amino acid L-arginine or L-lysine. Another example of the specificity of enzymes involves maltase and cellubiase. Maltase hydrolyzes maltose to glucose, whereas cellobiase hydrolyzes cellobiose to glucose but not vice versa. Differences between the two substrates seem slight in that

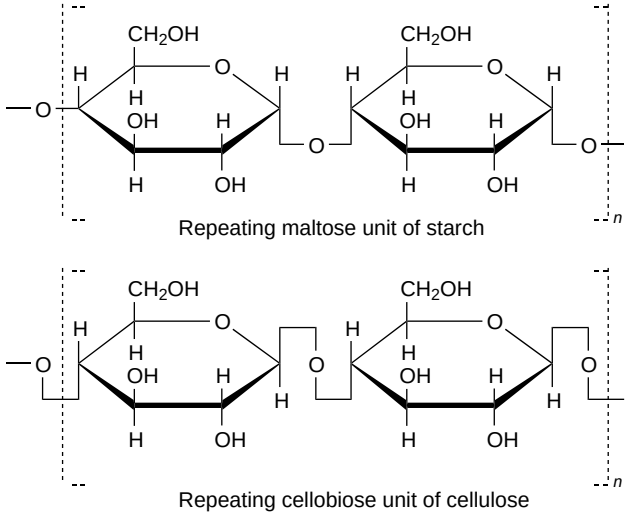

Figure 2. Repeating units of starch and cellulose.

maltose (repeating unit of starch) is an α-glucoside and cellobiose (repeating unit of cellulose) is a β-glucoside (Fig. 2).

All living systems, ranging from bacteria to the members of the animal kingdom, from algae and molds to the higher members of the plant kingdom contain myriad of enzymes catalyzing complex network of chemical reactions. Enzymes also are found in ponds, lakes, rivers, water-treatment plants, and animal manures. They exist either in extracellular forms separate from any living cell or intracellular forms as part of the living biomass. These enzymes are involved in the synthesis of proteins, carbohydrates, nucleic acids, and other components of living systems and also in the degradation of, and the cycling of, nutrients.

The study of enzymes, in general, is a subject of interest to many disciplines in science ranging from biology to physical sciences. Enzymes have a significant place in biology. Life on this planet depends on the complex of chemical reactions facilitated by specific enzymes, and any alterations in the enzyme protein structure that affect activity might have far-reaching consequences for living organisms. It is safe to say that soil would remain lifeless and basically unaltered without enzymatic reactions. Within the past five decades, enzymology, the science of studying enzymes, has developed rapidly. Scientists may now specialize in this specific field of biochemistry and often this specialty can be focused on a group of enzymes or on even a single enzyme.

FACTORS AFFECTING ENZYME REACTIONS

Temperature

The activity of any chemical reaction increases with temperature, approximately doubling for every increase of 10 °C. The rate of enzyme-catalyzed reaction increases as the temperature increases until some high temperature is reached at which the rate begins to decrease because of enzyme inactivation. Enzyme-catalyzed reactions, however, are less sensitive to temperature changes than their uncatalyzed counterparts. Whereas the uncatalyzed reaction rate may double with every 10 °C elevation of temperature, the enzyme-catalyzed reaction rate will increase by a factor of less than 2. The temperature dependence of the rate constant can be described by the Arrhenius equation:

$$k = A \exp\left(-\frac{E_a}{RT}\right), \tag{2}$$

where A is the preexponential factor, E_a is the energy of activation, R is the gas constant, and T is the absolute temperature in degree Kelvin. The Arrenhius equation can be expressed in log form

$$\log k = \left(-\frac{E_a}{2.303\,RT}\right) + \log A, \tag{3}$$

where $\log A$ and E_a can be determined from the intercept and slope, respectively, of a linear plot of the dependence of $\log k$ on $1/T$ at lower temperatures, generally between 10 and 50 °C. When the value of k is not available, apparent values or any parameter that is proportional to the rate constants, can be plotted.

pH

Changes in hydrogen ion activity influence enzymes, substrates, and cofactors by altering their ionization and solubility. Variations in such properties as ionization or solubility influences the rate of catalyzed reactions. Enzymes, being proteinaceous, exhibit marked changes in ionization with fluctuations in pH. Characteristically, each enzyme has a pH value at which the rate is optimum, and at each side of this optimum the rate is lower; thus, the catalytic action of enzymes operates in a somewhat restricted pH range. Enzymes are usually most stable in the vicinity of the optimum pH, and they are irreversibly denatured with extremes in acidity or alkalinity. Therefore, it is essential to assay (measure the reaction rate) enzyme-catalyzed reactions at, or close to, the optimum pH of activity by using a buffer. In addition to controlling the ionization of enzymes and substrates, the buffer used maintains the optimum pH for the duration of the reaction. This is especially important in enzyme assays involving substrates or products with acidic or alkaline properties (e.g., production of ammonium, NH_4^+) from hydrolysis of amides, urea, L-asparagine, and L-glutamine in soils). Also, because ionic species of the buffer might have a marked effect on enzyme activity, it is normally recommended that only one buffer system be used for determination of the pH profile.

Cofactors and Ionic Environment

Many enzymes are not catalytically active except when in combination with a nonprotein component. Generally, these nonprotein cofactors are heat-stable, dialyzable substances of low molecular weights. Cofactors are often described as activators, coenzymes, and prosthetic groups, and it is often difficult to distinguish between the meaning assigned to these terms. Prosthetic groups are usually defined as substances that are bound firmly to the enzyme, whereas, coenzymes are usually

classified as organic substances that freely dissociate from enzymes. Most coenzymes and prosthetic groups are transformed during the sequence of the catalytic reaction and need to be generated before they can again participate. Some enzymes are activated by inorganic ions furnished by mineral salts. Usually, these inorganic ions are not changed during the catalyzed process but are required before the enzyme can carry out the reaction.

Substrate Concentration

When the enzyme concentration is held constant and the substrate concentration is allowed to vary over a wide range, the velocity of the enzyme-catalyzed reaction may be described by a rectangular hyperbola (Fig. 3). At a low substrate concentration, the velocity of the reaction follows a first-order reaction equation. That is, the rate of product formation is proportional to the substrate concentration. At higher substrate concentrations, a maximum velocity is obtained, which is independent of increased concentrations of substrate, and a zero-order reaction equation applies. The magnitude of the maximum velocity is proportional to the enzyme concentration; the higher the enzyme concentration, the higher the maximum velocity. A mathematical equation describing the rate equation for the effect of substrate concentration on the velocity of enzyme-catalyzed reaction was first introduced by Michaelis and Menten (3). Derivation of their equation is presented by Neilands and Stumpf (4) and White and coworkers (5).

The Michaelis-Menten equation

$$v = \frac{V_{\max}[\mathrm{S}]}{(K_{\mathrm{m}} + [\mathrm{S}])} \tag{4}$$

satisfactorily describes the rectangular hyperbola curve shown in Figure 3. It agrees with the theory that enzymes act by forming an unstable complex of enzyme and substrate before forming a product. The symbol in the equation are as follows: v is the reaction velocity, $V_{\max}$ is the maximum reaction velocity, S is the substrate, [] is the concentration expressed in mole/liter, and K_{m} is the Michaelis constant. Equation [4] can be written in three linear transformations:

$$\frac{1}{v} = \frac{1}{V_{\max}} + \left(\frac{K_{\mathrm{m}}}{V_{\max}}\right)\left(\frac{1}{[\mathrm{S}]}\right) \tag{5}$$

Linweaver-Burk transformation

$$\frac{[\mathrm{S}]}{v} = \frac{K_{\mathrm{m}}}{V_{\max}} + \left(\frac{1}{V_{\max}}\right)[\mathrm{S}] \tag{6}$$

Hanes-Wolf transformation

$$v = V_{\max} - K_{\mathrm{m}}\left(\frac{v}{[\mathrm{S}]}\right) \tag{7}$$

Eadie-Hofstee transformation.

Plots of the variables of those relationships normally give straight lines. The values of the slopes and intercepts are commonly used for calculation of the constants from a set of experimental data. Once the K_{m} and $V_{\max}$ are known for a particular enzyme reaction under given set of conditions, the reaction velocity, v, can be calculated for any substrate concentration. The Michaelis constant (K_{m}) is the substrate concentration at which the reaction velocity is one-half of $V_{\max}$ (Fig. 3), and it is by far the most fundamental constant in enzyme chemistry. It has dimensions of concentration (mole/liter), and is constant for the enzyme under rigidly specified conditions. In addition to providing an index of the affinity of the enzyme to its substrate (the lower the K_{m} values, the greater the affinity), this constant is useful for estimating the substrate concentration necessary to give a maximum velocity. The form of the Michaelis-Menten equation is such that approximately 10 and 90% of the $V_{\max}$ is achieved at substrate concentration corresponding to $K_{\mathrm{m}} \times 0.1$ and $K_{\mathrm{m}} \times 10$, respectively (4).

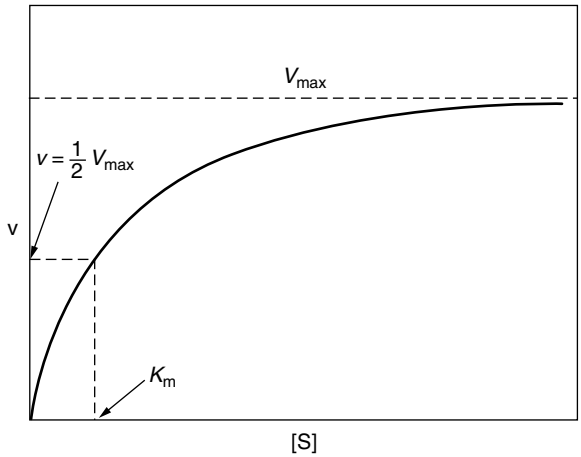

Figure 3. The rectangular hyperbola describing the effect of substrate concentration [S] on reaction velocity (v).

ENZYME INHIBITION

The subject of enzyme inhibition requires special consideration because soils receive a variety of organic and inorganic chemicals. Some of the compounds, such as fertilizers, pesticides, and animal, municipal, and industrial wastes, are added in practices of soil and crop management. Other compounds, such as salts or trace elements, are added to soils as impurities in lime and fertilizers and as industrial pollutants. Also, inhibition of soil enzymes for controlling the release of fertilizer nutrients has received attention within the past 30 years. Most of this research, however, has been concerned with the use of enzyme inhibitors for controlling urea hydrolysis in soils because urea-N is one of the most widely used nitrogen fertilizers. Unfortunately, most of the compounds tested for inhibition of urease in soils are general enzyme inhibitors, affecting not just urease activity but a wide range of soil enzymes. With the exception of the mechanisms of inhibition of soil enzymes by trace elements, generally, little information is available on the mechanisms of inhibition of soil enzymes by various inhibitors.

An inhibitor may produce an irreversible or reversible decrease in the enzyme rate constant or reaction velocity. An irreversible inhibitor forms a stable compound, often by

the formation of a covalent bond with a particular amino acid residue in the enzyme structure, which is essential for the catalytic activity. The phenomenon of reversible inhibition is characterized by equilibrium between the enzyme and inhibitor defined by an equilibrium constant (*Ki*), which is a measure of the affinity of the enzyme for the inhibitor.

Although the kinetics of enzyme inhibition are complex and varies with the enzyme, substrate, and inhibitor, three main groups of reversible inhibition can be distinguished by their characteristic effects on plots of $1/v$ vs. 1/[S] (Lineweaver-Burk plot). The kinetics of most enzyme reactions in the presence of varying concentrations of inhibitors are such that the linear double reciprocal plots of $1/v$ vs. 1/[S] show lines similar to those in the absence of inhibitor except that (*1*) the slope, (*2*) the intercept, or (*3*) both are altered. The first case is called competitive (Fig. 4a), the second uncompetitive, and the third noncompetitive inhibition (Fig. 4b). The kinetic diagnostic for uncompetitive inhibition (case 2) is that in the double reciprocal plot the slopes remain constant (i.e., the lines are parallel), but the intercepts vary. This form of inhibition is rare with single substrates. One possible, but not likely, mechanism entails combination of the inhibitors exclusively with the ES complex. This type of mechanism, however, is more common in more complex cases. The other two cases are more common with single substrates and are likely the mechanisms of inhibition of most soil enzymes (Figs. 4a and b).

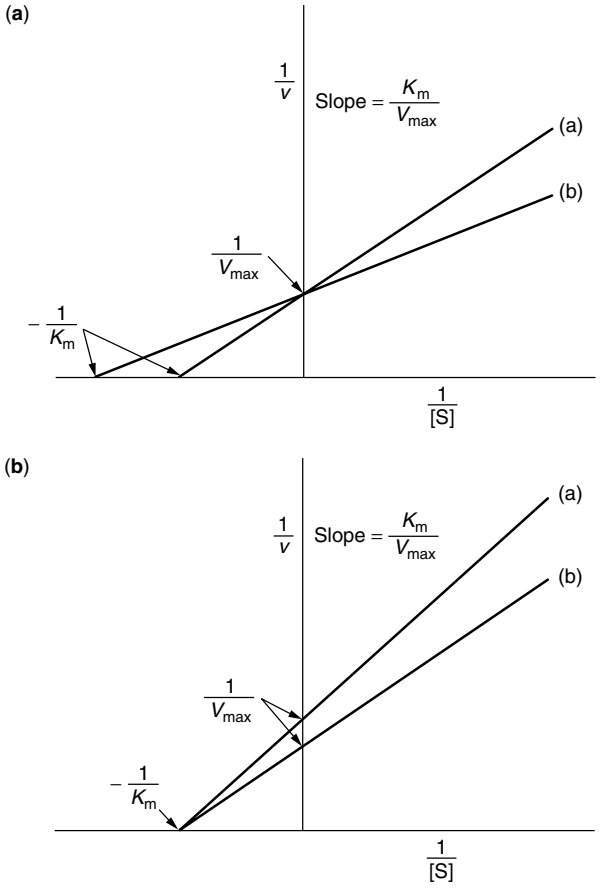

Figure 4. Linweaver-Burk plots of the Michaelis-Menten equation describing competitive inhibition; (**a**) in the presence of inhibitor and (**b**) in the absence of inhibitor. A, competitive inhibition; B, noncompetitive inhibition.

ENZYMES IN SOILS

The first known report on enzymes in soils is the paper presented by Woods at the 1899 Annual Meeting of the American Association for the advancement of Science in Columbus, Ohio (6). Little significant progress was made, however, in the area of soil enzymology until the late 1950s. This lack of progress was mainly due to lack of appropriate methods and procedures for enzyme activity measurement, especially in soils, and the lack of understanding the true chemical nature of enzymes. Although Sumner first isolated urease in crystalline form from jack bean (*Canavalia ensiformis*) meal in 1926, for which he received a Nobel Prize, it took several decades for this field of biochemistry to mature. Questions asked during the early years of soil enzyme research dealt with the origin, stabilization, importance in plant nutrition, and the role of soil enzymes in organic matter turnover. After several decades of research, many of these questions still remain to be answered.

The history of abiontic (free extracellular enzymes, enzymes bound to inert soil components, active enzymes within dead microbial cells, and others associated with the dead cell fragments collectively called abiontic enzymes) soil enzyme research has been elegantly prepared by Skujins (6), and reviews of recent advances and state of knowledge in this field are presented in a book by Burns (7) and in book articles by Kiss and coworkers (8) Skujins (9,10), Ladd (11), Dick and Tabatabai (12), Tabatabai (13), Gianfreda and Bollag (14), and Ruggiero and coworkers (15). Many of the enzymes detected in soils are hydrolases, but others fall in the class of oxidoreductases, transferases, and lyases (Table 1).

Sources of Enzymes in Soils

Microorganisms, soil animals, and plants release enzymes into the soil environment. A conceptual scheme of the composition of soil enzyme activities is illustrated by Skujins (6). It has long been known that ribonucleases and alkaline phosphatase, for example, are excreted by *Bacillus subtilis* under certain conditions, and pyrophosphatase and acid phosphatase may exist extracellularly on the surface of cell walls of *Saccharomyces mellis*. Microbial production of useful enzymes is a well-developed process. The enzymes produced include protease, amylase, glucose isomerase, pictinase, and lipase. Therefore, it is not surprising that microorganisms seem the logical choice for supplying most of the soil enzyme activity. This is because of their large biomass, high metabolic activity and short lifetimes, which allow them to produce and release relatively larger amounts of extracellular enzymes than can plants or animals.

State of Enzymes in Soils

The term *state of enzymes in soils* has been used to describe the phenomenon whereby enzymes exist in the

Table 1. Enzymes Assayed in Soils

Class	EC Number[a]	Recommended Name	Substrate
Oxidoreductases	1.1.3.4	Glucose oxidase	Glucose
	1.7.3.3	Urate oxidase	Uric Acid
	1.10.3.1	Catechol oxidase	Catechol
	1.10.3.2	Laccase	Phenylenediamine
	1.11.1.6	Catalase	Hydrogen peroxide
	1.11.1.7	Peroxidase	Pyrogallol, chloroanilines
	1.14.18.1	Monophenol monooxygenase	Catechol, pyrogallol, hydroquinone
Transferases	2.4.1.5	Dextransucrase	Sucrose
	2.4.1.10	Levansucrase	Sucrose
	2.8.1.1	Thiosulfate *S*-transferase (rhodanese)	Thiosulfate + cyanide
Hydrolases	3.1.1.1	Carboxylesterase	Hydroxymethylcoumarin butyrate, malathion
	3.1.1.2	Arylesterase	Phenyl acetate
	3.1.1.3	Triacylglycerol lipase	4-Methylumbelliferone nonanoate
	3.1.3.1	Alkaline phosphatase	*p*-Nitrophenyl phosphate
	3.1.3.2	Acid phosphatase	*p*-Nitrophenyl phosphate
	3.1.4.1	Phosphodiesterase	*Bis-p*-nitrophenyl phosphate
	3.1.6.1	Arylsulfatase	*p*-Nitrophenyl sulfate
	3.2.1.1	α-Amylase	Starch
	3.2.1.2	β-Amylase	Starch
	3.2.1.4	Cellulase	Cellulose, carboxymethylcellulose
	3.2.1.6	Endo-1,3(4)-β-D-glucanase	Laminarin
	3.2.1.8	Xylanase	Xylan
	3.2.1.20	α-D-Glucosidase	*p*-Nitrophenyl-α-D-glucoside, maltose
	3.2.1.21	β-D-Glucosidase	*p*-Nitrophenyl-β-D-glucoside, cellobiose
	3.2.1.22	α-D-Galactosidase	*p*-Nitrophenyl-α-D-galactoside, melibiose
	3.2.1.23	β-D-Galactosidase	*p*-Nitrophenyl-β-D-galactoside, lactose
		Peptidases	*N*-benzoyl-L-arginine amide, benzyloxycarbonyl
		Proteinases	Casein, gelatine
	3.5.1.1	Asparaginase	Asparagine
	3.5.1.2	Glutaminase	Glutamine
	3.5.1.4	Amidase	Formamide, acetamide
	3.5.1.5	Urease	Urea
	3.5.1.13	Arylacylamidase	Propanil
	3.6.1.1	Pyrophosphatase	Na-pyrophosphate
Lyases	4.1.1.15	Glutamate decarboxylase	Aspartic acid

	4.3.1.3	L-Histidine ammonia lyase	L-Histidine

[a]EC number, Enzyme Commission number authorized by the International Union of Biochemistry.

soil. Describing the state of an enzyme in soils is an attempt to describe the location and microenvironment in which it functions and how the enzyme is bound or stabilized within that microhabitat. Several theories have been proposed to explain the protective influence of soil on extracellular enzyme activity. The dominant mechanisms of enzyme immobilization and stabilization that have been proposed (16) are summarized in Fig. 5. These are most likely mechanisms of enzyme immobilization in soils.

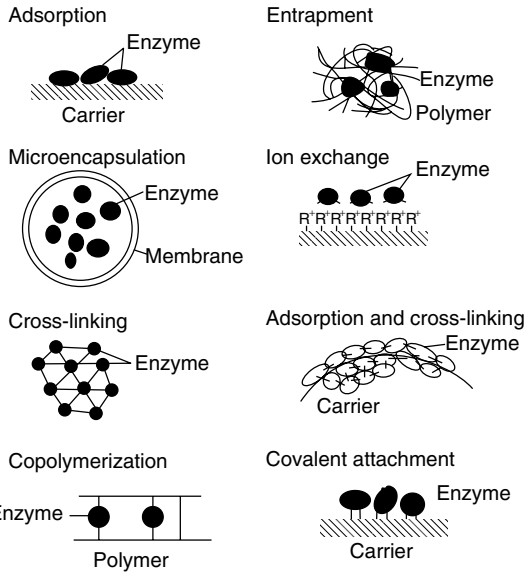

Figure 5. Schematic representation of methods of immobilizing enzymes (16). Most likely that enzymes are present in soils in more than one of those forms.

Soil Enzyme Assays

Anyone who studies enzymes is concerned with the general area of catalysis, and anyone who works with catalysis is most certainly concerned with the velocity of chemical reactions (chemical kinetics). Therefore, to understand the kinetics of an enzyme reaction in soils, it is fundamental that the meaning of the results obtained for a given sample be understood.

At the simplest level, the development of an assay procedure is necessary when investigating enzyme reactions in soils. This involves adding a known amount of soil

to a solution containing a known concentration of substrate and determining the rate at which the substrate is converted to products, under carefully controlled conditions of temperature, pH, and ionic strength. To design an adequate assay, one must know (*1*) the stoichiometry of the reaction catalyzed; (*2*) chemical species that must be present in addition to the substrate (e.g., Mg^{2+} is required for the reaction catalyzed by pyrophosphatase; the enzyme that catalyzes the hydrolysis of pyrophosphate fertilizer to the plant-available form, orthophosphate); (*3*) the kinetic dependence of the reaction on such required species; (*4*) the optimum conditions of temperature, pH, and ionic strength; and (*5*) a suitable means for monitoring product appearance or substrate disappearance. Methods used for assay of several enzymes are summarized in Table 2.

Concentrations of Active Enzyme Protein Equivalents in Soils

One of the most difficult problems currently facing soil biochemists is the separation of extracellular enzymatic activity from activity associated with living organisms

Table 2. Methods Used for Assay of Enzyme Activities in Soils

Class/EC Number	Recommended Name[a]	Reaction	Assay Conditions	
			Substrate[b]	Optimum pH
		Glycosidases		
3.2.1.20	α-Glucosidase	Glucoside-R + H_2O → Glucose + R−OH	*p*-Nitrophenyl-α-D glucopyranoside (10 m*M*)	6.0
3.2.1.21	β-Glucosidase	Glucoside-R + H_2O → Glucose + R−OH	*p*-Nitrophenyl-β-D glucopyranoside (10 m*M*)	6.0
3.2.1.22	α-Galactosidase	Galactoside-R + H_2O → Galactose + R−OH	*p*-Nitrophenyl-α-D galactopyranoside (10 m*M*)	6.0
3.2.1.23	β-Galactosidase	Galactoside-R + H_2O → Galactose + R−OH	*p*-Nitrophenyl-β-D galactopyranoside (10 m*M*)	6.0
		Amidohydrolases and arylamidase		
3.4.11.2	Arylamidase[c]	L-leucine β-naphthylamide → L-leucine + β-naphthylamide	L-leucine β-naphthylamide (2.0 m*M*)	8.0
3.5.1.1	L-Asparaginase	L-Asparagine + H_2O → L-aspartate + NH_3	L-Asparagine (50 m*M*)	10.0
3.5.1.2	L-Glutaminase	L-Glutamine + H_2O → L-glutamate + NH_3	L-Glutamine (50 m*M*)	10.0
3.5.1.4	Amidase	R−$CONH_2$ + H_2O → NH_3 + R−COOH	Formamide (50 m*M*)	8.5
3.5.1.5	Urease	Urea + H_2O → CO_2 + $2NH_3$	Urea (20 m*M*)	9.0
4.3.1.1	L-Aspartase[d]	L-Aspartate + H_2O → Fumarate + NH_3	L-Aspartate (200 m*M*)	8.5
		Phosphatases		
3.1.3.1	Alkaline Phosphatase	RNa_2PO_4 + H_2O → R−OH + Na_2HPO_4	*p*-Nitrophenyl phosphate (10 m*M*)	11.0
3.1.3.2	Acid Phosphatase	RNa_2PO_4 + H_2O → R−OH + Na_2HPO_4	*p*-Nitrophenyl phosphate (10 m*M*)	6.5
3.1.4.1	Phosphodiesterase	R_2NaPO_4 + H_2O → R−OH + $RNaHPO_4$	*Bis*-*p*-Nitrophenyl phosphate (10 m*M*)	8.0
		Sulfatase		
3.1.6.1	Arylsulfatase	$ROSO_3^-$ + H_2O → R−OH + H^+ + SO_4^{2-}	*p*-Nitrophenyl sulfate (10 m*M*)	5.8

in soils. Although antiseptic agents have been used to retard or minimize microbial metabolism during the assay, especially in assay involving long incubation time (several hours), it is essential to evaluate the effect of the antiseptic agent on the enzyme-catalyzed reaction rate before it is used in soil assays. Methods that are based on sterilization of soil samples with high-energy irradiation or with use of antibiotics have also been evaluated, but such methods also alter enzyme reaction rates.

Recent work at Iowa State University showed that a chloroform fumigation technique, coupled with the use of a reference protein preparation could be used to estimate the enzyme activity associated with the microbial population and the extracellular enzyme activity in soils. Because enzyme proteins are present at different locations in the microbial cells, this method was useful in estimation of activities of urease (the enzyme involved in hydrolysis of urea fertilizer in soils) and arylsulfatase (the enzyme involved in hydrolysis of ester sulfate of soil organic matter to plant-available form, sulfate). Results with 10 Iowa surface soils (0 to 15 cm) showed that, expressed as percentages of total activity, the urease activity of the microbial biomass ranged from 37 to 73% (average = 54%). The remaining activity (27 to 63%, average 46%) was extracellular (Table 3) (19). The arylsulfatase activity of the microbial biomass ranged from 40 to 73% (avearge = 58%). The remaining activity (27-60, average = 43%) was extracellular (Table 4) (20).

Table 3. Urease Activity of Various Pools in Selected Iowa Surface Soils

	Urease Activity[a]			
Soil	Total mg NH_4^+-N kg^{-1}2 h^{-1}	Extracellular mg NH_4^+-N kg^{-1} 2 h^{-1}	Microbial Biomass	Specific Activity μg NH_4^+-N mg^{-1} C_{mic} $2h^{-1}$

[e] A: source: *H. pomatia*; B: source: *P. vulgata*.

Other recent studies estimated the concentrations of 12 enzyme proteins in soils (21). The averages in 10 Iowa surface soils ranged from 0.014 mg active protein kg^{-1} soil for β-glucosidase to 22.5 mg active protein kg^{-1} soil for acids phosphatase (Table 5). These calculations were not intended to give accurate concentration of enzyme proteins in soils but instead provide some quantitation of enzyme protein equivalent. Actual concentrations of enzyme proteins in soils are undoubtedly much greater than those calculated because many soil components can inhibit activity, and structural stabilization also leads to decreases in the activity. The calculation do illustrate one reason for the difficulty encountered in the extraction and purification of enzymes from soils (22). From the results reported in Table 5, it is clear that the small concentrations of enzyme proteins in soils are either denatured during extraction or bound tightly with the soluble carbohydrates in soils that makes their separation very difficult.

FACTORS AFFECTING ENZYME ACTIVITIES IN SOILS

Among the many factors that may affect enzyme activities in soils, cropping history, soil amendments, and some environmental factors have the most influence. Seasonal variation in urease and arylsulfatase activities has been documented (23). Waterlogging (flooding) of soil produces changes in the redox potential and pH, and consequently, in the activity of many enzymes (24). Other studies on the extracellular enzyme activities in ecosystems have shown that vegetation cover, agricultural chemicals, and industrial pollutants have a marked influence on soil enzymes (25). Generally, the effect observed differ markedly and depend on many factors. Because of the importance of urea as a fertilizer in world agriculture and the potential of soil urease to cause volatilization of NH_3 produced from urea hydrolysis in soils, especially from calcareous soils, several workers have investigated various enzyme inhibitors for agricultural application. Discussion of the inhibitors tested on urease activity in soils and enzyme interactions with various agricultural and

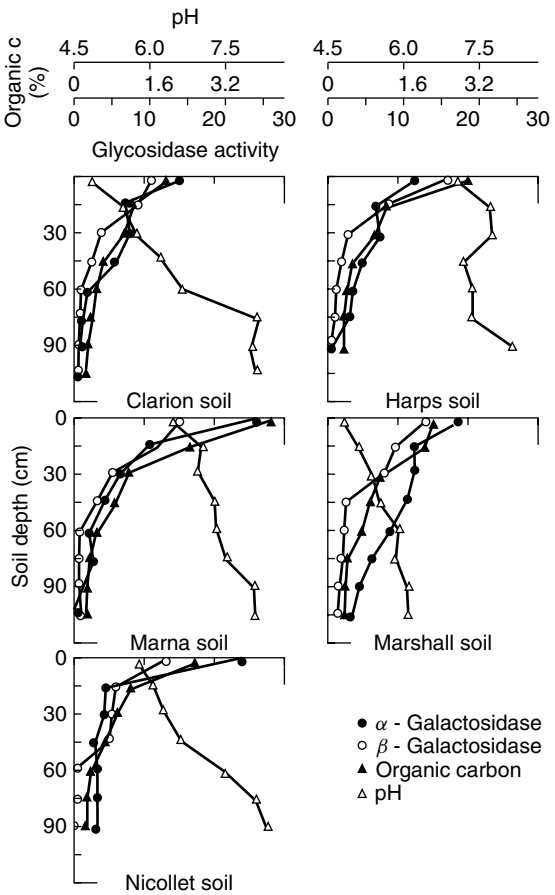

Figure 6. Distribution of organic C, α- and β-gactosidase activities and trends of pH with depth in soil profile samples. Galactosidase activity is expressed in mg of *p*-nitrophenol released kg^{-1} soil h^{-1} at 37 °C (29).

industrial chemicals, including pesticides, is presented by Kiss and coworkers (8) and Bremner and Mulvaney (25).

Distribution in Soil Profiles

Although the patterns of distribution of the activities of several enzymes in soil profiles have been studied by many workers, the relative factors that affect the activities through the profile have not been clearly established. As with other biochemical reactions in soils, however, enzyme activities are associated with organic matter distribution profile and generally decrease with depth (Fig. 6). This has been demonstrated for arylamidase (26), arylsulfatase (27), urease (28), glycosidases (29), amidase (30), L-asparginase (31), and L-glutaminase (32).

Cropping Systems

Sustainable management practices in agriculture, including crop rotations and fertilization systems to maintain soil quality and productivity and minimize the negative effects of agricultural production on the environment, have significant effects on soil biochemical processes. Long-term cropping systems and fertilization can influence important soil properties such as soil structure and density, pH, the quantity, quality, and distribution of soil organic matter and nutrient cycles within the soil profile. Most of those effects are derived from changes in microbial biomass carbon and nitrogen. In general, the highest microbial biomass carbon and nitrogen contents are found in multicropping systems involving oats or meadow, and the lowest in continuous corn and soybean systems (33). Similarly, the highest enzyme activities are found in systems that contain oats or meadow in the rotation and the lowest in soils under continuous corn or soybean system, as shown for total, activity of the microbial biomass, and extracellular activity of arylsulfatase in Fig. 7. This is mainly derived from the fact that the fine root systems of oats and meadow (alfalfa) have much greater surface area and rhizosphere than the roots systems of corn and soybean.

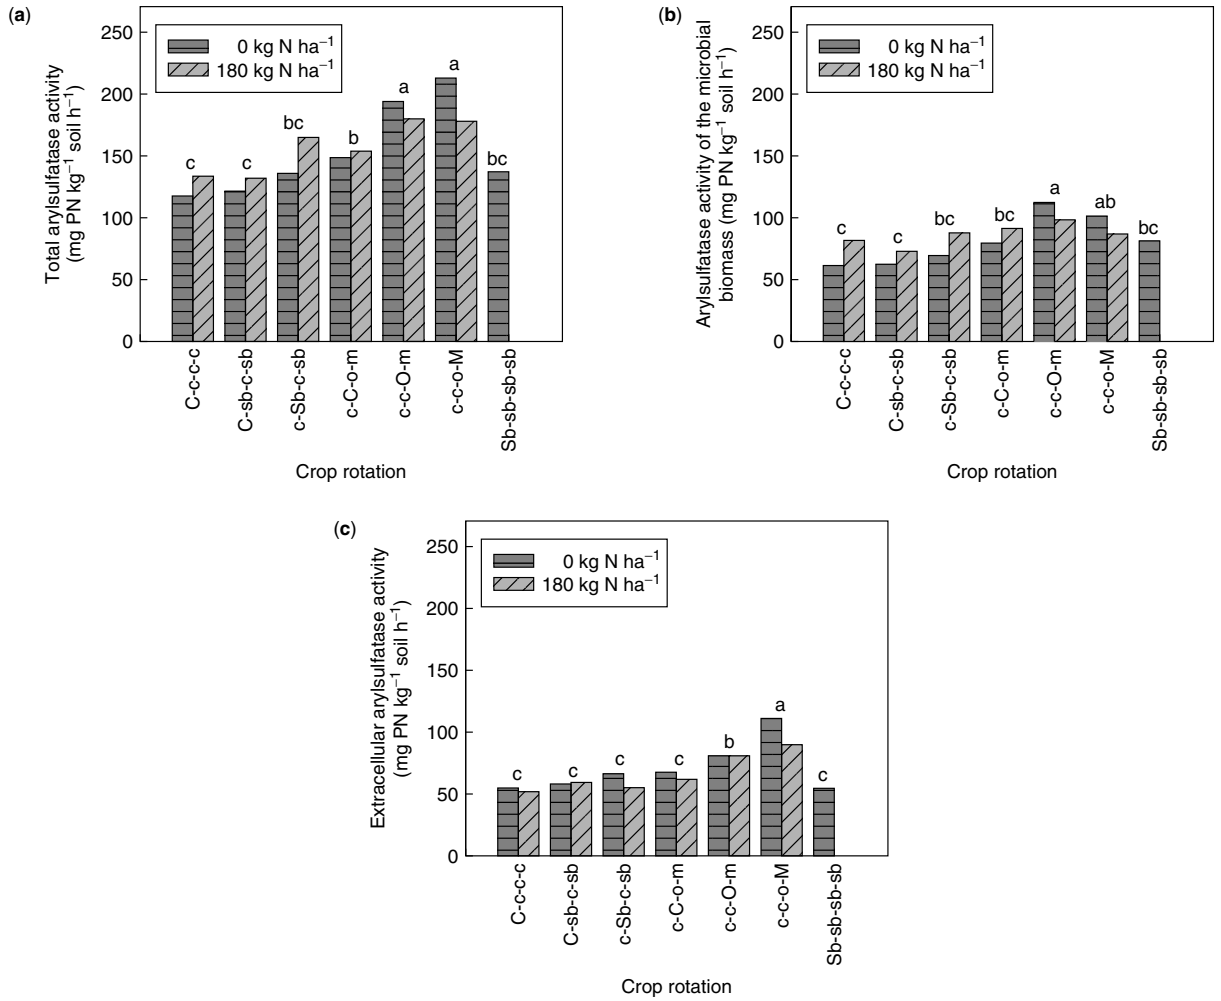

Figure 7. Effect of crop rotation on total (A), microbial biomass (B), and extracellular (C) arylsulfatase activity in soils at the Northeast Research Center, Iowa in 1996. *Different letters* indicate significantly different means at $P < 0.05$ according to the least significant difference test. For crop rotations, *capital letter* indicates crop in which samples were taken. *C* corn, *Sb* soybean, *O* oats, *M* meadow, *PN* *p*-nitrophenol (40).

Tillage and Residue Management

Tillage and crop-residue management practices may lead to significant changes in biological, chemical, and biochemical properties of soils and alter the composition, distribution, and activities of soil microbial community and enzymes. Organic carbon and nitrogen accumulate at the surface soil (0–2.5 cm) under reduced tillage involving crop-residue placement. Accumulation of inorganic nitrogen, sulfur, and phosphorus at the surface soils may also occur under no-till systems with residue placement. In addition, fungal densities are affected by long-term tillage practice, with higher densities of fungal hyphae but lower colony-forming units in buried residues of conventional tillage than in surface residues on no-till. The difference in microbial dynamics and population, due to soil management practices, may also be reflected in the differences in enzyme activities of soils, as have been shown for the activities of glycosidases, amidohydrolases, phosphatases, and arylsulfatase by Deng and Tabatabai (34–36).

pH and Lime Treatment

Soil acidity or alkalinity under field conditions affect numerous biochemical reactions. Among the many enzymes studied in soils, the activities of phosphomonoestearses are the most interesting because there are two such enzymes (acid and alkaline phosphatases). Studies have shown that acid phosphatase is predominant in acid soils and that alkaline phosphatase is predominant in alkaline soils (37–39). There are two reasons for this phenomenon. The first reason is that acid phosphatase is produced by fungi, which are predominant in acid soils, and that alkaline phosphatase is produced by bacteria, which are predominant in alkaline soils. The second reason is that these enzymes are induced in the microbial population and this induction is affected by the soil environment; to overcome the environmental limitations the organisms produce more enzyme proteins to release inorganic phosphorus for microbial nutrition. The effect of soil pH on the distribution of acid and alkaline phosphatases is shown in Fig. 8.

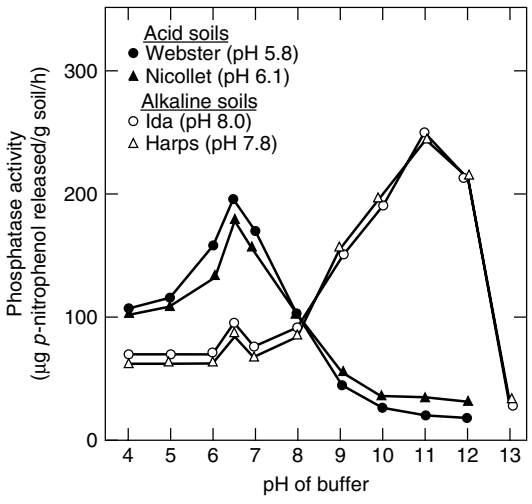

Figure 8. Phosphatase activity in acid and alkaline soils (38).

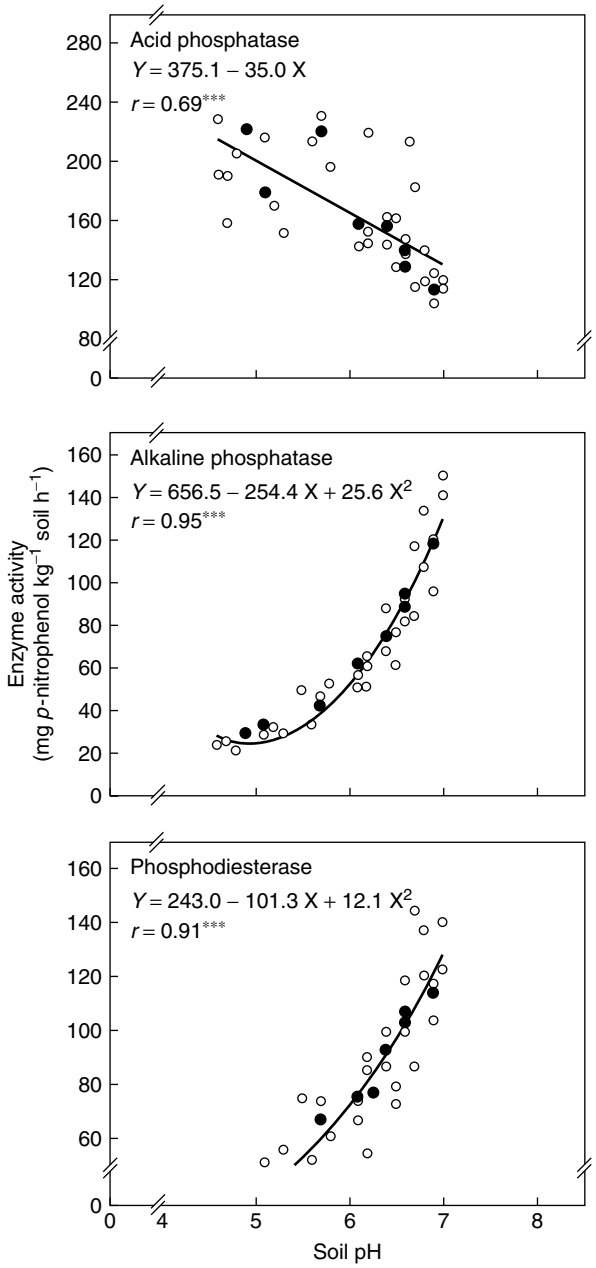

Figure 9. Effect of soil pH on the activities of phosphatases. Open symbols are results obtained for individual soil samples and solid symbols are averages obtained for four field replicates (41).

Application of lime to acid soils normally leads to significant increases in pH and, thus, in the chemical and biochemical reactions, and microbiological processes. Such treatment results in changes in the solubility of many chemical compounds and improvement in the environment of plant roots, increasing soil microbial biomass, with impacts on dynamics and diversity and, therefore causing significant changes in enzyme activities. With the exception of acid phosphatase activity, which decreases with increasing soil pH, the activities of all other enzymes increase with increasing pH (Fig. 9).

Table 6. Correlation Coefficients (r) and Slopes of Linear Relationships Between Soil pH and Enzyme Activities

Enzyme	Enzyme Activity vs. Soil pH[a] r	Δ Enzyme Activity[b]/ Δ Soil pH
Glycosidases		
α-Glucosidase	0.56***	4.4
β-Glucosidase	0.87***	38.5
α-Galactosidase	0.53**	4.5
β-Galactosidase	0.81***	8.8
Amidohydrolases and arylamidase		
Arylamidase	0.74***	9.0
L-Asparaginase	0.84***	15.8
L-Glutaminase	0.73***	107
Amidase	0.61***	14.4
Urease	0.71***	6.2

[a] $^{**}p < 0.01$, $^{***}p < 0.001$.

[b] All activities are expressed in mg product released kg^{-1} soil h^{-1} (change in enzyme activity per a unit change in pH).

[c] Linear regression for soils with pH > 6.0.

[d] Second linear regression values.

The Δ activity/Δ soil pH ratios (change in enzyme activity per one unit change in soil pH) for L-glutaminase is the highest, followed by those of L-asparaginase, amidase, arylamidase, urease, and L-aspartase. This ratio for L-glutaminase is not only the most sensitive to soil pH changes among those involved in N cycling, but also the most sensitive among the 14 enzymes listed in Table 6. The activity of L-glutaminase could be used as an early and sensitive indicator of soil stress (41).

Toxic metals

The activities of many enzymes are inhibited by trace elements. The enzyme affected include α- and β-glucosidases and α- and β-galactosidases (29,42), urease (28), phosphatases (43), arylsulfatase (44), nitrate reductase (45), L-asparaginase (31), L-glutaminase (32), L-aspartase (46), and cellulase (47). Trace elements are added to soils as impurities in fertilizers, as components of industrial wastes or sewage sludges (48,49), or present in fuel oils and gasoline (e.g., Pb, V) (50,51). The degree of enzyme inhibition varies with the concentration and form of trace element, the soil investigated, and the type of enzyme assayed (11,52). Several soil properties may influence the toxic effect of trace elements, including organic matter content, type and amount of clay, and soil pH. In general, Ag (II) and Hg (II) are the most effective enzyme inhibitors. These elements react with the sulfydryl groups (−SH) of the active enzyme sites and effectively inhibit the catalytic property of the enzyme. The sulfhydryl groups are present in the active sites of most enzymes.

Pesticides

Pesticides have significant direct and indirect effects on the activity of various enzymes. The outcomes depend on the complex reactions between the compound and the microbial population, the enzymes and or the soil colloids (31,52,53).

CONCLUSION

Soils as biological systems contain numerous enzymes derived from the microbial community and soil animals, and plant residues, and roots systems. Methods are available for assay of activities of many enzymes in soils. Human activities such as cultivation, cropping, fertilization, lime application, tillage and residue management, and waste disposal affect the levels and distribution of enzyme activities in soils. The activities of some enzymes can be used as a monitoring tool to assess the effect of pollutants on ecosystem stress, health, and quality.

SOIL FUNGI: NATURE'S NUTRITIONAL NETWORK

R. GREG THORN
University of Western Ontario
London, Canada

Fungi are among the most important, numerous, and diverse denizens of soil. Mycologists and microbiologists have frequently treated soil as a single, uniform habitat for fungi and other microbes. In fact, soil is a complex ecosystem comprising myriad minuscule habitats and niches for microorganisms. Soil is a three-dimensional matrix of organic and mineral particles and their decomposition products (1). It is interlaced with plant roots and has islands of resources swarming with invertebrates and microbes. On top of this complexity is the fourth dimension of time, as organic additions from above and mineral substrates from below are broken down and subsequently moved through the soil by the action of earthworms and other invertebrates (2). Different soils, including the soils of different biomes, have widely differing physical and biotic characteristics (3). As a result, different soils may have different fungal populations and activity. Fungi are dominant both numerically and by biomass in many soil ecosystems, particularly in temperate, boreal, and arctic-alpine regions and in other areas where soils have high organic matter contents (4). The incredibly important individual roles of fungi, such as decomposition and mycorrhizal

symbioses are now well recognized. However, these represent just part of the connections made by soil fungi among members of all trophic levels and organic and inorganic nutrient sources (5). The functioning of this belowground nutritional network may have significant impacts on the aboveground community (6–9) and on important environmental variables such as global levels of atmospheric carbon dioxide (10).

As will be discussed later, it is difficult to create a definition of a fungus that is applicable to all fungi. However, one of the characteristic features of most fungi is filamentous growth, and it is this feature that allows fungi to make connections within the soil ecosystem. The microscopic, filamentous cells of fungi are called hyphae (singular hypha), and the fungal individual often consists of a highly branched network of millions of hyphae, together called a mycelium. The mycelium is the original Internet, capable of exploring the multidimensional space of soil and of rapid, long-distance transport of energy (carbon compounds), resources (nutrients), and information (proteins and nucleic acids, including mitochondria, nuclei, and viruses) (11–13).

A brief article such as this one can barely touch on the wealth of research on soil fungi, and so I have chosen to provide an overview with references to major literature, and a discussion of interesting topics about which we still know very little.

DECOMPOSITION, MYCORRHIZAE, AND BEYOND

Fungi are heterotrophic eukaryotes. As such, they must obtain their metabolic carbon either by symbiosis or by absorption from their environment, often preceded by enzymatic digestion of insoluble organic compounds. Thus, there are two fundamental (but not necessarily separate) modes of nutrition among the fungi: as decomposers of dead organic matter or as symbionts (parasites, commensals, or mutualists) of other living organisms ranging from bacteria to other fungi, plants, and animals. Whereas bacteria are the primary decomposers of dead animal matter, fungi are the decomposers par excellence of the other 90% of the organic wastes in terrestrial ecosystems. This is because the fungi, especially the Homobasidiomycetes, are the best equipped with enzymes such as laccases, lignin, peroxidases, manganese peroxidases, and cellulases for degrading lignocellulosic plant wastes (14–16). In addition, their hyphal growth form allows them to penetrate solid substrates such as wood (17) and to communicate among distant resource units (18,19). Decomposer fungi lacking enzymes to degrade intact lignin chew away at the cellulose exposed as the lignin is removed by other fungi, and on the breakdown products of lignin, until much of the original plant biomass is respired as carbon dioxide (17,20,21). The remaining recalcitrant phenolic fractions become complexed with fungal and microbial cell wall or sheath materials and subsequently add to the humic fraction of soil (3). During the decomposition process, many or most fungi act in consortium, either as a result of coevolved symbioses or by circumstance of physical proximity, with other fungi, protists, and prokaryotic microbes. In addition, some ectomycorrhizal (and possibly also decomposer) fungi may etch micropores in feldspar, hornblende, and other soil minerals by release of organic acids, and subsequently use and transport these nutrients to their mycorrhizal host plants (22).

Fungi are also well known as parasites and pathogens of plants, but the range of organisms that fungi attack and consume in soil spans the range of organisms that occur there. Probably no soil organism, from bacterium to macroinvertebrate, is immune to attack by fungi, and some examples of these relationships are described in the following sections. Many symbioses involving fungi are more mutually beneficial, and the most important of these relationships are the mycorrhizae (from the Greek, meaning fungus roots) formed with plants (23–28) (see also MYCORRHIZAE: ARBUSCULAR MYCORRHIZAE and MYCORRHIZAE: ECTOMYCORRHIZAL FUNGI, this Encyclopedia). There are several morphological types of mycorrhizae, and many terms for these types of associations. The simplest summary is to divide mycorrhizal types into those formed by members of the Glomales (Zygomycota) with about 90% of the world's vascular plants, and those formed by members of the Ascomycota and Basidiomycota with selected families and genera of trees and woody perennials. In the former, variously called endomycorrhizae, arbuscular mycorrhizae (AM) or vesicular-arbuscular mycorrhizae (VAM), a coenocytic (multinucleate) fungus forms shrubby structures called arbuscules for nutrient transfer within root cortical cells. Swollen cells called vesicles may also be formed, either within or between root cortical cells. An extensive mycelium explores the soil for nutrients and water, which are exchanged via arbuscules for plant photosynthate. Spores are usually formed on the external mycelium and, although large for fungal spores (up to 1 mm in diameter), are not produced in the massive fruiting bodies that characterize the other group of mycorrhizal fungi. The other group of mycorrhizae includes some associations in which the fungal cells remain outside of root cortical cells (called ectomycorrhizae or ECM), and also mycorrhizae formed by the same fungi in orchids, ericaceous shrubs, herbs, and even liverworts in which there is cellular penetration by the fungus (26,29–31). In both cases, plants benefit most from mycorrhizal associations when growing under conditions of nutrient or drought stress — in other words, when growing under most natural conditions (26). A number of tree genera, including *Populus* (Salicaceae) and *Eucayptus* (Myrtaceae) are known to form both vesicular-arbuscular mycorrhizae and ectomycorrhizae (32,33) and, in both cases, the proportion of VAM-infected roots declines as the trees mature. The effects of the different (or combined) mycorrhizae on the host plants may differ, particularly under different nutrient regimes (33,34). Mycorrhizae may be maintained whether they are cost-efficient or cost-inefficient in terms of carbon cost per unit of acquired mineral nutrient, so long as photosynthesis or growth are strongly nutrient limited (35).

There has been a tendency to treat the mycorrhizal fungi as solely symbiotic and without saprotrophic capabilities. Among plant pathologists, the ability of many fungi to form a continuum from decomposer to plant parasitic symbiont has been recognized for many years, and

known to aid in establishment and persistence in the absence of susceptible plant hosts (36). A similar continuum from decomposers to mutualist ectomycorrhizal symbionts helps to explain the tremendous connections that may be made by such fungi within the soil ecosystem, from recalcitrant organic or inorganic sources of mineral nutrients to one or more plant hosts (26). At the base of this saprotroph-mutualist continuum may be the evolutionary switches that have evidently occurred from saprotroph to ectomycorrhizal habit (and perhaps back again) in multiple lineages (37). I will return to these community-level and ecosystem-level connections after introducing the major groups of fungi and funguslike organisms.

GROUPS OF FUNGI AND FUNGUSLIKE ORGANISMS

Over the years, mycologists have studied fungi and organisms that have been thought to be fungi, united by possession of one or more of the following "fungal" characteristics: extracellular digestion, absorptive nutrition, filamentous growth, reproduction by spores, or causing disease in plants or animals. For more than a century, morphological evidence has been used to exclude some of these organisms from the Fungi, and now modern evidence based on molecular phylogenetic analyses has provided support for these decisions. The fungi and funguslike organisms belong in two Domains (Bacteria and Eukarya) (38,39) and at least four Kingdoms of the Eukarya (Mycetozoa, Stramenopila, or Heterokonta, Heterolobosea, and Fungi) (40). McLaughlin and coworkers (41) provide a recent synthesis of the classification and ecology of fungi and funguslike organisms excluding actinomycetes and slime moulds. This brief review is based on that synthesis, and landmark papers in the systematics of prokaryotes (42–46) and protistan eukaryotes (40,47–51).

Nonfungi

Actinomycetes. The Actinomycetes (or "Ray Fungi") are not fungi, nor even eukaryotes. Actinomycetes resemble fungi in their filamentous growth and reproduction by spores. In addition, actinomycetes have the very fungal characteristic of producing extracellular digestive enzymes and subsequently absorbing selected breakdown products as food. However, actinomycetes are best classified among the G+C-rich gram-positive Bacteria (43,44). Many, particularly in the genera *Streptomyces* and *Streptoverticillium*, are important soil organisms, which contribute to the breakdown of lignocellulosic plant residues (52,53) and produce geosmin, a secondary metabolite responsible for the characteristic odor of freshly tilled soil (54). Members of the genus *Frankia* form N-fixing symbioses with the roots of *Alnus*, *Myrica*, and other shrubs and trees (55). It was recently discovered that the fungus-gardening ants make use of an antibiotic-producing streptomycete to control weed molds in their fungus gardens (56). For reviews on the biology and identification of actinomycetes, see (57–60).

"Water Molds" (Oomycota, Hyphochytriomycota). These two groups are united by the possession of motile, flagellated spores: the zoospores of Hyphochytriomycota ("hyphochytrids") have one anterior flagellum; those of Oomycota ("water molds") have two flagella — one posterior and one anterior. The anterior flagella in both groups have two rows of fine, tubular hairs and are called tinsel flagella or stramenopile flagella. The phylogenetic relations of both groups appear to be with the golden-brown (chromophyte) algae in what is sometimes called the Kingdom Stramenopila (47,61,62) or Heterokonta (40). Because members of both groups are dependent on free water for zoospore dispersal, they are found most commonly in consistently moist soils and freshwater ecosystems (63,64), although many oomycotans also produce drought resistant resting spores. Soil-inhabiting Oomycota include the important plant pathogens *Pythium* and *Phytophthora*, which cause damping off and root rots that affect nearly all vascular plants, including many crops (65–68). Other genera of Oomycota in soil are saprotrophic, or parasitic on algae, rotifers, nematodes, and other minute soil fauna (63,69,70). The hyphochytrids of soil are poorly known, but generally regarded as relatively unimportant saprotrophs or parasites of soil algae and fungi (64). The Oomyota comprise approximately 700 (71) to 1100 species (63) and the Hyphochytriomycota 24 or 25 species (63,71). The Labyrinthulomycota ("net slime molds") of marine environments, which possess zoospores similar to those of the Oomyota, are related to the Stramenopila and not to other slime molds (72,73).

"Slime Molds" (Myxomycota and Dictyostelids, Acrasiomycota, and Plasmodiophoromycota). This is a polyphyletic group of "slime molds," with the most species-rich group being the Myxomycota (74) and the best-studied being *Dictyostelium* (75,76). At one stage of their life cycle, all of these organisms have an amoeboid motile stage, and the amoeboid forms of dictyostelids, acrasids, and myxomycetes may be abundant in rhizosphere soil (77). Individual amoebae aggregate to form multicellular pseudoplasmodia (dictyostelids) or multinucleate, acellular plasmodia (myxomycetes). This "slime stage" is motile and continues to feed on small organic particles and microbes before climbing to fruit, often on the surfaces of grass, wood, or bark (78). Plasmodia and fruiting bodies of certain myxomycetes may be conspicuous on lawns or gardens, but (should the homeowner not feel blessed by their presence) can readily be washed away with a blast from the garden hose. Evidence from morphology and the few taxa included in molecular phylogenetic analyses suggest that the Myxomycota (with approximately 720 species; 71) and Dictyosteliomycota (with 46 species; 71) form a monophyletic group that is basal to the clade containing true fungi and metazoan animals (40,50). The name Mycetozoa ("fungus animals") has been revived and suggested as the kingdom name of this group by Baldauf and coworkers (40). The dozen or so known species of Acrasiomycota (71), although morphologically and ecologically similar to the dictyostelids, are very distantly related and are members of the protistan kingdom Heterolobosea (40). The Plasmodiophoromycota, whose members are primarily known as root pathogens of vascular plants, are the exception within this otherwise peaceable group, and in fact they

too are not apparently related to the Mycetozoa. *Plasmodiophora brassicae* is the cause of club root in crops of the cabbage family and *Spongospora subterranea* causes powdery scab of potatoes (65,79). Sequences of small-subunit ribosomal DNA place *Plasmodiophora* in a clade with the alveolate and heterokont protists (49). Available rDNA sequences support the relatedness of *Spongospora* and *Polymyxa* but do not provide sufficient evidence to place this clade with any certainty (80).

True Fungi

"Chytrids" (Chytridiomycota). Although the Chytrids and Zygomycetes as currently defined appear to be paraphyletic with respect to one another (48,81–83), each group shares certain morphological and ecological characteristics that make it worth continuing to recognize these phyla for the present. Chytrids are aquatic fungi in the sense that they, such as the Oomycota, possess flagellate zoospores that require free water for motility. However, they may frequently be isolated from soils, including soils of very dry environments such as deserts (84,85). There are approximately 800 to 1,000 described species (71,85). Soil-inhabiting chytrids include saprotrophs with the ability to decompose cellulose, chitin, and keratin, as well as species that are parasites of soil algae, nematodes, tardigrades, and vascular plants (69,85). The chytrid *Synchytrium endobioticum*, the causal agent of potato wart disease (86), recently made international news when it was discovered in Prince Edward Island, and the United States government temporarily halted import of all potatoes from this important potato-growing region of Canada. Zoospores of most chytrids have one posterior flagellum, but members of the order Neocallimastigales are multiflagellate. The latter are an important group found in the rumen of herbivorous mammals, where they contribute to the digestion of cellulosic plant cell walls in the animals' food (87). The rumen fungi may have a reservoir (or an unknown part of their life cycle) in soil or dung (85).

Zygomycota. The Zygomycota is a diverse group of fungi in terms of morphology and ecology, but with approximately 1,056 accepted species (71), a relatively small group in number. Among the Zygomycota are some groups that are mycorrhizal with green plants (Glomales forming arbuscular or vesicular-arbuscular mycorrhizae, and Endogonales forming ectomycorrhizae), and these are arguably among the world's most important fungi. Glomalean mycorrhizal symbioses enable approximately 90% of the vascular plants in the world, including many crops grown in low-input cropping systems, to survive drought and nutrient stress (26). The Zygomycota also includes many groups that are soil saprobes, others that are parasites of other soil fungi or algae, and still others that are parasitoids of insects (Entomophthorales) or minute soil invertebrates (Zoopagales) (88–90). It has been suggested that the Glomales evolved in symbiosis with the emergence of land plants (91–93), and that they are the most ancient of the Zygomycota, with saprotrophic, mycoparasitic, and other lifestyles having evolved subsequently. This idea is not supported by current phylogenetic analyses (82–83,90) but there is unfortunately little or no bootstrap support for the basal topology indicated in these studies. Resolution of the relationships among deeply diverging lineages of fungi (and other organisms) will require the combined force of additional sequences from proteins or other gene regions. The arbuscular mycorrhizal Glomales, such as most Zygomycota, are coenocytic and have up to 2,000 nuclei per spore. These nuclei show intraspecific levels of genetic variation (94) but more widely divergent sequences recovered from glomalean spores should be viewed with caution as possible contaminants (95).

Ascomycota (including most "Deuteromycota," "Lichenomycota" and Yeasts). The Ascomycota are the largest group of fungi, with approximately 33,000 described species (71). Inclusion of organisms in the Ascomycota has traditionally been based on their production of sexual spores (meiospores) in a sac-shaped cell called an ascus (plural asci). For this reason, a separate class (Deuteromycetes) or phylum (Deuteromycota) has been used for fungi that lack known sexual structures. The majority of these are asexual relatives of Ascomycota (96). Most fungal systematists have abandoned the Deuteromycota, and many are now trying to unify the classification of these fungi (97–99). Asexually reproducing or nonsporulating fungi may be identified as members of the Ascomycota or Basidiomycota by various morphological or chemotaxonomic methods (reviewed in 100), as well as by phylogenetic analyses of their DNA sequences (101–103). Among the filamentous Ascomycota are many of the most important soilborne pathogens of crop plants, including wilts caused by *Fusarium* and *Verticillium* and root and stem rots caused by *Cochliobolus, Giberella, Gaeumannomyces, Phymatotrichopsis*, and *Sclerotinia* (36,67,104). Other Ascomycota, particularly in the Clavicipitaceae, grow as endophytes within plant tissues, usually without causing disease symptoms (105–107). When growing in the leaves and stems of grasses, they may decrease flowering, and by production of toxic secondary metabolites, reduce the palatability of the grass to grazers or cause physiological harm to herbivores that consume infected plants (105,106,108). Other Ascomycota, ranging from the cultivated or wild-harvested truffles (Tuberaceae) to inconspicuous cup-fungi (e.g., *Hymenoscyphus ericae*), form mutually beneficial mycorrhizal relationships with the roots of vascular plants (26). Still others are obligately or facultatively parasitic on other soil fungi, and offer the possibility of biological control of soilborne fungal diseases of crop plants (109–114). The Ascomycota includes nematode-destroying fungi such as *Arthrobotrys* (69,115), and fungal parasitoids of insects (e.g., *Cordyceps*, 116–118) and other soil invertebrates (119).

Yeasts are fungi adapted to life in aqueous environments through growth of separate, usually elliptical cells that divide by budding or fission (120,121). Their growth form makes them more suitable for study by microbiologists trained in bacteriological techniques than by classical mycologists used to dealing with filamentous fungi (122). A majority of yeasts, including the most economically important ones such as *Saccharomyces cerevisiae*, belong

in the Ascomycota (123). Although many yeasts are found in association with fruits, flowers, and other sources of readily assimilated sugars and other carbohydrates, some are more oligotrophic in their growth requirements and are found in soil, where they may be important members of the decomposer consortium breaking down plant and animal wastes (122,124).

Lichens are symbiotic associations between fungi and green algae or cyanobacteria, in which the fungal partner (myobiont) forms a characteristic structure (what is seen as a lichen) that encloses and protects the alga or cyanobacterium (photobiont) (125–128). Just as with mycorrhizal symbioses, lichens evolved independently in the Zygomycota, Ascomycota, and Basiomycota (129), but by far the majority of lichen species (more than 20,000 described species) are in the Ascomycota (71). Lichens form the dominant ground cover over large areas of arctic and alpine environments and, together with "independent" fungi, algae, and cyanobacteria (or more likely consortia of these), form soil crusts that protect soils in arid environments such as the southwestern United States (130–132) (see DESERT ENVIRONMENTS: BIOLOGICAL SOIL CRUSTS, this Encyclopedia).

Basidiomycota. The Basidiomycota are the second-largest group of true fungi, with more than 22,000 described species (71). The Basidiomycota may be divided into four major groups, the Ustilaginomycetes (smuts), Urediniomycetes (rusts), Heterobasidiomycetes (jelly fungi) and Homobasidiomycetes (mushrooms and relatives). Only the latter group is important in soil, although various stages of the life cycles of smuts and jelly fungi may occur in soil and be important to their survival. The Homobasidiomycetes, with approximately 13,000 described species, include gilled mushrooms, boletes, polypores, coral fungi, stinkhorns, and crust fungi, many with their mycelial phase occurring in soil (133). This great diversity has mostly been overlooked in surveys of soil fungi. Within the Homobasidiomycetes are some very important plant pathogens, including *Rhizoctonia* (sexual state *Thanatephorus*, 134–136) and timber pathogens *Armillaria*, *Phellinus*, and *Ganoderma* (137,138). The majority of Homobasidiomycetes (perhaps 8,500 described species) are saprotrophic leaf and wood-decomposing fungi (6–8,37). Some of these same fungi are also important within soil, breaking down recalcitrant components of plant cell walls and also forming recalcitrant compounds themselves, which become part of the humic fraction in soil (3). Approximately 4,500 described species of Homobasidiomycetes form ectomycorrhizal relations with woody vascular plants in 30 families (26,31,37). Forests of ectomycorrhizal trees are dominant over much of the temperate, boreal, and alpine regions of the world, whereas ectomycorrhizal trees may be locally dominant or widely dispersed in tropical forests (26). The Homobasidiomycetes also include two groups of nematode-destroying fungi, in *Hyphoderma* (139) and the Pleurotaceae (140). Homobasidiomycetes related to *Leucocoprinus* and *Crinipellis* are the fungi cultivated by leaf-cutting ants and their relatives (141). In addition, a great many saprotrophic Homobasidiomycetes are bacterivorous, attacking and consuming live colonies of bacteria in their nitrogen-limited environments (101,142–144). And, both saprotrophic (e.g., *Tephrocybe*) and ectomycorrhizal (e.g., *Hebeloma*) Homobasidiomycetes are included in a group known as ammonia fungi or corpse-finder fungi (145–147), which fruit near animal corpses or accumulations of dung or urine. Given the recent discovery of nitrogen transfer from living or dead collembolans to a host tree by the ectomycorrhizal Homobasidiomycete *Laccaria bicolor* (148), the idea of linking nutrients in a dead rabbit directly to a pine tree through an ectomycorrhizal *Hebeloma* no longer seems so far-fetched.

FUNGI AS LINKS BETWEEN RESOURCES AND TROPHIC GROUPS, OVER DISTANCE AND TIME

Since Trappe and Luoma (5) wrote their stimulating chapter entitled *The ties that bind: fungi in ecosystems* there has been a growing awareness among mycologists and ecologists of the abilities of fungi to link different individuals and species of the plant community with each other and with nutrients and other resources (22). There is now an ample literature showing connections made by glomalean mycorrhizae between herbs and trees (149), or by ectomycorrhizal fungi between different forest tree species (150,151), tree age classes (152), from trees to understory ericoid shrubs (29) or herbaceous plants including achlorophyllous species (153–154), and even thalloid liverworts (30). This sharing of carbon, nutrients, and water within ecosystems via the fungal network has great implications for ecological paradigms such as competition, succession, and patterns of diversity. In this section I will briefly review some of these findings and try to extend the concept of fungal nutrient networking to include members of all trophic levels and the abiotic nutrient resources in soil.

In many soils, there is more fungal biomass than that of all other organisms, excepting plant roots, combined. However, soil is also teeming with bacteria, a diversity of microscopically exquisite protists including amoeboid and ciliate forms, and micro- and macroinvertebrates including nematodes, mites, collembolans, larval and adult insects, and earthworms (155). Among these, the most numerically abundant include the bacteria (approximately 10^9 or more cells per gram of dry soil) and nematodes (often 10^6 or more per square meter). Various fungi have evolved to make use of this entire gastronomic smorgasbord. Although some are specialists that feed on just one or a few species of nematodes, rotifers, or amoebae (156), others are more generalist and also have enzymatic abilities to decompose lignocellulosic plant wastes (143)—in other words, to tap into both biotic and abiotic sources of nutrients and energy and make these available across all trophic levels.

Pioneers in the study of fungi that attack soil microfauna were Charles Drechsler (157–159) and George Barron (69,120). Their wonderful illustrations gave glimpses into a world that few others have seen: amoebae, mites, nematodes, tardigrades, and even springtails (Collembola; 160) falling prey to fungi armed with adhesive knobs or nets, constricting or nonconstricting rings, or even miniature ballistic missiles (161). Although most of the

fungi attacking small animals are microfungi, members of the Ascomycota, Zygomycota, and Chytridiomycota, a few mushrooms from the Basidiomycota are also known to attack nematodes (139,140,162). The study of the oyster mushroom (*Pleurotus ostreatus*) as a nematode-destroying fungus led to the discovery that it and several other lignin-degrading mushrooms attack and consume living colonies of bacteria (142), including gram-positive, gram-negative, and nitrogen-fixing species (163). The list of known bacterivorous fungi includes most saprotrophic species of Homobasidiomycetes that have been tested (144), and the list of potential prey has been extended to include yeasts (164), plant pollen (165) and algae (166). Ectomycorrhizal Homobasidiomycetes that were tested for this ability in vitro all proved unsuccessful, but the results might have been different had the tests been done while the fungi were in association with a photosynthetic host.

Perhaps most interesting to ecologists is the possibility of a short-circuit in nutrient cycles, whereby mycorrhizal fungi tap into nutrients in plant litter, other fungi, fauna, and microbes in soil, and pass these nutrients on to their plant hosts. Evidence for this possibility is certainly accumulating. David Read and coworkers have published numerous studies on the nutritional capabilities of *Hymenoscyphus ericae*, the mycorrhizal associate of most ericoid shrubs, which typically grow in low pH, nitrogen-starved environments (167,168). This fungus has the ability to utilize nutrients in lignin (169), chitin (170), and dead plant and fungal tissues (171), and can transport nitrogen from plant litter to mycorrhizal seedlings (172). It was subsequently discovered that this same fungus also forms mycorrhizal associations with the dominant tree species (29) and thalloid liverworts (30), opening the possibility for community-wide nutrient exchange. Lindahl and coworkers (173) provided a very nice demonstration of the potential for a short-circuit in nutrient cycling by the ectomycorrhizal fungi *Suillus* and *Paxillus*, which captured radiolabeled phosphorus from a saprotrophic mushroom (*Hypholoma*) and transferred this phosphorus to mycorrhizal pine seedlings. Koide and Kabir (174) found that the effects on nitrogen and phosphorus contents of red pine seedlings grown with both the ectomycorrhizal fungus *Pisolithus* and saprotrophic soil microbes were additive or synergistic, depending on soil nitrogen content. The mechanism of the effects seen, whether based in exploitative or interference competition, was not determined.

The interactions between collembolans and soil fungi, including those forming arbuscular mycorrhizae and ectomycorrhizae, have been a hot topic for many years (175,176). Approximately 50% of all studies on the effects of collembolan grazing on mycorrhizal symbioses have used *Folsomia candida* (177), which, however, feeds preferentially on nematodes, not fungi (178). More ecologically realistic studies are needed, including collembolan densities similar to those in nature and sensible combinations of collembolan and fungal taxa (177). Nonetheless, there is a general consensus that grazing by collembolans and other arthropods regulates the activities, biomass, and numbers of spores of soil fungi (175,179,180). However, it is important to remember those fungi that attack and may be regulating the numbers of soil fauna. Among these, it seems, is an ectomycorrhizal mushroom, *Laccaria bicolor*, which was found to reduce numbers of collembolans living in microcosms where the fungal mycelium was present and to transfer nitrogen from living or dead collembolans to the mycorrhizal plant, in exchange for photosynthetic carbon (148). The mechanism of the capture or attack of collembolans by *Laccaria* remains unknown — many marvelous mysteries remain among the soil fungi.

CONCLUSION

The importance of fungi in terrestrial soil ecosystems is becoming more widely recognized by ecologists, agronomists, and microbiologists. Fungi are physically dominant in terms of biomass in many soils, particularly in boreal, arctic, and alpine areas. Their abilities to enzymatically degrade complex plant polymers and xenobiotic compounds and to connect members of many different trophic levels within the soil system make them a force to reckon with, whether you are a nematode or an ecosystem ecologist. Molecular methods are increasingly making it possible to determine the diversity and activities of fungi in selected soil microhabitats and will be critical in finally opening up the most pressing and interesting questions in soil biology.

SOIL GENETIC ECOLOGY

Hector Castro
Andrew Ogram
University of Florida
Gainesville, Florida

The term *soil genetic ecology* is broadly defined as the study of nucleic acids (RNA and DNA) in an ecological context. Soil genetic ecology encompasses a diverse range of topics, including methodologies (1), genetic exchange (2,3), and biodiversity studies (4), although, it commonly implies a methodological approach that uses nucleic acids as indicators of microbial community composition and activity. This entry will focus on the latter topic.

The introduction into soil ecology of methods derived from molecular genetics greatly advanced scientists' understanding of the functioning and diversity of soil microbial communities. These communities are among the most diverse and complex in nature, and molecular genetic approaches allow insights into these complex systems, which were previously inaccessible. Genetic methods are now commonly employed by soil microbiologists and are routinely used in a range of applications. A few examples of these applications include:

- evaluation of biodegradative potential in a soil contaminated with organic pollutants (5,6),
- characterization of nitrogen-fixing bacteria in agricultural soils (7,8),
- discovery of new groups of bacteria and characterization of their distribution in the environment (9,10),
- insight into the evolution and spread of microbial genes in nature (11,12), and
- discovery of novel enzymes and antibiotics that may be of use in industrial and pharmaceutical applications (13,14).

The primary advantage of using nucleic acids to study soil microbial community requirements for laboratory cultivation are bypassed, thereby avoiding biases resulting from limitations in current abilities to cultivate many microorganisms in the laboratory. Soils are complex systems that provide diverse and spatially separated bacterial habitats, and support a great diversity of soil bacteria. A recent molecular study estimated that more than 10,000 bacterial species were present in a gram of forest soil, and a significant number of these species may not be included in standard cultivation-based laboratory studies due to unknown growth requirements (15). Direct

microscopic total bacterial counts in soils typically range from 10^9 to 10^{10} bacteria per gram of soil, although numbers based on cultivable methods may be two to three orders of magnitude lower, suggesting an inability to cultivate more than 0.01% of soil bacteria.

Analysis of nucleic acids extracted directly from environmental samples allows information encoded in DNA and RNA to be accessed directly without laboratory cultivation. Depending on the application, DNA or RNA is directly extracted from the sample without initial separation of microbial cells from the samples. Different types of information are available depending on whether DNA or RNA is analyzed. The "blueprint" of an individual organism is encoded in its DNA, and information regarding the composition of a community is contained in the community genome. RNA is transcribed (produced) from DNA when a particular gene is active, such that RNA provides information on the activity of a gene of interest.

As with all methods, those used in genetic ecology are subject to limitations and biases. At this time, most soil genetic ecology studies focus solely on assessing or comparing microbial species present in different environments. This type of study does not take into consideration the physiology or ecological role of the target species. Questions related to physiology and functional role in a community are difficult to address, and most methods currently available are not appropriate for addressing these questions (16). Physiology and ecology can, in some cases, be tentatively inferred from the phylogenetic placement of the target groups (e.g., most photosynthetic bacteria fall into a closely related phylogenetic group). This type of estimation is not generally applicable, however.

Most applications of molecular methods currently in use are based on characterization of ribosomal RNA (rRNA) or the genes, which encode rRNA (rDNA). Ribosomes are the sites of protein synthesis in all cells and are composed of specific ribosomal proteins and ribosomal RNAs. Ribosomes are composed of two subunits, the large (LSU) and small subunit (SSU). In prokaryotes, the LSU is composed of specific ribosomal proteins and two types of RNA (5S and 23S). The SSU is composed of ribosomal proteins and 16S rRNA (17). Most environmental and phylogenetic analyses focus on 16S rRNA and its corresponding gene (16S rDNA).

The genetic sequence, or order of nucleotides, in rDNA and the corresponding rRNA is characteristic of an individual phylogenetic group, and knowledge of the genetic sequence may be used to infer the phylogenetic affiliation of a bacterial strain. rDNA sequence alone cannot, however, be used to determine affiliation to the level of species. Information regarding the species composition of a community may be obtained by characterization of rDNA present in DNA extracted from the sample. Concentrations of ribosomes, and hence of rRNA, present in a cell are directly related to the growth rate of the cell, such that concentrations of rRNA in soil are characteristic of the activity of a given phylogenetic group of bacteria (18).

rRNA and rDNA analyses are particularly powerful approaches toward characterization of soil microbial communities because individual groups of bacteria may be targeted for analysis. Most 16S rRNA genes are approximately 1,500 base pairs in length, and certain regions of these genes are characteristic of broad phylogenetic groups such as domains (Archaea, Eucarya, and Bacteria), while other regions are characteristic of more narrow groups such as phyla, families, and genera (19). The most commonly used approach toward targeting individual regions of rDNA is via the polymerase chain reaction (PCR), as will be discussed in the following section on methods (20).

METHODS

As is true for all soil ecology studies, the first step must be to establish an appropriate sampling design and to thoroughly mix the soil samples after collection. Most soil genetic ecology studies follow a general structure as outlined in Figure 1. The first step is typically to isolate the desired nucleic acids (DNA, RNA, or both) from the sample, followed by amplification of the target genetic segments by the polymerase chain reaction, and subsequent analysis of the target sequences by any of a number of approaches.

Isolation of Nucleic Acids from Soil Samples

Purification of nucleic acids from soils can be problematic due to copurification of humic contaminants that may inhibit further enzymatic manipulation of the nucleic acids (e.g., polymerase chain reaction) (21), although significant advances have been made in this regard in recent years. Commercial kits for isolation of DNA and RNA are available, and work quite well for many applications and many soil samples. These kits may not be satisfactory for some soils, however, and a general description of principles involved in nucleic acid isolation is presented in the following paragraphs.

In most studies, microbial cells are lysed in the presence of the soil particles to release RNA and DNA. A preliminary wash with phosphate buffer is occasionally conducted prior to lysis in order to remove extracellular DNA, which may interfere with subsequent analysis. Cell lysis can be achieved by physical or chemical means or by a combination of both. The most efficient method is a combination of physical disruption ("bead-beating," in which the sample is mixed with glass beads and shaken) and treatment with detergents and enzymes, which disrupt microbial cell walls. This general lysis approach is very efficient for lysing most gram-negative bacteria, and to a lesser extent efficient for gram-positives and fungi. After nucleic acids are released from the cells, they are extracted from the soil particles by washing with a phosphate or salt buffer. Humic compounds typically coextract with the nucleic acids and must be removed prior to analysis. Many methods have been devised to remove humic compounds, but the purification method of choice may depend on the soil sample. These methods include selective binding and elution to chromatographic resins and selective precipitations (22).

Polymerase Chain Reaction (PCR)

PCR is used to synthesize many copies of a particular region of a gene from a DNA sample, thereby increasing (or

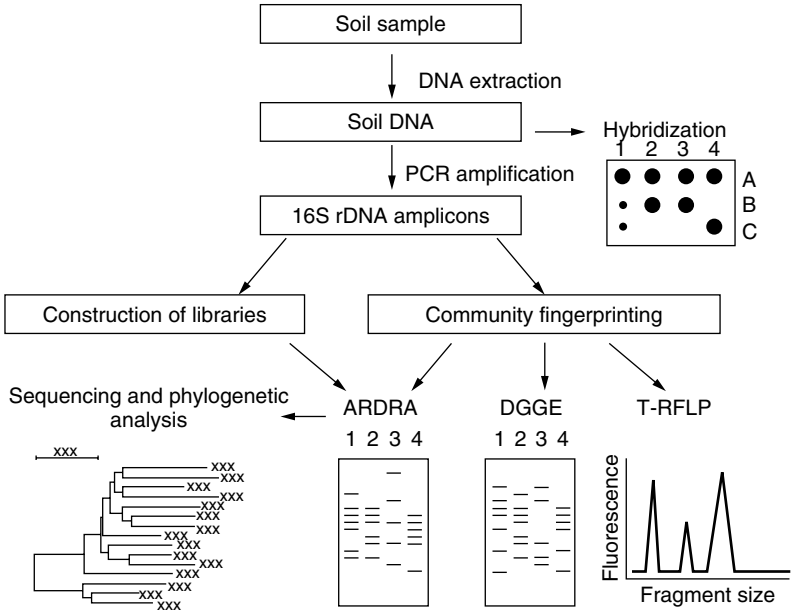

Figure 1. General methodological scheme for most soil genetic ecology studies. The individual method chosen depends on the application.

amplifying) the concentrations of the gene of interest over a million-fold. This allows genes of interest to be produced in such high quantities relative to other DNA in the sample. Nontarget DNA may be considered background and will not enter into analysis. Briefly, PCR is accomplished by using small synthetic pieces of DNA ("primers") that are complimentary to DNA, which flanks the gene of interest (e.g., 16S rDNA). These primer DNAs bind to their complimentary regions within the sample, or template, DNA. DNA polymerase (the enzyme that synthesizes DNA) begins copying DNA between the primers. Once the DNA between the primers has been copied, the DNA is split apart by heat, and the reaction begins again (23).

The PCR reaction mixture consists of DNA template (soil DNA), deoxyribonucleotides (dATP, dCTP, dGTP, and TTP), primers, $MgCl_2$, and DNA polymerase. This mixture is incubated in a thermal cycler that precisely controls the temperature of the individual wells in which reactions are conducted. Three steps compose a PCR cycle: (*1*) denaturation, in which the strands of DNA are separated at high temperature (approximately 92 °C); (*2*) annealing, when the temperature is lowered to allow the primers to anneal to the complimentary regions in the template DNA (typically between 50 and 60 °C, depending on the primers); and (*3*) extension, during which most of the synthesis of DNA occurs (72 °C). This process is repeated between 20 and 40 cycles (23).

The specificity of the PCR is based to a large degree on the selection of primers. Regions of 16S rDNA that are specific to a phylogenetic group of interest, such as the Proteobacteria, may be targeted such that only 16S rDNA from Proteobacteria will be amplified. Conversely, if one is interested in characterizing most of the bacterial groups in a sample, primers that target regions of the gene that are common to all bacteria may be used. In the latter case, 16S rDNA from many of the thousands of bacterial species present in a soil sample may be amplified. Genes other than rDNA may be analyzed in this fashion depending on the type of information desired. For example, if one is interested in nitrogen cycling, primers directed toward regions of genes controlling nitrogen fixation, nitrification, or denitrification may be targeted (23).

PCR amplification of a set of genes from a soil sample may result in amplification from hundreds or thousands of different strains. Genes from these different species must be separated, so that the individual genes may be analyzed. Several approaches for separation and analysis of these genetic sequences are in common usage, although they vary with regard to resolution and expense (Fig. 1).

Cloning and Sequence Analysis

The approach with the greatest resolution for separation and analysis of genes from mixtures of organisms is cloning the individual genes and determining their genetic sequence. In this approach, PCR amplification products (amplicons) are inserted into an appropriate plasmid-cloning vector through the action of the enzyme ligase. These recombinant molecules are introduced into bacterial cells (typically, a specific strain of *E. coli*) by transformation, a process in which cells are induced to take up DNA. Transformed colonies are grown on petri plates, and individual colonies are assumed to have arisen from a single cell that has taken up one of the original recombinant plasmids. Recombinant plasmids are extracted from selected colonies, and the distribution of different 16S rDNA molecules may be estimated by Amplified Ribosomal DNA Restriction Analysis (ARDRA) (24).

ARDRA employs enzymes (restriction endonucleases) that cut DNA at specific recognition sites based on different genetic sequences. This results in the production of fragments of different sizes and numbers that are approximately characteristic of the 16S rDNA. When these digestion products are electrophoresed on an agarose gel, a pattern of different DNA fragments are observed that are similar to a merchandizing bar code. These "bar codes"

may be regarded as operational taxonomic units (OTUs) that estimate the richness of genotypes in the clone library. They are also used to select unique clones to be sequenced, such that similar clones are not sequenced and efforts duplicated.

Once unique clones are selected, the genetic sequence of the inserted 16S rDNA is typically determined by an automatic sequencer. The sequences are compared with known sequences from one of a number of databases available on the Internet, such as the Ribosomal Database Project (*http://rdp.cme.msu.edu/html/*) or Genbank (*http://www.ncbi.nlm.nih.gov/GenBank/*). The phylogenetic affiliation of the different sequences recovered can be determined by placing them into a phylogenetic tree using one of a variety of software packages designed for this purpose (25). Not surprisingly, most DNA sequences analyzed in this manner belong to individual strains that have not been studied previously. In a recent analysis of this type of data, Pace and colleagues concluded that 12 of 35 total divisions of bacteria have not been cultivated in the laboratory (26).

Denaturing Gradient Gel Electrophoresis (DGGE)

Cloning and sequence analysis of PCR amplification products is time consuming and expensive, and is rarely conducted on more than a few samples. Fingerprinting methods, such as Denaturing Gradient Gel Electrophoresis (DGGE) (27) and Terminal Restriction Fragment Length Polymorphism (T-RFLP) (28), are commonly employed for rapidly comparing compositions of multiple samples. These methods provide information on the relative compositions of communities, but do not directly provide information on the nature of individual species in the samples. DGGE is based on PCR amplification of relatively short segments (approximately 500 base pairs) of DNA from the gene of interest. If segments of this gene from different strains differ slightly in their DNA composition, they may be separated on an electrophoresis gel that has increasing concentrations of a DNA denaturant (e.g., urea or formamide) along the direction of DNA travel through the gel. PCR primers used in DGGE are designed such that one primer has a very long stretch of the nucleotides G and C (the "GC clamp") that will prevent the product from completely denaturing. Instead, the rDNA portion of the amplification product will denature while the clamp remains closed. This results in a "butterfly" type of conformation that stops the fragment from moving in the gel. DNAs of different sequences denature at different points along the denaturant gradient, and under these conditions DNA that has been denatured stops moving through the electrophoresis gel. DNA from different strains denature at different positions in the denaturing gradient gel and stop migrating, resulting in the separation of DNAs from different strains in the sample. The resulting electrophoresis gel is stained with ethidium bromide so that the DNA is visible under ultraviolet light, and a banding pattern, or fingerprint, characteristic of the different forms of the gene of interest present in the sample is observed. Each band of DNA represents an individual form of the gene. Individual bands may be compared to determine its presence or absence between samples. These bands may be excised from the gel and the genetic sequence determined, or they may be transferred to a DNA-binding membrane and hybridized to specific gene probes to yield specific information on the origin of the bands (27).

A limitation of DGGE is that it should be used for narrow phylogenetic groups rather than larger ones (such as all bacteria). When broad phylogenetic groups are targeted, resolution of individual bands is difficult, if not impossible, and a smear rather than discrete bands is observed.

Terminal Restriction Fragment Length Polymorphism (t-RFLP)

T-RFLP is also a PCR-based approach used to compare the composition of different samples, but which may have a lower degree of resolution than DGGE. In T-RFLP, target genes are amplified by PCR such that one end of the amplification products are labeled with a fluorescent molecule. These labeled amplification products are digested with one or more enzymes that cut DNA at specific locations, which may vary between different sequences (28,29). The lengths of the individual digestion products are characteristic of the individual gene form (or strain). The lengths of the end, or terminal, fragments may be accurately determined by an automatic sequencer, and are characteristic of given strains. Limitations of this approach include the possibility that terminal fragment lengths are not unique to an individual strain or phylogenetic group of interest. In addition, the limit of detection of individual fragment sizes may be rather low, and will underestimate the number of phylotypes present in the sample. This is particularly true when using PCR primers that are directed toward broad phylogenetic groups, such as the bacteria. This limitation is alleviated somewhat by using primers that are directed toward narrow phylogenetic groups.

Limitations of PCR-Based Methods

Most genetic ecology approaches in use at this time are based on PCR, which has a specific set of considerations that should be understood to prevent misinterpretation of data. Among these considerations are

- misamplification caused by improper reaction conditions. This may lead to analysis of genes that differ from the desired targets;
- diversity that may be masked as a result of focusing solely on a single gene. Most analyses are based on variability within the 16S rDNA of different phylogenetic groups, and relatively little variability exists between strains with regard to their 16S rDNA. Considerable diversity may exist between the genomes of strains that have very similar 16S rDNA. Horizontal gene exchange over many thousands or millions of years may have resulted in one strain having several important genes that may be lacking in another strain, although they may share 99% similar 16S rDNA (30).
- chimera formation. Chimeras are PCR artifacts that result in one end of the amplification product arising

from one gene, and the other end arising from another gene (31). This type of PCR artifact can only be detected by determining the genetic sequence and statistical analysis of the sequence (32).

- PCR that is not inherently quantitative. The concentrations of individual PCR amplification products may not be used to estimate concentrations of the gene in the sample without appropriate controls (33).

Hybridization

One of the most commonly used approaches for analysis of community composition is hybridization. This approach offers a lower degree of resolution than those based on PCR, but has the advantage that it may be quantitative and relatively simple. Quantitative hybridization is frequently used when concentrations of rRNA from various phylogenetic groups are measured, such that information regarding relative activities of specific functional groups is obtained (34). When DNA is the target, information regarding the relative abundances of specific genotypes is obtained.

In this analysis, the primary requirement is that a gene probe be available for the genetic sequence of interest (the target sequence). The gene probe is usually either a cloned version of the target gene or a synthetic oligonucleotide (short piece of DNA), that is complimentary to the target sequence. Probes can be directed toward specific functions, such as enzymes encoding the degradation of an organic contaminant or nitrogen fixation, or toward specific phylogenetic groups in which rRNA or rDNA would be the target. The gene probe is labeled either radioactively (usually with ^{32}P) or nonradioactively (with a fluorescent molecule). Target nucleic acids (either DNA or RNA) from the sample are spotted on a nucleic acid–binding membrane through a vacuum filtration manifold. Alternatively, whole colonies may be fixed to the membrane and lysed to release their nucleic acids. Nucleic acids bound to the membrane are denatured (the strands of DNA are separated) by alkali and then neutralized. The labeled probe is added to a salt solution with the membrane and the probe allowed to hybridize, or combine with, its complimentary sequences within the target nucleic acids. Excess probe is washed off and the amount of label remaining on the filter is usually detected by exposure to X-ray film. The amount of exposure of the X-ray film is directly proportional to the amount of label, and hence target, on the filter (35).

The greatest limitation of hybridization is the current lack of knowledge concerning the molecular genetics of soil microorganisms. In order to apply gene probe analysis to soil microorganisms, the molecular genetics of both the gene probe and the target sequences must be known. The gene of interest must have been cloned, and the nucleotide sequence of the target gene must be similar enough to that of the gene probe for hybridization to occur. If there is more than one type of gene responsible for a given function, hybridization may underestimate the total numbers of colonies capable of performing the function of interest. Conversely, if nontarget genes share enough sequence similarity with the gene probe for hybridization, overestimation of the numbers of target cells will occur. Underestimation due to the presence of alternative genes coding for similar functions is the most common source of error, and it is impossible to control without a detailed knowledge of the genetics of soil microorganisms. Overestimation of target colonies by hybridization with similar genes can be controlled to some extent by including closely related genes as negative controls during hybridization.

ENVIRONMENTAL GENOMICS AND THE FUTURE OF SOIL GENETIC ECOLOGY

Genetic methods are developing at a very rapid rate, thanks in large part to recent initiatives to determine the DNA sequence of the human genome. Many of these innovations are being transferred to soil microbiology and are forming the next generation of methodological advances in soil ecology (16). A general theme of many of these novel approaches is a movement away from the current reliance on PCR due to problems with PCR as previously discussed.

Among the most promising innovations transferred from genomics is the development of microarrays, or gene chips. Microarrays are small pieces of glass that may contain thousands of unique pieces of DNA that represent a genome of interest, such as a human genome or a soil microbial "community genome." DNA or RNA from soil samples may be hybridized to a microarray containing 16S rDNA sequences representative of a suite of phylogenetic groups of interest and/or specific functional genes (e.g., genes involved in biodegradation of a given pollutant) to rapidly determine the presence or relative activities of these groups. Application of microarrays to microbial ecology is still in the developmental phase, but the approach is very promising and may become routine in the near future (36). (See MICROARRAYS: APPLICATIONS IN ENVIRONMENTAL MICROBIOLOGY, this Encyclopedia.)

Tremendous genetic potential is present in a gram of common garden soil, and genomic tools are opening this potential to industrial applications. Advances in the ability to clone large fragments of DNA and rapidly screen these clones for specific functions are making possible exploration of soil DNA for genes encoding novel biosynthetic and catalytic enzymes and antibiotics for medical and industrial applications. This approach is also in the development stages, but discovery of novel antibiotics has demonstrated the promise of this approach (13,14).

As mentioned earlier, one of the major limitations of 16S rDNA analysis is that it may mask microbial diversity. Sequence analysis of 16S rDNA may indicate the general phylogenetic placement of a strain, but little else. Novel cloning strategies are currently being applied in marine microbial ecology that clones large segments of DNA, including 16S rDNA and adjacent genes. This strategy may allow more information regarding the ecological role of the strain to be inferred, and is likely to be applied to soil microbial ecology soon.

Historically, one of the most troublesome aspects of soil genetic ecology has been isolation of DNA and RNA of sufficient purity for the desired application. Automated

purification of soil DNA is currently under development, and will be a great advance for all genetic applications when completely optimized (37).

SOIL MICROORGANISMS: ROLE IN BIODEGRADATION

RON TURCO
Purdue University
West Lafayette, Indiana

While the production of food and fiber is directly dependent on soil, the importance of microorganism to the formation and stability of soil has only been fully realized in the last 100 years. The contributions of the soil organisms to the function of soil can be viewed as being the biochemical engine that drives most of the important soil processes. The microorganisms are responsible for the breakdown of dead plant and animal materials, effectively ridding the earth of millions of tons of organic materials each year. It is during this process that the microorganisms provide the organic building blocks that are used to establish soil structure, helping to form a stable land surface. A well-structured soil contributes to good plant growth and water infiltration, which diminish the potential for runoff events and protects water quality. It is during the plant and animal degradation process that microorganisms begin a recycling process, which converts organic forms of nutrients to inorganic and plant available forms. Microorganisms have been playing an even more important role. It is now clearly established that microorganisms not only degrade natural organic materials but they are responsible for degradation

of many materials of human origin. These materials can include oils, pesticides, gasoline, and organic solvents. The soil microbial populations have been shown to be responsible for the conversion of contaminants to less dangerous materials, although toxic products are possible.

This article's focus is on the factors that affect the functioning of the microbial component of soil. We will address this by providing information describing the resident status of organisms in soil, and then describing the factors that control their activity and finally, describe how microbial population responds to pressures from humans and how we harness their inherent abilities. In this regard, we will show how inputs from humans can both suppress and maximize the functioning of soil microbial populations. A clear understanding of these factors is needed if we are to successfully manage soil to maintain both its inherent functions and to meet secondary goals such as allowing environmental cleanup.

THE SOIL STRUCTURE

Defining the Microbial Habitat

Soil particles, sand, silt, clay (i.e., the components of soil texture) are the base units of soil structure and it is the arrangement of these particles that results in soil that are typically viewed in the landscape. Soil particles range in size from sand particles as large as 2 mm to tiny clay particles (i.e., very coarse sand 2.0 to 1.0 mm, coarse sand 1.0 to 0.5 mm, medium sand 0.5 to 0.25 mm, fine sand 0.25 to 0.10 mm, very fine sand 0.10 to 0.05 mm, silt 0.05 to 0.002 mm, clay less than 0.002 mm). These particles rarely exist as independent units. Soil particles are more typically found bound together as aggregates with the linkage between particles resulting from organic bridges and binding agents often of microbial origin. In turn, it is the size and stability of all of the aggregates that determine the size and arrangement of soil pores. It is the soil pores that control the flow of air and water in soil (Fig. 1).

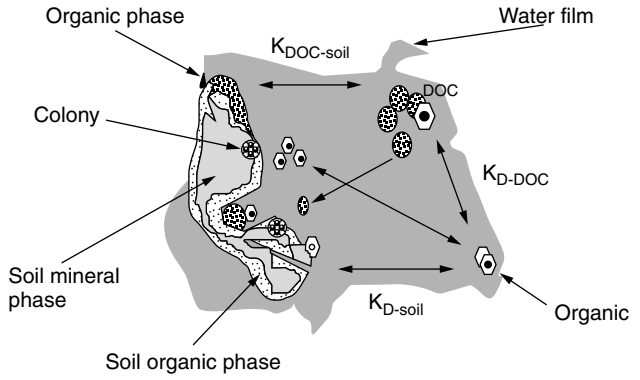

Figure 1. Diagram depicting the relationship between organic contaminants and the microbial populations. The distribution of contaminants between the soil surface and the soil solution is indicated by the K_D. The value K_{DOC} indicates the distribution of soil organic matter between surface and solution, and K_{D-DOC} indicates the reaction between contaminants and the dissolved organic matter in soil. In the case of K_D and K_{DOC}, a lager value indicates more solid-phase retention and a smaller dissolved solution content for the organic matter. In the case of K_{D-DOC}, a larger value indicates more interaction between the dissolved organic matter than the contaminant and less contaminant in solution. The shaded areas represent water films.

Although it was pointed out in 1927 (1), we are only now fully appreciating the importance of the soil aggregate as a habitat for soil microorganisms. Because of the microorganism's size (typically 1 μM or less), a tendency toward sessile growth, the soil's low intrinsic nutrient status (2), and their resulting slow growth rates, soil microorganisms are generally required to function under multiple limitations. In response to these multiple stresses, a typical terrestrial bacterium is found to colonize mineral surfaces often within a soil aggregate. In turn, they become indirectly responsible for improving the stability of the soil aggregates as the microcolony of cells grows and produces polysaccharides and other agents that bind the cells to the surface and also bind smaller soil particles together.

Aggregate Formation

The exact process of aggregate formation is speculative but is thought to follow a sequence in which a few particles become bound into a microaggregate. The microaggregates are then bridged or combined with other microaggregates to form larger aggregates (3). Both biological and physical processes aid in the formation of soil aggregates. Soil freeze and thawing cycles, soil drying, and fungal hyphae growth tend to push particles together. Microbial decomposition of organic residues (plant materials) releases many organic materials that act as bridge and then stabilize the adjoining particles. These materials become the core of what will be soil organic matter. Recent work has shown the organic materials released by the microorganisms to be biophysically complex with molecular weights exceeding 7,000 $gmol^{-1}$ (4).

It is generally thought that stable aggregates are created largely by microbial processes as the binding agents, which hold the aggregate together, are the materials released by cells during the degradation of plant materials or resident soil organic matter. Burrowing soil animals such as worms and insects and the growth of plant roots also push the smaller aggregates together and the reoriented surfaces act as locations for microbial colonization and additional fungal growth. Fungi have been shown to release compounds such as glomalin (a glycoprotein), which further stabilizes the matrix (5,6). Singh and Singh (7) demonstrated differences in the portion of microaggregates and macroaggregates as a function of soil use. Forest soil, with little disturbance, showed the greatest number of macroaggregates, whereas cropland soils were formed primarily from microaggregates. During aggregate formation, soil organic matter begins to buildup, as it was made unavailable within the newly formed microaggregates. Soils that have high levels of contamination (metals or organics) tend to be reduced in structure (8), possibly associated with lower microbial activity and impact from antropogenic actions. Clearly, significant changes in microbial biomass and metabolism along with soil management will alter the soil structure (9).

The distribution of aggregate sizes within a unit of soil will alter the resulting pore size distribution in that soil.

Tillage or other disturbance greatly reduces the aggregate size and liberates entrained (trapped) carbon that became resident in the formation process (10). These changes can affect subsequent plant growth (11). A high-quality soil will have a range of aggregate sizes from small to large; correlated to this is a range of pore space sizes. From the microbial perspective, aggregate geometry and size along with the resulting pore spaces are critical to their function both directly from the perspective of water and air infiltration and indirectly from the perspective of the improved plant growth, which becomes a source of carbon (11,12).

The net effect is that biological processes form the aggregates and the arrangement of both the sizes of aggregates will create pore spaces because pore spaces are found within and between both small and large aggregates. The pore spaces inside the aggregates are sometimes referred to as occurring within the soil matrix because they occur inside a soil structural unit (13). These matrix pores may connect to the larger pore spaces that occur between the stable soil aggregates. However, matrix pores may occur within an aggregate without being connected to the larger aggregate pore spaces. As a result, a typical soil is intermixed with small and large holes and connected and unconnected channels.

The soil microbial community is associated with both types of pore spaces as the population is found both in and outside the aggregate. However, most microbial populations tend to be found on the inside of pore spaces within aggregates. Transport of air and water within soil is governed by the three-dimensional arrangement of pores. Thus, the proximity to pores strongly influences functioning of the soil microorganisms inside the aggregate. Therefore, soil aggregate stability is a key soil property affecting the functioning of the soil (14). The stability of the aggregate reflects both microbial and nonmicrobial processes. At many contaminated or deteriorated sites, the soil structure has been lost, which then limits the soil's ability to function.

Soil Microorganism — Living in an Aquatic World

Even in what seems to be a dry soil, soil bacteria function best in an aquatic environment. They function best when covered by a water film. This water film fills small soil pores and acting as transport system for nutrients and dissolved oxygen. Soil water is described using units of megapascals (MPa). These are tension values and indicate the amount of energy needed to extract free water. Different soil types (i.e., clay, silt, or sand) will have different contents (percentage moisture) at the same water potential. For example, at 20% moisture, a clay soil has a greater ability to hold water (lower water potential) than a sandy soil. A saturated soil has a water content equivalent to 0 mPa, whereas at a water potential of -1.5 mPa, little water is available and the soil is dry. Soil microbial populations function best at water contents (%) equivalent to -0.01 MPa of water potential pressure (15). At the -0.01 MPa the water potential–content combination, the soil tends to have an optimum arrangement in terms of both water film thickness and open space for the exchange of oxygen from the air (Fig. 1). Soil microbial activity will decline as the soil dries (moves toward more negative water potentials) because without water, the bacteria will dehydrate and lose function and they are unable to receive nutrients. Conversely, too much water will suppress aerobic metabolic activity because the soil water near the cells cannot be replenished with oxygen at a rate corresponding to microbial consumption.

As a result, interactions between oxygen and water within the soil are complex because the gas that enters the soil in the open portion of the pore must dissolve in water before the bacteria use it. The solubility of oxygen in water is 0.028 mL O_2 mL^{-1} H_2O atm^{-1} (16) or as the more common expression 8 mg O_2 L^{-1} (70 °C). The situation is further complicated by the diffusion rate of O_2 in water which is about 1×10^4 of the diffusion of oxygen in air [values of diffusion coefficients are 2.5×10^5 cm^2 sec^{-1} in water versus 0.189 cm^2 sec^{-1} for air (17)]. As a result, the level of oxygen tends to decrease with soil depth as both poor water solubility and low diffusion rates limit oxygen transport. The decline in oxygen levels down the soil profile reflects both respiration by organisms near the soil surface and restriction on flow related to decreasing pore size and increasing water content with depth in the profile. However, the larger pore spaces near the soil surface generally allow for oxygen diffusion for the upper portions of the profile keeping it aerobic.

A somewhat analogous situation occurs at a smaller scale within soil aggregates. The population near the aggregate surface first uses the available oxygen. As was found with the soil profile, free water in the soil pores limits the inward flow of oxygen. However, in the case of the aggregate, the restrictions on the flow of oxygen into the aggregate are even more significant because the oxygen must diffuse down very small pore spaces. As a result, an aggregate within an otherwise aerobic soil can develop an anaerobic core. Smith and Arah in 1986 (18) and others (19) demonstrated the presence of anaerobic microsites or conditions in otherwise aerobic soil.

MICROORGANISMS IN SOIL

Diversity and Cell Density in Soil

Trevors (20) has described soil as a "virtually limitless pool of genetic information contained in bacteria." This conclusion reflects the fact that surface soil can contain some 4,000 different microbial genotypes with as many as 10^9 (one billion) cells in 1 g (21,22). Others have suggested the number could be as high as 40,000 bacterial species in 1 g. Subsurface soils tend to have lower population levels but can exceed 10^7 cells g^{-1} (23,24). Surprisingly, given the sheer numbers of microorganisms, the microbial population comprises less than 3% of the soils organic carbon and occupy only 0.001% of the soil's volume (25). Therefore, microorganisms are not densely packed but rather live as "islands" or microcolonies on soil surfaces in aggregates or embedded in decaying organic matter (26). Hissett and Gray (27) have shown that microorganisms reside on less than 0.17% of the surface of the organic matter of the soil and less than 0.02% of the mineral surfaces of the soil. This pattern of distribution reflects

the lager surface area of the soil. For example, the specific surface area of soil clay can range from 5 to more than 750 $m^2 g^{-1}$.

Movement of Cells in Soil

Microorganisms generally adhere to soil surfaces by electrostatic interactions, London-van der Waals forces, and hydrophobic interactions (28,29). The overall movement of bacteria in soil is controlled by their tendency to undergo sorption onto soil particles or their transport and trapping in small soil pores (30). Most movement of bacteria in soil occurs by passive transport where the cells are moved with flowing water. On the other hand, active transport that is facilitated through the expenditure of energy is fairly limited (31–33). Tan and coworkers (34) found that passive movement was retarded by the adsorption of bacteria onto surfaces. Generally, passive movement will carry bacteria greater distances, over several centimeters, than active movement (35), which carries then over a few millimeters.

The predominant factors affecting bacterial transport are the ionic strength of the suspending solutions, which affects the charge properties of the cell and the surface, the soil surface properties, and the flux rate of water through the system. Trevors and coworkers (36) found that the movement of a genetically engineered strain of *Pseudomonas* through a soil column was a function of water flow rate and the number of times the column was flushed. This is supported by the work of Gagliardi and Karns (37) who showed for *Escherichia coli* that high levels of bacterial penetration into the subsurface could be seen when high rates of water input occurred along with the application of the bacteria. Cho and Kim (38) demonstrated using *Salmonella typhi* that bacteria introduced with manure could survive in both viable and viable but nonculturable (resting) states. Longer-term survival was not addressed in either study but Gagliardi and Karns (37) showed that significant growth could be seen even in the short periods (18 days) following application of bacteria and manure. They reported a 15-fold increase in the number of bacteria going in and leaving the system, when compared with the numbers inoculated into the system.

Cell Retention on Surfaces

Cell retention in soil is a function of the type of bacterium and the soil surfaces. It has been reported that the migration of bacteria with a hydrophobic exterior was two to three times slower compared with a similar strain with hydrophilic surface properties (31); authors were able to correlate cell retention with the adhesion of the hydrophobic strains. Other work has shown that the contribution of flagella to movement declines as the soil dries and the water film thickness decreases. As opposed to increasing the potential for movement, it is suggested that presence of flagella may enhance cell sorption onto soil surfaces (32). The movement of motile bacteria, especially ones with large numbers of flagella, may be impaired as the flagella increase the cell's overall volume preventing its movement through small pore necks (32,33).

Surface and Pore Neck Colonization

The location of bacterial colonies within soil is influenced by soil structure, the location of nutrients, and pore size (39–42). The exact factors that lead to colonization of a given pore or surface region of a pore space are unresolved. However, detailed analysis of soil structure has shown that greater than 80% of the cells found in soil are located within the smaller aggregate fractions of the soil (43) rather than on outer surfaces. Work by Fisk and coworkers (44) has shown that for introduced bacteria, a prime location for colonization is along the intergrain area where mineral and organic materials meet. They also observed that most of the resident bacteria are located along the same interfacial areas.

At the microscale, the arrangement of cells in soil aggregates is the predominant factor influencing cell behavior. Soil bacteria are sessile and become physically resident on soil surface. The size of the actual pore space in which bacteria reside governs the amount of available oxygen and nutrients. Pores between areas colonized by bacteria and areas colonized by predators such as protozoa also affect the long-term survival of the bacteria. They are most often found within pore spaces connected to adjoining interaggregate spaces through a channel with a pore neck sized between 0.25 and 6 μm in diameter (45,46) (Figs. 1 and 2). A pore with a 0.25 μm diameter limits entry of bacteria, whereas sizes in excess of 6 μm allows entry of protozoa. By colonizing pore spaces connected with a pore neck size of less than 6 μm, the bacteria can be protected from protozoa, which require a larger pore diameter to invade the space (40,46–49). It has also been shown that protozoan activity and predation often coincide with high bacterial numbers and activity (50). Therefore, the feeding activities of protozoa are effective in controlling the size of active population of soil bacteria and may control the establishment of inoculated species sometimes used in remediation situations or as seed inoculants (46,51).

Microorganisms colonize the soil matrix as the soil is forming and have also been reported to occur in the microaggregate soil fractions between 2 and 53 μM in size (50). Recent work has suggested soil bacteria to be mainly associated with the clay and silt fractions and

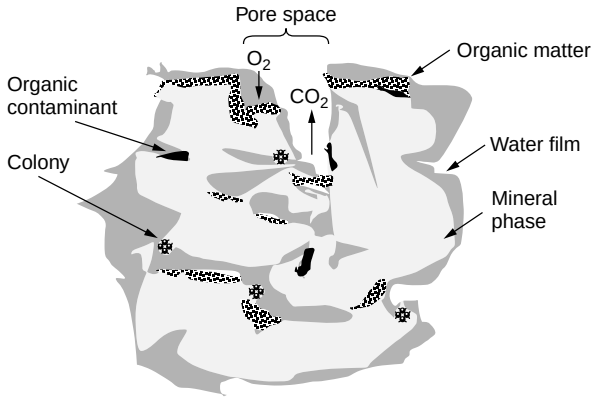

Figure 2. Diagram depicting the relationship of a resident soil microbial populations to the open pore space, organic matter, and organic pollution. Water film thickness is variable as is the distribution of both natural organic matter and the contaminant.

fungi to be associated with the organic materials and coarse sand fractions (52).

A ready supply of carbon and electron acceptors (oxygen, Mn^{4+}, Fe^{3+}, SO_4^{2-}) is thought to be a controlling factor for the active colonization of an area (53,54). Gram-positive bacteria are often found on the outside surface. In contrast, gram-negative bacteria are generally found within the aggregates and pore spaces (47). This distribution may reflect a selective pressure applied by changes in water availability because gram-positive bacteria are generally more resistant to drying than are gram-negative bacteria (15). The internal regions of the aggregate will have more stable water content because the small pores spaces are slower to dry when compared with the outside that is exposed to the pore space air. The slower drying rate reflects the smaller pore necks and a lower flux of water. On the other hand, the wetter conditions can also lead to anaerobic conditions. These findings support the conclusion that the soil microbial population is discontinuous, not forming a biofilm as is found in the typical wastewater biotreatment facilities (44).

Feeding the Microbial Community

Once attached to soil, soil microorganisms remain relatively immobile for the majority of their existence. As a result, organic materials must be transported to the microorganisms to be used. Therefore, the arrangement of micropores, which controls the flow of water in turn controls, the flow of nutrients, will influence the locations where colonies develop. The discontinuous arrangement of microbial population structure in and out of the pore spaces is a key factor affecting transformations of organic compounds. While the residency of the bacterial population inside small pore necks protects them from predation, small pore neck sizes also limit access to nutrients, which must diffuse inside the soil aggregate to be used. This diffusion-linked pattern of growth accounts for the microorganism's occurrence along interfacial areas between regions of soil organic matter and mineral surfaces. The mineral surface gives the bacteria a point of attachment, access to potential electron acceptors other than oxygen, whereas the adjacent organic materials provide a long-term source of nutrients over a short diffusion pathway (Fig. 2).

The active portion of the soil microbial community makes use of carbon and nitrogen derived from/during plant decomposition or the mineralization of native soil organic matter (55). A strong correlation between plant productivity and active soil microbial population has been shown (56). Others have shown a strong correlation between microbial biomass and available soil carbon (57). Subsurface microorganisms are dependent on carbon leached from surface materials or materials delivered from adjacent aquifers and the capillary rise of groundwater. Patterns of microbial activity reflect the pattern of available carbon. In particular, long-term undisturbed sites tend to have higher carbon and activity levels (enzymes, respiration) deeper in the soil profile than do sites that are routinely tilled (58). Mixing of the active soil population with residues and the inclusion of air and water that enhances the degradation processes. Of particular note is the finding that manure, which is high in dissolved organic carbon (DOC), can significantly increase the size of soil microbial biomass (59) and can influence subsequent degradation rates of chemicals (60). Work has shown that soil microbial diversity is also affected during the composting of manure in the soil (61). These findings suggest that the microorganisms in soil and the subsurface are generally faced with a poor nutrient availability and that increasing the nutrient availability will alter the composition of the population.

Because of the lack of available nutrients, the majority of the organisms in soil are in a "resting stage"; they are alive but are maintaining themselves in a low level of activity (25,62). In fact, less than 1% of the soil bacteria are typically recovered using typical laboratory isolation procedures (63). Studies to compare soils have confirmed this finding. Direct isolation of DNA from soil shows a higher phylogenetic diversity than does isolation of individual colonies (64). Indeed, the inactive biomass constitutes the major portion of the "limitless pool of genetic resource" described by Trevors (20). Environmental stress or other situations (e.g., an input of nutrients or chemicals) can cause part of these inactive members to respond and become active, whereas other parts of the active population may become inactive. This switching allows a staged response to an outside perturbation and avoids the need for all members of the population to maintain themselves at high levels of activity under all conditions. This is a critical consideration because most soil and subsurface material has limited available nutrients. Shift ability is most clearly demonstrated in an example of microbial response between acttive and inactive states in a special region near the roots called the *rhizosphere*. This rhizosphere region forms near a growing root (approximately 1 mm away) when microbial populations are consuming carbon, and other materials, released from the root. Recent studies (65) have confirmed earlier reports and shown that the types of active microorganisms near the root are responding to the types of available nutrients in the rhizosphere. Before these studies, most rhizosphere work indicated the number of cells increased in the rhizosphere, but a clear correlation to changes in the population structure (types of organisms) had not been made (66).

Like the situation occurring for surface soil, the subsurface is composed of diverse microbial population capable of many biochemical processes. The subsurface tend to have smaller pore spaces as the geologic materials are more tightly packed and as a result, the size of the biomass and its activity tends to decrease with increasing depth. Small pore neck size, high bulk densities [low nutrients, poor water availability, and few dissolved electron acceptors (especially oxygen)]. The literature on the subsurface has shown it to be both complex and heterogeneous (67,68).

SOIL MICROBIOLOGY AND CONTAMINATION

Transport and Delivery of Contamination in Soil Influences Biodegradation

Contaminant metabolism (or any metabolism) is governed by transport and the availability of substrates. As

Andersson and Henrysson (69) point out, contaminants such as polycyclic aromatic hydrocarbons (PAH) are limited in their availability to indigenous microflora and this makes degradation or remediation difficult. Malina and coworkers (70) and Welp and Brümmer 1999 (71) describe three factors as limiting hydrocarbon biodegradation in the field. These are the inherent toxic nature of the material and metabolites that may form, the net availability of the chemicals as modulated by surface sorption, solubility, and speciation, and changes that may occur in the microbial population in response to the chemical. Ogram and coworkers (72) showed the organic molecule 2,4-D once sorbed to soil was recalcitrant to biodegradation and Shelton and Parkin (73) reported that desorption of carbofuran in soil limited biodegradation. Moreover, Scribner and coworkers (74) reported that the biodegradation of simazine was limited by desorption. These studies indicate that sorption-desorption processes play a major role in biodegradation by affecting bioavailability of contaminants in the soil. This is because soil is a surface-dominated environment and sorption is the main mechanism controlling the level of the chemical in solution. In general, the level of organic carbon and pH of the system, which affects both the chemical and the surface chemistry, control sorption processes. The toxicity of some materials is modulated by the interactions with a surface that retains some fraction of the material lessening the solution concentration.

The majority of studies investigating sorption and transformation of chemicals in soil have been conducted at relatively low chemical concentrations. The dominant mechanisms responsible for the retention of chemicals in soil and subsurface environments are hydrophobic partitioning (in organic matter), hydrogen bonding, and dipolar interactions. Soil organic matter has been consistently implicated as a major component in controlling the sorption in soil. The early work of Talbert and Fletchall (75) showed strong positive correlation between the chemical retention by soil and organic matter. Others have confirmed this (76–78). In studies of sorption using Atlantic coastal plain soils, Johnson and Sims (76) observed that retention of several chemicals correlated strongly with organic matter content and exchangeable acidity. These data suggest that although hydrophobic partitioning of chemicals into soil organic matter is an important mechanism, electrostatic and pH effects are also important (79,78). These mechanisms do not act independently, however, and the relative contribution of one mechanism over another will depend strongly on the amount of soil organic matter, pH, and clay content. The sorption of dissolved, nonpolar organic compounds in soil and sediment is a widely studied phenomenon (80,81). This process is described as an equilibrium distribution of the nonpolar organic solute between the aqueous phase and the organic matter in the soil. The mechanism of retention is thought to be a partitioning phenomenon, similar to the partitioning of hydrophobic organic compounds between an organic solvent phase and aqueous phase in a biphasic solvent system. This process is often characterized by linear sorption isotherms in which the sorbed concentration is directly proportional to the solution phase concentration. However, there have been a number of other studies to show that surface hydrolysis, hydrogen bonding, and surface-mediated chemisorption can occur and will affect the retention of the material (82–84).

High concentrations of chemicals pose a significant nonpoint source pollutant contamination potential at contaminated sites (24,85). Sorption as identified by studies at dilute aqueous solution may not be a predominant mechanism controlling the retention of concentrated chemicals typically encountered at contaminated sites. This is because at contaminated sites, bulk chemical trapping in pore spaces and matrix creates a chemical "source zone" because organic compounds in pore spaces diffuse into soil aggregates (86). Bulk chemical trapping retains a higher fraction of the total load. Whereas sorption and trapping in the smallest pores may hold a fraction of the material that is more difficult to degrade. Microbial degradation of source zones tends to be from the outside of the zone inward. This reflects the fact that chemicals are often toxic in the source zone and that microorganisms may be limited by the supply of oxygen or secondary nutrients (Fig. 3).

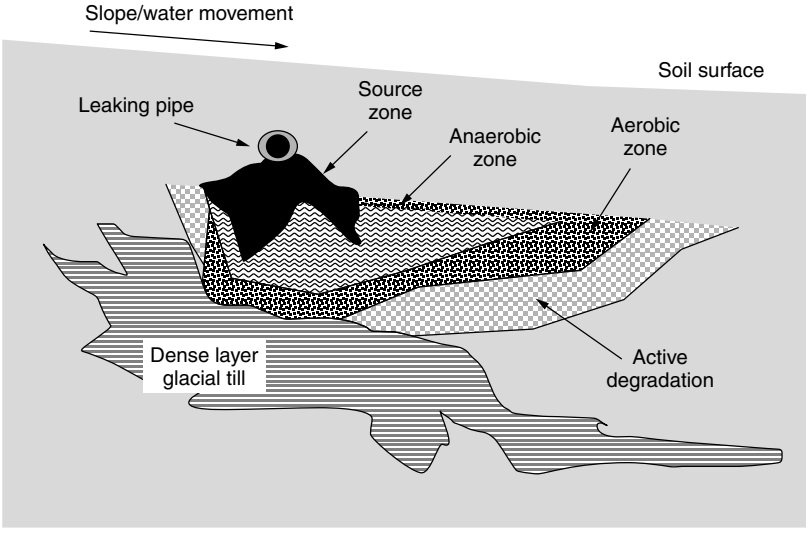

Figure 3. The zones typically encountered near a hydrocarbon leak or spill. The source zone is surrounded by a zone of oxygen depletion, an aerobic zone, and zone of active degradation. The zone of active aerobic degradation is influenced by both the availability of oxygen and the availability of secondary nutrients, primarily nitrogen, and phosphorus. Movement of the hydrocarbon is often influenced by the presence of dense subsurface layers.

Overall distribution and transport of chemicals to a location in the profile is limited by the flux of water through the system and retention. Vapor transport of chemicals may also occur. The retention reactions for either can include surface sorption and trapping in small pores and spaces. In terms of biodegradation of introduced materials, Sawhney and coworkers (87) and Steinberg and coworkers (88) showed that 1,2-dibromoethane (EDB), a water-soluble, biodegradable, and weakly sorbed organic molecule, persisted in soil for long periods. This is in contrast to controlled laboratory studies in which it was shown that the material could be rapidly degraded in culture. In soil, the chemical appears to become entrapped in the soil matrix passing down soil pores (possibly smaller than 0.25 μm) where it is protected from degradation. Others, Borchers and Perry (89) and Powlson (90), have shown that in soil, there are pools of physically protected nitrogen and carbon, which act as a slow-release source of the nutrient. Again, it seems the pore neck size may limit diffusion of nutrients to microorganisms and the soil solution. Roberston and coworkers (168) found that there was a significant patterning of NO_3^- release across a landscape indicating localized differences in microbial ability and the formation of NO_3^-.

Studies to address the temporal and spatial variability associated with the field-scale distribution of microorganism and their abilities to degrade recalcitrant organic compounds are limited (91). Evaluation of field-scale variability in a soil microbial populations has found that major differences in a *Rhizobium* population are evident at sampling distances of less than 0.2 μm (92) and that there is a spatial variability in the degradation of pesticides in soil (41). Others have shown similar results and confirm that the distribution of bacteria in soil is not uniform, but that the distribution reflects both the soil structure and available nutrient supply (42). Coresuil and Weber (93) suggest that a correlation between the size of the standing biomass and the onset of hydrocarbon degradation exists and as a result, a critical population size is needed before rapid degradation becomes possible. This has also been shown for the degradation of propylene glycol (85).

PHYSIOLOGICAL PRINCIPLES AND THE UNDERLYING BIODEGRADATION REACTIONS

Using Soil Organisms for Biodegradation

Biodegradation describes the processes microorganisms use to catabolize (i.e., break down and simplify) a variety of compounds (chemicals, soil organic matter, and plant and animal residues) that would otherwise persist in the environment. In general, these simplification processes are used by the resident soil microflora as a means of obtaining both nutrients (carbon, nitrogen, phosphorus) and energy (ATP). Biodegradation describes a fundamental set of processes in which microorganisms are converting materials to recover energy and materials for building new cells. Madsen (94) has defined bioremediation as "a managed or spontaneous process in which biological, especially microbial, catalysis acts on pollutant compounds, thereby remedying or eliminating environmental contamination." Therefore, bioremediation is a direct utilization of inherent microbial abilities and can take many forms (Fig. 4).

Three factors, namely, the microorganisms, the contaminant, and the environmental setting function to modulate the field-scale biodegradation and bioremediation process (94–98). The contaminant's chemical structure (i.e., the number of carbon rings, side chains, halogens, and bonding arrangement), concentration (ngg^{-1} to gg^{-1}), physical placement (either the soil surface or in solution), the presence of electron donors or acceptors, and the physiological abilities of the microorganisms, either resident or introduced, interact to control the success of biodegradation or bioremediation. If any of these components are less than optimum, microbial-mediated degradation will be slow or not take place. In fact, it has been suggested that the long-term residency of contaminants in soil and the subsurface indicate the presence of poor or suboptimal conditions and the suboptimal condition has caused the contaminated site to form in the first place. The operational goal of a successful bioremediation program is to overcome the suboptimal conditions at the site by maximizing the functioning of the resident or applied microbial population to achieve a biodegradation of the materials. Removing the rate-limiting factors and promoting the activity of the microbial populations should allow

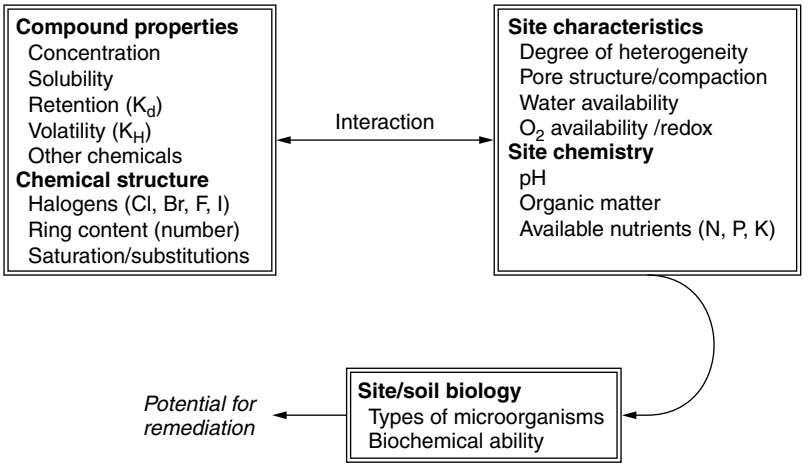

Figure 4. A diagram relating the three major components in site remediation, the compounds chemistry, the site properties, and the abilities of the microbial populations.

the community to destroy the pollutant. In essence, the key question in bioremediation becomes: what chemical or biological feature of the site has prevented the microbial population from removing the pollutant?

Successful bioremediation of surface and subsurface environments can result from a manipulation of the contaminated system to encourage the destruction of the contaminant by the microorganisms. This approach is bolstered by the fact that many laboratory studies have shown that biodegradation of pollutant chemicals can occur. However, the transformation rates estimated in the laboratory studies tend to be much higher than that found in the field. It is suggested that this difference reflects a spatial variability that hampers the microbial population. Therefore, the microbial community's ability to respond to the chemical is lessened in the field, as compared with the response at the laboratory scale (69).

Microbial Processing of Contamination

Long and coworkers (24) showed that exposure to high-level ($mg\,kg^{-1}$) petroleum contamination alters the characteristics of a subsurface microbial community. These results indicate that high levels of petroleum contaminants can exert toxic effects on microorganisms, but at low concentrations it is possible to enrich specific degraders. Contamination of a forest soil with pentachlorophenol was shown to reduce both soil microbial biomass and the numbers of collembolans, enchytraeids, and fungal-feeding nematodes. Therefore, it was felt that the diversity of soil fauna was reduced with the high-level contamination (99).

Low levels of contaminants (a few $\mu g\,kg^{-1}$) can result in the development of chemical-adapted microbial communities in the contaminated samples. This illustrates an outcome of Trevors (20) concept of "limitless genetic resource" as portions of the population are able to adapt to the situation. However, in highly contaminated materials, containing metals, or organics, or both, total microbial biomass is generally lower (52,24) indicating that a toxic effect has occurred. It has been shown that the chemical 1,2-dicholorobenzene reduces the fungal population size and can selectively reduce bacterial numbers (100). Function can also be impacted. Contamination of soil with copper has been shown to alter nitrification rates (101). These findings, in part, explain why some contamination can persist as it impacts basic microbial functions.

Soil microbial populations have been shown to adopt to materials such as aircraft deicing fluids (ADF) — Propylene Glycol, provided the population is not exposed to extremely high levels at the outset (85). With exposure to low levels of ADF (5 to 10%) the onset of degradation was delayed, but the overall rate of degradation was high. They found that high levels of ADF (40%) inhibited all degradation, a situation that is analogous to that described by Long and coworkers (24). It is also clear that mixed contamination can have differential effects on the response of the population. Gasoline, which is composed of many organic molecules, will degrade in soil. However, the presence of high levels of 2-ethyltoluene and trimethylbenzene will inhibit the degradation of other fractions of the gasoline, again showing the interrelatedness of the response (102).

Assimilatory and Dissimilatory Reactions and the Removal of Contamination — Aerobic

What is clear from the available wealth of reaction data is that bioremediation can make use of the four features of an active population, that is, their need for assimilatory nutrients such as carbon, nitrogen, sulfur, phosphorus, their need for a source of electrons, their enzymatic nonspecificity (co-oxidation), and their need for terminal electron acceptors. A detailed assessment of the redox and energy needs of microorganisms set in the context of biodegradation of contaminants in soil and water can be found in Harris and Arnold (103). They state that growth of an organism is a function of both assimilatory and dissimilatory steps, whereas maintenance of the organisms is primarily dissimilatory. Assimilatory reactions gather the required carbon, nitrogen, sulfur, and phosphorus for biomass (cell) production. Dissimilatory reactions provide the energy for assimilatory reactions and any subsequent maintenance processes. In general, the utilization of nitrogen and phosphorus is to satisfy the assimilatory aspects of the degradation process and the oxidation of material is to release reducing power from the substrate to generate ATP. Most efforts at bioremediation presumed that microbial populations respond to the targeted material as a source of carbon under aerobic conditions. Only recently has the potential of anaerobic processes been exploited.

For assimilatory processes the ratio of carbon to nitrogen should approach 30 : 1 (104) if optimum microbial biomass production is to occur. However, Dibble and Bartha (105) have shown oil degradation to be most rapid at C : N rations of 60 : 1, whereas others (106) have shown that degradation of propane and butane quickly becomes nitrogen-limited and that in response, the population may begin to fix gaseous nitrogen. The application of nitrogen sources should be done with care. Wrenn and coworkers (107) showed that in poorly buffered sea salt solutions, application of NH_4^+ to aid in the degradation of crude oil reduced the pH and degradation rates as compared with other nitrogen sources. O'Connor and Young (108) showed that nitrogen additions to phenol-contaminated sites would enhance degradation of the organic as much as twofold. They pointed out that the effectiveness of the nitrogen source was related to the type and position of the substitution on the phenol. Zhou and Crawford (109) provided an evaluation of nutrient application and the kinetics of BTEX degradation. They showed that all types of nitrogen (NH_4^+ as vapor, NH_4NO_3) were equal in their effectiveness as nitrogen source for BTEX degradation. One of the interesting findings of their work was that very low C : N ratios (1.8 : 1) suppressed degradation as compared with a ratio of 50 : 1. They also showed that in subsurface samples, an optimum oxygen addition giving a 10% enrichment was the most effective in stimulating degradation. The importance of adding phosphorous to the bioremediation system was also noted. Mills and Frankenberger (110) have shown that the addition of K_2HPO_4 at up to $500\,mg\,kg^{-1}$ would enhance degradation of diesel fuel. Rasiah and coworkers (111) have also indicated the

importance of added phosphorous sources in oil degradation. They found an effect from the type of nitrogen source added. In general, they rated the effectiveness of the nitrogen sources as $Ca(NO_3)_2 > NaNO_3 > KNO_3 > NH_4NO_3 > NH_4Cl$. Others have indicated that for bioremediation, the ratio should be in the range of 120 : 10 : 1, C : N : P, respectively (112).

Pope and Matthews (113) point out that nutrient requirements for enhancing biodegradation in the field have not been thoroughly studied. Finklea and Fontenot (114) showed that typical field cultivation (to enhance air and water entry) combined with an addition of nitrogen, phosphorus, and potassium (13-13-13) was effective in stimulating the degradation of atrazine in contaminated soil. Applications of manures were shown to stimulate the degradation of atrazine and 2,4-D in soil. It is suggested that the DOC in the manure stimulated the general soil growth of the population. However, other work has shown atrazine to be a ready source of nitrogen (115) and the addition of soluble carbon could have stimulated a demand for nitrogen resulting in the degradation of the chemical. A large-scale use of fertilizer was made in efforts to remediate the Exxon Valdez oil spill in Prince William Sound, Alaska (116). Work by Ilyinsky and coworkers (117) had indicated that fertilizer materials coated in oil or an oil membrane would have improved penetration into oils in the environment. The fertilizer addition gave higher hexadecane and phenanthrene mineralization than was found in the untreated soil (118).

Mineral nutrients have been effective in stimulating the degradation of petroleum wastes in surface soil (111) and *p*-nitrophenol in aquifer solids (119). In contrast, addition of nitrogen of up to 80 mg kg^{-1} did not affect the mineralization of added atrazine in a surface soil (115). Pothuluri and coworkers (120) were able to increase the degradation of alachlor in a subsurface soil 15 to 35% by adding a mixture of glucose and hydrolyzed casein. In contrast, glucose reduced the degradation of several xenobiotic compounds (119,121,122) in lake water and aquifer solids. A consideration of the importance of minor or trace elements is lacking for bioremediation systems.

Semprini and coworkers (123–126) have shown that it is possible to use substrate co-oxidation to degrade groundwater resident contaminants, in particular, chlorinated aliphatic hydrocarbons (CAH). The system is based on the co-oxidation, or the fortuitous transformation, of an organic compound by microorganisms. The microorganism receives no direct benefit from the fortuitous transformation of the CAH material. In the case of CAHs, few with more than two chlorine substitutions have been shown to support aerobic microbial growth as a carbon source. Semprini (123–126) has shown that methane monooxygenase used to oxidize methane by methanotrophic bacteria is able to concurrently oxidize CAHs. When the contaminated site is flushed with methane and oxygen to stimulate the methanogens, the co-oxidation of the CAHs may also occur. In other studies, they have shown a similar approach using the co-oxidation CAHs with phenol as the primary substrate in a cometabolizing system (127). A co-oxidation approach has been used by Aziz and coworkers (128) in the construction of a hollow-fiber flow-through system that couples a CH_4 oxidation by a methanotrophic bacteria with the co-oxidation of a CAH — tricloroethlyene (TCE) — in contaminated groundwater. They were able to show a significant reduction in TCE with co-oxidation.

Regardless of the types of available carbon and nitrogen, microorganisms must use an electron donor/acceptor couple to capture energy derived from dissimilatory reactions. This approach is universal and used in fermentative, anaerobic or aerobic reactions. For aerobic processes, the cell's biochemical system is routed to capture the generated energy (electrons released) during oxidation by reducing NAD+ (nicotinamide adenine dinucleotide) to NADH. ATP is generated while the NADH is being reoxidized to NAD+. In aerobic systems, the electrons are passed down the electron transport chain, across the cell membrane, and this creates an energy gradient. Under aerobic conditions, the electron acceptor is oxygen. However, other substances such as NO_3^- and SO_4^- are also selectively used. ATP synthase enzymes capture the electrical and chemical potential of the gradient and the overall process is referred to as *oxidative phosphorylation* as it results in the formation of ATP.

In aerobic systems, the combined dissimilatory and assimilatory reactions using oxygen as an electron acceptor are described by the following reaction:

$$\text{Substrate} + \text{Nutrients} + O_2 \rightarrow \text{Biomass} + CO_2 + H_2O + \text{Metabolites} + \text{Energy}$$

An example reaction (disregarding biomass production) to illustrate the process is the oxidation of glucose:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{energy}.$$

This translates to two moles of oxygen per mole of carbon utilized. The stoichiometry for toluene oxidation is:

$$C_6H_5 - CH_3 + 9O_2 \rightarrow 7CO_2 + 4H_2O + \text{energy}.$$

This translates to 2.57 moles oxygen per mole of carbon oxidized to carbon dioxide. If we consider benzene (and disregard biomass production), we find the following reaction:

$$C_6H_6 + 7.5O_2 \rightarrow 6CO_2 + 3H_2O$$

The transfer of electrons demands 7.5 moles or 240 g of oxygen per mole of benzene when an aerobic system is in place. This translates to 3.15 g of oxygen per gram of benzene. A 10,000 kg hydrocarbon plume contained in soil would require 3.15×10^4 kg of oxygen for complete mineralization. Air contains 21% oxygen by volume; to complete the degradation, a total of about 1.5×10^5 kg of air would be required. Assuming the contaminated soil has a bulk density of 1.33 Mg m^{-3}, it would contain 50% pore space and 50% solids. Assuming half of the pore space is filled with water, we would have an available air supply of about 0.33 Mg or 3,300 kg of air. Under these conditions it would take some 45 replacement volumes of

air to supply enough oxygen to allow mineralization of the plume. This assumes that all of the material is available for degradation, the material is evenly distributed within the site, the bulk density is uniform throughout the profile, the oxygen that is available instantaneously and other nutrients (nitrogen and potassium) that are not limiting, and that the chemical levels are not toxic. Few of the constraints aforementioned are commonly found to occur at a contaminated site. For example, the level of oxygen within the soil profile will tend to decrease with depth and the secondary nutrients tend to be limited. Moreover, as the biomass builds up, it will require a significant level of oxygen to maintain itself. When the concentration of oxygen in the profile is decreased by 5%, reflecting oxygen utilization at the surface, the volume of air needed to resupply the degradation processes in the subsurface is increased by 150% to 3.8×10^5 kg.

It stands to reason that the aerobic degradation rate may become a function of oxygen resupply to the regions undergoing degradation processes. The resupply is a function of transfer into and through both the soil profile and the water films. Some have suggested the use of hydrogen peroxide (47% oxygen), and not soil, as a soluble form of oxygen for groundwater supplementation. Oxygen is rapidly released from the hydrogen peroxide as the liquid encounters enzymes and metals. However, hydrogen peroxide is toxic to microorganisms at concentrations above 100 mgL^{-1} and successful use has been limited (129,130). Prosen and coworkers (131) suggested a system in which pure oxygen is generated on-site and this, instead of air, is pumped into the subsurface. Because air is 21% oxygen, use of pure oxygen would increase the efficiency fivefold. In all cases, the introduction of air or oxygen into anoxic subsurface conditions can be problematic because the oxygen can undergo abiotic reactions with reduced mineral surfaces and can be removed from the solution before it can serve as a terminal electron acceptor for microbial processes (132).

Assimilatory and Dissimilatory Reactions and the Removal of Contamination — Anaerobic

Modeling efforts for subsurface systems support the finding that for xenobiotic compounds, lack of oxygen is a limitation for degradation (133). Under aerobic conditions, pyridine and hydroxylated pyridines were more rapidly transformed than under anaerobic conditions (134). They tested surface and subsurface soil that had been exposed to these compounds for several decades. All the pyridine derivatives tested were degraded within two weeks in the presence of oxygen. Under anaerobic conditions, however, longer time periods were required. Jet fuel in the subsurface environments can have a long-term residence as a result of a lack of available oxygen (135). A similar situation is suggested for propylene glycol because oxidative degradation was enhanced by the presence of oxygen (85). Remediation sites can have a further complication because of the presence of a second material such as oil that can inhibit the flow of air or water. Oil perched on water changes the diffusion profile and acts as a barrier for oxygen transfer into water (136) providing a diffusivity of about 2×10^3 $cm^2\,s^{-1}$ for oxygen moving in oil (137). Moreover, the film thickness will change the transfer rate; films thicker than 100 μm will diminish the overall transfer velocity by as much as half.

Under oxygen-limited conditions, strict and facultative anaerobic bacteria are able to metabolize and grow if supplied with one of a number of alternative electron acceptors. The use of anaerobic organisms offers possibilities in bioremediation applications (95,138). In contrast to aerobic respiration, anaerobic organisms make use of a number of electron acceptors. A general reaction scheme for various electron acceptors typically used by microorganism is given by:

$$\text{Substrate} + \{NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2\}$$

$$\downarrow$$

$$\text{Biomass} + CO_2 + \{N_2, Mn^{2+}\ Fe^{2+}\ S^{2-}\ CH_4\}$$

The type of electron acceptor favored will reflect the redox status of the system. Therefore, the sequence of reduction, NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2 reflects the oxidizing capacity of the chemical half-reaction (139). Kazumi and coworkers (140) showed that 3-chlorobenzoate could be degraded with NO_3^-, Fe^{3+}, or SO_4^{2-} acting as the electron acceptor. McFarland and Sims (141) have developed a conceptual framework for interpreting the thermodynamics of PAH degradation in the environment. They extended their model to not only oxygen as an electron acceptor, but also NO_3^-, Mn^{4+}, Fe^{3+}, SO_4^{2-}, CO_2. They pointed out that thermodynamically the reduction of Mn^{4+} may be favored in groundwater and subsurface systems given its widespread availability and that the ΔG° for the reduction of Mn^{4+} gives a free energy change similar to that found with oxygen. However, the usefulness of Mn^{+4} as an electron acceptor is limited by the low solubility of the mineral (141).

At the center of a subsurface hydrocarbon plume, the conditions may be anoxic and highly reduced (142). At the edges of the plume, the conditions are more aerobic and better oxygenated because the contaminated water mixes with noncontaminated water. Others (143) have used the subsurface formation of methane, an indicator of extremely reduced conditions, to map plume migration in soil and aquifers. More recently, Lovely and coworkers (144) have demonstrated the use of dissolved hydrogen to describe the predominant terminal electron accepting processes (TEAPs) occurring in an aquifer. This approach allows a better description of the redox chemistry and contaminant transformation processes occurring in anoxic groundwater systems. The TEAPs method is more robust than other signature processes because it relies on the occurrence of characteristic concentrations of hydrogen. Hydrogen values are less ambiguous than CH_4 or SO_4 because hydrogen is quickly cycled, is poorly reactive with mineral surfaces, and has a short half-life (145). Chapelle and coworkers (145) used the TEAPs concept to describe the distribution of redox states within a hydrocarbon-contaminated aquifer.

Nitrogen as NO_3^- can be introduced to serve as an electron acceptor in moderately reduced or hypoxic (low oxygen) conditions. For example, it has been shown that

for toluene, the following reaction is possible:

$$C_6H_5 - C_6 + 6NO_3^- \rightarrow 7CO_2 + 4H_2O + 3N_2 + \text{energy}$$

The advantage of NO_3^- as an electron acceptor is that it is more soluble than oxygen (660 g NO_3^- $L^{-1}H_2O$), allowing it to be distributed throughout a contaminated aquifer or subsurface material. Dissolved NO_3^- will move with water through flow paths and into micropores and spaces. NO_3^- will serve as an electron acceptor in the remediation of contaminated aquifers in which BTEX is the primary contaminant (132,146,147). Gersberg and coworkers (148) used NO_3^- as an electron acceptor in the remediation of BTEX in an oxygen-poor aquifer. This NO_3^- approach was also used by Burland and Edwards to degrade benzene under anaerobic conditions and supported other studies that had shown that anaerobic removal of benzene was possible (149). Kazumi and coworkers (140) showed that the utilization of monochlorobenzoate isomers (2-,3-, and 4-chlorobenzoate) by microbial consortia in river sediments was possible under denitrifying conditions. They were also able to show that a loss of 3-chlorobenzoate would occur under iron- and sulfate-reducing conditions and under methanogenic conditions. For a given hydrocarbon, the NO_3/N_2 couple is energetically similar to the O_2/H_2O couple. The standard-state reduction potential for oxygen is 1.22 volts, whereas NO_3^- reduction to nitrogen gas an E_h^0 of 1.24 volts. This shows the relative energy available in the redox couples is quite similar.

Not all bacteria capable of aerobic degradation of a given aromatic contaminant and capable of NO_3^- reduction are automatically capable of degradation of the same contaminant when using NO_3^- as the electron acceptor. It is unclear as to the exact pathway used by facultative microorganisms when degrading aromatic compounds under NO_3^--reduction conditions. Downs and coworkers (150) has used NO_3^- in an approach similar to that of Hutchins and coworkers (132) to degrade BTEX, but they implicated that aerobic step was needed in the degradation of benzene. Others have reported a similar finding (132,152). Rate constants developed for the comparative studies of BEXT removal under either aerobic or denitrifying conditions indicated that reactions occurring under denitrifying conditions are somewhat slower than that reported for aerobic processes (132). Leahy and coworkers (152) demonstrated the potential of toluene-oxidizing bacteria to degrade trichloroethylene (TCE) under hypoxic conditions when NO_3^- was present. They also demonstrated that TCE could act as its own inducer suggesting the possibility that concurrent introductions of toluene into TCE-contaminated sites is not necessary to achieve degradation.

Anaerobic processes are particularly effective in removing halogens from haloorganic compounds; however, the rates are relatively slow. Nozawa and Maruyama (153) demonstrated that the anaerobic metabolism of phthalate and other aromatic compounds can be conducted by the denitrifying soil bacterium *Pseudomonas* sp. strain P136. In addition, dinoseb (an insecticide) that is not degraded in contaminated soil under aerobic conditions can be degraded when anaerobic conditions are established (155,156). In this study, anaerobiosis was developed by treating the soil with starchy potato-processing waste materials and allowing the aerobic population to deplete the available oxygen. The anaerobic microbial consortium degraded dinoseb completely, and the formation of polymerization products produced aerobically was avoided. This approach has been applied to the removal of munition-contaminated soil. Funk and coworkers (157) reported that a wide spectrum of explosives materials, including 2,4,6-trinitrotoluene, could be rapidly reduced and then degraded in soil systems when anaerobic conditions were established. The anaerobic transformation of polychlorinated biphenyls, DDT, and percholoroethylene has also been reported (158). Moreover, the nematicide 1,2-dibromo-3-chloropropane (DBCP), which persists in groundwater and soil, has been shown to be converted to organic products and carbon dioxide when soil suspensions are placed under anaerobic conditions (159).

CONCLUSION

Over the last 100 years, the study of soil microbiology has revealed that a wide array of inherent biochemical abilities exist in each gram of soil. Trevors' (20) statement describing soil as a virtual limitless pool of genetic information contained in bacteria can be coupled to other work that has shown microorganisms to be distributed in almost every type of soil and terrestrial location. The importance of the soil organisms to the ecosystem stability is clear. In fact, the study of soil microorganisms was hampered for years by our inability to separate the cells from their growth environment. This makes the study of soil ecology unique because few other areas of ecological investigation have such difficulty in separating the studied organisms from their habitat.

Therefore, the structure and function of soil reflects the interrelatedness of the organism and their habitat. This habitat is constantly changing in response to the actions of the population of cells that are present. This is somewhat surprising, given the wide distribution of cells across a volume of soil, but illustrates the importance of their biochemical processing abilities. Our use of soil is dependent on the microbial population and their ability to reduce the waste and recycle these stored nutrients. In recent years, our dependence on soil microorganisms has expanded as we now rely on them to remove pollutant materials.

SOIL NITROGEN CYCLE

DAVID D. MYROLD
Oregon State University
Corvallis, Oregon

Nitrogen is an essential element for life. It is found in key biological compounds, such as nucleic acids and proteins. Microorganisms and their activities are crucial to supplying biologically available nitrogen; in fact, only certain prokaryotes (and more recently, humans) can produce such nitrogen. In general, microorganisms play a key role in the transformation of nitrogen into its many available forms and thereby influence primary productivity in terrestrial and aquatic ecosystems.

Nitrogen in its various naturally occurring organic and inorganic forms is usually benign, at least at concentrations typically encountered by living organisms. Indeed, nitrogen is very often the nutrient most limiting productivity in many terrestrial and some aquatic systems. Increased exogenous inputs of nitrogen from chemical nitrogen fertilization or other anthropogenic activities have in some cases altered the natural balance, thereby contributing to environmental problems such as soil acidification, surface water eutrophication, groundwater contamination, and atmospheric pollution.

An understanding of nitrogen cycling in soils is critical to sustain the productivity of natural and managed ecosystems without environmental degradation.

FORMS OF SOIL NITROGEN

Although we tend to think of soil as solid, composed only of mineral particles and organic substances, it also has varying fractions of liquid, the soil solution, and gas, the soil atmosphere. Nitrogenous compounds exist in each of these phases (Table 1).

It is perhaps surprising that such a large fraction of soil nitrogen is composed of the relatively inert gaseous N_2. With the exception of the N_2-fixing prokaryotes that possess the remarkable ability to convert N_2 into biologically available forms, no other organisms can utilize N_2. Dinitrogen is returned to the atmosphere by denitrifying bacteria, as the metabolic end-product of NO_3^- reduction. Although N_2 is environmentally benign, the same is not true for other nitrogenous gases. Nitrous oxide (N_2O) is found at low concentrations and, on release to the atmosphere, it acts as a greenhouse gas and is implicated in the destruction of stratospheric ozone. Other nitrogenous gases present in soil at low levels include NH_3, which is in chemical equilibrium with NH_4^+ in the soil solution, and NO, an intermediate or by-product of several nitrogen cycle processes. Elevated NH_3 concentrations volatilizing from animal manures, in combination with the release of anthropogenically produced NO_x compounds, have increased the input of nitrogen in precipitation in many parts of the world with unintended effects on nitrogen cycling.

Soil solution contains organic and inorganic forms of nitrogen. Ammonium (NH_4^+) and nitrate (NO_3^-) are commonly considered the most soluble nitrogen forms; however, in some soils, soluble organic nitrogen is present

Table 1. Amounts of Important Forms of Soil Nitrogen (1). For Comparison, a Typical Agronomic Crop Might Contain About 25 g N m^{-2}

Nitrogen Form	Concentration	Content[a] (g N m^{-2})	Relative Fraction (%)
N_2	78 kPa	230	20.6
N_2O	≥31 mPa	90×10^{-6}	~0
NH_4^+	<0.05 to 5 mM	2.2	0.2
NO_3^-	<0.05 to 20 mM	4.4	0.4
Organic N	<0.1 to 5 g N kg^{-1} soil	880	78.8

[a]Based on median concentrations for 1 m^3 of soil at a bulk density of 1.25 Mg m^{-3} with a pore space fraction of 0.5 that is filled half with air and half with soil solution.

in greater concentrations (2). Soluble organic nitrogen may be a more important pool of available nitrogen than previously thought. Recent studies have shown that it can be a major source of nitrogen assimilated by microorganisms and plants (3,4). Just as different soils contain different proportions of soluble organic and inorganic nitrogen, the relative amounts of NH_4^+ and NO_3^- also vary, primarily because of the activity of nitrifying bacteria. In many undisturbed systems, especially temperate and boreal forests and heathlands, NH_4^+ is the dominant form. In most agricultural systems, native grasslands, and many tropical forests, NO_3^- is present in higher concentrations. In some aridic soils with high pH (>8), there may be measurable concentrations of NO_2^-, an intermediate in several nitrogen cycle processes.

Nitrogen associated with the solid matrix of the soil is largely insoluble organic matter, although soluble forms can be held on cation and anion exchange sites of the solid matrix and NH_4^+ can be sequestered, or fixed, within the interlayers of certain 2 : 1 clay minerals, such as the illites. Soil organic nitrogen typically comprises most (>90%) of the total soil nitrogen and exists in numerous forms, many of which defy clear chemical characterization. Those forms of organic nitrogen that can be identified are termed nonhumic substances, and include fragments of nucleic acids, peptides, and oligomers of amino sugars found in microbial cell walls. The bulk of soil organic nitrogen is made up of humic substances, nitrogenous compounds of varying size and complexity, which make up the amorphous organic material in soil. Historically, several chemical-fractionation schemes, on the basis of solubility in organic solvents or inorganic acids and bases, have been used to characterize soil organic nitrogen and assess its availability to plants. These methods, which have been greatly enhanced by modern spectroscopic methods, have provided some insight into the chemical nature of soil organic nitrogen but have not been particularly useful in explaining the biological availability of soil organic nitrogen. It should be noted that generally 2 to 5% of soil organic nitrogen is found in the living microbial biomass, which represents a source of organic nitrogen that is biologically active and turns over relatively quickly as will be discussed later.

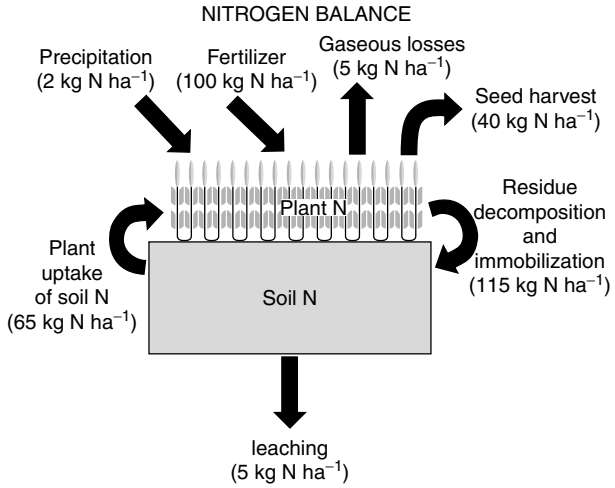

Figure 1. A nitrogen balance for grass seed production in the Willamette Valley of Oregon. Major inputs and outputs of the plant-soil system are shown along with the internal transfers between plant and soil (5–9).

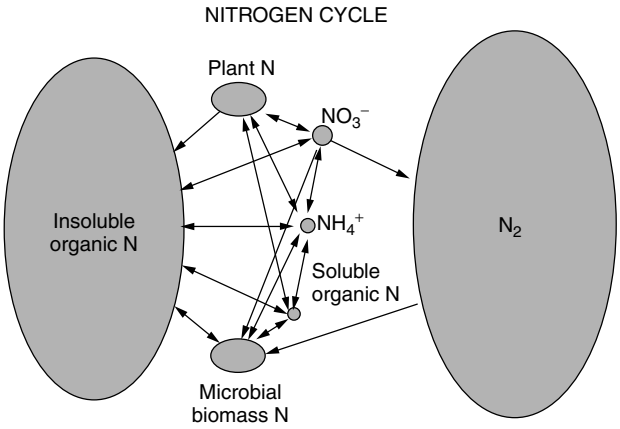

Figure 2. Diagram of a soil nitrogen cycle. Sizes of the pools are proportional to typical nitrogen concentrations. Arrows indicate nitrogen transformations that are described throughout this article.

THE NITROGEN CYCLE AND NITROGEN BALANCES

The conversions of nitrogen from one form to another are generally depicted in a diagram consisting of boxes, which represent the several pools of nitrogen, connected by arrows, which represent the various biological processes that transform nitrogen into its different forms. Such abstractions of the nitrogen cycle can be quite simple, showing only the major pools and transformations, or can be exceedingly intricate, showing all pools and known reactions.

A relatively simple nitrogen cycle model often suffices to represent the nitrogen balance for a given system, whether that is an individual field or the globe. The example shown in Figure 1 represents the nitrogen balance for a perennial grass seed crop. Such diagrams often emphasize the inputs and outputs and are less concerned with the transformations of nitrogen that occur within the system.

A reasonably detailed nitrogen cycle is depicted in Figure 2 and serves to illustrate several important principles. As mentioned previously, nitrogen exists in many chemical forms and these pools differ in size. Although the relative rates of the processes in Figure 2 are not depicted, it is generally true that the turnover rates of the nitrogen pools are inversely proportional to their size. The nitrogen in plants and microorganisms turn over in the range of 0.5 to 5 years; soluble nitrogen pools turn over much faster, perhaps daily in some systems (10); the nitrogen in insoluble soil organic matter turns over at the scale of decades to centuries; and the N_2 pool of the atmosphere is so large that it may not turnover completely in a million years. Except for N_2, all nitrogen pools are affected by at least four or five processes. This clearly lends

complexity to the nitrogen cycle but also emphasizes the importance of competition among different fates of each nitrogen pool. Most often, this competition is between different types of organisms and the outcome of the competition is a key to regulating nitrogen cycle processes.

DINITROGEN FIXATION

The production of biologically useful 'fixed' nitrogen from the large, relatively inert pool of N_2 gas in the atmosphere is dominated by biological N_2 fixation. About 175 Tg (10^{12} g) of nitrogen are fixed annually in terrestrial ecosystems by N_2-fixing prokaryotic microorganisms whereas only about 10 Tg are fixed by atmospheric chemical processes, such as the production of nitrogen oxides by lightning (11–13). In the history of the Earth, biological N_2 fixation has been the major input of nitrogen into terrestrial and aquatic ecosystems. During the last century human activities, such as fossil fuel consumption, biomass burning, and industrial production of chemical fertilizers, have increased inputs of nitrogen to the point that anthropogenic inputs are now comparable to natural processes. Enhanced utilization of symbiotic, N_2-fixing plants–particularly legumes–for agricultural production has also been an additional input locally and globally. In fact, enhancement of N_2 fixation has been a major impetus for research in an effort to meet the food and fiber needs of mankind.

Biochemical Process

The reduction of N_2 to NH_3 that requires breaking a triple bond, is an energy intensive, reductive process performed by the nitrogenase enzyme complex. The nitrogenase complex is composed of two proteins: Dinitrogenase, an enzyme with a MoFe cofactor, which reduces N_2 to NH_3, and dinitrogenase reductase, an Fe-containing enzyme, which provides the reducing equivalents for the reaction. In addition to reducing N_2, nitrogenase also reduces H^+ to H_2 and a variety of other alternate substrates, including acetylene. The ability to reduce acetylene to ethylene has been widely used as an assay for nitrogenase activity and a means of estimating N_2-fixation rates (14).

The highly reducing conditions required for N_2 fixation can only occur in the absence of oxygen. Nitrogenase itself is completely inactivated by oxygen. Several strategies have been developed by N_2-fixing prokaryotes to deal with oxygen, including: avoidance by living in anoxic environments, high respiratory activity, and the production of specialized structures that are relatively impermeable to oxygen.

Under optimum conditions, the balanced reaction requires 16 ATPs for each N_2 fixed, but under normal conditions perhaps 50% more energy is used. This high-energy cost has a direct impact on the amounts of N_2 fixed by different types of N_2-fixing prokaryotes and is also a likely reason why N_2 fixation is under tight genetic and biochemical regulation.

N_2-Fixing Organisms

Dinitrogen fixation is limited to prokaryotic microorganisms, mainly bacteria plus some archaea. This capability is quite widespread among the bacteria, possibly because of lateral transfer of key genes involved in N_2 fixation among taxonomic groups. From an ecological perspective, however, a phylogenetic classification is not especially useful. It is more helpful to group N_2-fixing microorganisms as either free-living or as more or less closely associated with other organisms, typically plants. Such a categorization is useful because there is a general relationship between the type of association and the amount, or rate, of N_2 fixation (Table 2).

Free-living N_2-fixers, such as *Azotobacter*, an aerobe, and *Clostridium*, an anaerobe, normally fix less than 1 kg N ha^{-1} yr^{-1} because they must compete with other heterotrophic microorganisms for available carbon. Dinitrogen fixation rates are higher for free-living cyanobacteria because they can derive energy directly from sunlight.

Dinitrogen-fixing bacteria are commonly found associated with the surfaces of plant leaves or roots. These habitats are relatively rich in available carbon compared with soils and tend to have higher rates of N_2 fixation. *Azospirillum* associated with the rhizospheres of tropical grasses, can fix up to 25 kg N ha^{-1} yr^{-1}, but even higher rates have been found for *Acetobacter diazotrophicus*, which lives in the internal tissues of sugarcane. Some of the cyanobacterial associations, such as the one with *Azolla*, can fix very large amounts of N_2.

Table 2. Estimated Average Rates of Biological N_2 Fixation for Specific Organisms and Associations (14)

Organism or System	N_2 Fixed (kg ha^{-1} y^{-1})
Free-living microorganisms	
Cyanobacteria	25
Azotobacter	0.3
Clostridium pasteurianum	0.1–0.5
Grass-bacteria associative symbioses	
Azospirillum	5–25
Cyanobacterial associations	
Gunnera	10–20
Azolla	300
Lichens	40–80
Leguminous plant symbioses with rhizobia	
Grain legumes (*Glycine, Vigna, Lespedeza, Phaseolus*)	50–100
Pasture legumes (*Trifolium, Medicago, Lupinus*)	100–600
Actinorhizal plant symbioses with Frankia	
Alnus	40–300
Hippophaë	1–150
Ceanothus	1–50
Coriaria	50–150
Casuarina	50

Mutualistic symbioses between root-nodulating bacteria and plants allow for the highest rates of N_2 fixation. These tightly-coupled associations can fix more than 100 kg N ha^{-1} yr^{-1} and are probably responsible for the bulk of the N_2 fixed biologically each year. The legume-rhizobia symbiosis is the most well known and characterized, in part because legumes have been used in agriculture for thousands of years. In general, grain legumes fix less N_2 than small-seeded leguminous plants used for pasture (Table 2). The actinorhizal symbiosis (so-called because the N_2-fixing partner, *Frankia*, is an actinomycete) can fix N_2 at rates comparable to legumes and represent a major input of nitrogen during primary and secondary succession in many ecosystems. In general, the amounts of N_2 fixed by these root-nodulating symbioses are proportional to the primary production of the host plant.

AMMONIFICATION

Ammonification, the production of NH_4^+ from organic nitrogen compounds, is sometimes loosely referred to as nitrogen mineralization, although the latter term sometimes refers to the production of both NH_4^+ and NO_3^-. Because organic nitrogen compounds in soil range widely in their diversity and complexity, the production of NH_4^+ is an amalgamation of several enzymatic processes. The general pattern is the depolymerization of large organic nitrogen compounds by extracellular enzymes followed by microbial uptake of the monomers and subsequent release of NH_4^+ by the activity of intracellular enzymes. These pathways are understood quite well for individual biopolymers, such as the proteins, aminopolysaccharides, and nucleic acids, which comprise living cells (15). However, the organic nitrogen that has been stabilized in humic substances may be more protected from enzymatic attack. It is important to note that predation of bacteria and fungi by the soil fauna can contribute to ammonification, partly through enzymatic processes in their guts and also as a result of the subsequent degradation of their nitrogen-containing waste products, such as urea. Urea is rapidly broken down to NH_4^+ and CO_2 by extracellular ureases in most soils.

Ammonification is not restricted to a narrow group of organisms, rather it is carried out by all heterotrophic microorganisms. In many cases, NH_4^+ production is probably a by-product from the search for available carbon, although it is possible that the production of the various extracellular enzymes and regulation of intracellular enzymes is under regulatory control, which is dependent on the relative availability of carbon and nitrogen. Consequently, there is a balance between the production of NH_4^+ by ammonification and its consumption by assimilation.

ASSIMILATION

Assimilation is the incorporation of nitrogen compounds into microbial or plant biomass. Microbial assimilation of nitrogen is often used interchangeably with the term, nitrogen immobilization. Most often assimilation refers to the uptake of inorganic nitrogen, NH_4^+ and NO_3^-, and subsequent conversion to organic nitrogen; however, organisms are also capable of directly assimilating small, soluble organic nitrogen compounds.

Biological Assimilation of Nitrogen

It is generally held that NH_4^+ assimilation is the dominant nitrogen assimilation mechanism in soils. This principle is based in part on empirical studies and partly on the theoretical preference for NH_4^+ by heterotrophic microorganisms, which are limited by carbon. When present in high concentrations, NH_4^+ is assimilated by glutamate dehydrogenase; however, at the low NH_4^+ concentrations (Table 1) typically found in soils, the glutamine synthetase-glutamate synthase pathway, which requires energy, is used (11,14).

Although many microorganisms are known to take up and utilize small organic nitrogen molecules, such as amino acids, the importance of this nitrogen assimilation pathway is not well established. Traditionally, it is assumed that organic nitrogen compounds are first mineralized, releasing NH_4^+ as a by-product, which is subsequently assimilated as microorganisms build biomass. This has been termed the MIT (mineralization-immobilization turnover) process. Several recent studies, however, have suggested that the direct uptake and assimilation of amino acids can be important in soils (16).

Assimilatory NO_3^- reduction has long been viewed as a minor pathway of biological nitrogen immobilization in soils. Extrapolating from studies of bacteria growing in pure culture, NH_4^+ concentrations in most soils are high enough to inhibit NO_3^- assimilation, and this has been shown in some studies with soil (17). Furthermore, because NO_3^- reduction to NH_4^+ requires energy, assimilatory NO_3^- reduction is more costly for heterotrophic soil organisms, which are often carbon limited. However, immobilization of NO_3^- has been observed after the addition of fresh residues, and more recent studies of forest soils high in organic matter have shown that NO_3^- assimilation may be more common than previously thought (10).

Chemical Immobilization of Inorganic Nitrogen

Not all immobilization of inorganic nitrogen into organic forms is biological in nature. Studies using ^{15}N-labeled NH_4^+ or NO_3^- often show rapid incorporation of the label into soil organic matter at rates that appear to be too quick to be biologically mediated (18,19). The exact mechanisms of this abiotic fixation of inorganic nitrogen are not clearly known, but probably involve reactions with active phenol or quinone moieties of the soil organic matter (20).

NET PRODUCTION AND CONSUMPTION OF NH_4^+

The balance between ammonification and NH_4^+ assimilation is of practical importance. A soil poised to immobilize NH_4^+ will be nitrogen deficient in terms of plant productivity. However, a soil with high rates of ammonification relative to NH_4^+ assimilation is likely to lose a significant

amount of nitrogen to the environment through leaching or gaseous losses, which result from nitrification and denitrification, as will be discussed later.

Effect of Substrate C : N Ratio

During decomposition, several factors affect the balance between NH_4^+ production and consumption. These factors include: the 'quality' of the substrate, the types of organisms involved in decomposition, and their growth efficiency and nitrogen content. Substrate quality refers to how easily it can be degraded, which in turn is related to its chemical composition, e.g., the relative amounts of nitrogen, lignin, soluble organics, etc. A good general index of substrate quality is its C : N ratio, at least during the initial phases of decomposition. The major decomposing organisms, fungi, and bacteria, differ in their C : N ratios and how efficiently they incorporate substrate carbon into biomass. In general, fungi have a wider C : N ratio (perhaps 10 vs. 4) and are slightly more efficient (50 vs. 40%) than bacteria. When these factors are combined (Fig. 3), one can determine the C : N ratio of the substrate, which just balances the decomposers' needs for carbon and nitrogen. As a rule of thumb, net nitrogen immobilization occurs when the substrate has a C : N ratio wider than about 20 or 25 and net nitrogen mineralization occurs when it is narrower. A more efficient use of carbon and/or a lower decomposer C : N ratio causes this 'critical' substrate C : N ratio to decrease.

Measuring Gross Production and Consumption Rates

Because changes in the size of the NH_4^+, or NO_3^-, pool provide information only about the net processes of production and consumption, alternative methods must be used to determine the gross rates of production and of consumption. In some cases this may be done using

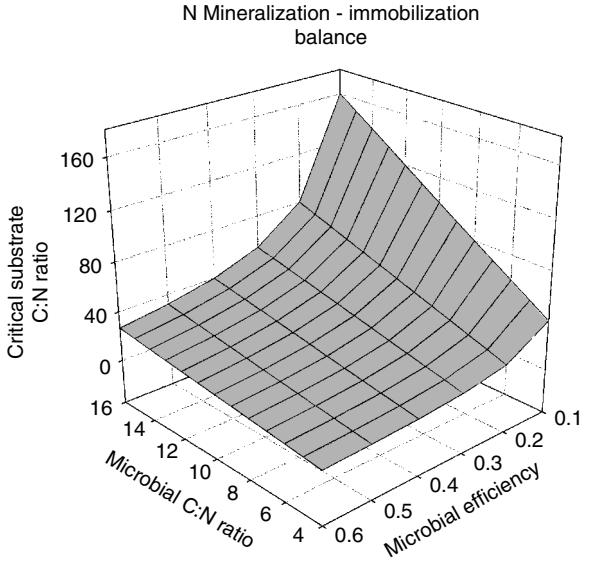

Figure 3. The critical substrate C : N ratio–the ratio in which ammonification and nitrogen immobilization are balanced–as a function of microbial efficiency and C : N ratio. When substrate C : N ratio exceeds the critical value, nitrogen is immobilized.

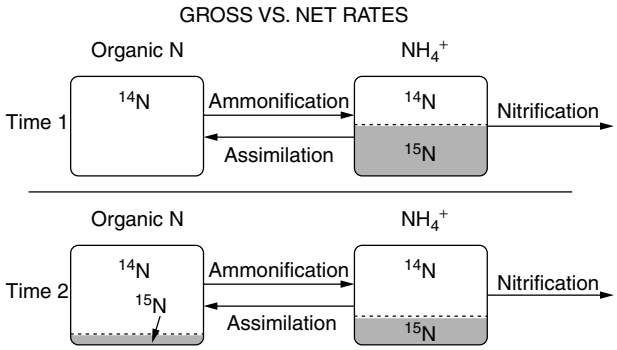

Figure 4. A diagrammatic example of how ^{15}N can be used to determine the gross rates of NH_4^+ production and consumption. Gross rates of NO_3^- production and consumption can be obtained in an analogous fashion.

a process-specific inhibitor or alternative substrate. For example, acetylene can be used to specifically block NH_3 oxidation and the difference between the NO_3^- produced in the presence and absence of acetylene is equal to the gross nitrification, or NO_3^- production rate. This assumes that the inhibitor does not influence any other processes related to the availability of substrate or the consumption of NO_3^-.

The potential limitations involved in using inhibitors can be circumvented by using ^{15}N-labeled substrates or products and measuring the changes in the ^{15}N-abundance as well as total pool size of the product pool (21). The basic principle of this approach can be illustrated by taking the simple case where the production and consumption of NH_4^+ are equal (Fig. 4). In this case it is obvious that the size of the NH_4^+ pool does not change with time; however, if some $^{15}NH_4^+$ was added to this pool, its ^{15}N abundance would decline. Such data can be analyzed to determine the individual rates of NH_4^+ production and consumption (21,22).

NITRIFICATION

Nitrification is the production of NO_3^- by microorganisms. It is of particular practical interest because NO_3^- is the form of inorganic nitrogen that is most susceptible to loss from the soil, either through leaching or subsequent transformation to gaseous endproducts via dentrification. These losses are of concern because they reduce the amount of nitrogen available for plant production, which is often the major nutrient limitation, and because of undesirable environmental consequences of NO_3^- in surface and groundwaters.

The Autotrophic Nitrification Process

Typically nitrification refers to the sequential oxidation of NH_3, which is in equilibrium with NH_4^+, to NO_2^- and then to NO_3^- by two groups of autotrophic bacteria. The conversion of NH_3 to NO_2^- involves several steps and results in the production of energy:

$$2NH_3 + 3O_2 \rightarrow NO_2^- + H^+ + H_2O$$

$$\Delta G_0' = -45\ \text{kJ mol}^{-1}\ e^-$$

Ammonia monooxygenase converts NH_3 to NH_2OH (hydroxylamine), which is subsequently oxidized to NO_2^- by hydroxylamine oxidoreductase. In addition to NO_2^-, H^+ is produced, and NO and N_2O can be produced as by-products. Thus, NH_3 oxidation has the potential to acidify soils and also release radiatively active greenhouse gases. There are several closely related genera of autotrophic NH_3-oxidizing bacteria. *Nitrosomonas* are often the most easily isolated NH_3-oxidizers but often *Nitrosospira* are numerically dominant in soils (11,14).

The oxidation of NO_2^- to NO_3^- is a one-step process carried out by NO_2^--oxidizing bacteria via the enzyme nitrite oxidoreductase:

$$2NO_2^- + O_2 \rightarrow 2NO_3^-$$

$$\Delta G_0' = -39\ \text{kJ mol}^{-1}\, e^-$$

This reaction is less energetically favorable than that for NH_3 oxidation. The NO_2^--oxidizing bacteria also form a cohesive taxonomic group, with *Nitrobacter* being the representative genera. Because NO_2^--oxidizers utilize the NO_2^- produced by NH_3-oxidizers, autotrophic nitrification can be thought of as a commensalistic relationship, in which both partners benefit. In fact, studies in other environments, such as sewage treatment plants and aquatic systems, have found nitrifying bacteria growing in association in dense aggregates of cells (23).

The Heterotrophic Nitrification Process

It is recognized that NO_2^-, and in some cases NO_3^-, can be produced by the activities of heterotrophic microorganisms or nonspecific monooxygenase enzymes. Several heterotrophic bacteria and fungi can oxidize NH_4^+ or organic nitrogen compounds to NO_2^- or NO_3^- without gaining energy from the process. Furthermore, the low specificity of monooxygenase enzymes, e.g., methane monooxygenase, can result in NH_3 oxidation to NH_2OH (24). The rates of heterotrophic nitrification are generally thought to be low relative to the autotrophic process and the ecological importance of heterotrophic nitrification is unclear. Nevertheless, the heterotrophic process has been found to dominate in some habitats, such as acidic forest litters and soils (25).

Factors Affecting Nitrification

Nitrification obviously requires that microorganisms capable of producing NO_3^- are present. With rare exceptions, such as following soil fumigation, this is the case. Another requirement that is usually met is the availability of O_2. Because nitrification is dependent on molecular oxygen, aerobic conditions are required for the production of NO_3^-. This is true for most soils, except when fully saturated.

As with most microbial processes, the most common limitation to growth or activity is the supply of the energy-supplying substrate. In the case of nitrification, this is NH_4^+, or more precisely NH_3. Consequently, soils with high NH_4^+ concentrations, or high rates of NH_4^+ production, generally have higher rates of nitrification. Typical examples are arable soils, which often receive relatively large inputs of nitrogenous fertilizers, and are mixed and otherwise managed to promote good fertility and water availability. After an initial lag period, nitrification rates are often elevated following a physical disturbance and/or the removal of vegetation. This is thought to be largely a response of increased NH_4^+ availability resulting from enhanced ammonification and the reduction of plant nitrogen uptake, which allows an increased population of nitrifying bacteria and concomitant net production of NO_3^-.

Additional constraints on autotrophic nitrification include a variety of environmental and edaphic factors; however, pH and specific inhibitors require special mention. It is generally observed that nitrification rates are very sensitive to low pH. This may be because nitrifying bacteria are relatively sensitive to pH but may also be caused by the relatively high pK_a (9.5) of the NH_4^+-NH_3 equilibrium, which means that at pH 5.5, the ratio of NH_3 to NH_4^+ is 1 : 10, 000. At low pH, NO_2^- is present primarily as HNO_2, which is toxic to nitrifying bacteria.

The observation that NO_3^- concentrations or net production of NO_3^- are often low in soils under late successional or climax vegetation has led to the speculation that there may be specific chemicals associated with, or produced from, the plant litter than inhibit nitrifying bacteria (26). Furthermore, the wide substrate range of the ammonia monooxygenase enzyme makes it susceptible to inhibition by a range of substrates, which can compete with NH_3, such as methane and other hydrocarbons (27,28). Although this potential is real, and may occur in some cases, most tests of specific inhibitors thought to be associated with late successional plants (e.g., phenolics, tannins, etc.) have not been found to be inhibitory (29). Therefore, it is more likely that the lack of observed nitrification is caused by intense competition among nitrifying bacteria, heterotrophic microorganisms, and plants for available NH_4^+.

Although naturally occurring inhibitors of nitrification may be of minor importance, several effective chemical inhibitors have been developed for use in agriculture. nitrogen-serve (nitrapyrin) was one of the first commercial nitrification inhibitors but many others are used world-wide, including DCD (dicyandiamide) and Dwell (etridiazole). The use of these inhibitors slows the nitrification of fertilizer nitrogen, which can enhance plant nitrogen uptake and limit losses to the environment (11,14).

DENITRIFICATION

Denitrification involves anaerobic reduction of NO_3^- to gaseous end-products, dominantly N_2 (30). Through denitrification nitrogen is recycled into the atmosphere, which represents the largest annual export of nitrogen from terrestrial ecosystems at about 140 Tg (11,12). Normally NO_3^- reduction is associated with bacterial respiration in which the NO_3^- is used as an alternate electron acceptor in place of O_2; however, gaseous nitrogen oxides can be produced by other biotic and abiotic (chemodenitrification) processes. Furthermore, some bacteria can reduce NO_3^- to NO_2^- (nitrate

respiration) or to NH_4^+ (DNRA–dissimilatory nitrate reduction to ammonium).

The reduction of NO_3^- to N_2 is a multistep process, which involves four enzymes, which function sequentially to carry out the following reaction:

$$2NO_3^- + 12H^+ + 10e^- \rightarrow N_2 + 6H_2O;$$
$$\Delta G_0' = -112\ \text{kJ mol}^{-1}\ e^-$$

Nitrate is reduced to NO_2^- by dissimilatory nitrate reductase, an enzyme that is in common with all bacteria, which dissimilate NO_3^-. Generation of ATP is linked with this reaction. Nitrite is reduced to NO by nitrite reductase, of which there are two types. Heme-containing nitrite reductases are more common, occurring in about two-thirds of all denitrifiers, which have been tested; the remainder have a Cu-containing nitrite reductase. Currently, it is not clear whether there are major differences in the kinetics or regulation of these two types of nitrite reductase, which thereby confers some type of competitive advantage in certain environments. Nitric oxide is a freely diffusible intermediate, which is reduced to N_2O by nitric oxide reductase and is the step during which the N–N bond is formed. The final reduction of N_2O to N_2 is done by nitrous oxide reductase, a Cu-containing enzyme, which is inhibited by acetylene. These last two steps also appear to be linked to ATP production. It should be noted that the inhibition of nitrous oxide reductase by acetylene, the so-called acetylene block technique, allows denitrification to be measured with great sensitivity using gas chromatography.

A relatively large fraction of soil bacteria, between 0.1 and 5%, can denitrify, and denitrifiers represent a diverse group of bacteria. In this respect, denitrification is more like ammonification than nitrification. Some of the more common denitrifying genera include *Alcaligenes*, *Bacillus*, and *Pseudomonas*.

Factors Affecting Denitrification

As with nitrification, a heirarchy of factors influence the denitrification rate. Oxygen availability, or rather its absence, exerts the greatest effect on denitrification in soil because denitrification occurs anaerobically. Oxygen acts by regulating denitrifier enzyme synthesis and directly affecting enzyme activity. Nevertheless, soils do not have to be completely free of O_2 for denitrification to be detected because even well-aerated soils can have microsites devoid of O_2, such as the interior of soil aggregates (31). These anaerobic microsites occur because the supply of O_2 by diffusion that is greatly slowed by water-filled pores, can be insufficient to meet the respiratory needs of heterotrophic microorganisms, resulting in zones of anaerobiosis. This microscale heterogeneity is one reason for the high variability in denitrification rates often observed in the field.

The next most limiting factor to denitrification is either the supply of carbon, the source of reducing equivalents for most denitrifiers, or NO_3^-, the alternate electron acceptor. The relative balance of available carbon to NO_3^- varies by management and soil type. Because of inputs of fertilizer nitrogen and loss of soil carbon as a result of tillage, denitrification in agricultural soils tends to be most often limited by carbon. In most unmanaged systems NO_3^- tends to be more limiting, with the exception of soils that receive high anthropogenic inputs of atmospheric nitrogen or some native tropical soils that often have high concentrations of NO_3^- and low organic matter content (32).

Additional soil characteristics, such as temperature and pH tend to be of less importance in determining the denitrification rates, except at extremes of their range. Soil pH does, however, exert an effect on the relative proportions of gaseous products, with relatively higher ratios of N_2O to N_2 occurring at lower soil pH. The proportion of N_2O produced also tends to be greater in soils that have an excess of NO_3^- relative to available carbon.

Dissimilatory Reduction of NO_3^- to NH_4^+

Many genera of bacteria can reduce NO_3^- to NH_4^+ under anaerobic conditions. Although less energy is gained in this dissimilatory process compared to denitrification, more reducing equivalents per NO_3^- are used:

$$NO_3^- + 10H^+ + 8e^- \rightarrow NH_4^+ + 3H_2O;$$
$$\Delta G_0' = -75\ \text{kJ mol}^{-1}\ e^-$$

This has led to the concept that DNRA is most important in energy-rich (high carbon), low NO_3^- environments, such as sediments, and would therefore be minor compared with denitrification in most soils (30). Recent investigations have suggested that DNRA may be more prevalent in soils than previously thought (33).

ENVIRONMENTAL CONSEQUENCES OF NITROGEN CYCLING

It is well known that nitrogen is often the primary nutrient limiting primary productivity in most terrestrial and some aquatic ecosystems. But too much nitrogen, especially in the forms of NO_3^-, NO, and N_2O, can create problems for environmental and human health, whether these excesses are of natural origin or the result of human activity (34).

Acute Toxicity

The greatest direct human health concern related to excess nitrogen is high concentrations of NO_3^- in drinking water. Federal drinking water standards require less than 10 mg NO_3^--N L^{-1}. Ingested NO_3^- that is converted to NO_2^- interferes with O_2 transport by hemoglobin, causing a condition known as methemoglobinemia. Infants are especially sensitive, hence the common name of "blue-baby syndrome" for this condition. Fortunately, this affliction is uncommon. High NO_3^- concentrations in water may also enhance formation of carcinogenic nitrosoamines.

Eutrophication and Acidification

Because ecosystem productivity is often limited by nitrogen, excess nitrogen in any forms (organic, NH_4^+, or

NO_3^-) and delivered by any means (direct fertilization, leaching or overland flow, atmospheric deposition) can potentially alter the biomass and composition of ecosystems. Eutrophication was first observed in aquatic systems, where enhanced biomass production resulted in higher decomposition, which in turn created anaerobic conditions. Aquatic eutrophication as a result of nutrient loading remains a concern (35). The large areas of hypoxia or anoxia in the Gulf of Mexico are one contemporary example.

In some industrialized regions of the world, increased inputs of nitrogen into forested ecosystems has led to the phenomenon of nitrogen saturation. When terrestrial ecosystems become saturated with nitrogen, it results not only in larger inputs of nitrogen into associated aquatic ecosystems but also can directly affect the productivity and species composition of the terrestrial system. Acidification as a result of increased fertilizer nitrogen inputs has long been observed in agricultural systems as well as in natural systems that have active N_2-fixation, such as stands of red alder (36). Therefore it is not surprising that atmospheric deposition of nitrogen oxides that are accompanied by H^+, and NH_3 deposition, which can result in enhanced nitrification, result in the acidification of water and soil. Nitrogen saturated forests can display signs of decline, such as the loss of productivity or an increase in mortality. In some cases this has been attributed to nutrient imbalances resulting from acidification and leaching of base cations. Changes in vegetative composition have also been observed in terrestrial systems receiving elevated inputs of nitrogen (37).

Ozone Dynamics and Climate Change

Nitrogen oxides emitted into the atmosphere influence ozone concentrations in several ways. Nitric oxide is a precursor of tropospheric ozone and contributes to photochemical smog, a phenomenon associated with high density of motor vehicles. Conversely, N_2O catalyzes the destruction of ozone in the stratosphere, reducing the effectiveness of this layer in blocking incoming UV radiation.

Concentrations of tropospheric N_2O are increasing at a rate of about 0.25% per year (38). Most of this increase results from increased losses of N_2O during the biological processes of nitrification and denitrification, which in turn are enhanced by anthropogenic nitrogen inputs into ecosystems. Although concentrations of N_2O in the atmosphere are smaller than those of CO_2 by a factor of 1,000, N_2O is 150-fold more efficient than CO_2 at absorbing infrared radiation. Furthermore, N_2O absorbs radiation in a different spectral region than CO_2. Therefore, a similar increase in N_2O has a disproportionately large effect on climate change.

CONCLUSION

It is clear that much is known about the nitrogen cycle — the organisms involved, the transformations that occur, and their interactions with environmental factors. It is also clear that new information continues to be discovered, both about the basic properties of the nitrogen cycle and about its practical implications. Some of the key areas that require additional work include:

- Better quantitation of global flux estimates. Although not as publicized as the "missing C," the errors in estimating global fluxes of nitrogen are still large.
- More data on the importance of soluble organic nitrogen in different terrestrial ecosystems. This pool may represent a significant amount of nitrogen that is taken up by plants and microorganisms, and may also represent a larger loss to ground and surface waters than expected.
- Better understanding of the gross production and consumption of NO_3^- in soil and the controls on these processes. The processes of NO_3^- assimilation by microorganisms and of DNRA are particular voids in our understanding.
- Determining relationships between the composition and activity of the microbial communities that cycle nitrogen. For example, we know that there are many species of denitrifying bacteria in soil but we do not know if they vary in their activities or respond differently to environmental changes. Potential commensalistic associations among nitrogen cycling microorganisms are also unexplored.

It will be important to incorporate what we learn from such new areas of research with our current knowledge of the nitrogen cycle in order to balance the needs for increased supplies of food and fiber, with those of ensuring a clean and safe environment for the future.

SOIL QUALITY: THE ROLE OF MICROORGANISMS

JEFFREY L. SMITH
USDA–Agricultural Research Service
Washington State University
Pullman, Washington

Soil quality is important because of the unique role soil plays in the human environment. From foundations for buildings to contamination buffers and a water regulator to a medium for the production of food and fiber, soils are important in everyday life. Soil quality or the capacity of the soil to function is dependent on its intended use, its inherent properties, and its current condition. Society should equate soil quality with air and water quality for sustainability. Thus, the concern is not only the state or condition of soil quality but also its direction and rate of change as measured by sensitive soil indicators with quantifiable limits and interpretations. Soil microorganisms (termed in general microbial biomass) and their physiological functioning have been promoted as essential soil quality indicators. If microbial biomass is indicative of the health of the soil and its functioning capacity, the microbial biomass dynamics (state, mass, and activity) should be apparent in both aggrading and degrading soil systems. This paper describes microbial biomass as it is related to soil quality. Evaluation of microbial biomass as a soil quality indicator is explored in some aggrading and degrading systems. The use of microbial biomass and its metabolic functions for the monitoring and analysis of soil quality is examined.

SOIL QUALITY

In the last 10 years, there has been an increased interest in the concept of soil quality because it relates to the health of the global biosphere. In a global context, soil quality affects not only soil productivity but also is a significant factor governing environmental quality, human and animal health, and food safety and quality (1). Soil quality is of equal importance to humankind as is air and water quality, thus it is apparent that simply protecting soil quality by slowing soil degradation or maintaining the current level of soil health will not provide the soil quality that will be needed for future generations. Soil quality must be improved as well.

Soil quality per se is not a new concept, having for centuries been related to soil degradation. The degradation of soil or soil quality from human activities has affected many civilizations over the last 7,000 years (2). Good soil quality means different things to different people, influenced by our relationship to the land, what we use it for, and how much of it is available. Evaluation of soil quality is thus context sensitive, a fact appreciated early by soil scientists such as Hilgard (3), who advised "The observer's field of vision should be broad enough to embrace concurrently the several points of view... must be conjointly considered in forming one's judgment of

land." Recent recognition of the importance of soil quality is evidenced by the worldwide activity to identify and quantify land degradation. Programs of the United nations Environment Programme (4), the Food and Agriculture Organization (5) and the International Soil Reference and Information Center (6) have attempted to map human-induced soil degradation worldwide.

The recent interest and activity in soil quality research can easily be put in perspective by a quick search of the Internet. In addition, it is well known that professional soil science and ecological societies have championed this concept and produced official definitions and terminology. Whether we define soil quality (or soil health) as "the soil's fitness to support crop growth without resulting in soil degradation or otherwise harming the environment" (7), or as "the continued capacity of soil to function as a vital living system, within ecosystem and land-use boundaries, to sustain biological productivity, promote the quality of air and water environments, and maintain plant, animal, and human health" (8), we seem to all be speaking the same language. Soil provides for human sustainability by functioning as a medium for plant growth and as an environmental buffer and filter for cycling water, altering chemicals, and cleaning air.

Unfortunately, our ability to quantitatively assess soil quality has lagged far behind our ability to produce articles and speculation on the subject of soil quality. Developing a soil quality index cannot simply be an academic exercise because it will be called on not only to provide a basis for land capability classification (e.g., for productivity, health, or environmental quality) but also to assess the impact of management practices, to quantify the value of land as a base for taxation or land credit, to establish regulatory compliance, and to provide information for monitoring or modeling environmental changes.

Because soil systems are complex, evaluating soil quality will require the integration of biological, chemical, and physical soil parameters as well as human influences (1,9,10). Much effort has been directed toward identifying the soil variables that can be used to estimate soil quality because several different assessments may be derived from the same set of data (Table 1). Measuring, monitoring, and evaluating soil's biological characteristics for relationships with changes in soil quality is very promising because these properties are believed to change most rapidly with changing environmental conditions. Thus, a great deal of effort has been given to identifying key biological indicators and interpreting their characteristics and fluctuations with respect to soil quality (see *Biological Indicators of Soil Health* (8), *Methods for Assessing Soil Quality* (11) and (12)).

Two biological parameters that may be potential indicators of soil quality are soil respiration (CO_2) and microbial biomass. These parameters have extensively been examined (5,13,14) for their ability to predict changes in soil properties and processes under laboratory and field conditions. The calculation of an active soil carbon fraction from respiration that turns over rapidly in short-term soil incubation studies may provide a uniform entity that may be more widely comparable among soils (16).

Soil Organic Matter (SOM)

Soil organic matter plays a major role in terrestrial ecosystem development and functioning. In both undisturbed and cultivated systems, potential productivity is directly related to SOM concentrations. Organic matter contents range from less than 0.2% in desert soils to more than 80% in peat soils. In temperate regions, SOM ranges between 0.4 and 10.0%, with humid region soils averaging 3 to 4% and semiarid soils 1 to 3%. Although it is only a small fraction of the soil, components of SOM control air and water relationships for root growth and provide resistance to wind and water erosion.

Soil organic matter is a complex mixture of living, dead and decomposing material, and inorganic compounds. Most of the SOM is derived from plant tissue decomposition but some is formed from decomposing microfauna and microorganisms. This mixture of decomposing entities makes the chemical composition of SOM difficult to determine. About 15% of SOM is identified as polysaccharides, polypeptides, and phenols (17). This includes 20% carbohydrates, 20% amino acids and amino sugars, and 10 to 20% aliphatic fatty acids (18). The rest of SOM is humic material, which is a dark amorphous substance derived from the transformation of organic residues.

The dynamic nature and complex chemistry of SOM makes it a major source of plant nutrients. With 95% of soil nitrogen, 40% of soil phosphorus, and 90% of soil sulfur being associated with the SOM fraction, decomposition and turnover can supply the majority of macronutrients required for plant growth. The organic nitrogen content of soils ranges from 0.02 to 1.0%. Soil organic nitrogen is dominated by amino acids and amino sugars, which constitute 20% of the soil carbon but 30 to 40% of the soil nitrogen. Other constituents identified after acid hydrolysis of SOM are ammonia (NH_3) and an acid insoluble

Table 2. General Properties of Soil Organic Matter (SOM) and Associated Effects on Soil Properties

Property	Remarks	Effect on Soil
Color	Organic matter causes typical dark color	Facilitates warming
Water Retention	SOM holds up to 20 times its weight	Prevents drying, significantly improves moisture retaining properties
SOM and Clay	Forms structural aggregates	Facilitates gas exchange, increases permeability
Chelation	Forms stable complexes with polyvalent cations	Enhances micronutrient availability
Buffer Action	Exhibits buffering from changes in pH	Helps to maintain uniform reaction in soils
Cation Exchange	Increases holding capacity for cations in soil	SOM can increase cation exchange capacity by 20 to 70%
Mineralization	Decomposition of SOM yields NH_4, PO_4 and SO_4	A source of nutrients for plant growth

fraction and hydrolyzable unknown nitrogen. The amino acids and sugars are the major source of inorganic nitrogen from SOM via the decomposition process.

It is the biological interaction between SOM and microorganisms that promotes aggregation and good soil structure. In long-term field studies in which residue is conserved or added water stable aggregates increase in mass and stability (19). The biological metabolism of organic residues by microorganisms produces binding agents such as polysaccharides that "glue" mineral particles into aggregates. The benefit of aggregation, which is influenced by crop rotation and microorganisms (20), is increased porosity that increases water infiltration and provides proper aeration for microbial and plant root activity. More detailed analysis of the role of microorganisms in soil aggregation can be found in Tate (21) and Paul and Clark (18). A summary of the effects of SOM on soil properties is presented in Table 2.

Soil Microorganisms

The soil microorganisms are predominately bacteria and fungi existing in different proportions, depending on the soil system. Soil microorganisms constitute the dynamic fraction of soils and play a major role in soil functioning because of interactions with SOM and the cycling of nutrients. Microorganisms also interact chemically and physically with soil mineral particles and soil water. In general, soil organisms take up and release nutrients, decompose organic substrates, produce soil gases, and promote soil aggregation.

Figure 1 depicts the cycling of organic substrates and nutrients in soil by microorganisms or microbial biomass. The mineralization process produces nutrients, and the oxidation and reduction processes can decrease nutrients. This process is controlled by temperature, moisture, soil disturbance, and the quality of SOM. These factors, together with the size and activity of the microbial population regulate the rate of decomposition and release of macro and micronutrients essential for plant growth.

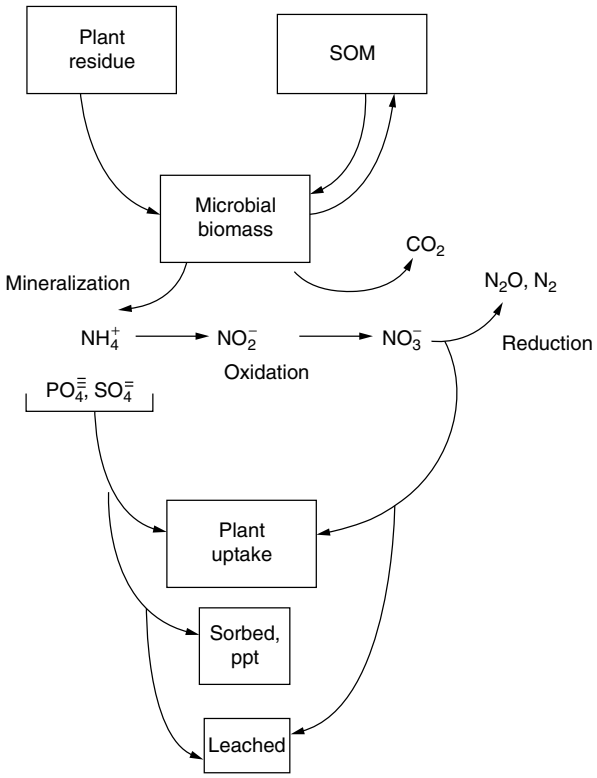

Figure 1. The cycling of nutrients and residues by soil microorganisms.

The biological mineralization of organic residues will produce inorganic NH_4^+, PO_4^{-3}, and SO_4^{-2} in ratios similar to the material being decomposed. Thus, it is evident that the inorganic nutrient cycles are linked to each other and are driven by microbial utilization of carbon for energy, which also influences the microbial diversity and community composition (22).

In the absence of externally applied nutrients, the limiting factor for plant production will be the mineralization

rate of macronutrients and the quality and quantity of SOM. It has been shown that for a winter wheat crop producing 16 tons/ha of dry matter, 302, 36, and 32 kg/ha of nitrogen, phosphorus and sulfur, respectively, are needed for plant uptake. The average nitrogen, phosphorus, and sulfur in the readily available (labile) SOM pool is 180, 17 and 9 kg/ha, respectively, which is 60, 47, and 28% of the nitrogen, phosphorus and sulfur requirements for the crop (23). With the turnover of the labile pool being quite rapid, the natural cycle of these elements possibly could supply the majority of the crop nutrient requirement.

Nutrient cycles in natural ecosystems have slower transformation rates but are more efficient, decreasing the chance for losses. In agricultural systems, with the addition of fertilizers, losses can be substantial if not highly managed. Because the active soil nitrogen is related to the microbial biomass (24) the addition of inorganic fertilizers, especially anhydrous ammonia, can adversely affect the pH of the soil, and eventually the microflora, decreasing the soil quality (25).

Microorganisms' Influence on Soil Quality

Being closely associated with SOM, soil microorganisms can have both positive and negative effects on soil quality. Table 3 gives some beneficial and detrimental effects of microorganisms in relation to soil quality attributes. As discussed previously, the mineralization of plant nutrients is critical for healthy plant growth and development. The processing of plant litter and residues into SOM increases soil aggregation and thus water infiltration and aeration. This process increases soil structure and decreases bulk density. Microorganisms detoxify soil by degrading toxic compounds, both natural and man made. Organisms also consume greenhouse gases such as methane and in some cases, nitrous oxide.

On the negative side, soil microorganisms can decrease soil quality by producing leachable compounds that may escape plant uptake and may contaminate surface or groundwater. Microbial metabolism of SOM decreases the positive effects of SOM over time and produces more recalcitrant compounds with less fertility. Soil organisms will also compete with plants for nutrients, decreasing plant production and quality. Soil microorganisms produce greenhouse gases through the decomposition of SOM and the reduction of inorganic nutrients.

These beneficial and detrimental effects of soil microorganisms on soil quality are somewhat offset by each other but in some ecosystems or agricultural management systems the balance can be pushed more toward a positive or negative. This will result in systems aggrading or degrading in soil quality.

Table 3. Beneficial and Detrimental Effects of Microorganisms on Soil Quality

Beneficial Effects
Mineralization of nutrients for plants
Processing residues into organic matter
Increasing soil structure
Degrading toxic compounds
Consume greenhouse gases
Detrimental Effects
Producing leachable compounds
Metabolizing SOM
Compete with plants for nutrients
Produce greenhouse gases
Pathogens on plants

Biological Soil Quality Measurements

As discussed before, biological indicators are thought to be more sensitive to change than chemical and physical parameters because of the rapid turnover of the active biological fraction. The rapid turnover of this fraction, including microbial biomass, makes it sensitive to changes in climate, crop rotations, tillage, and other management practices in agricultural systems (26). In natural systems, the active fraction would be sensitive to disturbance, species invasion, and atmospheric pollution inputs.

Soil organic matter is often included with biological indicators because of its close relationship with soil microorganisms and nutrient cycling. The soil microbial biomass constitutes 1 to 4% of the total soil organic carbon (23) and is associated with light density fractions of SOM (27). It is difficult to measure small changes in SOM even after several years of alternative management. Thus, surrogate measurements that have been developed to reflect changes in SOM may also be used to describe changes in soil organisms. Some of these measurements are microbial biomass, soil respiration, soil enzymes, and measurements such as nitrification or mineralization potential (12).

Microbial indicators of soil quality can be used at three levels of organization. The hierarchical stratification of microbial populations, microbial communities, and process level measurements can be of use in determining the direction and change in soil quality. The population or species level would serve as a bioindicator of perturbation or change. Because there are approximately 10,000 different species of organisms in a gram of soil (17), the form and function of the bioindicator species needs to be rigorously defined and interpreted. In addition, environmental effects on the population dynamics of these bioindicator species needs to be considered (28). Microbial community analysis describes species diversity and composition, for example, fungal: bacterial ratio. Fungal to bacteria ratios can be used as a measure of balance of nutrient cycling and decomposition (18,21). These types of studies have been successful in evaluating degraded soil, however, their usefulness for routine soil quality monitoring has been questioned because different systems respond differently to management or change (28,29). Process level studies describe the cycling of nutrients and organic matter in soil and the transformations of elements and ions. Soil processes are fundamentally easier to measure than microbial species or diversity because it is usually a product formation or a substrate disappearance that is measured. These chemical constants can be analytically quantified whereas many species and diversity measurements are qualitatively interpreted.

Thus in general, microbiological indicators of soil quality are better suited for describing natural and managed systems than are chemical and physical indicators. The microbial parameters or indicators integrate the physical and chemical environment into their function in soil systems. Microbial indicators reflect system decomposition and nutrient regulation and respond quickly to changes in the soil environment. This is not necessarily true of physical and chemical soil properties that may change slowly or become buffered to the extent that change is difficult to measure until the soil is highly degraded.

Microbial Biomass

Several procedures have been developed for estimating soil microbial biomass carbon and other cell constituents. A widely used method is the chloroform fumigation incubation method (CFIM) (30). The method is based on killing the soil organisms with chloroform and measuring the decomposition of the dead organisms as carbon dioxide during a subsequent ten-day incubation. Because less than 100% of a dead organism will be released as carbon dioxide, a conversion factor (k_c) is used to relate the carbon dioxide evolved to the total mass of organisms. The conversion factor is estimated to be 0.41. During the incubation, native organic carbon is also mineralized to some extent and thus the biomass calculation becomes

$$\text{Microbial biomass} - \text{C} = \frac{\text{CO}_2(\text{f}) - \text{CO}_2(\text{c})}{k_c}$$

where f is the fumigated sample and c is the unfumigated control sample. There has been significant debate over the proper control because nonbiomass carbon may be mineralized at different rates in fumigated and unfumigated samples (31,32).

Direct extraction methods for carbon and nitrogen that will alleviate some of the problems with incubation after fumigation and provide for a more rapid analysis, have been developed (33,34). The fumigation extraction method (FE) involves fumigating a soil sample, removing the chloroform, and extracting the sample with 0.5 M K_2SO_4. The filtered K_2SO_4 extract is analyzed carbon for and nitrogen (35,21). This method appears to be affected by moisture content of the sample (36–38) but, unlike the CFIM, is suitable for acid forest soils (39,40).

The substrate induced respiration (SIR) method involves inducement of respiration by adding glucose to a soil sample in which the increase in respiration before microbial growth is related to microbial biomass carbon (41). This method was initially developed to distinguish bacterial and fungal biomass and has been calibrated to the CFIM. This method is rapid and conducive to analyzing numerous soil samples at one time, although it cannot be modified to include biomass nitrogen. In addition, the moisture and nutrient status of the soil may make interpretation of the biomass values between ecosystems difficult (42).

Another method relies on measurement of adenosine triphosphate (ATP) extracted from a soil sample (43,44). The extraction of ATP from soils may vary depending on SOM concentration and texture, which can create problems in calculating total biomass. In addition, available phosphorus and other amendments can effect the results of ATP analysis. This method has been used for studying microbial energetics but has been used less often for biomass estimations and appears to be more related to biomass activity than microbial biomass (45). However, recently Contin and coworkers (46) found that ATP varied insignificantly (9–12 umole ATP g^{-1} biomass carbon) over a variety of soils and suggested that the measurement was a valid estimate of microbial biomass.

Of the methods discussed only the CFIM and FE can provide biomass nitrogen values by extracting the inorganic nitrogen after fumigation (47,48). As with the biomass carbon method, the nitrogen method also requires a factor to relate nitrogen mineralized to total biomass nitrogen. This factor (k_n) has been determined by a number of procedures, and ranges from 0.32 to 0.68 (49–51). There is little agreement on the correct k_n value, and it has been suggested that investigators simply report the nitrogen flush after incubation (23).

The method used to measure microbial biomass is investigator-driven, with ease of analysis, soil type, and management information being some of the criteria for choice. The three methods have been correlated in a number of studies, though the correlation can be highly variable across different scales (52,53). Beck and coworkers (54) reported microbial biomass data on 20 different soils analyzed by seven different laboratories using 10 variant methods of the SIR, FE, and CFIM. They found all of the methods to give almost identical rankings for microbial biomass in the soil samples, however, there were soil to soil variations and systematic calibration errors that hampered detailed comparison of the data. They also found that vegetation and land use affected the conversion factors to total microbial biomass among the methods as did the changes in the microbial community structure and sample prehandling. Thus, close attention to the literature on microbial biomass methodology is required to produce and interpret microbial biomass data.

Respiration

Soil or microbial respiration is measured as carbon dioxide, either in laboratory incubations or in situ field measurements and is a measure of microbial activity and substrate quality. Respiration measurements can be coupled with biomass measurements and process measurements to produce ratios that may be more applicable for comparing management or ecosystem differences. For example, Anderson and Domsch (55,56) found the ratio of respiration to microbial biomass to be a sensitive indicator of cropping systems and temperature regimes. Smith (16,57) used the nitrogen mineralized per unit of microbial biomass (qN) to describe differences between forest clearcuts and within a semiarid shrub-steppe ecosystem.

Respiration under laboratory conditions usually is quantified in two ways. First, incubating a soil sample in a container closed by a septa and analysis of the headspace by a gas chromatograph (GC) with a thermal conductivity detector (TCD). This method is rapid (2 min/sample) and accurate even with inexpensive GCs. The second method is the incubation of soil in a closed container containing

a vial of strong base to trap the carbon dioxide. After the incubation period the trap is removed and the excess base titrated with acid and the carbon dioxide is calculated from the base used to trap carbon dioxide (58).

Field measurements of respiration can range from simple to complex with varying degrees of precision. The simplest measurement of in situ soil respiration is the closed chamber method. The chamber can be fitted with a septum for headspace gas extraction or a vial of base can be placed on the soil surface and covered with the chamber. Once the chamber is placed on the soil, or pushed slightly into the soil, the carbon dioxide evolving from the soil is allowed to accumulate for a certain period of time. Several measurements should be made during a one-hour period. Other measurement options such as Draeger gas detection tubes and the use of flow though infrared spectrometers are available (15).

In situ soil respiration is sensitive to the abiotic influences of temperature and moisture and thus will vary diurnally and seasonally. If systems are to be compared, respiration measurements should be conducted throughout the year and twice during a sampling day, preferably morning and afternoon. The addition of fresh organic residues or other perturbations to the soil will significantly affect respiration measurements. For comparing substrate availability and microbial activity between systems, the laboratory incubation for potential respiration is recommended.

Enzymes

Microbial enzymes exist as both intercellular and extracellular proteins in soil. More than 50 soil enzymes have been identified but only a few have received much attention because of the ease of detection or measurement and their role in nutrient cycling. The enzymes amylase, lipase, and glucosidases are involved in the carbon cycle; proteases, deaminases, and ureases in the nitrogen cycle; phosphatases in the phosphorus cycle; and arylsulfatase in the sulfur cycle. The oxidoreductase, dehydrogenase, cycles carbon from SOM and has been widely studied as an indicator of microbial activity. Dehydrogenase is an intracellular enzyme that is thought to reflect only viable microorganisms in soil, though it has not always been reflective of numbers of viable organisms by plate count or O_2 consumption (59,60). However, other studies found a significant correlation between dehydrogenase and other microbial parameters (61). Long-term studies also show that dehydrogenase and other enzymes are sensitive to changes in management systems (62,63), levels of soil nutrients (64), and organic matter additions (65).

Enzyme activities are attractive as indicators of soil quality because they are related to SOM and microbial biomass, are sensitive and change more quickly than chemical or physical properties, can indicate past management conditions, and are relatively simple and rapid to measure (66–68). Most enzymes correlate positively with pH, which is important in soil quality and plant growth (69). Literature studies indicate that dehydrogenase is the enzyme that correlates most with microbial biomass, respiration, and organic matter. The analytical method for dehydrogenase is simple enough to process numerous samples per day and is a good check on respiration and biomass measurements.

The method for dehydrogenase activity is a reaction of the enzyme with 2,3,5 triphenyltetrazolium chloride (TTC) for 24 hours to form triphenyl formazan (TPF) that is detected colorimetrically using a spectrophotometer at 485 nm. A standard curve is prepared from a standard TPF solution. The results are reported as mg TPF kg^{-1} soil 24 h^{-1} (66).

For a comprehensive treatment on enzymes and soil processes see the special issue of the international conference on "Enzymes in the Environment" (70).

Microbial Processes

There are a number of measurements that can provide information on how a system is functioning, the presence or absence of communities of organisms, and even the cycling of nutrients in the system. These measurements are termed *potentials* because they usually are carried out under ideal conditions in the laboratory. Some potential measurements are nitrogen mineralization potential (N_{min}), nitrification potential (N_{nit}), denitrification potential (DNP), phosphorus mineralization potential (P_{min}), sulfur mineralization potential (S_{min}), and substrate utilization potential (C_{min}). These process potentials usually are laboratory-based measurements, however, theoretically they could be completed in the field.

The mineralization potential measurements for nitrogen, phosphorus, and sulfur can be measured with carbon dioxide evolved during soil incubation if no carbon was added. Incubation times range from a few days to weeks depending on the objectives. A seven-day incubation will give the amount of nutrient mineralized during that time. A three-week incubation in which the nutrient is measured several times (destructive sampling) can provide a kinetic analysis of mineralization. The respiration measurement can be conducted by the methods outlined previously, and the soil extracted for the nutrient(s) at the time of interest, (see *Methods of Soil Analysis* (71) for further information on extracting nitrogen, phosphorus, and sulfur).

Some of the measurements such as nitrification, denitrification, and substrate utilization require the addition of substrates and the measurement of an end product. In the case of nitrification, the soil is supplemented with ammonium (NH_4^+) and incubated. At the end of the incubation, the soil is extracted and the extract analyzed for nitrate (NO_3^-), the product of nitrification. Similarly, NO_3^- is added to soil under anaerobic conditions for analysis of denitrification potential. In this assay, the disappearance NO_3^- can be considered to be the denitrification potential, or the formation of an intermediate nitrous oxide (N_2O) can be measured. The substrate utilization assay is similar to N_{nit} and DP assays with the addition of different carbon substrates and the measurement of product formation, in this case carbon dioxide. Consult *Methods of Soil Analysis* (71) for more details on process potential measurements.

Soil Sampling Strategy and Pretreatment

The temporal and spatial variability of soil attributes and processes is substantial (9,15,53,59). Biological parameters can have a coefficient of variation (CV%) of 50 to

70% over small areas, whereas physical attributes may range from 25 to 40% CV and chemical properties from 5 to 30% (53). It is important to be consistent in sampling from the field to landscape scales both for spatial and temporal considerations (53). Some simple considerations for soil sampling are discussed later, for a more exhaustive analysis of sampling strategies consult these cited articles (1,7–9,11,12,71).

The two most important aspects of soil sampling are spatial representation and landscape topography. In a geostatistic sampling of a 60×60 km area it was found that slope position was the dominate factor in the variability of soil parameters, even exceeding rainfall zones (author, unpublished data). Thus when soil sampling, particular attention should be given to incorporate topography into the scheme. Within topographic position transects of samples should be taken (even if composited) to address the spatial variability of the landscape.

Temporal variability of soil properties, especially biological attributes, can also be large even on a small scale (53). Because temperature and moisture are regulating factors of biological activity, the more stable these parameters are when the soil is sampled, the more consistent are the data, both temporally and spatially. Sampling in spring or in fall provides soil with more uniform soil moisture and average temperature.

Sample pretreatment can have a great effect on many soil attributes, particularly biological parameters. In general, for biomass measurements it is desirable to preincubate the soil sample under ideal moisture conditions. To avoid a drastic soil perturbation, such as wetting up a dry soil, sampling should be conducted when field soils are at optimum moisture content, mostly in spring and fall. In many soil process studies, such as soil respiration, soils are not preincubated and measurements are started the day after the incubation begins. In process studies in which potentials are measured, it is not necessary to preincubate the soil sample.

Interpretation of Biological Indicators of Soil Quality

The interpretation of biological indicators of soil quality is difficult because of several factors: (*1*) temporal and spatial variability of soil biological parameters, (*2*) the high variability of in vivo laboratory analysis for incubations and potential measurements, (*3*) the interaction of chemical and physical properties on biological variables, and (*4*) the lack of knowledge of the magnitude of the biological indicator in relationship to soil quality.

Because nutrient cycling, residue and litter decomposition, and SOM transformations are catalyzed by soil microorganisms some measure of biological activity is necessary to evaluate soil quality. Changes in microbial biomass with changes in management and methodology can be detected (63,72,73). However, microbial biomass is highly variable in both time and space and can be affected by simple agricultural management operations. Thus, long-term monitoring of biomass numbers is necessary to establish a baseline for changes in management. In natural ecosystems this monitoring is also important to monitor trends in biomass to determine if the system is aggrading or degrading.

As previously mentioned microbial biomass measurements may be useful in soil quality analysis when expressed as a ratio. The most common ratio is the microbial carbon/total soil carbon (C_{mic}/C_{tot}) that ranges between 1 and 4% (74,23). Deviations from this ratio could indicate soil degradation, or perhaps soil aggradation. It is not known why this ratio is so narrow for soil throughout the world, however, it is possible that the factors controlling this ratio are similar across a range of soils.

Biological activity may be best indicated by respiration that may be high or low, which may be good or bad. Because respiration means SOM turnover and litter decomposition accompanied by nutrient release, from a plants perspective the higher the activity the better. However, this activity also increases SOM loss from the system that if not retarded, will decrease soil quality. These conclusions by themselves are contradictory, although if we consider respiration activity and total carbon inputs, we may come to a different conclusion. Thus, carbon loss must be considered relative to carbon inputs in which a high respiration rate may be beneficial in releasing plant nutrients, yet not decrease SOM because of high organic inputs. The C_{loss}/C_{inputs} depicts the microbial yield or efficiency ratio for carbon metabolism; if this ratio is high the system will sequester more carbon per unit input. These types of calculations can be useful in determining the change in SOM with time.

As is discussed in detail the next section, the metabolic quotient (qCO_2) expressed as basal respiration per unit of microbial biomass, is useful in describing aggrading and degrading soils. It also appears to be a useful index to compare cropping systems, chronosequences, and different ecosystems. Although the interpretation may be difficult, this property, if measured properly, is a fundamental characteristic of soil and soil development.

Process measurements, as discussed earlier, usually are interpreted as indicators of nutrient supplying power or potential nutrient loss. Because these complex biochemical processes are highly sensitive to stress, they may be useful for evaluating soil quality and the direction of change in soil quality (75). Nitrogen mineralization data is usually thought of as plant available nitrogen, however, coupled with high nitrification rates (N_{nit}) this process becomes less beneficial because of the potential for gaseous loss and nitrate leaching. The biogeochemistry of sulfur and phosphorus is more stable with respect to gaseous and leaching losses (Fig. 2), thus high rates of S_{min} and P_{min} are more likely positive processes involving soil microorganisms. Process measurements have been coupled with field measurements to evaluate soil quality relationships (76).

The interpretation of any indicator, chemical, physical, or biological, for soil quality evaluation, is complicated by external factors such abiotic factors of temperature and precipitation, and management factors such as tillage, cropping systems, residue quality fertilization, forest clearing, grass harvesting, and grazing.

Many studies have compared tillage and soil quality (77,78). Most have shown that no-tillage increases

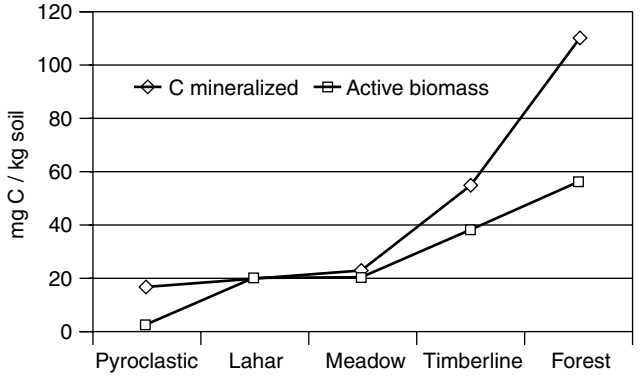

Figure 2. Carbon mineralized and the amount of active microbial biomass (MB) from lupine rhizosphere soil from the disturbed areas of Mount Saint Helens (92).

SOM, infiltration, soil structure and crop yields while decreasing soil erosion (77,79). Some of the most sensitive indicators to conservation management (no-tillage) practices are fractions of SOM, microbial biomas, and respiratory activity (80,81). No-tillage systems often conserve carbon and support greater microbial activity and biomass than tillage systems (82–84). However, because of some compaction and lack of residue incorporation, no-tillage may increase nitrous oxide (N_2O) production from soils and decrease methane (CH_4) consumption (85).

Crop rotations maintain higher levels of soil biochemical activity than monocropping and rotations with a fallow period (86–88). Also forage systems and grasslands maintain greater microbial activity and biomass than do arable cropping systems (89–91). Much of this phenomenon can be attributed to greater residue inputs; however, the litter or residue quality also plays an important role in the decomposition and sequestration of carbon and nitrogen through microbial action.

THE METABOLIC STATE OF MICROORGANISMS AND SOIL QUALITY

Because of the interest in using microbial biomass to assess soil quality, in the following section data from aggrading and degrading systems are analyzed to find out to what extent measurements of microbial biomass are useful were in characterizing these systems. In addition, an analysis of the potential and limitations of the metabolic quotient (qCO_2) is presented. The overall objective is not to provide an exhaustive review of the subject but to provide the reader with a flavor for the potential use of microbial biomass and related parameters in soil quality analysis and assessment.

Aggrading Systems

Systems recovering from various degrees of disturbance rely on vegetation for initial carbon inputs to induce microbial activity and the subsequent buildup of SOM. If microbial biomass or the active SOM fraction is indicative of the health of a soil and its functioning as a quality medium, then its dynamics (state, mass, and activity) should be discernible in aggrading soil systems.

Mount Saint Helens. In 1980, the volcano Mount Saint Helens erupted in the state of Washington in the United States. This eruption produced massive destruction of a mixed high meadow-forest ecosystem. The aftermath produced five distinct systems including areas of pyroclastic volcanic substrate, mudflow material, tephra-covered meadow, and relatively undisturbed timberline and forest. These systems formed a disturbance gradient that was inversely related to soil carbon and nitrogen concentrations from the pyroclastic material to the areas of original forest. By 1987, the most disturbed sites had been recolonized by nitrogen-fixing lupines.

Seven years after these areas were disturbed by the eruption lupine root zone soil (LR) showed greater increases in carbon and nitrogen concentration compared with non-lupine root zone soil (NR) (92). Figure 2 depicts the quantity of carbon mineralized during laboratory incubation and the amount of active microbial biomass, determined by substrate induced respiration (SIR), from LR soil in each of the five disturbed areas of Mount Saint Helens (92). These trends are similar to the total carbon and nitrogen concentrations of the soils and are significantly greater than for NR soil (not shown). This suggests that there is a significant relationship between the recolonization of disturbed areas by lupines and the advent of significant microbial activity.

Nitrogen fixation was highest at the more disturbed low nitrogen sites (93) totaling 10.3 $kg\,ha^{-1}\,y^{-1}$ for LR soil and 3.3 $kg\,ha^{-1}\,y^{-1}$ for NR soil. Thus an increase of 7 $kg\,ha^{-1}\,y^{-1}$ could be attributed to lupines. The retention of fixed nitrogen over these aggrading sites is related to the increasing microbial biomass and activity in these systems.

This data showed that ecosystem development was correlated with increased soil carbon and nitrogen, microbial activity and respiration efficiencies. The increase in microbial biomass, activity and carbon and nitrogen cycling is a positive feedback to the further development of soil that can support ecosystem succession from a lupine to a forest system.

Conservation Reserve Program. The Conservation Reserve Program was initiated in the United States in 1985 to retire highly erodable farmland from crop production to reduce soil erosion and to increase soil quality. By 1993, 14.6 Mha had been planted to grass or trees with a contract period of 10 years. Much research has been devoted to the degrading effects of cultivation on soil; however, little information is available on the recovery of cultivated land after the cessation of farming. Two studies have recently investigated the process of aggrading soils converted from agriculture to grasslands over periods of 50 and 7 years.

Burke and coworkers (94) sampled 12 sites in northeastern Colorado, that had been abandoned from cultivation for 50 years. Total and active carbon and nitrogen pools for the native, cultivated, and abandoned sites were determined. As expected the degradation of SOM from 50 yrs of cultivation resulted in a loss of approximately 50% of the total carbon and nitrogen from the system (Table 4). After 50 years of recovery and the establishment of perennial grass, soil total carbon and nitrogen

Table 4. Carbon and Nitrogen Pools and Mineralization Rates from Native, Abandoned from Cultivation and Cultivated Shortgrass Steppe Soils (94)

	Native	Abandoned	Cultivated
Total C (g/m^2)	1,479	987	823
Total N (g/m^2)	86	62	46
N min ($g/m^2/d$)	0.12	0.12	0.10
C min ($g/m^2/d$)	2.33	2.54	1.86
Microbial C (g/m^2)	93.9	91.3	54.3
Microbial nitrogen (g/m^2)	10.2	10.5	8.8

increased by about 20 and 35%, respectively, compared to the cultivated soils. Soil microbial biomass, measured by CFIM, and microbial activity had totally recovered to levels found in native grasslands that had never been cultivated (Table 4). The carbon and nitrogen mineralization rates were about 30% and 20% greater for soils of the native and abandoned sites, respectively, compared with the cultivated sites. Microbial biomass carbon in the native and abandoned sites was about double that of the cultivated site, however, the biomass nitrogen was only about 20% greater, resulting in a curious biomass carbon/nitrogen ratio for the cultivated soil of 6 compared to about 9 for the native and abandoned sites. It is most likely this result is due to the fertilizer nitrogen inputs to the cultivated system because all the sites have a similar total soil carbon/nitrogen ratio of about 17.

This data shows that after cultivation ceases, the nutrient and active SOM pools increase fairly rapidly, although the total SOM recovers slowly. This slow recovery for total SOM is likely because of the greater levels and activity of microbial biomass and to the slow buildup of stable organic matter pools that were lost during the cultivation period.

In a study of soil quality in CRP and wheat-fallow (W-F) soils, Staben and coworkers (72) found that after 4 to 7 years in CRP, the soils did not increase significantly in total carbon but had more total nitrogen. The study on 20 paired sites in eastern Washington showed few significant differences in soil biota measurements, however, the trends in the activity data suggest that the active SOM fraction is increasing. Figure 3 shows the cumulative carbon evolved and the rate of carbon evolved from the CRP and W-F soils during a 60-day incubation. The CRP soil continued to rapidly mineralize carbon after the initial two-week period and mineralized 25% more carbon than the W-F soil (Fig. 3a). The higher decomposition rate in the CRP soil after the initial flush of carbon dioxide indicates shows that this "extra" carbon being mineralized is from a secondary carbon pool, mainly cellulose and hemi-cellulose compounds (Fig. 3b). Secondary carbon pools are important in soils because they serve as energy and nutrient reserves for microorganisms. The building of these pools and reserves is an indicator that the soil is increasing in soil quality.

Although these are "young" recovering soils, the increase in pH with the CRP treatment (6.4 CRP versus 5.7 wheat fallow) will have a positive effect on nutrients, plant growth, and microbial activity. The buildup of a

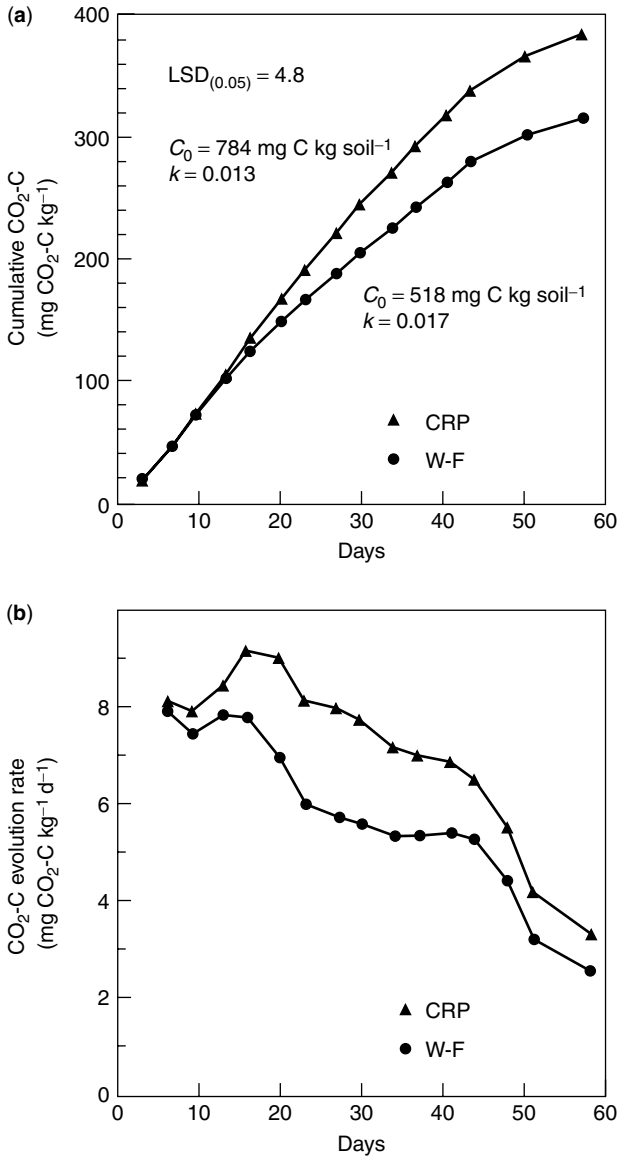

Figure 3. Cumulative carbon evolved and the rate of carbon evolved from the conservation reserve program (CRP) and wheat-fallow (W-F) soils during a 60-day incubation (72).

secondary carbon pool is important for soil structure, microbial activity, and as a precursor to more resistant and stable carbon pools. From the mineralization studies on these soils it was apparent that the W-F soils were carbon limited and that in moving to a carbon-rich system such as CRP, the soils were conserving nitrogen, thus preventing nitrogen loss through leaching and denitrification. These very subtle changes in the soil chemistry and biota indicate that the CRP soils are increasing in soil quality and that differences will become more evident with time since cultivation increases

Degrading Systems

Of even greater interest on a global basis is the development of sensitive biomarkers that would indicate if

soils were degrading or potentially could be susceptible to desertification. Significant efforts have already been made to evaluate the effects of tillage, management, crop rotation, soil erosion, and toxicology on microbial biomass (77,81,82,86). However, there has been little use of these measures to explain entire systems and whether they may be aggrading or degrading. An important question in this analysis is whether to measure the microbial biomass concentration, its activity, or its response.

Bioindicators. Gallardo and Schlesinger (95) hypothesized that as organic matter is lost because of desertification of semiarid grasslands and that the soil microbial biomass will shift from being nitrogen limited to carbon limited. If this were true, metabolic activity or response to substrates could potentially be used as a sensitive indicator of degrading soils subject to desertification. On a global basis these bioindicator methods are important because an estimated two billion hectares of soil have been degraded, either chemically, physically, or biologically (96).

Using a desertification sequence of grassland, mesquite, creosotebush, and tarbush vegetation in the Chihuahuan Desert, Gallardo and Schlesinger (97) measured microbial biomass nitrogen by fumigation-extraction (FE), in carbon and nitrogen amended soil. Figure 4 shows the response of the biomass-nitrogen to carbon and nitrogen amendments. The grassland soil showed a significant increase in biomass nitrogen with nitrogen and C + N additions as compared with the water-only control. Statistical interaction between the carbon and nitrogen treatments indicated a response to carbon addition only when nitrogen was also applied. In the mesquite soil there was an independent response to carbon and nitrogen with no interaction indicating the soil was mainly nitrogen limited. The soil with creosotebush exhibited a significant and comparable response to carbon and C + N additions. Similar responses were observed with the soil with tarbush in which a significant response to carbon and C + N was observed and not to nitrogen fertilization alone.

In the nitrogen-limited soils, supporting grassland and mesquite, the microbial biomass nitrogen of the water control averaged 10.7 and 11.3 ug/g soil, respectively, whereas the carbon-limited systems with creosotebush and tarbush had biomass nitrogen levels of 18.2 and 16.7 ug/g soil, respectively. The shifting of nutrient limitations from nitrogen to carbon during desertification or shrub invasion is supported by this data. However, the higher levels of microbial biomass nitrogen in the carbon-limited soils suggest possibly a higher retention of nitrogen and a tighter nitrogen cycling in these soils. This hypothesis is supported by the relative response of the systems in which the biomass nitrogen of the grassland and mesquite soils increased by 100% with the addition of C + N and the creosotebush and tarbush soils only increased about 30% to 50%.

Garcia and Henandez (98) sampled 21 degraded soils from the semiarid Spanish Mediterranean to determine their biological characteristics and to develop bioindicators for these soils. The soils were grouped by texture and compared with undisturbed and reforested soils. A suite of biological and enzyme activity measurements was conducted and principal component analysis was used to determine the most relevant indicators of degradation.

Table 5 gives three properties of the 21 degraded soils grouped by texture. The average decrease in organic matter was 67%, which correlates well with the observed decrease in microbial biomass (FE) and basal respiration (Table 5). Dehydrogenase concentration, an indicator of microbial activity, was lowest in the more clay soils and was reduced by 50 to 80% in all soils compared with the undisturbed soils. The loss of SOM was most closely related to changes in the microbial biomass, B-glucosidase, and arylsulphatase as modeled by stepwise variable analysis.

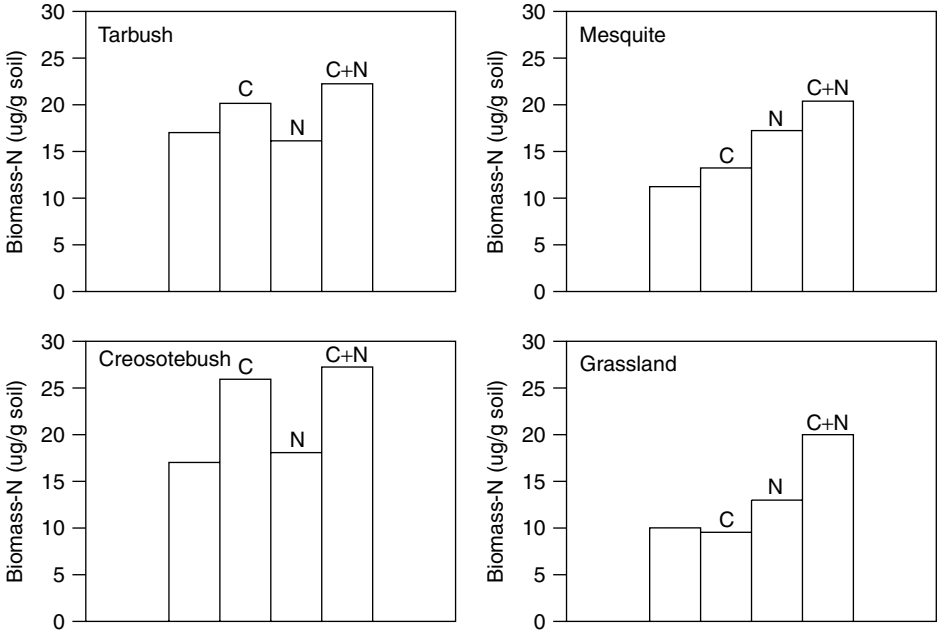

Figure 4. The response of biomass nitrogen to carbon and nitrogen amendment for the desertification sequence of grassland, mesquite, creosotebush, tarbush vegetation in the Chihuahuan Desert (97).

Table 5. Biological Analysis of Intensely Degraded Soils Subject to Desertification in Spain (98)

	Microbial Biomass ug-C/g-soil	Dehydrogenase ug INTF*/g-soil	Basal Respiration ug-C/g-soil/d

The two studies mentioned in the preceding section demonstrate the potential usefulness of biological parameters for evaluating changing systems and degraded soils. In the Gallardo and Schlesinger (97) study, changes in system direction from nitrogen-limited to carbon-limited could now possibly be inferred by the simple measurement of biomass nitrogen. Whereas, in the Garica and Henandez (98) study, a broader suite of parameters was needed to show the reduced soil health because some of the key activity measurements did not follow the overall trend. The interacting and complex factors controlling microbial activity make it difficult to choose a few simple biological measurements that can be universally used to evaluate soil quality.

The Case for qCO_2 and Soil Quality

The objective for developing soil quality methodology is to provide sensitive measures that will detect the rate and direction of change in the quality of a given soil. However, defining a "silver bullet" soil quality indicator is proving to be elusive because of the previously stated complex factors controlling biological parameters in soils. Soils are buffers, and as with any good buffer, absorption or change is slow until the end point. The end point, however, is of little use in soil quality analysis.

A measure of microbial activity that has received significant attention as a sensitive indicator of soil development and quality is the metabolic quotient or basal respiration to biomass ratio. The metabolic quotient has been used to evaluate microbial physiological conditions (55), plant ecosystem succession (99,100), soils with different cropping histories (56), and effects of environmental conditions on soil microbial biomass (101,102). The history and application of qCO_2 are also detailed in Anderson (103) and Wardle and Ghani (104).

Besides the effects of disturbance on microbial metabolism, qCO_2 may be useful as an indicator of systems under stress (104). The current popular interpretation of qCO_2 is that under ecosystem development from young to mature, qCO_2 values will decrease due to increased efficiency of microorganisms (see following). In contrast, in disturbed or stressed ecosystems, qCO_2 will increase due to reduced efficiency of microbial biomass.

The metabolic quotient and its relationship to ecosystem development is an interpretation of ecosystem energetics as put forth by Odum (105,106) in which ecosystems are hypothesized to develop toward a lower primary production to respiration ratio. In the early stages of ecosystem development, primary production exceeds system respiration and organic matter and microbial biomass will accumulate. As the system matures this ratio decreases until the system enters the climax stage. Insam and Haselwandter (99) proposed that the primary decomposer level could be substituted for the system level and thus microbial respiration per unit of microbial biomass (R_{micr}/B_{micr}) should decrease with ecosystem maturity.

The hypothesis mentioned in the preceding section was tested by Insam and Haselwandter (99) on two primary

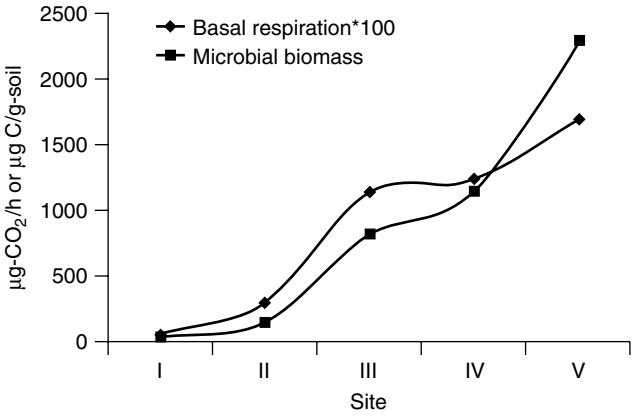

Figure 5. Soil microbial biomass (MB) and basal respiration (BR) from the Rotmoos moriane succession in Austria. Sites I to V have development ages of 1, 5, 65, 135, and 1,000 years, respectively (99).

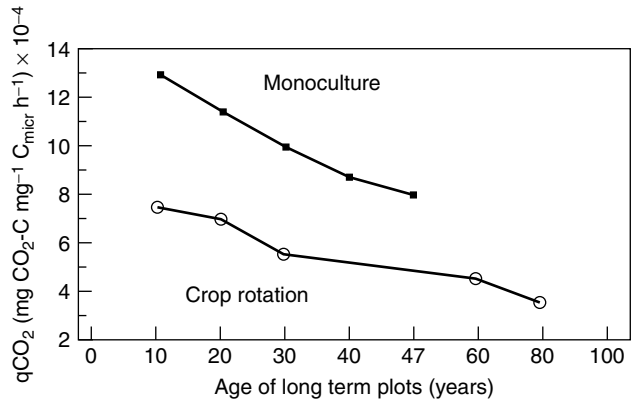

Figure 6. Metabolic quotients (qCO_2) of soils under crop rotation and monoculture for varying lengths of time (56).

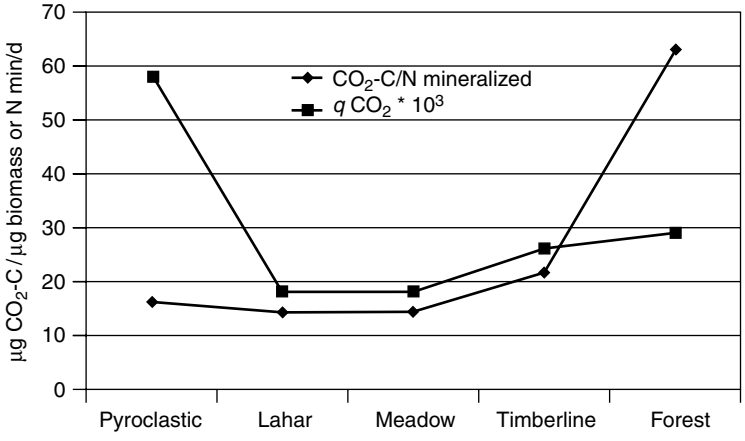

Figure 7. Metabolic quotient (qCO_2) and mineralization ratio (CO_2/N_{min}) for five sites at Mount Saint Helens ranging in disturbance from the pyroclastic site (volcanic tephra) to relatively undisturbed forest sites (92).

successions on receding moraines in Austria and Canada. The age of the soils formed on the Rotmoos moriane succession in Austria range from one and three years to over 1,000 years. Figure 5 shows the data for microbial biomass (SIR) and basal respiration (original Table 2) for sites I to V with development ages of 1, 5, 65, 135, and 1,000 years, respectively. For sites I to III the biomass and basal respiration increased exponentially; however, site IV had significantly greater biomass than site III but the same basal respiration. The significant increase in biomass from site I to V with a less rapid increase in basal respiration resulted in an exponential decrease in qCO_2 over the succession.

Anderson and Domsch (56) used the concept of qCO_2 to evaluate soils with different cropping histories. When comparing soils with different crop rotations, they found that the metabolic quotient decreased with the length of time the soil had been in rotation (i.e., age of plot, Fig. 6). In addition, they found the same trend for soils under monoculture, but the monoculture soils had significantly greater respiration per unit of SIR than did soils in crop rotation. Statistical analysis of the 20 monoculture plots versus the 21 crop rotation plots showed a significant difference for qCO_2 but not for other variables such as pH, organic matter, percentage of clay, or fertilizer. The observed differences in qCO_2 may be due to differences in complexity of organic substrates and the soil enzymatic structure.

The relationships of qCO_2 and CO_2/N mineralized were used to determine the substrate quality relationships of sites devastated by the 1980 eruption of Mt. St. Helens volcano in U.S.A. (70). Figure 7 shows the qCO_2 and mineralization ratio for five sites ranging in disturbance from the pyroclastic site (volcanic tephra) to the relatively undisturbed forest site. qCO_2 was highest for the most disturbed site, decreased dramatically for all other sites, then increased slightly from the moderately disturbed lahar site to the forest site. The CO_2/N mineralized relationship showed an opposite trend possibly indicating rapid cycling of nitrogen at the disturbed sites and greater immobilization at the less disturbed sites.

These seemingly contradictory trends for physiological attributes of qCO_2 have not gone unnoticed. Wardle and Ghani (104) reviewed the literature concerning the use of qCO_2 as an indicator of disturbance and ecosystem development. They evaluated studies of primary and secondary succession, a 10,000-year chronosequence, and the Mt. St. Helens data presented earlier to show the inconsistency of qCO_2 to decrease with succession. They used data from numerous studies to show that although qCO_2 was generally negatively correlated with soil properties such as biomass, percentage of carbon, percentage of nitrogen, pH, and clay, there was very little statistical significance. They also evaluated 16 studies of environmental disturbance such as chemical and manure additions and cultivation and concluded that qCO_2 did not consistently increase with disturbance.

Wardle and Ghani (104) concluded that qCO_2 was not useful for describing ecosystem development because it responded unpredictably and did not always decline along successional gradients. In addition, qCO_2 can be insensitive to disturbance and unable to distinguish between the effects of disturbance and stress. However, the utility of the metabolic quotient may be in its sensitivity to environmental degradation and its use as a measure of substrate quality and microbial efficiency.

Although qCO_2 may not be the best ecosystem development indicator, it may be used to investigate changes in soil systems to establish metabolic efficiencies, energy flow, and potential stress caused by nutrient limitations. Other relationships such as microbial biomass carbon to total carbon ratio (C_{mic}/C_{org}) may be useful in conjunction with qCO_2. This relationship has been useful in studies of SOM and carbon turnover (107,108), and in studying chronosequences (109) and the impact of climate and temperature on microbial activity (55,110). The C_{mic}/C_{org} ratio can also be an indicator for changes in soil texture (111,112), aggregation and structure (113,114), toxicity (115) and tillage (116). Other useful ratios, which have not received much attention, are respiration to mineralized nitrogen (CO_2/N_{min}) discussed in this paper and the ratio of nitrogen mineralized to microbial biomass (qN) discussed in Smith (16).

Soil quality changes are not likely to be quantified with a single measure. Most soil scientists agree that a suite of biological, chemical, and physical properties will be required to quantify the direction and rate of soil quality change. However, attention should be focused on

microbial physiological parameters and their relationships to each other to detect small changes in the quality of soils. It is evident from the forgoing discussion, that whatever parameters are chosen, the measurement and understanding of the state and function of the soil microbial biomass will play an important role in soil quality analysis.

SORPTION PROPERTIES OF BIOFILMS

Hans-Curt Flemming
Andrew Leis
University of Duisburg
Duisburg, Germany

Microbial aggregates such as films, microbial mats, flocs, and sludge are commonly subsumed under the expression "biofilms" (1). All of these aggregates represent three-dimensional, spongelike hydrogels with a considerable sorption capacity. From an ecological point of view, this facilitates the sequestering of organic molecules from the water phase, providing nutrients for the immobilized organisms (2). This is considered as part of the survival strategy for biofilm organisms in oligotrophic environments. Also, biofilms influence the distribution and fate of pollutants in soils, sediments, and waters. Sorption to biofilms represents a significant aspect of the general phenomenon of "biosorption." Material sorbed to biofilms is biodegradable and can be metabolized or otherwise chemically altered, or it can remain unchanged, with a potential to be remobilized when the biofilm decomposes. Thus, biofilms represent both a sink and a source for sorbed substances. These can be: inorganic ions, organic substances, precipitates, particulate matter and, last but not least, the water that is retained in the biofilm matrix. This is schematically depicted in Figure 1 (after Ref. 3).

The reason that the term "sorption" has been chosen for this article is that both *ad*sorption and *ab*sorption can occur in biofilms. The polymer matrix allows the incorporation of abiotic substances by various retention mechanisms, which are not yet known in all cases. There are different sites within a biofilm in which the interaction may take place, such as cell walls, membranes, and interior and matrix molecules. Also, sequestering of matter from the bulk aqueous phase occurs not only by adhesion to biofilm components but also by complexation, redox reactions, or by precipitation caused by microbial metabolites or owing to entrapment in pores and channels of the biofilm matrix. In all of these cases, the sequestered substances accumulate within the biofilm and, thus, are regarded as "sorbed." This interpretation may be considerably broader than allowed by a definition that is based solely on thermodynamic properties. However, all of these kinds of mechanisms are the basis for many published and patented attempts to purify water from pollutants by "biosorption." In most of these cases, "biomass" and the actual retention mechanisms are treated as black boxes, with emphasis being placed on the final outcome of the many interactions (e.g., percentage removal of a pollutant), rather than the mechanisms. The objective of this article is to shed some light on these black boxes.

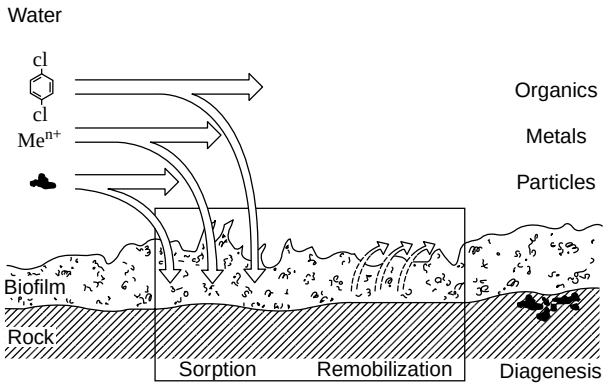

Figure 1. Interaction of dissolved and suspended material at interfaces covered with biofilms. (After H.-C. Flemming, J. Schmitt, and K. C. Marshall, in W. Calmano and U. Förstner, eds., *Environmental Behavior of Sediments*, Lewis Publishers, Chelsea, Mass., 1996, pp. 115–157.)

SORPTION SITES IN BIOFILMS

When a dissolved or particulate substance transported by the water phase meets a biofilm, it encounters a highly heterogeneous hydrogel with very different sorption sites. These include:

- Extracellular polymer substances (EPS), mainly consisting of polysaccharides and proteins (see Refs. 1 and 4);
  - Charged groups, for example, $-COO^{-1}$, $-SH^{-}$, $-SO_4^{2-}$, $-H_2PO_4^{-}$, $-NH_4^{+}$, $-NRH_2^{+}$, etc.
  - Apolar groups, for example, aromatics, aliphatics such as found in proteins; also, hydrophobic regions in polysaccharides.
- Cell walls (see Ref. 5)
  - Outer membrane of gram-negative cells (lipids)
  - Murein or teichoic acid layer of gram-negative and gram-positive bacteria, respectively.
- Cytoplasmic membrane (lipids).
- Cytoplasm.

Figure 2 shows the complex structure in a transmission electron micrograph of a bacterial monolayer on a synthetic polymer after exposure to river water (courtesy of G. Geesey). The organisms can be clearly seen. The fibrillar structures represent the EPS matrix after desiccation. The black spots are particles entrapped by the matrix. In Figure 3, the sorption sites in biofilms are schematically depicted.

Extracellular Polymeric Substances

EPS consist of polysaccharides, proteins, and lipids. In gram-negative cells, the EPS are composed of lipopolysaccharides, capsule polysaccharides, and other excreted polysaccharides and proteins that are less firmly bound to the cell surface (1,7). In gram-positive cells, lipoteichoic acids as well as polysaccharides and proteins, which are not anchored in the cell wall, contribute to the

Figure 2. Transmission electron micrograph of bacteria attached to a synthetic polymer exposed to river water (courtesy of G. Geesey and L. Jang, in H. C. Ehrlich and C. L. Brierley, eds., *Microbial Mineral Recovery*, McGraw-Hill, New York, 1990, pp. 223–247).

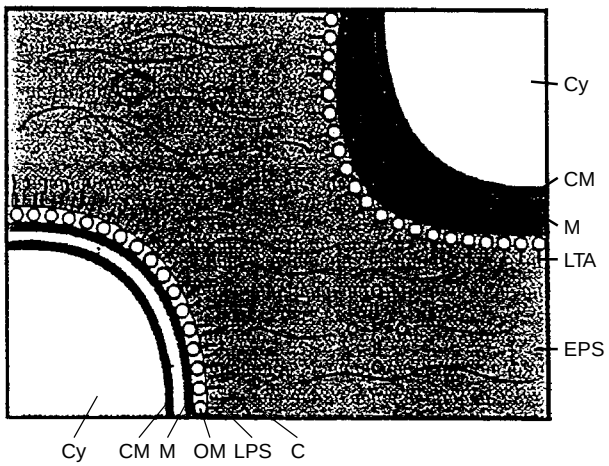

Figure 3. Different sorption sites in a biofilm, including a gram-negative (left) and a gram-positive organism (right). CY, cytoplasm; CM, cytoplasmic membrane; M, murein; OM, outer membrane; LPS, lipopolysaccharide; C, capsule; LTA, lipoteichoic acid. (After H.-C. Flemming, *Water Sci. Technol.* **32**, 27–33 (1995). J. Wingender, T. Neu, and H.-C. Flemming, eds., *Microbial Extracellular Polymeric Substances: Characterization, Structure and Function*, Springer, Berlin, Germany, 1999 (6).

Figure 4. EPS microdomains of different density. (After A. W. Decho, in R. E. Riding, and S. M. Awramik, eds., *Microbial Sediments*, Springer, Heidelberg, Germany, 2000, pp. 9–15).

EPS. Many microorganisms produce EPS, whether grown in suspended cultures or in biofilms. A considerable part of the protein moiety of the EPS may be extracellular enzymes. It seems that the composition of EPS is not constant but is influenced by growth conditions and environmental stress (8). Many strains form more than one specific type of EPS, and the composition of the EPS may change during the life cycle of such organisms (9). The EPS molecules provide the forces responsible for cohesion of the biofilm and adhesion to the substratum. This is performed by weak interactions such as van der Waals forces, electrostatic interactions, and hydrogen bonds (10). The density of the EPS matrix seems to vary considerably as can be demonstrated by various staining techniques. Decho (11) has introduced a concept of "exopolymer microdomains" in order to describe these inhomogeneities (Fig. 4).

Cell Walls

Gram-positive. The cell wall of gram-positive cells (see Fig. 3) is composed of teichoic acids. The structure

contains both positively and negatively charged sites. The teichoic acid portion may contain a D-alanine residue in place of the β-D-glucose as shown. Anionic sites include carboxylate (from peptidoglycan) and phosphate (from teichoic acid). Positively charged sites are exclusively ammonium, from D-alanine (teichoic acid), amino sugar (glycan), and diaminopimelic acid (peptide portion of peptidoglycan).

Gram-negative. The envelopes of gram-negative cells (see Fig. 3) display a lower overall charge density and are chemically and structurally very different from gram-positive cell walls (12). As in the case of gram-positive bacteria such as *Bacillus subtilis*, purified peptidoglycan from the gram-negative organism *Escherichia coli* binds metals quite efficiently. The overall contribution of peptidoglycan to metal binding in gram-negative organisms is quite small because of the limited quantity of this substance in the cell envelope and its shielding from the environment by the overlying outer membrane.

Lipopolysaccharides and Lipid Membranes

Definite hydrophobic compartments in a biofilm are represented by the lipopolysaccharide layer of gram-negative cells and the lipid membranes. The membranes are composed of phospholipids with the hydrophobic groups directed inward and the hydrophilic groups toward the outside, where they associate with water. Embedded in the matrix are hydrophobic proteins. Hydrophilic proteins and other charged substances, such as metal ions, are attached to the hydrophilic surface. The membranes make up about 2% of the overall dry biomass, thus representing only a small capacity for the sorption of hydrophobic substances.

Cytoplasm

The interior of bacteria also represents a possible location for the accumulation of dissolved substances (13). It represents a water phase separated from the environment by the lipid membranes and controlled by selective transfer mechanisms across these membranes.

SORPTION OF WATER, METALS, ORGANIC SUBSTANCES, AND PARTICLES

Water

Biofilms are highly hydrated, containing 85 to 98% water. As water is the main component of biofilms, effective mechanisms must be present to retain the water. Most of the water is associated with the EPS matrix as the following assessment demonstrates: the cell density in a biofilm ranges between 10^{10} and 10^{11} cells mL^{-1} of biofilm mass, and one cell has an estimated mass of 10^{-12} g. The water content of a cell is about 85%; thus, only about 1 to 10% of the water in a biofilm is cytoplasmic whereas 90 to 99% is retained by the EPS matrix. The mobility and viscosity of this water is crucial for the biological processes in biofilms as these factors have a strong impact on the transport of substrates and products, although very little research on the role of water has been performed. More than 99% of the water molecules in biofilms seem to be as mobile as in the free (bulk) water phase, as investigated by NMR spectroscopy (14); however, another investigation by ATR-FTIR spectroscopy indicates discrete steps in the exchange kinetics of H_2O and D_2O (15). From this study, it was concluded that the water in the EPS matrix is organized in a fine structure, which influences its properties in the biofilm.

In air-exposed habitats, water retention is considered to be an important mechanism for resistance to desiccation (16,17). The importance of the water structure in microbial aggregates has been acknowledged in the context of sludge dewatering, in which the immobilization of water by biofilms has significant economical and ecological implications. Here, pore and channel water is classified as *free* and behaves thermodynamically in the same way as pure water. It can be efficiently removed by mechanical pressure, but with considerable energy cost. *Bound* water has been defined as the proportion of the overall water content that is removed only by thermal drying processes and is retained by mechanisms other than entrapment; it makes up 5 to 7% of the overall water content (18). However, the exact binding mechanisms are still not clear, and the definitions of strongly bound and weakly bound water are hypothetical (19). If the EPS structures could be changed in such a way that they release the water, this would represent substantial progress in sewage sludge dewatering. Attempts have been made to destroy the hydrated structure by enzymatic attack (20,21). Such processes have been patented (22,23), but they have not yet proven to be effective in practice. Water plays a key role in the corrosion of microbially colonized surfaces. The local accumulation of water at interfaces provides an important prerequisite for the dissolution processes occurring during microbially influenced corrosion and weathering. These processes are influenced by microbial products dissolved in the EPS matrix and interacting with the interfaces.

Metals

The deposition of metals in sedimentary biofilms represents a process of geological dimensions (24). This phenomenon is technically used for the removal of pollutants from wastewater and it can cause considerable problems when metals sorb to and thereby contaminate wastewater sludge, preventing its safe disposal. Metal binding in biofilms can occur in different ways, for example, by (*1*) ion exchange reactions, (*2*) complexation, and (*3*) precipitation, including redox reactions. The mechanisms can be both active and passive. Active binding occurs through the excretion of binding, chelating, or precipitating cell products in response to the presence of the dissolved substance. These mechanisms are known from studies on detoxification, mainly investigated in terms of heavy metal resistance (25). In addition, active transport systems may allow the uptake of, for example, metal ions into the cytoplasm. This might be because of the inability of the cell to discriminate between essential metal ions such as calcium and poisonous metal ions such as cadmium. Methylation and demethylation as well as oxidation and reduction are active processes altering the sorbed species and contributing to the overall sorption

capacity of a biofilm (26). Metal binding by bacterial surfaces is considered largely as a passive phenomenon within the process of electrostatic interaction between cationic metals and anionic cell surface groups. Consequently, it is not necessary that the organisms be viable, only that their surfaces remain intact (27). Passive binding mechanisms occur through ion exchange, mainly of the EPS and the cell wall, or through precipitation and/or complexation by biofilm components *already present* and not formed in response to the bound species. Passive binding can be performed by dead biomass as well as by living biomass through partitioning and nonmetabolic processes. In some instances, the sorption capacity of the dead biomass can be greater, which is utilized in metal recovery from wastewater streams (26).

Extensively studied for their metal-binding action are the EPS produced by bacteria in sewage treatment facilities (see Ref. 3). EPS bind a wide variety of metal ions such as Pb^{2+}, Sr^{2+}, Zn^{2+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Mg^{2+}, Fe^{2+}, Ni^{2+}, and Ag^{+}. Theoretical predictions of EPS-binding capacities, based on estimated numbers of available carboxyl and hydroxyl groups, suggest a very high capacity, especially for acidic polysaccharides. This means that a small amount of EPS could theoretically bind a large amount of a given metal. As EPS are sometimes composed of a matrix of fibrils with high molecular weight, the binding capacities of EPS cannot easily be expressed in terms of surface area, but rather must be expressed in terms of weight-specific binding (4,28).

Most empirical measurements so far have indicated high weight-specific binding capacities of EPS for many metals. The affinities of EPS for metals vary depending on the specific metal and microorganisms involved (4). Harvey and Luoma (28) found a binding capacity for lead to be 0.13 μmol of Pb per milligram EPS. They calculated that if EPS represented only a very small portion (ca. 3%) of the organic matter in sediments, the EPS could still complex all available Pb^{2+} in the surface-layer sediments of a Palo Alto salt marsh. As there exists a competition between H^{+} and metal ions, the stability constants strongly depend on the pH. Some EPS have a high affinity for particular metal ions (29,30). The stability constant of Cu^{2+} complexes with the EPS of bacterial isolates from river sediments has been reported to be 10^9; the stability of Cu^{2+}-complexes with humic substances is in the same range (31). Not all association of metals with EPS may, however, be because of adsorption. Because the solubility of the metal itself depends on pH, it is probable that the metals associated with EPS under natural conditions are the result of both ion-exchange binding processes and the precipitation and later physical entrapment of the metal by the polymer (32).

EPS binding processes can be important in the downward transport of metals in ocean environments. Close associations between bacterial EPS and a variety of metals have been found in both sediments (33) and the water column (34). Open-ocean bacterial aggregates called *bacterial snow* below 100 m often have been found with EPS capsules containing metal precipitates. Their frequency increased with depth and implies the downward accumulation of metals on EPS aggregates. Similar associations have been found in freshwater lakes (29).

Microbial Mineralization. Numerous bacteria in aquatic sediments encounter and bind a wide variety of metals in their environment. As the sediments accumulate, all of the microbial and mineral components become subject to geological forces that eventually result in rock formation. During this time, chemical and physical changes occur within the sediments as diagenetic processes. The cell walls of bacteria, present in these sediments, make suitable biological templates for the concentration of metals and the nucleation of crystals (35,36) and can often greatly influence the initial mineralization process (37). It has been demonstrated that Cd^{2+} in activated sludge was preferably bound to the cell walls and not to the EPS (38). Bacteria and their remains in metal-rich waters (39) and sediments around geothermal sites (40,41) have been shown by transmission electron microscopy (TEM), analytical electron microscopy, and electron diffraction to act as nucleation sites for authigenic minerals. Figure 5 is a scanning electron micrograph showing microorganisms as templates for the deposition of iron oxides.

Iron-silica precipitating species were associated with bacteria in geothermal sediments, whereas the bacteria in metal-rich waters were associated with Fe-Al silicate (clay) polymorphs, millerite (NiS), and mackinawite (FeS_{1-x}). In the latter environment, bacteria are thought to initially bind and concentrate iron and nickel. These concentrated metals then react with bacterially produced sulfide from the sediments or soluble silica to produce the corresponding mineral. Similarly, todokorite (MnO_6, 41) and Mg-calcite (marine peloids) deposits have also been shown to be nucleated by bacteria (27,42). A common example of bacterial metal binding is the slimy, rust-colored coating of Fe(III)-oxyhydrates in water pipes and in ponds and creeks. This is because of the binding of iron by the microbial biofilms that grow on these surfaces (43). Manganese(IV) oxide is found in similar environments, precipitated by biofilms (44,45).

There are many examples in which biotechnology uses the sorption capacity of biofilms. Chromium removal from synthetic waste streams by biofilms on disks of a laboratory-scale rotating biodisc contactor was about 98% effective during steady state addition of Cr(VI) at

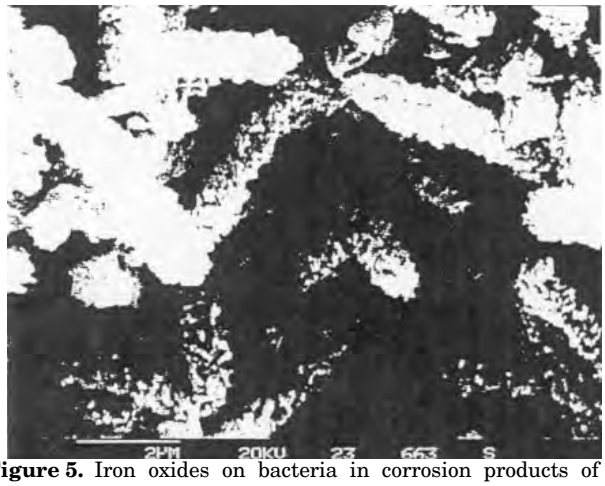

Figure 5. Iron oxides on bacteria in corrosion products of a drinking-water pipe.

concentrations of 100 to 200 mg L^{-1}. Analysis of the soluble chromium ions demonstrated that Cr(VI) was first reduced to Cr(III), which then appeared to be adsorbed by the biofilm. Chromium levels associated with the biofilm were found by chemical analysis to constitute 6.5 to 7.0% of its dry weight (46). Deans and Dixon (47) reported the biotechnological use of the uptake of Pb^{2+} and Cu^{2+} by EPS. The mechanisms of active and passive metal immobilization have been extensively reviewed (see Ref. 3).

The external environment and internal metabolism of living bacteria often exert a profound influence on the chemistry of bound metals. These influences include changes in oxidation state, formation of organometallic compounds, and formation of precipitates owing to detoxification or energy-yielding mechanisms of the bacterial protoplast. Alternatively, the metals may be affected indirectly by the production of metabolic end-products such as SO_4^{2-} and S^{2-} or an alteration in the local pH and/or E_h. The results of microbial activity may ultimately lead to metal immobilization, remobilization, and/or the formation of metal aggregates (27).

Microbial Precipitation. This results when living bacteria produce and excrete a substance that chemically reacts with metals present in solution to produce an insoluble metal compound. Next to carbonate deposition, the production of hydrogen sulfide by sulfate-reducing bacteria (SRB) and the subsequent formation of insoluble metal sulfides represent an important example. SRB, of which the most prevalent genera are *Desulfovibrio* and *Desulfotomaculum*, live in anaerobic environments such as lake sediments, swamps, and anoxic soils, but also in aerobic systems that contain biofilms above 50 to 200 μm of thickness. In biofilms of this thickness, the base region is mostly anaerobic and provides a habitat for anaerobic microorganisms such as SRB. Recent investigations, however, combining microelectrode measurements and scanning laser confocal microscopy reveal that there may exist anaerobic clusters of microconsortia rather than completely anaerobic layers, whereas channels penetrate the biofilms, implying that localized aerobic conditions may still prevail (48). The SRB oxidize organic matter and use sulfate as electron acceptor, reducing it to sulfide:

$$SO_4^{2-} + 10(H) \longrightarrow H_2S + 4H_2O$$

The hydrogen sulfide reacts with metals to form water-insoluble metal sulfide compounds. Precipitation of metals by the activity of SRB has been documented to occur in the natural environment leading to the removal of metals from streams and lakes (49). This naturally occurring activity has been reproduced in purpose-built impoundments to remove soluble metals emanating from mining operations (50). From calculations based on primary productivity and sulfate reduction rates in microbial mat communities, it has been estimated that sufficient sulfide could be produced in order for ore-grade iron and heavy metal sulfides to form (51).

Metals can also be precipitated from solution by HPO_4^{2-} derived from a phosphatase located on the bacterial cell surface. The phosphatase enzyme cleaves glycerol-2-phosphate liberating HPO_4^{2-}. Macaskie and Dean (52), working with *Citrobacter* sp., have demonstrated the cell-bound precipitation of Cd^{2+}, Pb^{2+}, and U^{4+} ions by HPO_4^{2-}. *Citrobacter* sp., immobilized as a biofilm on reticulated foam, was found to be effective in removing 90% of the uranium (1 mM uranyl acetate, pH 6.9) provided at a flow rate of 1.25 mL min^{-1}. After passage of 40 L of uranyl nitrate, the amount of uranium precipitated by the phosphatase activity was 9 g uranium per gram bacterial dry weight. Polyacrylamide gel-immobilized cells were comparably effective in removing uranium.

Bacterial calcification is another example for the precipitation of inorganic material by biofilms. The formation of calcium carbonate particles in microbial mats and other aggregates was suggested to be, at least in part, because of heterotrophic bacteria (53). On a global scale, bacterially induced precipitates of calcium carbonate can be the dominant component in thick sequences of traverine deposited from hot spring waters (54); thus, precipitation represents a biogeochemical mechanism of a geological dimension. From laboratory experiments, van Knorre and Krumbein (55) concluded that heterotrophic bacteria do not precipitate carbonate particles by a specific mechanism. An increase in carbonate alkalinity was sufficient to explain calcium carbonate precipitation. Increased carbonate alkalinity, if induced by bacteria, is usually a direct effect of physiological activities. Bacterial calcification is apparently only a side effect of bacterial metabolic activity and also largely depends on abiotic conditions; but, without bacteria, the formation of carbonate particles from precipitated calcium carbonate would not occur in some environments. Bacteria and other microorganisms influence the abiotic parameters of their environment considerably.

Oxidation and Reduction. Although oxidation and reduction of metals require the function of living organisms in most cases, some metal ion reductions can occur passively via chemically reactive sites on the cell walls of microorganisms. Depending on the metal species, both oxidation and reduction result in metal immobilization. Microgradients of oxygen and carbon dioxide produced by respiration play an important role in the oxidation and reduction potential within biofilms. The oxidation of manganese is performed by a limited number of bacterial species (see detailed review in Refs. 45,56) and mature spores, such as those of marine *Bacillus* species. The oxidation by bacterial cells and *Bacillus* spores results in the formation of insoluble manganese oxide:

$$Mn^{2+} + \tfrac{1}{2}O_2 + H_2O \longrightarrow MnO_2 + 2H^+$$

Microbially mediated oxidation of Mn^{2+} has been demonstrated to actively occur on a geological scale. Even under arctic conditions, rates were found to be sufficient to oxidize all of the Mn^{2+} in a lake under study (57).

Under anaerobic conditions, an acidothermophilic archaebacterium of the genus *Sulfolobolus* has been demonstrated to reduce Mo^{6+} to Mo^{5+}. This metal-ion reduction requires actively metabolizing bacteria because the reaction appears to be coupled to the oxidation of S° to SO_4^{2-} (50).

Methylation and Demethylation. Methylation and demethylation reactions are mechanisms that living bacteria can use to transform metals in their environment (58). Methylation reactions of tin, for example, are environmentally significant because methylation increases the volatility and the toxicity of tin, as well as altering its mobility in the environment. The same is true for mercury (59). Butylmethyltins have been reported in the sediments of several harbors. As antifouling paints from ship hulls were the principle source of tin in those harbors, it was assumed that butyltins could be partially degraded and then methylated in situ. Although 95% of the tributyltin in the water column is associated with particles, environmental concentrations are about three orders of magnitude greater in the microlayer of sediments than in the water column (60). Brinckman and coworkers (61) suggested that adsorption and concentration of tin compounds and microorganisms in surface slicks and on suspended particles could provide sites for biomethylation in aquatic systems. Dimethyltin and trimethyltin were detected by GC–MS when sediments of Chesapeake Bay were incubated with $SnCl_4$. Methylated tins were not detected in poisoned or in sterile controls (60). The production of monomethyltin was correlated positively with the number of sulfate-reducers and of sulfur oxidizers. *Desulfovibrio* spp. isolated from the sediments were able to carry out the methylation (62). Potential mechanisms for methylation were reviewed by Thayer and Brinckman (63).

A practical example may illustrate the importance of the sorption potential of biofilms, as it is exploited for the identification of emitters of pollutants into sewage lining systems. For this purpose, the metal content of the biofilms on the surfaces of the sewers is analyzed systematically upstream (64). As soon as the concentration of heavy metals decreases, the site of emission has been intersected and crossed. Thus, the emitter must be between the sampling points with the last high and the first low metal concentration. The "memory effect" of this biofilm is based on the accumulation of heavy metals from the wastewater stream. The system, based directly on the sorption properties of biofilms, has improved the effectiveness of the monitoring authorities and reputedly helped to maintain lower pollutant concentrations in sewage sludge (65).

Organic Substances

The sorption of organic solutes to biofilms is a well-known phenomenon. Biofilms sequester them as nutrients from the water stream and, thus, manage to maintain a complex habitat (2). The sorption is a prerequisite for biodegradation and as such, is part of any technology using biofilms for water purification. Only the less biodegradable substances accumulate. This is true for some pesticides and aromatic chlorinated hydrocarbons that occur in high concentrations in digested sewage sludge. The unwanted sorption of organic pollutants by biofilms is vastly documented, especially in sewage treatment plants (see Ref. 3).

The potential for enhanced mobility of hydrophobic pollutants by cotransport with bacteria in saturated soils was evaluated from measurements of biosorption of ^{14}C-labeled hexachlorobenzene and dichlorodiphenyltrichlorethane (DDT) to five strains of soil and sewage bacteria (66). The sorption process could be described by a linear partition equation and appeared to be reversible, but desorption kinetics were slow and/or partially irreversible. The DDT partition coefficients varied with equilibrium time, possibly reflecting DDT-induced changes in the physiology of the bacteria. The partition coefficients, normalized in the masses of bacteria, ranged from 250 to 14,000 for live cells, but the largest coefficients were associated with autoclaved cells of a *Pseudomonas* sp. This is an example of passive sorption. In a further experiment on the sorption capacity of the bacterial biomass, the sorption capacity was greater for DDT than for hexachlorobenzene, but was not correlated to overall bacterial hydrophobicity, measured by hydrophobic interaction chromatography. The 1.2×10^9 cells of a *Bacillus* sp. strain per milliliter enhanced DDT transport by about eightfold, whereas an advective–dispersive–sorptive equilibrium model for two mobile phases, waste and free-living bacteria, suggested a 14-fold enhancement, based on the DDT partition coefficient. Model calculations based on literature data covering a wide range of organisms and compounds suggested that 10^6 cells/mL would increase the mobility of very hydrophobic compounds (octanol-water partition coefficient $K_{ow} > 6$) whereas higher densities of bacteria (10^8 cells/mL) would have a significant impact on compounds with a $\log K_{ow} > 4$.

Investigations on the uptake of nutrients support considerations on the sorption properties of biofilms. Stream sediment with a natural biofilm generally adsorbed more glycine, aspartic acid, and lysine than sterile sediments (67). The adsorption of glycine, aspartic acid and lysine to glass-beads was measured at three pH values. The positively charged lysine molecules were generally adsorbed more readily than the others. Beads coated with sterile leaf leachate as opposed to sterile glass beads adsorbed more lysine and aspartic acid, but no glycine. The same pattern was found when beads coated with leachate and colonized by bacteria were compared with beads coated with sterile leachate. Killing the bacteria on the beads with glutaraldehyde did not affect adsorption rates. Increasing Ca^{2+} concentration from 5 to 50 mg L^{-1} decreased adsorption of lysine and increased adsorption of aspartic acid. In natural habitats, low molecular weight substrates are more likely to be used as substrates for bacteria suspended in the water phase. Macromolecules, however, are more likely to be sorbed at surfaces and in biofilms (68).

Sorption data gained in sterile systems may differ profoundly from those gained in the presence of microorganisms and colonized surfaces. It has been found that pesticides such as chlortolurone are not sorbed on clean clay surfaces and not degraded by a suspended mixed soil microbiota. However, in the presence of clay, significant sorption was observed and the microbiota were able to degrade the pesticide, as indicated by the occurrence of metabolites (3). Similar effects of clay surfaces on microbial activity were reported earlier (69,70). Higher concentrations of montmorillonite (10 g L^{-1}), however, might inhibit bacterial growth, as results from Marshman and

Marshall (71) indicate. The effect of surfaces on bacterial activity has certainly to be taken into account. Thus, organic substances in water, which may have appeared to be nonbiodegradable in suspended biodegradation tests, may under certain instances be degraded in the presence of surface-rich material. The most likely explanation for this effect is that the cells settle on the surfaces and then exhibit different physiological properties (72). This occurrence has been demonstrated by the experiments of Dagostino and coworkers (73).

As explained earlier, the EPS can contain significant amounts of proteins. These may well provide apolar sections that interact and sorb apolar organic molecules. However, the polysaccharide moiety, although hydrophilic by nature, must interact with hydrophobic molecules as well. This consideration is supported by the colonization of hydrophobic surfaces by means of the EPS of hydrophilic bacteria and by the performance of biofilm reactors that degrade hydrophobic organics. It is known that many EPS have surface-active properties (74) which must play a central role in such processes. It is especially the lipid moiety of the cell walls, such as the outer and inner membrane, which are predestined as sorption sites for hydrophobic pollutants. However, the sorption capacity of these must be considered as very limited. The amount of a hydrophobic compound that can be maximally bound to the lipid membranes of biofilm cells can be estimated from bioconcentration and K_{ow} factors. Especially for some pesticides and PCB, bioaccumulation in microorganisms in activated sludge has been reported. Accumulation rates are similar for dead and living cells, indicating a sorption process independent of physiological activity.

Bacterial sorption was characterized by the partition coefficient between biomass and medium (75); however, it has to be pointed out that many other authors could not confirm the correlation between K_{ow} and K_B and vast differences in the bioaccumulation by different bacteria have been observed in the meantime. Furthermore, such investigations do not differentiate between different sorption sites. Detailed research on the sorption site for benzene, toluene, and xylene (BTX) as examples for hydrophobic substances in an activated sludge system revealed that most of the BTX was accumulated in the EPS, whereas only a minor part was associated with the cells and their membranes (Fig. 6). This result was surprising because of the hydrophilic nature of the EPS matrix. However, obviously a substantial amount of hydrophobic substances (up to 8% w/w dry weight) such as pentachlorophenol can be accumulated in biofilms (38).

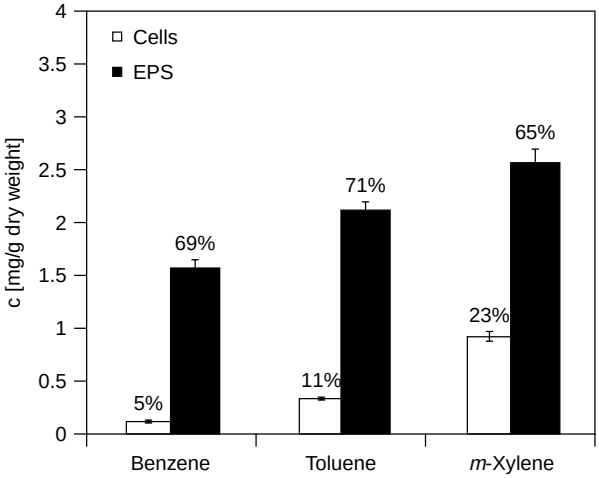

Figure 6. Partition of benzene, toluene, and xylene (BTX) between EPS and cells in activated sludge. (After R. Späth, H.-C. Flemming, and S. Wuertz, *Water Sci. Technol.* **37**, 207–210 (1998)).

Colloids

Colloids are solid or semi-solid particles of approximately 10 nm to 1 μm in diameter (76). They are ubiquitous and numerous components of natural soil and water environments (77) are present, which inevitably contact and permeate biofilms. The role of colloidal particles in natural environments has long been acknowledged as paramount to biogeochemical cycles (78). The importance of colloids in microbial ecology lies in their large sorption capacities, resulting from a collectively large surface area, and their ability to be transported through much of the biofilm matrix via pores and channels, thus acting as transport vectors for nutrients and contaminants. Some colloidal particles act as nucleation sites for the formation of particulate aggregates, which constitute the suspended "snow" in rivers, lakes, and oceans. In natural environments, colloids are represented by inorganic and organic particles of iron and aluminum oxides, and hydrophobic aggregates of macromolecules such as globular proteins and humic substances. Smaller bacteria and other microorganisms fall within the size range of colloidal particles and are thus regarded as living colloids biocolloily if they have no means of self-motility. Colloids and organic macromolecules including lignin and humic substances are responsible for binding and transporting organic and inorganic matter, including contaminants (79). Iron, manganese, and aluminum oxides, for example, strongly bind transition metals (80). As much of the dissolved organic matter possesses an affinity for solid surfaces (81), most of the suspended colloidal particles are associations of minerals and natural organic matter, such as organic acids. The behavior of colloids is strongly influenced by pH and electrostatic charge, and these properties influence the binding of other matter or flocculation. Therefore, colloidal particles, which become deposited on or within biofilms, have already sorbed significant quantities of organic and inorganic matter, and potentially constitute one of the major nutrient sources for biofilm organisms. Figure 7 shows two examples of particulate matter localized within biofilms.

The mechanisms for particle transport into biofilms were reviewed by Bouwer (82). This phenomenon can be most readily visualized using fluorescent microbeads and assessing their locations throughout the biofilm matrix using confocal laser microscopy or a combination of cryo-sectioning and epifluorescence microscopy (83). Small, chemically functionalized microspheres allow an assessment of interstitial binding sites, analogous to the labeling of cell surfaces with colloidal gold or ionic probes. Particles with a diameter of 10 μm can traverse thick biofilms by advection and convection owing to the pore and channel biofilm morphology (83). The deposition of Fe(III)

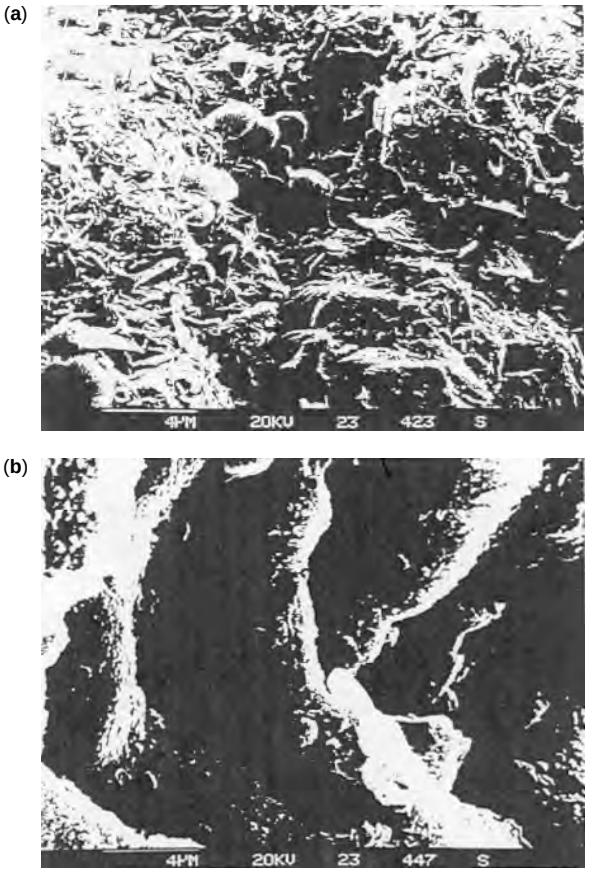

Figure 7. Particulate matter in microbial biofilms: (**a**) mixed consortium and (**b**) fungal hyphae with adsorbed particulates.

colloids within a biofilm of *Burkholderia cepacia* was shown to be only slightly higher than control surfaces (80); however, incorporation of clay particles by a *Pseudomonas fluorescens* biofilm was found to have a substantial impact on a number of parameters, including mass transfer and activity (84). Biofilms formed in the presence of kaolin particles had greater quantities of biomass, and a greater capacity to withstand substrate limitation. Another study showed the enhanced nitrification capacity of activated sludge biofilms in the presence of powdered clay (85). The inputs of biodegradable matter from colloids and their own sorbed components relative to other nutrient sources (cell turnover, macromolecular adsorption) is unknown, but in some systems, this may be a dominant mechanism sustaining the productivity of biofilm organisms.

REMOBILIZATION

From the preceding examples, it is clear that bacterial surfaces and biofilms are not inert chemical structures. They represent a dynamic system in which the various components are synthesized, assembled, modified, and finally broken down by autolysins and sloughed off into the environment. Thus, they may contribute to the remobilization of the sorbed substances. McLean and Beveridge (27) pointed out: "When the effects of pH, E_h, interfacial nature, and chemical attributes of the metal (heat of hydration, charge density, electronic shell, etc.) and the presence of competing ions and other biological surfaces are also taken into account, we can begin to grasp the true complexity of bacterial metal binding." Obviously, some or all of these parameters are applicable to all sorbed substances in natural environments, but the ability to accurately measure metal species provides one of the best examples to enable an assessment of remobilization events. By nature, the immobilization of metal ions in biomass cannot be irreversible. The biological binding sites sooner or later will be degraded. The fate and transport of the metal is directly related to the fate and transport of the bacterial cell. In some instances, this process will lead to mineral formation (86) and is responsible for the deposition of large ores. However, in other cases the sorbed metal ions will return to their more soluble form and be remobilized.

Experiments with cell walls of *B. subtilis* and *E. coli* envelopes adsorbed to kaolinite and smectite clays and with the corresponding organic material–clay aggregates showed the complexity of remobilization processes (87). Bound to these substances were Ag(I), Cu(II), and Cr(III). The sorbed metals were then leached with HNO_3, $Ca(NO_3)_2$, EDTA, fulvic acids, and lysozyme at several concentrations. The findings on remobilization of the sorbed metals, in general showed the order $Cr^{2+} < Ag^{+} < Cu^{2+}$. In the cell wall, clay, and composite systems, Cr^{3+} was very stable; at pH 3, 500 mm EDTA, 120 ppm fulvic acid, and 160 ppm Ca^{2+} released less than 32% (wet weight) of the sorbed chromium. Silver (45 to 87%) and copper (up to 100%) were readily removed by these agents. The organic chelators were in general less effective at mobilizing certain metals than elevated Ca^{2+} or low (acidic) pH values. Lysozyme digestion of *Bacillus* walls remobilized Cu^{2+} from walls and Cu–wall–kaolinite composites. Ag^{+} and Cr^{3+} smectite inhibited enzyme activity to some extent, and the metals remained insoluble. The concentration dependency of the leaching agents was not always given; for example, the Ag^{+} mobility decreased with some clays and composites treated with high fulvic acid, EDTA, and lysozyme concentrations. It was assumed that the particle size of the deposited metal may account for some stability changes. The large and compact aggregates of Cr^{3+} and Ag^{+} as seen in TEM were less likely to be remobilized. Interesting is the comparison of the stability of metal complexes of low molecular weight complexing agents with the stability of metal—EPS complexes. The EDTA complexes have stability constants of up to 10^{18}, and the complex of Cu^{2+} with 1-hydroxyethane-1, 1-diphosphonic acid (HEDP) is about 10^{19} (88). If these complexing agents occur in the water phase, it should be expected that eventually sorbed metal ions are rapidly complexed. However, the remobilization in this case is unexpectedly low. Gutekunst (64) carried out elution experiments with EDTA and HEDP, which showed only marginal remobilization of biofilm-bound metal ions. These observations indicate that separate mechanisms in addition to complex formation must be effective in metal binding by biofilms. Considering organic pollutants bound in lipid membranes, a rapid release after death of a cell is probable as the phospholipids belong to the first cell components to degrade when a cell dies (89).

CONCLUSION

In the complex system of sorbing species in soils and sediments, biofilms are a part of the "organic matter." In this lumped parameter, the biofilm organisms and their polymer matrix represent a dynamic sink and source for sorbed substances. The biofilm forms a gel phase between the solid mineral surface and the liquid phase. Sorption and desorption occur passively and actively. Both biotic and abiotic processes can be involved in the sorption process. The sorption capacity of biofilms has not yet been assessed. A prerequisite will be that biomass can be discriminated from other soil or sediment components, in particular humic acids. It is possible that the overall sorption capacity of biofilms is not impressively high compared to abiotic sorbents; however, as the biofilm can influence all parameters involved in the sorption process such as pH, E_h, oxygen content, and ionic strength, abiotic sorption will be influenced by biofilm processes as well. This is the indirect effect of the physiological activity of biofilm organisms, and this effect depends not on the amount of biomass but rather on its activity at specific sites. This aspect will have to be addressed in further research. Although it is possible that the sorption capacity of biofilms does not exceed that of abiotic organic components such as humic acids, the dynamic nature of biofilms gives them a particular role in the sorption process. This is why they have to be considered in the assessment of the distribution of pollutants in surface and groundwater, if models of the distribution of pollutants in the aquatic or soil environment are to be realistic. The existing data on adsorption must be questioned if these are obtained under microbiologically undefined conditions. This review reveals a substantial research need in many aspects. Usually, biomass is still taken as a black box; and the specific binding sites for different sorbents are evaluated only in very few cases. The binding mechanisms for lipophilic molecules by EPS in particular are not well understood. The overall binding capacity of biofilms remains unclear as well as the remobilization potential.

SOURCE WATER PROTECTION: MICROBIOLOGY OF SOURCE WATER

PAUL S. BERGER
ROBIN K. OSHIRO
U.S. Environmental Protection Agency
Washington, DC

The control of waterborne diseases depends on a multiple barrier approach: source water protection, adequate and

reliable water treatment, measures to prevent a breach in the integrity of the oftentimes vast network of pipes known as the distribution system that carry the treated water to the customer, and the use of a disinfectant such as chlorine to control any waterborne pathogens that do manage to enter the distribution system. A breach in any one of these barriers undermines consumer protection.

Source waters, as used in this overview, are defined as those surface waters and ground waters used by drinking water systems. Some of these source waters may also be used for swimming, bathing, and other recreational activities, and waterborne disease associated with such activities occurs with some frequency.

The overview begins with a survey of the sources of disease-causing organisms (pathogens) that might contaminate water, the factors that affect whether the pathogens reach a water body (surface or ground), and the environmental factors that affect waterborne pathogen survival in the water. This is followed by a short review of commonly used indicators of source water quality. A brief summary of governmental requirements that protect source waters closes the overview.

PATHOGEN SOURCES

Human pathogens in source waters may come from point sources, non-point sources, and recreational water activities, or they may be indigenous to the source water. Point sources are those in which the source can be clearly identified, such as wastewater treatment plants, wastewater and sludge disposal sites on land, septic tanks, and sewage spills. Usually, the greatest concentration of waterborne fecal pathogens infective for humans originate from point sources (1). Point sources may include wastes of human origin as well as livestock origin. The United States has about 45,000 animal feedlot operations (2), and fecal waste from these operations is often stored in waste ponds or as solid manure piles. Heavy rains can cause pond overflow and manure pile dissolution, resulting in severe contamination of water sources (3). Such animal waste may also contain human pathogens of significant public health importance, including *Cryptosporidium parvum*, *Salmonella*, and *Escherichia coli* O157:H7. Additionally, use of antibiotics in livestock and the resultant release of antibiotic-resistant pathogens into the environment, as well as zoonotic transfer of resistant strains, are also of concern (4).

Nonpoint sources are those in which the source of contamination is not clearly defined or is unknown. Thus, control of these sources is much more difficult to achieve. Examples of nonpoint sources associated with human pathogens include urban runoff, water recreation activities, and wildlife. Urban runoff and stormwaters are transported to source waters either directly via storm drains or, in older cities, to wastewater treatment plants (combined sewers), which during a heavy rainfall may exceed their capacity and cause the release of untreated sewage into the source water. The pathogens in urban runoff can originate from soil, street runoff, animal wastes, and other sources. The fecal bacteria density is much higher in sewered than nonsewered areas and is directly related to housing density, urban development, and domestic animal density (5).

Table 1. Waterborne Disease Associated with Recreational Water in U.S.: 1986–1998[a,b]

Disease	Outbreaks	Cases
AGI[c]	23	2,111
Shigellosis	19	1,716
Amoebic meningoencephalitis	18	18
E. coli O157 gastroenteritis	9	293
Dermatitis c/w[d] schistosoma	7	203
Giardiasis	4	65
Norwalk-like gastroenteritis	3	89
Leptospirosis	3	389
Cryptosporidiosis	3	429
Aseptic meningitis	1	4
Pseudomonas aeruginosa dermatitis	1	50
Pharyngitis (adenovirus 3)	1	595

[a]Includes water types that might be used as sources for drinking water, such as lakes, streams, creeks, ponds, and canals. Excludes swimming pools, hottubs, hot springs, puddles, water slides, and fountains.
[b]Data are adapted from Refs. 6–11.
[c]AGI is acute gastroenteritis of unknown etiology.
[d]c/w = consistent with.

Water recreation activities such as swimming, bathing, and boating may be a major nonpoint source of pathogens in ambient waters. A number of outbreaks associated with recreational waters have been attributed to fecal discharges during such activities (Table 1). Wildlife sources may also carry human pathogens such as *Cryptosporidium parvum*, *Giardia lamblia*, and *Salmonella* species. Animals often defecate near water sources and thus their fecal material is easily washed into these waters, especially during a rainfall. Table 2 illustrates the variety of animals that are infected by pathogens that also infect humans. Other animals may carry human pathogens, but are not infected by them. For example, *Cryptosporidium parvum* is transported in aquatic birds, but does not infect and grow in the birds (34).

Some pathogens are normal inhabitants of ambient waters and soil. Most are opportunistic bacterial pathogens such as *Pseudomonas aeruginosa*, *Mycobacterium avium intracellulare*, *Legionella pneumophila*, and several strains of aeromonads, flavobacteria, and *Klebsiella*. (Opportunistic pathogens generally only infect those individuals who have a weakened immune system or who are particularly sensitive for other reasons.) In addition to the opportunistic pathogens, at least two protozoan species indigenous to water, *Naegleria fowleri* and *Acanthamoeba* spp., can cause illness in healthy individuals. Several species of cyanobacteria (blue-green algae) are also free-living pathogens. Wastewater and agricultural runoff, even in the absence of fecal pathogens, increase the nitrogen and phosphorous levels in a water source, which may increase the levels of these free-living pathogens.

FACTORS AFFECTING THE TRANSPORT OF FECAL PATHOGENS TO SURFACE WATER

Some sources discharge fecal pathogens directly into surface water. Among these sources are many sewage

Table 2. Natural Animal Reservoirs for Waterborne Disease Pathogens of Humans

Organism	Major Disease	Animal
Bacteria		
Aeromonas hydrophila	Gastroenteritis	None (free-living)
Campylobacter jejuni	Gastroenteritis	Poultry, pigs, cattle, sheep, dogs, cats, and many others (12,13)
Escherichia coli O157:H7	Hemorrhagic colitis, hemolytic-uremic syndrome	Cattle and other ruminants (12,14)
Other pathogenic *E. coli*	Gastroenteritis	Cattle and pigs (uncommon) (15–17)
Helicobacter pylori	Peptic ulcers, stomach cancer	None known (18)
Legionella pneumophila	Legionnaires Disease, Pontiac fever	None (free-living)
Mycobacterium avian intracellulare	Pulmonary disease, gastroenteritis	None (free-living) (19)
Pseudomonas aeruginosa	Dermatitis	None (free-living)
Salmonella typhi	Typhoid fever	None known (12)
Salmonella paratyphi	Paratyphoid fever	Rarely domestic animals (12)
Other *Salmonella* spp.	Gastroenteritis (salmonellosis)	Poultry, pigs, cattle, rodents, reptiles, and many other domestic and wild animals (12,20)
Shigella spp.	Bacillary dysentery	Nonhuman primates (12)
Vibrio cholerae	Cholera	None (free-living in brackish and estuary waters)
Yersinia enterocolitica	Gastroenteritis	Primarily pigs, rarely other domestic and wild animals (12,21,22)
Enteric viruses (human strains)		
Norwalk and other caliciviruses	Gastroenteritis	Humans only (12)
Rotaviruses	Gastroenteritis	Humans only (12)
Enteric adenoviruses	Gastroenteritis	Humans only (12)
Astroviruses	Gastroenteritis	Humans only (23)
Polioviruses	Polio	Humans only (23)
Coxsackieviruses	Upper respiratory disease	Humans only (23)
Echoviruses	Upper respiratory disease	Humans only (24)
Hepatitis A virus	Infectious hepatitis	Nonhuman primates rarely (12)
Hepatitis E virus	Hepatitis	Unknown, but evidence exists for pigs, rats, and other animals (12,24,25)
Protozoa		
Acanthamoeba spp.	Eye infection	None (free-living)
Cyclospora cayetanesis	Gastroenteritis	None known (26,27)
Cryptosporidium parvum	Cryptosporidiosis (gastroenteritis)	Many mammals, especially calves (28)
Entamoeba histolytica	Amoebic dysentery	Nonhuman primates (29)
Giardia lamblia	Giardiasis (gastroenteritis)	Muskrats, beavers, small rodents, and many other domestic and wild animals (30)
Enterocytozoon bieneusi	Gastroenteritis	Nonhuman primates, pigs, several other mammals (31)
Encephalitozoon intestinalis (a microsporidium)	Gastroenteritis	Pigs, cattle, goats, dogs, donkeys (32)
Naegleria fowleri	Primary amebic meningoencephalitis	None (free-living)
Toxoplasma gondii	Flu-like symptoms	Cats (33)
Blue-green algae (Cyanobacteria)	Gastroenteritis, liver damage, nerve damage	None (free-living)

Note: spp. means species.

treatment facilities and water recreational activities. Sewage treatment facilities provide secondary treatment that usually includes disinfection to kill pathogens before discharging the effluent into the receiving water, but some level of pathogens survive. Also, water supply plants need to clean their filters occasionally by reversing the flow of water. This filter backwash water may contain high levels of pathogens, including *Cryptosporidium* and *Giardia*, that contaminate the source water.

For pathogens not directly discharged into surface water, the likelihood of a fecal pathogen reaching a surface water body from its point of origin depends on the climate, watershed terrain, soil properties, filtering capacity of the vegetation cover, nature of the pathogen, and proximity of the fecal source to the water body. Pathogens may even reach surface water via groundwater discharge if the aquifer is unconfined and highly transmissible (35,36).

Stormwater is the most obvious vehicle for transporting fecal pathogens from animal feedlots and other fecal sources in the watershed that are not deliberately discharged directly into the water. Major storms can result in rapid movement of pathogens over the watershed and into receiving streams and lakes. Depending on soil characteristics, fecal pathogens may move into the

subsurface and contaminate groundwater. Air and water temperature play a role in pathogen survival; colder temperatures increase fecal pathogen survival.

Generally, fecal pathogens in the environment are bound. They are adsorbed to organic or inorganic particles or embedded in fecal matter, and are often aggregated with other microbes. This association usually greatly enhances the survival of fecal pathogens in the environment. *Salmonella*, for example, can be excreted by cattle in levels up to 10^7 per gram of feces (37) and can survive for between 8 (poultry slurry) (38) and 286 days (cattle slurry) (39). (Slurry is a watery mixture of animal feces, urine, and small amounts of bedding.) *E. coli* O157:H7 can survive in sheep manure in the field for 21 months, for 47 days in cattle manure (40) and for eight days in cattle slurry (41) at room temperature. At lower temperatures (4 °C), this organism can survive for 38 days in cattle slurry, whereas *Salmonella typhimurium* can survive for 66 days under the same conditions (41). Viruses such as picornaviruses, rotaviruses, parvoviruses, adenoviruses, and herpesviruses have been found to survive for many weeks (greater than six months for rotaviruses) in manure under nonaerated, dry conditions (42).

ENVIRONMENTAL FACTORS IN PATHOGEN SURVIVAL IN AMBIENT WATERS

The survival of human fecal pathogens in a water body is affected by a number of physical, chemical, and physiological factors. The more important ones are indicated next.

Water Temperature

Generally, fecal pathogens can survive longer in colder waters because metabolic processes slow down (43). Some may also survive longer in very warm waters with a high organic load. In tropical and subtropical regions, the higher temperatures and organic loading of water is more similar to that of the gut of humans and other warm-blooded animals. In these water, *E. coli* can survive and even grow (see section on Indicators of source water quality). The density of *Salmonella typhimurium* declined by 90% in 28.8 hours in a temperate source water as against 131 hours in a tropical source water (44). Other enteric bacterial pathogens may show a similar temperature effect. Nonfecal pathogens indigenous to water (e.g., *Pseudomonas aeruginosa*, *Legionella pneumophila*) also increase in density with warmer waters. In contrast, the survival of enteroviruses, *Cryptosporidium* oocysts, and *Giardia* cysts decreases with increasing water temperatures (45,46,47).

Competition

The enteric bacterial pathogens discharged into ambient water face stiff competition for nutrients by indigenous aquatic bacteria. Moreover, the aquatic bacteria may produce substances that inhibit the enteric pathogens (43,48). Thus, the aquatic bacteria place the enteric pathogens at a selective disadvantage and reduce their survival time.

Protozoan grazing is a major factor in the decrease of enteric bacteria in natural water (49,50). However, a few waterborne pathogens such as *Legionella pneumophila*, *Mycobacterium avium*, *Vibrio cholerae*, and *E. coli* O157:H7 survive and even grow within certain common amoeba (51–55). A few other bacteria may form filaments as a defense strategy against grazing by protozoa (56), but it is not known whether enteric pathogens have this capability. Bacteria can also be protected from predation by adsorption onto clay particles (57).

Available Nutrients

Opportunistic bacterial pathogens indigenous to water, especially *Pseudomonas aeruginosa*, quickly increase in density upon the introduction of organic matter into the water body. In contrast, the effect of organic load on enteric pathogens is variable. In one study, higher turbidity and suspended solids protected enteroviruses at 1 °C, but the reverse was found at 22 °C, possibly because the warmer temperature increased total bacterial growth (58). Survival of enteric viruses is greatly enhanced in sewage sludge disposal sites in marine waters (59). Enteric bacteria, as noted in the previous section, including pathogens, may survive longer in very warm waters with a high organic load. Higher levels of organic material (diluted sewage) increased the survival time of *Salmonella enteritidis* at 37 °C (60), but decreased survival at 20 °C (61). At cold temperatures, *Salmonella* survival increased with higher organic levels (62). Survival may be significantly enhanced if the enteric bacteria sink into the freshwater sediment, especially an organically rich one (63,64). Because enteric protozoa and viruses do not grow outside a host animal, changes in the nutrient level should not directly affect their numbers or survival in the water environment.

Sunlight

The deleterious effect of ultraviolet (UV) light on genetic material of microorganisms is well known (43). Published studies on the effect of sunlight, which includes UV light, have focused on the inactivation of microbial indicators (see section on Indicators of source water quality) rather than on waterborne pathogens (65,66). Waterborne pathogens shown to be inactivated by UV light include the hepatitis A virus (67), *E. coli* O157 (68), *Legionella* (69), *Cryptosporidium parvum* oocysts (70), cyanobacteria (71), and poliovirus (72). In waste stabilization ponds, it has been shown that sunlight, as well as high dissolved oxygen concentrations and high pH, is required for significant reductions of fecal coliform densities (73).

Means of Protection

Survival of fecal pathogens in ambient water is enhanced by adsorption onto organic matter. However, some pathogens have other means for protecting themselves in the water environment. *Cryptosporidium parvum*, *Giardia lamblia*, and other pathogenic protozoa can form resistant cysts, oocysts, or spores that protect them from environmental stresses. In addition, when nutrients are low, some bacteria can activate genes to become more

efficient scavengers and can acquire a spore-like state (74). It is not known whether any fecal pathogens can do this.

Some fecal bacterial pathogens enter a viable but nonculturable (VNC) state in water as a result of environmental stress. In this condition, the bacteria apparently remain viable but lose their ability to grow on either nonselective media or on culture media normally used for their recovery. There is a strong debate about cell viability in the VNC state. Some believe that these bacteria remain viable and infective but have become dormant as a survival measure against environmental stress (75). Others contend that these organisms are dead or are dying and that successful attempts to resuscitate them merely indicate that a few bacterial cells remained alive (76). Regardless, it is known that some pathogens in the VNC state retain their pathogenicity (77). A VNC state has been reported for most waterborne pathogens (Table 3).

PATHOGEN OCCURRENCE IN SURFACE WATERS

Few large surveys have been conducted on any waterborne pathogen in ambient water. In one study, the source waters for 72 water treatment plants in 15 States (United States) and two Canadian provinces were analyzed for *Giardia* and *Cryptosporidium*. *Giardia* and *Cryptosporidium* cysts or oocysts were detected in 53.9% and 60.2% of the 347 samples, respectively (average sample volume was 499 L, with a range of 87 L to 3,394 L). For the last 262 water samples, the geometric mean for *Giardia* was 2.0 cysts/L, whereas that for *Cryptosporidium* was 2.4 oocysts/L (91). A large percentage of the cysts or oocysts were considered dead because of the absence of observable internal structures.

In another survey, 29 surface source waters used by large water supply systems were tested for the presence of astroviruses, enteroviruses, and adenovirus types 40 and 41 (92). Testing was accomplished by an integrated cell culture-reverse transcription nested polymerase chain reaction procedure. Of the 29 samples concentrated from large water volumes (generally 10 L–100 L), astroviruses were detected in 51.7%, enteroviruses in 58.6%, and adenoviruses in 48.3%.

In a third survey, source water samples were collected on a monthly basis from 350 large surface water systems for 18 months and the samples were tested for *Cryptosporidium* and other organisms. Only 44% of the source waters were *Cryptosporidium*-positive in at least one of the 18 samples (median volume three liters). About 83% of the 350 systems had observed mean *Cryptosporidium* concentrations below 0.1 oocyst/L (93).

Table 3. Waterborne Pathogens and Fecal Indicators Known to Enter Viable but Nonculturable State

Organism	Medium	Reference
Campylobacter jejuni	Filter sterilized surface water	78
Shigella dysenteriae	Pond, river, drain, lake water	79
Salmonella enteriditis	Sterile river water	80
Salmonella typhimurium	Marine	81
Salmonella spp.	River	82
E. coli O157:H7	Sterile municipal water, lake, reservoir	83
Vibrio cholerae	Artificial seawater	84
Helicobacter pylori	Sterile river water, distilled water	85
Legionella pneumophila	Sterile tap water	86
Aeromonas hydrophila		87
Pseudomonas fluorescens	Soil	88
Enterococci	Freshwater, seawaters	89
Escherichia coli	Seawater, estuarine	90

GROUNDWATER

In the United States, 92% of the 168,000 water systems serving at least 25 people use groundwater, and more than 100 million people obtain most or all of their drinking water from these groundwater supplies (94). The majority of these systems (61%) serve fewer than 100 people. In addition, there are about 15 million private wells that serve fewer than 25 people. A well draws water from an aquifer, which is an underground water-bearing permeable material that contains significant amounts of water. An aquifer may be unconfined or confined. Confined aquifers possess an overlying boundary layer of low permeability rock or clay that acts as a barrier to prevent or slow the flow of water into, or out of, the underlying aquifer. As a result, pathogens from sources above the confining layer are prevented, or greatly impeded, from reaching the aquifer. Typically, groundwater percolates through confining layers very slowly; it may take over 100 years for the water to flow one meter.

In contrast, an unconfined aquifer does not have an overlying rock layer of low permeability and may thus be vulnerable to contamination from a fecal source at the surface or in the shallow subsurface (e.g., septic tank). Shallow wells in an unconfined aquifer are often characterized by significant and relatively rapid shifts in water characteristics such as turbidity, temperature, conductivity, or pH that correlate to climatological or surface water conditions. In addition, the pumping of shallow wells in an unconfined aquifer may pull in water from nearby lakes and other bodies of surface water. As a result, the well water may contain material normally associated with the surface, such as diatoms, insect parts, plant debris, pollen, crustaceans, or large-diameter pathogens such as *Giardia lamblia* and *Cryptosporidium parvum* that do not reproduce outside a mammalian host (95).

Wells may become fecally contaminated via infiltration from the surface or from underground sources of contamination. Surface sources include land application of wastewaters, seepage from waste lagoons, infiltration of polluted water from lakes and other surface water bodies, waste from livestock operations, and improperly constructed sanitary landfills (96). Contaminated surface water sources may also enter an improperly constructed, protected, or maintained well directly, either along the

casing or through cracks in the sanitary seal around the casing. Several groundwater systems have experienced a disease outbreak, including cryptosporidiosis, in this manner (97). Fecal contamination can also reach a drinking water well intake from underground sources such as septic systems, leach fields, cesspools, or leaking underground sewer lines. About 25 million septic tanks exist in the U.S. (98). The volume of septic tank waste released into the subsurface has been estimated at one trillion gallons per year (99).

Enteric pathogens, including viruses, are usually retained near the surface (or source in the case of a septic tank). However, a small fraction of the pathogens are carried along with the water flow through the surrounding soil and rock to collect within the water-saturated zone beneath the water table. Whether an infectious enteric pathogen reaches the area of a well intake depends on the rate of transport through the subsurface and how long the pathogen survives. Transport depends on a complex and site-specific interaction between the soil (and bedrock) characteristics, environmental factors, and the nature of the organism. The factors that affect the movement of enteric pathogens through the soil include the type of soil, pH, cation levels, amount of soluble organic matter, flow rate, degree of water saturation, and pathogen attributes (100).

As a pathogen moves downward and laterally with the water flow, it may become attached (adsorbed) to soil and rock particles. An adsorbed organism may detach (desorb), especially after a rainstorm, and readsorb to soil particles further along the flow path. Besides adsorption, larger microbes or microbial aggregates may be filtered out by tight pore spaces. Enteric pathogens may either slowly percolate through the soil and aquifer material or seep more rapidly through natural pathways in some types of bedrock. These pathways include (*1*) soil macropores, (*2*) large fractures in a fractured bedrock hydrogeology, (*3*) fractures in karst hydrogeology that enlarge through the dissolution of limestone, dolomite, or other soluble rock, and (*4*) large pore spaces characteristic of gravel bed hydrogeology. Karst land, which is often characterized by caves, caverns, and sinkholes, constitutes about 40% of the land in the United States east of Tulsa, Oklahoma (101). These natural pathways provide a direct and efficient link to and through the groundwater, and pathogens may reach the groundwater in as little as a few minutes or hours after release (102) with little loss in number from removal or inactivation.

Pathogen survival depends upon the characteristics of the soil, including moisture content, moisture-holding capacity, temperature, pH, and amount of organic matter (100). At the soil surface, sunlight reduces survival. The fate and transport of a particular species may be strain-specific. A factor in pathogen survival is the level and activity of the indigenous subsurface flora. Indigenous organisms, fully adapted to their environment, will normally outcompete the enteric pathogens for nutrients (103) and inactivate them with their toxins. The predominant group of soil bacteria is the gram-negative rods, especially the pseudomonads and flavobacteria. However, gram-positive rods and cocci are also common (104). Protozoa that graze on bacteria will thrive at fecally contaminated sites (104). Fungi and even algae are common in shallow groundwaters with sufficient oxygen (105), and may also compete with the enteric pathogens for nutrients. Because a pumped well draws in both aerobic and anaerobic waters, some strict anaerobes such as *Clostridium* and the methanogens may also be present in well water, although their effect on enteric pathogens in the water is not known.

With these inhibitions, it is unlikely that more than a small fraction of the original enteric pathogen densities would reach the well unless a rapid channel existed. Despite this, most documented waterborne disease outbreaks in the United States each year are associated with groundwater systems. Between 1971 and 1998, 59% of the 661 reported outbreaks, with more than 93,000 cases of illness, were associated with such systems (106,10,11). The actual incidence of waterborne disease is undoubtedly much higher than those documented.

INDICATORS OF SOURCE WATER QUALITY

A number of tools have been used to assess the quality of freshwaters, including source waters used by drinking water systems. Oxygen consumption is used in several ways to measure pollution in natural waters and wastewaters. Biochemical oxygen demand (BOD) is a measure of the biodegradable organics in water, chemical oxygen demand (COD) is the amount of an oxidant such as dichromate that reacts with the water sample, total oxygen demand (TOD) is a measure of the amount of oxygen required to completely oxidize all material in a sample, and dissolved oxygen (DO) is exactly that. The total organic carbon (TOC) and assimilable organic carbon (AOC) are also measures of pollutants in water, although the AOC is used primarily to assess the potential for biofilm growth in the pipes of the distribution system. Microbial types and diversity are also used to characterize water quality. For example, certain algae are associated with clean waters, other algae with polluted waters. Toxicity testing of freshwater using ciliates, mollusks, larvae, and many other organisms indigenous to the water is also a common procedure to assess water quality. Turbidity (opacity) is also used as an indicator of source water quality (107,108).

For groundwaters, the microscopic particulate analysis (MPA) is often used as an indicator of surface pollution. The MPA involves direct microscopic examination of material normally associated with the surface, such as diatoms, insect parts, plant debris, pollen, crustaceans, *Giardia lamblia* cysts and *Cryptosporidium parvum* oocysts (95).

To determine the potential public health risk associated with a source water, one could monitor pathogens directly. However, this is impractical because the variety of potential waterborne pathogens makes a search for all pathogens extremely difficult, time-consuming, and expensive. Moreover, a number of methodological problems exist, including the large sample volume often needed to recover a pathogen, the low efficiency of current techniques for recovering and detecting known waterborne pathogens in water, the lack of suitable culture media for

many pathogens, and the sparsity of laboratories with trained technicians needed to carry out the analyses.

Because of the problems with trying to detect specific enteric pathogens, indicators of fecal contamination are used instead of pathogens as indices of the potential health risk associated with source water. The presumption is that enteric pathogens, whose normal habitat is the gastrointestinal tract of warm-blooded animals, are always associated with fecal contamination. Thus, in theory, the absence of fecal contamination denotes the absence of enteric pathogens. An ideal indicator of fecal contamination in source waters (surface or ground waters) should possess the following characteristics.

- Always present in fecally contaminated water
- Always absent in water that is not fecally contaminated
- Present at a density related to the level of fecal contamination
- Present in polluted waters at much higher densities than fecal pathogens
- Suitable for all types of source water, both ground and surface
- Does not reproduce in water
- Rapid detection by simple, inexpensive, and reliable laboratory tests
- Stable and nonpathogenic

Extensive literature reviews of indicators in source waters have been published (103,109–112). The most widely used microbial indicators of fecal contamination are *E. coli*, fecal coliforms, fecal streptococci, and enterococci. These and several others used less frequently are discussed next. The densities of several indicators in human and animal feces are presented in Table 4.

Escherichia coli

Escherichia coli is common in the intestines of all warm-blooded animals, but does not normally survive for long in water. However, several studies have suggested that this bacterium can grow in waters in tropical and semitropical areas (120–123). *E. coli* is a member of both the fecal coliform group and the total coliform group (these two groups are defined next). Recent reports suggest that antibiotic resistance patterns and DNA fingerprinting may be useful in distinguishing among animal and human sources in fecally contaminated waters (124).

Fecal Coliforms

Fecal coliforms are members of the coliform group that can ferment lactose at 44°–45°C. The majority are *E. coli*, although some *Klebsiella* strains and more rarely *Enterobacter* strains are also fecal coliform-positive (123,125). One objection to the use of this group as a fecal indicator is that *Klebsiella* can proliferate outside a living host and are especially common in wastewaters from paper plants. However, clinical strains of *Klebsiella* are more likely to be fecal coliform-positive than environmental strains (85% vs. 16%) (126). Some fish, snakes, insects, and vegetation harbor fecal coliforms in low numbers (125,127). Fecal coliforms are a subset of the total coliform group.

Total Coliforms

Total coliforms are a group of related bacteria in the family *Enterobacteriaceae*. The group is not defined in precise

Table 4. Fecal Indicators: Density in Animal Feces (per *gram* × 1, 000)[a,b,c]

Animal	Fecal Coliforms	Fecal Streptococci	*C. perfringens*	*Bacteroides*	Male-specific Coliphage	Somatic Coliphage
Farm animals						
Cow	230	1,300	0.2	<0.001	0.084	400–22,000
Pig	3,300	84,000	4	500	4.137	3,400
Sheep	16,000	38,000	199	<0.001	0.0015	3,000
Horse	12.6	6,300	<0.001	<0.001	0.950	22
Duck	33,000	54,000	–	–	0.0131	–
Chicken	1,300	3,400	0.25	<0.001	1.867	11,000
Turkey	290	2,800	–	–	–	–
Pets						
Cat	7,900	27,000	25,100	795,000	–	–
Dog	23,000	980,000	251,000	500,000	0.0021	41
Wild animals						
Mouse	330	7,700	<0.001	795,000		–
Rabbit	0.020	47	<0.001	396,000		–
Chipmunk	148	6,000	–	–		–
Human[d]	13,000 (100%)	3,000 (100%)	1.6 (25–35%)	5,000,000 (100%?)	<0.01 (<10%)	<0.1–100 (23–77%)

[a] i.e., multiply the above values by 1,000.
[b] Adapted from Refs. 109–115.
[c] Considerable variation in the values have been reported among investigators in the literature.
[d] Values in parentheses in the "human" row are the percentages of healthy adults not on antibiotics that carry the specified fecal indicators in their gut (bacteria from Ref. 116, viruses from Refs. 115, 117–119).

taxonomic terms, but by whether they produce the enzyme β-galactosidase, which allows lactose metabolism. Total coliforms include most species of the genera *Enterobacter*, *Klebsiella*, *Citrobacter*, and *Escherichia*, as well as some species of *Serratia* and other genera. Total coliforms are not often used as a source water quality indicator because most species are natural and common inhabitants of the soil and ambient waters (e.g., lakes, rivers, and estuaries) as well as the gastrointestinal tract. However, they are useful as a drinking water indicator for assessing water treatment efficiency and for denoting possible breaches of distribution system integrity.

Fecal Streptococci/Enterococci

Fecal streptococci are members of the genus *Streptococcus* that are Lancefield Group D (one of several immunological groups based on the presence of specific carbohydrate antigens). Their normal habitat is the gastrointestinal tract of warm-blooded animals (107). The enterococci group (genus *Enterococcus*) is a subset of the fecal streptococci group that is able to grow in a medium containing 6.5% sodium chloride at pH 9.6 at both 10 °C and 45 °C (107). The two groups are almost identical, but the fecal streptococci group includes *S. bovis* and *S. equinus*, neither of which are enterococci (107). Preliminary evidence suggests that antibiotic resistance patterns in fecal streptococci can be used to determine the animal source of fecal contamination in water (128). Recent reports suggest that antibiotic resistance patterns, restriction enzyme analysis of chromosomal DNA, and species identification may be useful in distinguishing among animal and human sources in fecally contaminated waters (128–131). Data suggest that the fecal streptococci or enterococci groups do not proliferate to any extent in the environment, although they may be found occasionally on plants, probably as a result of insects (121,125,131).

Coliphage

Coliphage are viruses that infect *E. coli*, although a few may infect other bacteria (132). There are two major groups of coliphages: somatic and male-specific (also called F-specific). The somatic coliphages are a heterogenous group that enter the cell wall of *E. coli*. The male-specific coliphages are those that only enter tiny hair-like appendages (pili) found on some *E. coli*. Both groups have been found in ambient waters (133,134) and groundwaters (135). Subgrouping the male-specific RNA coliphages by serological and physicochemical properties helps distinguish among animal sources in fecally contaminated waters (136).

Clostridium perfringens

Clostridium perfringens is a bacterium that is consistently associated with human fecal wastes (137). The organism is a strict anaerobe that forms an endospore that is highly resistant to environmental stresses. Some question exists about the extent to which *C. perfringens* proliferates in the environment (123), perhaps because of its persistence in soil. The organism may be a more useful fecal indicator in raw surface waters (138–140) than in groundwater (141). Europeans use a somewhat broader indicator, the sulfite-reducing clostridia, the most common of which is *C. perfringens* (142).

NONMICROBIAL INDICATORS OF FECAL CONTAMINATION

Chemical substances such fecal sterols, caffeine, metals, and nitrate have also been proposed as fecal indicators. Fecal sterols have generated the most attention, and data suggest that it may be possible to differentiate human fecal contamination from that of herbivores by comparing the level of coprostanol, the principal human fecal sterol, with that of 24-ethylcoprostanol, which is most common in herbivores (143).

LAWS AND REGULATIONS PROTECTING DRINKING WATER SOURCES

The European Union requires secondary or equivalent treatment, before discharge, for urban wastewater that enters a collection system (EU document 391L0271). The requirement is less stringent for some wastewater facilities in high mountain regions where cold temperatures undermine biological treatment. The treatment standard is more stringent where wastewater is discharged into a sensitive water body, including those used by drinking water systems because a high nitrate concentration is of concern. To verify compliance, the wastewater facility must monitor BOD, and, for a sensitive water body, total phosphorus and/or total nitrogen in the wastewater discharge.

The World Health Organization (WHO) is currently preparing microbiology guidelines for the quality of recreational waters. Guideline values for coastal waters are to be based on the density of fecal streptococci (144). However, according to WHO (144), insufficient epidemiology information is available for deriving a separate guideline value for freshwater. Also, WHO has not established guideline values for wastewater discharge into water bodies.

In the Unites States, Congress has passed several environmental laws that affect discharges into ambient water or groundwater. The two key laws, with respect to the protection of drinking water sources, are the Safe Drinking Water Act (42 U.S.C 300f to 330j-26) and the Clean Water Act (33 U.S.C. 1251 to 1387). These two laws require the United States Environmental Protection Agency (EPA) to develop and implement regulations and programs that, among other provisions, protect waters used by drinking water systems. These regulations and programs are briefly described next.

Safe Drinking Water Act (SDWA)

The objective of the SDWA is to protect drinking water supplies from biological, chemical, and physical contamination. One SDWA provision (Section 1453) requires each State to develop and implement an EPA-approved source

water assessment program (SWAP) to determine the susceptibility of each public water system to potential threats of contamination from the source water. A public water system is one that regularly serves at least 25 people at least 60 days per year or has at least 15 service connections.

Another SDWA provision (Part C) requires EPA to regulate underground injection practices that may endanger drinking water sources. These practices involve the disposal of fluids into injection wells. Class V wells are the only type that pose a potential public health threat to groundwater systems and include large-capacity septic tanks, leach fields and cesspools associated solely with sanitary wastewater disposal. Currently, EPA regulations on Class V wells ban the use of large-capacity cesspools (used by 20 or more people) in which the waste has not received primary treatment.

As required by a third SDWA provision (Section 1412), EPA has published and subsequently strengthened a drinking water regulation that controls the levels of *Cryptosporidium*, *Giardia*, and viruses in drinking water systems that use surface water or groundwaters under the direct influence of surface water. Under this regulation (known as the Surface Water Treatment Rule), such a system must filter its source water unless the system can demonstrate that the source water is not subject to significant fecal contamination. Among the requirements for avoiding filtration, the system must collect source water samples one to five times per week, depending on the number of people served, and determine the density of either total coliforms or fecal coliforms. To avoid filtration, the source water must contain no greater than 100 total coliforms/100 mL or 20 fecal coliforms/100 mL. Also, the turbidity may not exceed 5 Nephelometric Units.

Clean Water Act (CWA)

The objective of the CWA is to restore and maintain the chemical, physical, and biological integrity of the Nation's waters. Under the CWA, a state must develop water quality standards for all surface waters, including wetlands, within its boundaries. A state water quality standard for a particular water body must (*1*) designate a beneficial use(s) for the water body (or for a segment of the water body), (*2*) identify the water quality criteria necessary to meet the designated use, and (*3*) protect existing uses and prevent the degradation of water quality. Types of designated beneficial uses include source waters for a drinking water supply, swimming and other recreational activities, shellfish harvesting, agriculture, industrial processes, and protection and propagation of desirable fish, shellfish, and wildlife.

EPA has not set mandatory microbial limits for any of these designated uses. However, EPA recommends that states use the following limits for primary contact recreational waters (i.e., swimming waters): for freshwaters, 126/100 mL *E. coli* or 33/100 mL enterococci; for marine waters, 35/100 mL enterococci. Many states use EPA's dated fecal coliforms (FC) criteria for such waters (a running geometric mean of 200 fecal coliforms/100 mL with no more than 10% of samples exceeding 400 fecal coliforms/100 mL). For shellfish growing waters the Food and Drug Administration recommends several fecal coliform limits (145); in the United States such limits have minimal affect on drinking water sources since few freshwater commercial shellfish harvesting areas exist.

As part of the state's program for implementing water quality standards, the state must issue permits for all point sources of pollution that discharge into water bodies. If the state determines that a water body fails to meet a water quality standard, it must establish a total maximum daily load for the specific pollutant(s) that causes the impairment. To meet this load limit, a state may prescribe a more stringent permit for a point source that discharges this specific pollutant(s) into the water body. For example, a discharge permit typically would require a wastewater treatment facility to practice secondary sewage treatment. However, for an impaired water body, the state may also set a maximum limit for the density of fecal coliforms, *E. coli*, or enterococci in secondary-treated sewage.

The implementation of state water quality standards should protect drinking water sources by minimizing the degradation of, and possibly even improving, the quality of surface waters used by drinking water systems.

CONCLUSION

Drinking water in developed countries is normally safe. Yet in the glow of technological wizardry that presently mesmerizes our society, we must not be lulled into a false complacency that our water systems are infallible. Over the course of the last century, developed countries have seen a dramatic decrease in waterborne diseases, especially in serious diseases. Yet we must not assume that lack of detection necessarily signifies its absence. Our institutional capability for recognizing a waterborne disease outbreak, much less the normal background (endemic) levels of waterborne disease, is poor. Even after an investigation of a documented outbreak, the source of the causative agent often remains speculative. Entry of pathogens into the distribution system can be insidious. And often, seemingly innocuous microbes are either later found to be pathogenic or evolve into pathogens by the incorporation of plasmids or by some other change in their genetic material.

To safeguard against this threat, we must rely on a multibarrier approach for the control of pathogens: protection of the source waters, provision of adequate and reliable water treatment, and protection of the integrity of the distribution system. Source water protection assumes proper control of point and nonpoint discharges into the water. The quality of source water can change quickly. A heavy rain will wash fecal contamination from the land into the water body or downward into the groundwater. The contamination load can be especially acute when a heavy rain occurs after a prolonged drought. Yet a healthy appreciation by drinking water system managers for the limits of mechanical and chemical processes and the extent of human fallibility will go a long way in guarding against any eventuality that might pose a serious health risk.

SPA AND HOT TUB MICROBIOLOGY

MIC H. STEWART
Metropolitan Water District of Southern California
Los Angeles, California

Historically, the practice of bathing in hot water has been practiced by many cultures since ancient times. Bathing in mineral and thermal water can be traced back to as early as 500 B.C. in Greece (1). Greek baths, frequently located near volcanoes, were extremely popular and were considered useful in the cure of physical ailments. The word "spa" originally derived from the name of a town located in eastern Belgium, which at the time was part of the Roman Empire (1). The therapeutic qualities of mineral baths located in this city became popular with the Romans, who eventually constructed elaborate public baths throughout their empire. Native American communities, including the Mohawks, Pawnees, and Lakotas, were also reported to have used heated mineral springs (1).

In the 1700s, physicians sent patients to resorts built around natural hot springs with bubbling mineral water. The physicians believed that bathing in or even consuming mineral water imparted medicinal advantages to their patients, including cures for rheumatism, skin infections, and poor digestion. Indeed, bathing in water that ranges from 98 to 112 °F (37 to 44 °C) is known to relax muscles, enlarge blood vessels near the surface of the skin, and improve circulation (2).

Over the past 30 years, spas have become extremely popular in the United States for relaxation and pleasure. The term "hot tubs" is sometimes used synonymously with "spas." Spas are similar to hot tubs except that they are constructed of plastic, concrete, or metal, whereas hot tubs have generally been constructed of wood. Moreover, spas are equipped with air jets, but many hot tubs are not (3).

Finally, it is important to distinguish whirlpool baths from either spas or hot tubs. Whirlpool baths are essentially bathtubs with water jets; they are commonly located in bathrooms, are drained after each use, and typically do not have separate heating devices.

OPERATIONAL PARAMETERS OF SPAS AND HOT TUBS

Hot tub or spa capacity varies considerably. The models found at public or commercial facilities, of course, typically accommodate greater numbers of people than do those in use at private homes. Resort spas developed from natural mineral springs are often the size of swimming pools. The temperature settings of spas vary according to preference, typically ranging up to 108 °F (4). However, professional trade associations, such as the National Spa and Pool Institute, as well as most operators of public hot tubs and

spas, recommend 104 °F as the maximum temperature. The water may be agitated by high-velocity pumps that can be adjusted to maximize bubbling. Water is recirculated for filtration and heating purposes.

Filtration is achieved by diatomaceous earth (DE), sand, or cartridge filters. DE and sand filters — referred to as granular filters — require backwashing to maintain proper performance and to minimize colonization of microorganisms (3). Cartridge filters are not backwashed, but they must be routinely serviced to ensure sanitary conditions and proper performance.

Disinfection is typically accomplished by chlorine- or bromine-based compounds (3,5). Chlorine is commonly applied as sodium hypochlorite or lithium hypochlorite, at concentrations ranging from 2 to 4 mg/L (as free chlorine). Chlorine gas can be used to produce the desired residual, but this is more commonly performed at commercial-size facilities. Levels of chlorine can dissipate rapidly, depending on bather loading, and frequent monitoring is required. Deposition of organic material from the bathers can build up a substrate for microbial growth and may form chloramines, limiting the effectiveness of chlorine as a disinfectant (6).

Manufacturers and health agencies recommend "shock dosing" (i.e., adding high levels of chlorine) to oxidize accumulated organic matter. If a chlorine residual of 0.5 mg/L cannot be achieved after shock dosing, it is recommended that the water be replaced (5). Bromine is also used as a disinfectant, but it must be applied at levels twice that of chlorine to achieve the same results. Bromine can be added as either sodium or potassium bromide in conjunction with sodium hypochlorite or potassium persulfate (1-bromo-3-chloro-4,4-dimethylhydantoin [BCDMH]).

Although ozone is known to be an effective disinfectant, it does not produce a stable residual and consequently must be supplemented with a secondary disinfectant, such as chlorine or bromine, when used in spas. Ozone is applied "off-pool" during the circulation process to enhance maximum mixing. Ultraviolet (UV) light is also used for spa disinfection, but, like ozone, it must be applied in an "off-pool" manner. UV light does not produce a residual and is commonly supplemented with hydrogen peroxide as part of the disinfection process. The concentration of free hydrogen peroxide in the spa should be at least 40 mg/L (5).

Table 1. Concentration of Enteric Pathogens Excreted by Infected Individuals

Organism	Concentration in Feces (per gram)	Reference Source
Giardia	$1 \text{ to } 5 \times 10^6$	10
Cryptosporidium	10^6 to 10^7	11
Poliovirus	10^2 to $10^{6.5}$	12
Coxsackie and echovirus	10^2 to $10^{7.2}$	12
Hepatitis A	10^8	13
Rotavirus	10^{10} to 10^{12}	14
Salmonella	10^{10}	15
Shigella	10^5 to 10^9	15

MICROBIAL LOADING IN HOT TUB AND SPA WATER

Microorganisms may be added to the spa indirectly, as a result of the shedding of organisms from the skin surfaces of bathers in the spa, or directly, from accidental fecal releases. Early studies by Hanes and Fossa (7) indicated that coliform release by bathers reached maximum levels within 15 minutes. Further work by Rose and Gerba (8) suggests that coliforms released by children aged 18 months to 9 years (10^5 to 10^6 coliforms per 100 mL) were much higher than those from adults (10^1 to 10^2 coliforms per 100 mL). Based on these observations, it has been estimated that the average amount of fecal material released during bathing in recreational waters is 0.14 g per person, with a worse case of 10 g (9). The amount of pathogens associated with this fecal material varies appreciably and is dependent on the infection status, age, and personal hygiene practices of the individual. Table 1 (10–15) summarizes concentrations of pathogens excreted by infected individuals. *Giardia* and *Cryptosporidium* concentrations can range from 10^6 to 10^7 per gram of feces, whereas viral pathogens, such as rotavirus, can be as high as 10^{12} per gram.

Studies directly assessing the release of pathogens by recreators are limited. Rose and coworkers (16), however, did evaluate enterovirus and rotavirus levels associated with bather activity in a small creek. In samples collected downstream from the recreators, these researchers noted that the average levels of enterovirus and rotavirus were 0.045 and 0.67 per 100 L, respectively, per individual. Given the inefficiency of virus detection methodology and the fact that the water was collected under flowing stream conditions, it is reasonable to assume that these values are far lower than the true values for what was actually excreted.

Although most studies focus on indirect pathogen loading associated with fecal material in the perineum area, it is important to note that fecal releases can contribute to significant pathogen loading of recreational waters. Bell and colleagues (17) reported that fecal releases do occur during recreational bathing activity, resulting in numerous outbreaks of disease. It has been calculated that such activity can result in the dissemination of up to 10^{14} enteric pathogens into the water column (9). Collectively, this information can be used to estimate pathogen loading under various recreational scenarios, including use of spas or hot tubs.

WATERBORNE ILLNESS ASSOCIATED WITH SPAS AND HOT TUBS

Spas may contain a wide range of microorganisms, including algae, protozoa, bacteria, viruses, fungi, and yeasts (5). Table 2 (18) lists human pathogens that may be present in aquatic environments as a result of human activity. Although the individuals using the spa introduce most of these organisms, some may also be introduced from the source water used to fill the spa or from contamination by surrounding environmental sources. Illnesses associated with spa usage include those caused by bacterial, viral, and protozoan organisms,

Table 2. Human Pathogens That May Be Present in Water as a Result of Human Contact

Virus	Bacteria	Protozoa
Adenovirus	*Salmonella*	*Entamoeba histolytica*
Astrovirus	*Shigella*	*Giardia lamblia*
Calicivirus	Enteropathogenic *E. coli*	*Balantidium coli*
Coronavirus	*Yersinia enterocolitica*	*Cryptosporidium*
Enteroviruses	*Campylobacter*	
Poliovirus	*Vibio cholerae*	
Coxsackie A, B	*Leptospira*	
Echovirus		
Hepatitis A, E		
Norwalk		
Reovirus		
Rotavirus		
Small round viruses

such as *Pseudomonas aeruginosa*, *Pseudomonas cepacia*, *Mycobacterium marinum*, *Legionella*, *Klebsiella*, *Yersinia*, *Acanthamoeba*, *Giardia*, *Cryptosporidium*, and papilloma viruses (5). Other pathogens that may be transmitted from one person to another via spa or hot tub usage include *Naegleria fowleri*, *Escherichia coli*, *Staphylococcus* species, *Streptococcus* species, *Salmonella*, and enteroviruses (5).

Skin diseases (folliculitis) are probably the most common ailments reported following hot tub use (6). Indeed, the term "hot tub burns" — commonly used in the hot tub and spa industry to describe skin rashes caused by the bacterium *Pseudomonas aeruginosa* — was first recognized in the 1970s (6). Zacherle and Silver (19) noted that with increasing use of hot tubs, there was a concomitant increase in cases of a distinct clinical syndrome appearing several hours or days after hot tub exposure. The syndrome consisted of a maculovesicular, often pruritic, rash, commonly associated with symptoms that included fever, upper respiratory tract complaints, axial adenopathy, and breast tenderness. Culturing of pustules from a patient with this syndrome revealed *P. aeruginosa*. The authors noted that serotypes of this organism are known to produce exotoxins that may be responsible for the folliculitis. In particular, serotype 0 : 11 has been isolated from patients' lesions and from whirlpool water in previous folliculitis outbreaks (20–22).

In a review of whirlpool-associated cases of folliculitis, Berger and Seifert (6) noted that the prevalence of *P. aeruginosa* suggests that this organism has developed a tolerance to relatively high temperatures and high levels of chlorine. They also pointed out that serotype 0 : 9 is a concern in folliculitis cases. These authors suggested three primary environmental conditions known to be associated with outbreaks of folliculitis: prolonged exposure to the water, excessive numbers of bathers, and inadequate pool care. Elevated temperatures, coupled with entry via hair follicles or breaks in the skin, were considered key factors in *P. aeruginosa* infection. In addition to causing folliculitis, *P. aeruginosa* was also implicated as the causative agent in four cases of severe hemorrhagic external otitis in a group of university students following hot tub exposure (4). In this episode, among 24 members of a university coeducational fraternity who used a hot tub, two had simple dermatitis, and four developed severe external otitis. Follow-up inspection and culturing of the hot tub revealed the presence of *P. aeruginosa* serotype 0 : 10. Two previous cases of pool-associated *P. aeruginosa* otitis were cited in the present study (20,21). In 1997 and 1998, more than 75 cases of *P. aeruginosa* dermatitis and otitis externa were reported with swimming pool and hot tub use, and from 1999 to 2000, 28 additional cases were described (23). These recent outbreaks were largely attributed to inadequate disinfection procedures (See PSEUDOMONAS, this Encyclopedia.).

Legionella infections have also been associated with hot tub usage. A compilation of these reports can be found on-line at:

http://www.q-net.net.au/~legion/Legionnaires_Disease_Spas_Hot_Tubs.htm

This site also summarizes several reports on spa-contracted folliculitis caused by *P. aeruginosa.* Miller and associates (24) reported that 34 resort guests experienced an illness that met a symptom-based case definition of Pontiac fever. Each of the ill guests either had used the indoor hot tub or had been within 3 m of it. Samples collected from the hot tub were positive for *Legionella pneumophilia* serogroup 6. Testing of convalescent-phase serum indicated that 64% of the ill guests had a fourfold or greater rise in antibody titer against *L. pneumophilia* serogroup 6. Maintenance records for the hot tub indicated that the temperature during the incident ranged from 38.9 to 40 °C, with a free bromine residual of 2 to 3 mg/L. This incident suggested that even properly operated hot tubs could be responsible for transmission of *Legionella*. Moreover, because of the aerosol produced by the hot tubs, even those in close proximity were found to have significant exposure to this organism.

Guerrero and coworkers (25) reported that 14 passengers contracted Legionnaires' disease through use of whirlpool water baths aboard a cruise ship. Cultures taken from a sand filter used in recirculation of the whirlpool water were positive for the presence of the same *L. pneumophilia* species (based on monoclonal antibody subtyping patterns) as found in clinical samples taken from the patients. In Virginia, 23 cases of Legionnaires' disease, resulting in two fatalities, were reported among customers visiting a large home-improvement center (26). Investigation of this outbreak indicated that these customers were in close proximity to a hot tub display, which illustrates the importance of aerosolization in transmission of these organisms. Testing of the hot tub filters revealed *L. pneumophilia* serotype 01 isolates that were identical to those obtained from the sputum of the patients. Miyamoto and coworkers (27) reported isolating *L. pneumophilia* serogroup 3 from a patient who had nearly drowned in a hot spring spa. Molecular-based testing revealed that the organism was associated with this spa. Significantly, this report also noted that in a survey of 135 hot springs in Japan, 62% were positive for the presence of legionellae.

Embil and associates (28) reported five cases of pulmonary illness associated with exposure to *Mycobacterium avium* complex in hot tub water. In this study, five healthy people developed respiratory illnesses characterized by bronchitis, fever, and "flulike" symptoms after using a hot tub. Sputum and lung biopsy samples collected from the patients, as well as water samples collected from the hot tub, were all positive for the presence of *M. avium* complex. The authors noted the ubiquitous nature of *Mycobacterium* in aquatic environments, aerosolization conditions in the hot tub, and resistance to disinfectants as predisposing conditions for contracting this illness. (see *MYCOBACTERIUM AVIUM* COMPLEX, this Encyclopedia.)

Nerurkar and coworkers (29) reported on the transmission of herpes simplex virus (HSV) in commercial spas in the Washington, D.C., area. Several of these businesses were closed when a large number of clients reported contracting genital HSV infections following use of the facilities. Water samples were collected from two of these health spas and examined for the presence of HSV; however, no HSV was recovered from the samples. Additional studies were conducted to assess the survival characteristics of HSV on plastic-coated benches and seats in spa facilities. It was noted that HSV could survive for up to 4.5 hours on these surfaces. The authors concluded that survival of HSV on plastic surfaces commonly associated with spas could be a factor in the nonvenereal spread of this virus.

Tallis and Gregory (30) reported an outbreak of hepatitis A associated with a spa. In this episode, six males (ages 8 to 15 years) contracted hepatitis A after recreating in a spa. Investigation of the case indicated that the infected individuals had been spitting mouthfuls of water at each other. The authors concluded that the infection was probably caused by the shedding of an infective individual, with subsequent ingestion by others using the spa. The spa was customarily disinfected with hydrogen peroxide and UV light. The investigators suggested that this disinfection protocol may not have been adequate to control the virus, as previous evaluations of hydrogen peroxide and UV light disinfection in Victoria had shown poor results.

Samples and colleagues (31) reported an instance of *Acanthamoeba keratitis* associated with the use of a hot tub. In this study, a 42-year-old man developed a severe case of optical keratitis. Samples from the subject's hot tub and from his eye revealed the presence of *Acanthamoeba castellani*. This organism was also isolated from the surrounding garden soil. The authors noted that amoebae can commonly be isolated from aquatic environments, including swimming pools, and have been shown to grow well in temperatures up to 36 °C. Indeed, the authors cited a report from northern Bohemia indicating that 16 fatal cases of primary amoebic meningoencephalitis were associated with recreation in a swimming pool. Although *Naegleria fowleri* was noted to be the agent responsible for the fatalities in this outbreak, several species of *Acanthamoeba* were also recovered from the swimming pool water. In the current study, the authors suggested that infection by *A. castellani* could be a public health concern and that further studies would be needed to establish the prevalence of this organism in hot tubs.

MICROBIAL PERSISTENCE IN AQUATIC ENVIRONMENTS

Elevated temperatures, filtration, and disinfectants are used to control microorganisms in spas and hot tubs. Disinfectants are probably the single most important factor in controlling contact with pathogenic microorganisms. Many investigators have reported that microorganisms may persist in aquatic environments in spite of the presence of a disinfectant agent (32–35).

Microbial resistance to disinfectants may be a function of: (*1*) the presence of physical or chemical agents that impair the ability of the disinfectant to inactivate the organism, (*2*) the presence of particulate matter that can provide physical protection from disinfection, and (*3*) association with nematodes or other vectors (e.g., amoebae) that can provide a physical barrier from the disinfectant (36). Microbial resistance to disinfectants may also result from factors that can be classified as cell-mediated processes. This form of resistance is physiological in nature and is based on the organism's ability to develop adaptive cellular features to survive under adverse environmental conditions. Examples of cell-mediated processes include polymer or capsule production, which may act to limit the penetration of disinfectant agents into the cell; cellular aggregation, which provides physical protection for internal organisms; and alteration of the cell envelope structures, which restricts the entrance of disinfectants into the cell (36). It is important to note that organic loading from bathers, high water temperatures, and aeration and agitation of the water can quickly deplete disinfectant residuals in the spa (4,6).

Microbial attachment to particulate material (e.g., organic compounds, plankton, microscopic organisms) has been observed to aid in survival against disinfectant agents (37). Under optimal chemical and physical conditions, maximum disinfectant efficiency is achieved when the disinfectant agent has unhindered access to the target organism. Particulate matter may interfere with this process, either by creating a disinfectant demand — thus neutralizing the action of the disinfectant — or by physically shielding the organisms from the disinfectant (38). Disinfectant protection is enhanced with decreasing organism size and increasing particle volume (39). Herson and associates (40) demonstrated that attachment of bacteria to particulate material aided survival in the presence of chlorine. These authors noted that levels of bacteria were higher in relation to increased turbidity. Scanning electron micrographs revealed the presence of particles colonized by bacteria.

The introduction of bacteria into potable water systems by nematodes or crustaceans was studied as early as 1911 by Hoerhammer (41), who found that the crustacean *Cyclops* could ingest large quantities of *Salmonella* and thus act as a reservoir for this pathogen. Chang and coworkers (42) observed that pathogenic bacteria and viruses ingested by nematodes were protected from high levels of chlorine (e.g., 80 to 90 mg/L). King and colleagues (43) found that coliforms as well as bacterial pathogens (*Salmonella*, *Yersinia*, *Shigella*, *Legionella*, *Camplyobacter*), when contained in either *A. castellanii*

or *Tetrahymena pyriformis*, were more resistant (e.g., 30- to 120-fold) to chlorine disinfection. Rowbotham (44) indicated that amoebae of the genera *Acanthamoeba* and *Naegleria* could harbor legionellae and act as infectious reservoirs for this organism. Kilvington and Price (45) observed that viable *Legionella* could be recovered from *Acanthamoeba polyphaga* exposed to 50 mg/L chlorine. Clearly, the presence of amoebae in aquatic environments may be a significant factor in *Legionella*-associated illnesses contracted in spas.

Many bacterial species are capable of producing an external layer composed predominantly of polysaccharides and, to a lesser extent, polypeptides or polysaccharide-protein complexes (46). Such a structure, commonly referred to as the *capsule* or *slime* layer, provides nutrient storage, protection from phagocytosis, and adhesion to surfaces to enhance survival in the environment (47,48). Several groups of investigators have indicated that bacteria associated with biofilms and capable of producing capsules are more resistant to disinfection. LeChevallier and coworkers (49) evaluated the role of biofilm formation (*Pseudomonas pickettii*, *Moraxella*, and *Pseudomonas pacumobilis*) in promoting resistance to chlorine, chloramines, and chlorine dioxide. They observed that resistance to chlorine or chlorine dioxide increased 150- to 3,000-fold compared to the resistance of unattached cells; resistance to chloramines, however, increased only twofold. Seyfried and Fraser (50) also noted that isolates of *P. aeruginosa* from swimming pools with chlorine residuals of 1.5 mg/L had more extensive capsule layers than those isolated under lower chlorine concentrations (0.4 mg/L), suggesting that this structure conferred enhanced resistance to disinfectants. It has been reported that such microorganisms as *Legionella* and *P. aeruginosa* have colonized filter material used for spas and hot tubs (5). This colonization, and the subsequent resistance to disinfection, was most likely facilitated by production of capsular material and formation of a biofilm layer. Moreover, Broadbent (5) reported that this situation has led to fatal cases of Legionnaires' disease.

Many investigators have studied antecedent growth conditions in relation to enhanced disinfection resistance (36). Favero and Drake (32) reported the isolation of *Staphylococcus*, *Streptococcus*, *Pseudomonas*, and *Alcaligenes* from swimming pools disinfected with chlorine and iodine. They observed that growth in swimming pool water conferred 10 times more resistance to iodine than did growth in trypticase soy broth.

Pyle and McFeters (51) noted that *P. aeruginosa* grown under low-nutrient conditions resulted in greater resistance to iodine disinfection. Cargill and coworkers (52) observed that growth under low-nutrient conditions increased the resistance of *L. pneumophilia* to iodine. The Cargill study concluded that the increased resistance resulted from possible increased aggregation, protective extracellular material, and/or other physiological changes under low-nutrient conditions. Stewart and Olson (53) observed that the resistance of *Klebsiella pneumoniae* to chloramines was increased when cells were grown under low-nutrient conditions. They attributed this enhanced resistance to (*1*) increased aggregation, (*2*) increased capsule material, and (*3*) changes in the cellular envelope structure.

The typical spa or hot tub environment, characterized by low-nutrient conditions, may foster development of the protective mechanisms that assist microorganisms to survive in the presence of the disinfectant agents most commonly used in spas and hot tubs. Frequent reports of *P. aeruginosa*-related folliculitis suggest that these organisms, in particular, have indeed developed survival mechanisms.

HEALTH GUIDELINES FOR SPAS AND HOT TUBS

Proper maintenance of spas and hot tubs is essential in the control of microbial disease. Specific microbial standards and monitoring frequencies for public spas and hot tubs vary with local and state regulatory agencies. South Australia's National Environmental Health Forum has published a guideline on water quality for heated spas (5). This document provides specific recommendations for disinfection, water chemistry, and general operation of spa pools. Monitoring recommendations for microbial agents contained in this publication include heterotrophic-plate-count bacteria, less than 1 in 100 mL; *P. aeruginosa*, not detected in 100 mL; *Legionella*, not detected in 1,000 mL; and pathogenic amoebae, not detected in 1,000 mL. This organization also recommends chlorine residuals of at least 2 to 4 mg/L. The U.S. Centers for Disease Control and Prevention (CDC) recommend a free residual of 3 mg/L for chlorine and 4 mg/L for bromine (54).

General recommendations to reduce microbial illness associated with spas and hot tubs (55) include the following:

- Adhere to pool and hot tub recommendations and regulatory requirements for pH and disinfectant levels.
- Have a thorough knowledge of basic aquatic facility operation.
- Provide training for maintenance staff on system capabilities, maintenance, and emergency monitoring systems.
- Monitor pool and hot tub disinfectant residuals frequently, especially during periods of heavy bather loading.
- Understand appropriate use of cyanurates in disinfection and testing.

Additional detailed information on guidelines for proper operation of spas and hot tubs can be obtained on-line from the National Spa and Pool Institute (*www.nspi.org*), from the CDC (*www.cdc.gov*), or from various local and state public health agency websites. Comprehensive reviews by Broadbent (5) and Freije (3) also provide excellent information on this topic.

CONCLUSION

Hot tubs and spas have become a popular means of recreation. Indeed, it has been reported that over a

million Americans have purchased spas and hot tubs since 1990 (56). Human contact with aquatic environments can clearly introduce pathogenic and nonpathogenic microorganisms, including bacterial, viral, and protozoan parasites. The concentration and persistence of these organisms in spas and hot tubs, as discussed in this current review, are subject to a number of complex factors. When spas and hot tubs are properly operated and maintained, the associated incidence of microbial illnesses is relatively low. However, numerous reports of illnesses related to spa and hot tub use suggest the necessity for continued vigilance over maintenance practices.

It is also important to note that even under proper maintenance conditions, cases of microbial illness have been reported. Contamination of spa and hot tub water during high pathogen loading events (e.g., excessive bather loading, or an accidental fecal release) can temporarily compromise the ability of the system to remove pathogenic organisms. Contact with this contaminated water can result in skin, ear, or eye infections and, if the water is ingested, can lead to gastrointestinal illness. As discussed in this current review, numerous studies have also indicated the unique adaptive ability of microorganisms to persist in treated spa and hot tub water. Microorganisms can colonize filtration devices and develop adaptive characteristics to enhance their resistance to disinfecting agents.

In recognition of potential illnesses associated with the use of spas, hot tubs, or pools, many regulatory agencies have developed guidelines to minimize the risk. Although most illnesses are generally self-limiting for immunocompetent individuals, the CDC has indicated that children, pregnant women, and people with weakened immune systems (e.g., persons infected with the human immunodeficiency virus [HIV], organ transplant recipients, or those receiving certain types of chemotherapy) are at greater risk of developing severe or life-threatening disease (57). The CDC admonishes these individuals to take additional precautionary measures, including consultation with health care providers or avoidance of high-risk environments.

SPACE MICROBIOLOGY: EFFECTS OF IONIZING RADIATION ON MICROORGANISMS IN SPACE

GERDA HORNECK
CHRISTA BAUMSTARK-KHAN
GUENTHER REITZ
German Aerospace Center DLR
Institute of Aerospace Medicine
Cologne, Germany

Cosmic radiation, of solar and of galactic origin, is one of the external sources of energy of significant impact on our biosphere. During the first billion years of Earth's history, solar ultra-violet (UV) radiation of wavelengths below 290 nm did penetrate the atmosphere and reach the surface of the Earth. This is the time span when the decisive processes of abiotic organic chemical evolution, appearance of life, and diversification of microorganisms took place on Earth (1). In these processes, solar UV radiation played a major role. The role of the heavy ions of cosmic radiation in the evolution of our biosphere is less clear because the surface of the Earth is largely spared from the cosmic radiation due to the deflecting effect of the geomagnetic field and the huge shield of 1,000 g/m^2 provided by the atmosphere. However, in space, the natural radiation encountered is a complex mixture of charged particles of galactic and solar origin and particles trapped by the geomagnetic field.

Since the advent of space flight and the establishment of long-duration space stations in Earth's orbit, such as Skylab, Salyut, MIR, and the International Space Station, the upper boundary of our biosphere has extended into space. Such space missions expose humans and any other biological system to a radiation environment of a composition and intensity not encountered on Earth. To prevent detrimental health effects caused by the radiation environment of space, radiation protection guidelines have been elaborated for humans in space. The guidelines are based on (*1*) dosimetry and modeling of the radiation field in space, (*2*) studies on the biological effects of the heavy ions of cosmic radiation encountered in space or produced at heavy ion accelerators on ground, and (*3*) studies on potential interactions of cosmic radiation and other parameters of space flight, above all microgravity. Among other test systems, microorganisms have been used in space experiments and on ground to determine the biological effectiveness of this particulate radiation in space (2). Furthermore, any habitat in space will inevitably be contaminated by a specific cabin microflora. Bacteria, fungi, and algae will grow on surfaces of the spacecraft and on the human body if there is sufficient supply of nutrients and water. If plants or animals are present, either as test systems or for bioregenerative life support purposes, their microflora has also to be considered. Knowledge of the effects of space radiation on this microflora inside the spacecraft is of utmost importance to safeguard the health and well-being of the crew and the liability of bioregenerative life support systems.

It might also be possible for life to be confronted with radiation in space by natural processes. Our atmosphere teems with viruses, bacteria, algae, microfungi, fungal spores, spores of mosses and ferns, pollen, minute seeds, and protozoan cysts. These are found at concentrations of possibly hundreds to thousands per cubic meter. Viable microorganisms, predominantly black conidia and fungal spores, have even been found at altitudes as high as 77 kilometers; it is assumed that in these instances, pigmentation offers a selective advantage by protecting against the intense solar UV radiation prevalent at these high altitudes (3).

Since the discovery of a certain group of meteorites of probable Martian origin, it has become obvious that matter can be exchanged between the planets of our solar system, for example, from Mars to Earth. Especially during the early phase of heavy bombardment, which lasted until approximately 3.8 billion years ago, impactors up to a kilometer in size have struck the planets of our solar system. Such gigantic impacts lead to the ejection of a considerable amount of soil and rocks that are thrown up at high velocities, some fractions reaching escape velocity (4). These ejecta leave the planet and orbit around the sun, usually for timescales of a few hundred thousand or several million years until they either impact another celestial body or are expelled out of the solar system. The question arises whether such rock or soil ejecta could also be the vehicle for life to leave its planet of origin. Soil microorganisms or endolithic microbial communities are candidate terrestrial microbial systems that might be ejected by such large impacts. If so, they will be exposed to space radiation during their interplanetary journey. Radiation effects and potential protection and repair mechanisms could have profoundly affected the chances for a viable transfer of microbes within our solar system.

Among the planets of our solar system, Mars and probably the Jovian moon Europa are considered the best candidates for providing the prerequisites for the support of life, either in the past or the present. However, a putative Martian biota would be exposed to much higher radiation dose levels than life on Earth. This is the consequence of the fact that Mars does not possess either an effective magnetic field or a thick atmosphere. Therefore, the biologically effective dose at the surface of Mars caused by ionizing radiation from space is about 100 times higher than that at the surface of the Earth.

After a short description of the general effects of radiation on microorganisms and their responses in order to cope with the radiation stress, specific biological problems resulting from exposure of microorganisms to the space radiation environment are examined. This will include the effects of the heavy ions of cosmic radiation on microorganisms as cellular model systems for radiation protection purposes or as part of the cabin microflora, the role of radiation in affecting interplanetary transfer of microorganisms as in the case of microbes inside meteorites, and the impact of the radiation climate on a putative extraterrestrial biota, as on Mars.

BIOLOGICAL WEIGHTING OF RADIATION

Ionizing radiation is measured in the S.I. unit of absorbed dose per mass unit, the Gray (Gy), with 1 Gy equal to

the net absorption of 1 J in 1 kg of material (water). However, the biological effectiveness of radiation depends largely on the local energy distribution, the Linear Energy Transfer (LET). Therefore, different qualities of radiation can have different biological effectiveness even at the same physical dose. The relative biological effectiveness (RBE) describes this dependence of the biological effectiveness on LET. RBE is the ratio of the physical doses of the test radiation and, for example, X-rays, leading to the same biological effect. The RBE value can be different for different biological systems, depending on their stage in the growth cycle and other environmental factors such as oxygen content. To assess the effectiveness posed by radiation to humans and to the whole biosphere, estimates must be made of both the amount and type of radiation under consideration and the radiobiological effectiveness of the different components of the radiation. For this purpose, the quality factor Q has been introduced. Q is the biological weighting function of ionizing radiation and has been obtained by averaging over a variety of RBE values for the same LET value. Its relation to the LET of the radiation is shown in Figure 1 (5). For X-rays and γ rays, Q is equal to 1. For a given dose of high-LET radiation, the dose equivalent, H, is the product of Q and the absorbed dose:

$$H = QD \tag{1}$$

with H = the dose equivalent, Q = the quality factor and D = the absorbed dose. The S.I. unit for the dose equivalent is Sievert (Sv). For a mixed-radiation field composed of ionizing radiations of different radiation qualities, i (as encountered in space), the dose equivalent, H, is given by

$$H = \sum N_i \, Q_i \, D_i \text{ (Sv)} \tag{2}$$

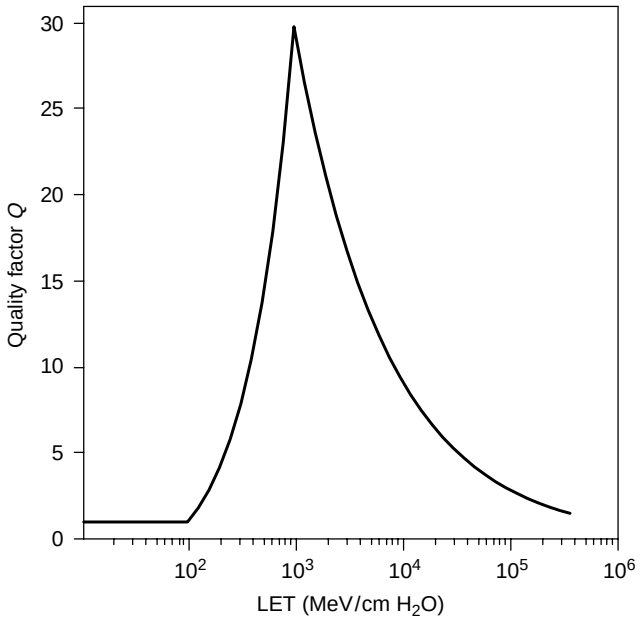

Figure 1. The quality factor Q is the biological weighting function of ionizing radiation and is dependent on the linear energy transfer (LET) of the radiation under consideration (5).

with D_i = absorbed dose, deposited in biological matter by the radiation i (Gy), Q_i = radiation quality that is described as a function of LET and N_i = a special factor that accounts for specific exposure conditions (e.g., dose rate, fractionated exposure, microgravity) or special physiological properties. Q has originally been developed for radiation protection purposes. Therefore, it is mainly based on radiation risks for cancer induction in mammals.

ENVIRONMENTAL RADIATION AND LIFE

Life on Earth, throughout its almost four billion years history, has been shaped by interactions of organisms with their environment and by numerous adaptive responses to environmental stressors. Among these, radiation, both of terrestrial and of cosmic origin, is a persistent stress factor that life has to cope with. Radiation interacts with matter, primarily through the ionization and excitation of electrons in atoms and molecules. These matter–energy interactions have been decisively involved in the creation and maintenance of living systems on Earth. Because it is a strong mutagen, radiation is considered a powerful promoter of biological evolution on the one hand and an account of deleterious consequences to individual cells and organisms (e.g., by causing inactivation or mutation induction) on the other. In response to the harmful effects of environmental radiation, life has developed a variety of defense mechanisms, including the increase in the production of stress proteins, the activation of the immune defense system, and a variety of efficient repair systems for radiation-induced DNA injury.

As a reactive chemical species, DNA is the target of numerous physical and chemical agents. These can induce a broad spectrum of DNA lesions (Fig. 2, Table 1), including damage to nucleotide bases, cross-linking, and DNA single- and double-strand breaks. Despite all of these lesions, the DNA is functionally more stable than the two other cellular macromolecules, RNA and protein. This stability can be attributed to the following three factors: (*1*) the primary structure of DNA is all that is needed for transfer of information; (*2*) because of the double-helical structure, DNA carries the information in duplicate; and (*3*) there are molecular mechanisms of different complexity to undo the DNA damage, thus maintaining cellular survival and genetic integrity (6,7).

DNA repair encompasses the molecular reactions that eliminate damaged or mismatched nucleotides from DNA. There is a variety of repair mechanisms, each catalyzed by a different set of enzymes. Nearly all of these mechanisms depend on the existence of two copies of the genetic information, one in each strand of the DNA double helix: if the sequence in one strand is accidentally changed, information is not lost irretrievably because a complementary copy of the altered strand remains in the sequence of nucleotides in the other strand. Examples are given below for different DNA repair mechanisms in microorganisms: (*1*) direct repair, (*2*) mismatch repair, (*3*) base excision repair, (*4*) nucleotide excision repair, (*5*) recombinational repair, and (*6*) the SOS response.

Direct repair mechanisms simply revert the damaged bases to their unmodified form. The ability of photolyase,

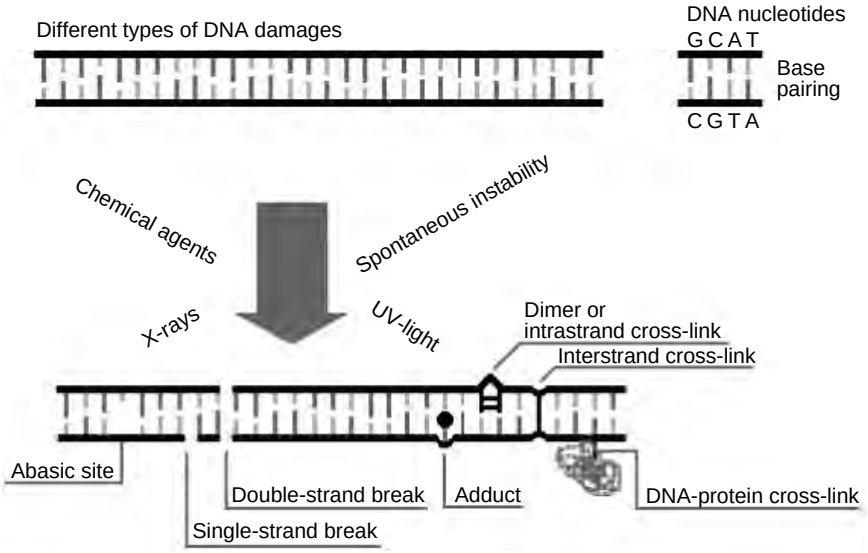

Figure 2. Different types of DNA damage.

Table 1. DNA Lesions Produced by Different Internal and External Conditions and the Pathways Used by Bacteria for their Repair

DNA Lesion	Cause	Repair Mechanism
Base mismatches, loops, bubble structure	Replication errors, recombination	Base excision, general mismatch repair
Deamination and depurination	Heat	Base excision
Oxidative damage	Oxidative metabolism, anoxia and hypoxia, ionizing radiation	Base excision
Alkylation and alkyl adducts (nonbulky and bulky adducts)	Nitrogen mustard, polyaromatic compounds	Direct repair, base excision, nucleotide excision
Intrastrand cross-links, (bulky adducts)	UV, cisplatin	Direct repair, nucleotide excision
Interstrand cross-links	Psoralen, malphalan	Nucleotide excision, recombination
Single-strand break	Ionizing radiation, oxidative stress	Ligation
Double-strand break	Ionizing radiation	Ligation, recombination

in the presence of light (photoreactivation), to remove UV-induced lesions in DNA is the best-studied repair reaction of this type (8). Genes coding for photolyase activities (PHR genes) have been found in many, but not all, prokaryotic and eukaryotic organisms. For example, among the prokaryotes, *E. coli* and *Synechocystis* sp. possess photolyase, but *Bacillus subtilis* and *Deinococcus radiodurans* do not. Among the eukaryotes, *Neurospora crassa* and *Saccharomyces cerevisiae* possess photolyases but *Schizosaccharomyces pombe* does not. Another example of direct damage reversal is repair of O^6-methylguanine by the transfer of the alkyl group from the DNA to a cysteine in a protein via an O^6-methylguanine-DNA methyltransferase (9). The enzyme removes other alkyl groups from the O^6 position of guanine and from the O^4 position of thymine with varying efficiencies. It appears to be present in all living organisms. A final example of direct damage reversal is the sealing of a subset of nicks in DNA by DNA ligase. Of course, DNA ligase can only seal nicks having 5′-phosphates and 3′-hydroxyls. Nicks with other configurations or nicks accompanied by additional backbone or base damage require more complicated repair mechanisms.

The mismatch repair pathway corrects DNA damages arising from replication mistakes (10). The distorted double helix is recognized by the MutS protein. Additional binding of the MutL stabilizes the complex. The MutS–MutL complex activates MutH, which locates a nearby methyl group and nicks the newly synthesized strand opposite the methyl group. The fact that the newly synthesized strand is not immediately methylated at GATC sequences in bacterial DNA, although the old strand carries methyl groups in proximity to the replication fork, allows *E. coli* cells to distinguish the presumably correct (old strand) from the presumably incorrect (newly synthesized) strand. This use of methylation to distinguish the parental strand is probably peculiar to bacteria. Data from yeast in vitro mismatch repair experiments suggest that single-strand nicks, which are present in nascent DNA strands, between Okazaki fragments (short stretches of 1,000–2,000 bases of the lagging (3′–>5′) strand of DNA, synthesized in the 5′–>3′ direction during discontinuous replication that are later joined by DNA ligase into a covalently intact strand), provide a signal for strand-specificity in these organisms. Excision is accomplished by

cooperation between the UvrD (Helicase II) protein, which unwinds from the nick in the direction of the mismatch, and a single-strand specific exonuclease of appropriate polarity (one of several in *E. coli*), followed by resynthesis (Polymerase III) and ligation (DNA ligase).

The base excision repair system removes the damaged base by means of a glycosylase. There are many glycosylases with narrow substrate ranges. Following removal of the damaged base by a glycosylase, the abasic sugar (AP site) is removed by cleavage of the 3′-phosphodiester bond by an AP lyase that is often associated with the glycolyase activity. Then the 5′ bond of the AP site is hydrolyzed by AP endonuclease. The resulting single nucleotide gap is filled in by DNA Pol I and then ligated. AP sites are also generated by spontaneous hydrolysis, by oxidative stress and by ionizing radiation, and hence are frequent lesions in DNA.

The nucleotide excision repair pathway is an elaborate repair system that removes bulky lesions from DNA (11–14). In *E. coli*, three proteins, the products of the *uvrA*, *uvrB*, and *uvrC* genes, are responsible for damage recognition and DNA nicking. The current model is that, in an ATP-dependent reaction, a dimer of the UvrA protein forms a complex with a single UvrB molecule. Next, the UvrC protein binds to the UvrB protein, thereby activating it to nick the DNA approximately four nucleotides 3′ to the damaged site. This, in turn, activates UvrC to nick the DNA approximately seven nucleotides 5′ to the damage. It is possible that activation of UvrC is a consequence of a conformational change in the DNA after nicking by UvrB. All these steps require ATP binding but not ATP hydrolysis. The fourth protein, the *uvrD* gene product known as DNA helicase II, displaces the damage-containing oligonucleotide. At the same time, the UvrC protein is released and afterwards the UvrB protein is displaced. Following the release of the excised oligonucleotide, the single-stranded gap is filled in by DNA Polymerase I in *E. coli* and then the newly synthesized DNA is ligated to the old one. The enzyme system that is responsible for the dual incision, which is also referred to as excision nuclease, is the sole repair system for removing bulky lesions from DNA and also plays a back-up role for other repair systems because it is capable of removing nonbulky lesions, such as O6-MeGua and AP sites.

Interstrand cross-links pose a unique problem for the cellular repair machinery. Both base excision and nucleotide excision rely on the redundant information in the undamaged strand to correctly fill in the excision gap, resulting from damage removal. In cross-linked DNA, both strands are damaged, and hence the genetic information in both strands has changed. The cell overcomes this dilemma by combining excision repair with recombinational repair (15–17). First, dual incisions are made in one strand by the excision nuclease; second, through homologous pairing of the incised duplex with the intact sister chromosome, a segment of the intact duplex is paired with the gap to generate a three-strand noncovalent intermediate and the transferred strand is ligated in to form a three-stranded covalent intermediate; third, the excised oligomer, remaining linked to the duplex through the cross-link is recognized as a bulky adduct and is excised by dual incisions. The gaps generated by repair and recombination in the damaged and sister duplex, respectively, are filled in by DNA polymerases and the newly synthesized DNA is ligated.

The best-studied example of an inducible repair pathway is the SOS response in *E. coli* and other bacteria (18,19). In these bacteria, any block to DNA replication caused by DNA damage produces a signal (thought to be an excess of single-stranded DNA) that induces an increase in the transcription of more than 15 genes, many of which code for proteins that function in DNA repair. The signal first activates the *E. coli* RecA protein, which then destroys a negatively acting gene regulatory protein (a repressor) that normally suppresses the transcription of the entire set of SOS response genes. Studies of mutant bacteria, deficient in different parts of the SOS response, indicate that the newly synthesized proteins have two effects. Firstly, as would be expected, the induction of new DNA repair enzymes increases cell survival. When the mutants deficient in this part of the SOS response are treated with a DNA-damaging agent such as ultraviolet radiation, an unusually high proportion of them die. Secondly, several of the induced-proteins transiently increase the mutation rate by greatly increasing the number of errors made in copying DNA sequences. Although this has little effect on short-term survival, it is presumably advantageous in the long term because it produces a burst of genetic variability in the bacterial population and hence increases the chance that a mutant cell with increased fitness will arise. The DNA repair system activated in the SOS response is not the only inducible DNA repair system known. Bacteria have another system that is activated specifically by the presence of methylated nucleotides in DNA and there is at least one inducible DNA repair system in yeast cells.

In addition to repair systems, several other feedback controls operate to restrain the cell cycle control in eukaryotic systems until particular conditions are satisfied. A well-characterized feedback control operates at the mitotic entry checkpoint to prevent cells with damaged DNA from entering mitosis until the damage is repaired (20,21). The response to DNA damage is usually studied using experimentally induced lesions in DNA, such as those created by X-rays. Many radiation-sensitive (rad) mutations have been isolated in budding yeast and at least one, called rad9, has been shown to code for an essential component of the feedback control mechanism. Mutants lacking rad9 still possess the machinery for DNA repair but fail to delay in G2 when they have been irradiated. Therefore, they proceed into mitosis with damaged chromosomes; not surprisingly, they are killed by doses of radiation that normal cells would survive.

The most radiation-resistant bacterium known is *D. radiodurans*. It was originally isolated from samples of canned meat that were thought to be sterilized by high doses of γ-radiation. Typically, it is found in locations where most other bacteria have died under extreme conditions, ranging from the shielding pond of a radioactive cesium source to the surfaces of Arctic rocks. Researchers examined the bacterium's cellular

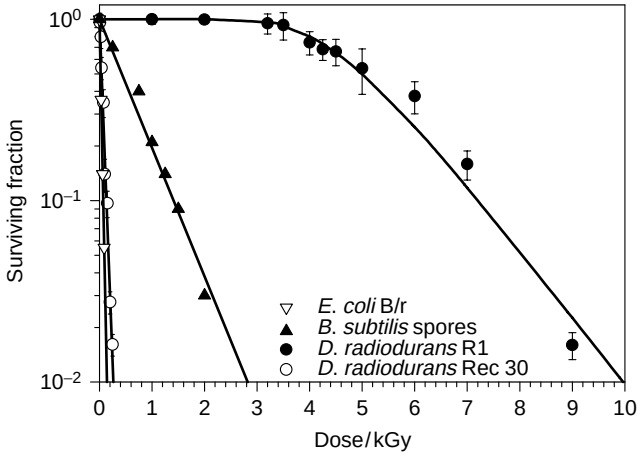

Figure 3. Representative survival curves for *D. radiodurans* R1 (closed circles) and its recombination deficient mutant Rec30 (open circles), compared to survival curves for spores of *Bacillus subtilis* (closed triangles) and *E. coli* B/r (open triangles), following exposure to X-rays (23).

repair genes and discovered that although *D. radiodurans* contained the usual complement of repair genes found in other radiation-sensitive bacteria, it has an unusually large redundancy of repair functions (22). Furthermore, the regulation of its repair activities is highly coordinated with the cell cycle. In Figure 3, the radiation sensitivity of the highly radiation resistant bacterium *D. radiodurans* R1 is compared with that of a mutant, *D. radiodurans* Rec30, that is deficient in DNA repair and two other bacterial representatives, that is, spores of *B. subtilis* and cells of *E. coli*. Each major designation on the *y*-axis represents a reduction in viability by a factor of 10. The D_{37} dose (i.e., the dose of radiation required to reduce the population by 37% of its original size, or e^{-1}; this is interpreted as the average dose required to inactivate a single colony-forming unit) for the *E. coli* culture is 30 Gy, which is approximately 200 times lower than that of *D. radiodurans*. *D. radiodurans* has a characteristic shoulder of resistance to approximately 3,000 Gy; at doses below that value there is no loss of viability, although up to about 100 double-strand breaks have been induced in the chromosome of each cell (22). Above 5,000 Gy, there is an exponential decline in viability and a D_{37} dose of between 6,000 Gy and 7,000 Gy for cultures in exponential phase. It is remarkable that in *D. radiodurans* Rec30 that has lost its repair capacities, the radiation sensitivity reaches similar values as in *E. coli* (23).

TERRESTRIAL RADIATION ENVIRONMENT

On Earth, the ionizing component of the radiation environment originates from primordial radionuclides of the Earth's crust, from radionuclides produced by cosmic rays in the Earth atmosphere, and for the last 100 years, from anthropogenic components of different sources, including nuclear weapons, nuclear power technology, increased radon exposure inside buildings, and medical applications of radiation and radiomimetric pharmaceuticals. In addition, our planet is continuously bombarded by charged particles coming from the sun and from sources outside our solar system. However, the surface of the Earth is largely spared from the cosmic radiation source because of the deflecting effect of the geomagnetic field and the huge shield provided by the atmosphere.

The dominant portion of energy loss in matter is contributed by the ionization of orbital electrons in the shielding material via Coulomb interaction. For protons and heavy ions, continuous deceleration can be assumed. With electrons, slowing is not continuous; straggling effects occur. Bremsstrahlung because of deceleration is important only for electrons. For higher particle energies, collisions between the primary ions and the nuclei of the shielding material represent a significant interaction. Through fragmentation of the incoming particles and disintegration of the target nucleus, new particles such as mesons, pions, secondary protons, neutrons, alpha particles, and some heavier components, which again can interact with the shielding material, are produced.

Collisions of cosmic ray particles with the nuclei of molecules of the atmosphere generate secondary radiation, creating and increasing a cascade that reaches a maximum radiation dose at an altitude of 25 km and then decreases to sea level. Mass shielding of the Earth's atmosphere amounts to 1,000 g/cm^2, thereby attenuating the cosmic radiation dose rate received at sea level by a factor of nearly 1,000, to 0.35 mSv/a (24). Hence, on Earth, the cosmogenic component contributes about one-sixth to one-tenth to the average annual terrestrial dose rate of natural ionizing radiation, which on most parts of the Earth amounts to 2.4–4.1 mSv/a. (However, in areas with a high concentration of radioactive rock components (e.g., in Kerala, India), the annual terrestrial dose rate can reach values up to 13 mSv/a). This dose rate increases with altitude; at an altitude of 10 km, the cosmic radiation rate is approximately 100 times higher than that at sea level (25). At an altitude of 25 km, the dose equivalent rates per hour are of the same order of magnitude as in Earth orbit at an altitude of about 300 km (Fig. 4).

THE RADIATION ENVIRONMENT OF SPACE

Radiation conditions in space are quite different from those on Earth. In interplanetary space, the radiation field is composed mainly of two groups: (*1*) the solar cosmic radiation (SCR) and (*2*) the galactic cosmic radiation (GCR) (26,27). Near the Earth, a third radiation component is present: the radiation trapped by the Earth's magnetosphere, the so-called radiation belts. Typical integral energy spectra for these components are shown in Figure 5.

Solar cosmic radiation (SCR) consists of the low-energy solar wind particles that flow constantly from the sun and the so-called solar particles events (SPEs) that originate from magnetically disturbed regions of the sun that sporadically emit bursts of charged particles with high energies (28). These events are composed primarily of

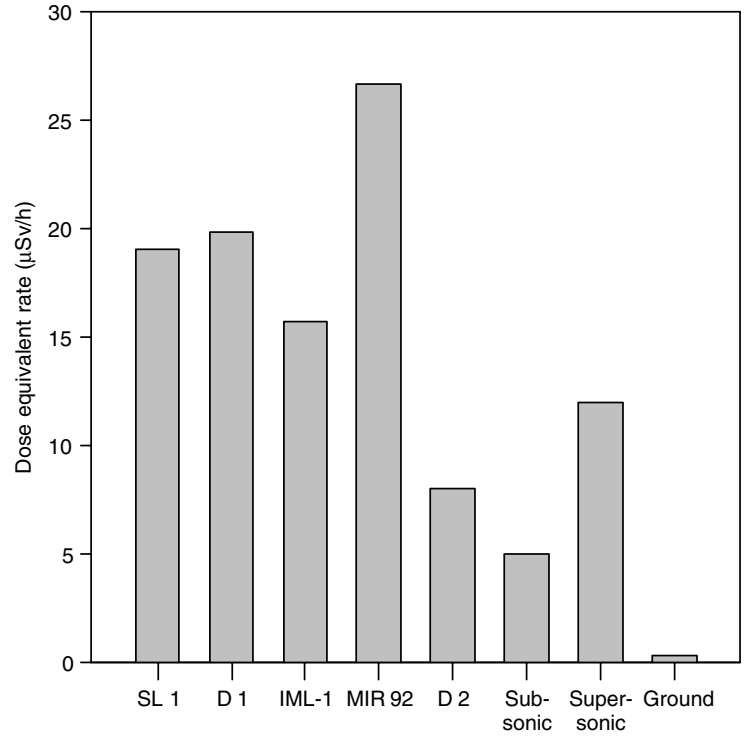

Figure 4. Dose equivalent rates (μSv/h) caused by the components of cosmic radiation in Earth orbit at altitudes of about 300 km as measured on board of Spacelab 1 (SL 1), Spacelab D1 (D 1), International Microgravity Laboratory (IML-1), the MIR station (MIR 92), and Spacelab D2 (D 2), in air traffic for subsonic conditions (about 10-km altitude) and supersonic conditions (about 25-km altitude), and at sea level on Earth.

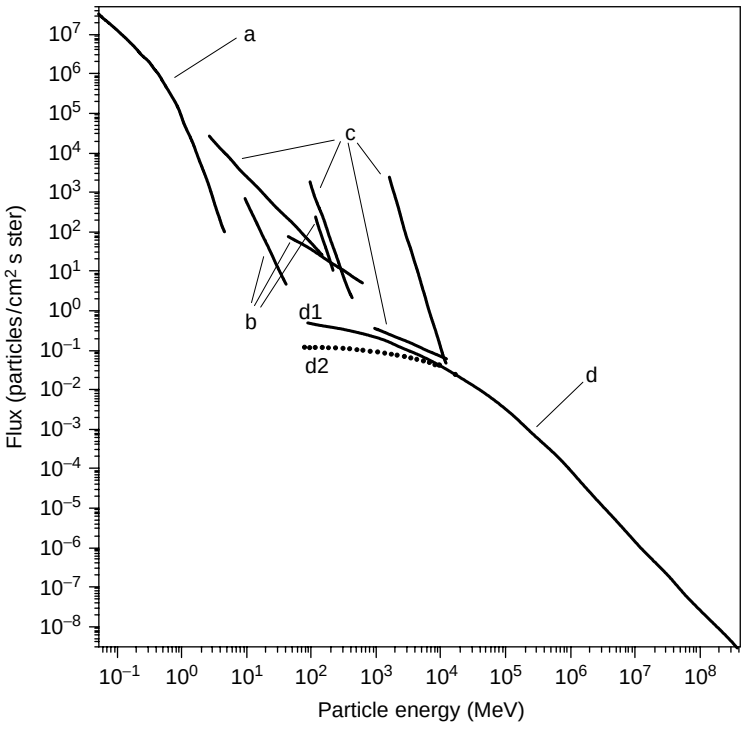

Figure 5. The energy spectra of the components of the radiation field in space near the Earth: a) electrons (belts); b) protons (belts); c) SPEs; d) heavy ions of galactic cosmic radiation; d1) during solar minimum; d1) during solar maximum.

protons, with a minor component (5–10%) being helium nuclei (alpha particles) and an even smaller part (1%) being heavy ions and electrons. SPEs develop rapidly and generally last for no more than some hours. However, some proton events observed near the Earth may continue over several days. The emitted particles can reach energies up to several GeV. Doses as high as 10 Gy could be received in a worst-case scenario within a short time. Such strong events are very rare, typically less than three events during the 11-year solar cycle. For low Earth orbit (LEO), the Earth's magnetic field provides a latitude-dependent shielding against SPE particles. Only in high-inclination orbits, SPEs create a hazard to man in space, especially during extravehicular activities.

Galactic cosmic radiation (GCR) originates outside the solar system. They have their origin in previous cataclysmic astronomical events such as supernova explosions. Detected particles consist of 98% baryons and 2% electrons. The baryonic component is composed of 85% protons (hydrogen nuclei), with the remainder being alpha particles (helium nuclei) (14%) and heavier nuclei (about 1%). The fluence of GCR is isotropic and energies up to 10^{20} eV can be present. Although iron ions are one-tenth as abundant as carbon or oxygen, their contribution to the GCR dose is substantial, as dose is proportional to the square of the charge. With increasing solar activity the interplanetary magnetic field increases, resulting in a decrease in the intensity of GCR of low energies. This modulation is effective for particles below some GeV per nucleon. The fluxes are further modified by the geomagnetic field. Only particles of very high energy have access to low-inclination orbits. Toward higher inclination, particles of lower energies are allowed. At the pole, particles of all energies can impinge in the direction of the magnetic field axes. Because of this inclination-dependent shielding, the number of particles increases from lower to higher inclination.

The radiation belts are a result of the interaction of GCR and SCR with the Earth's magnetic field and the atmosphere. Two belts of radiation are formed, comprising electrons and protons and some heavier particles trapped in closed orbits by the Earth's magnetic field. The main production process for the inner belt particles is the decay of neutrons produced in cosmic particle interactions with the atmosphere. The outer belt consists mainly of trapped solar particles. In each zone the charged particles spiral around the geomagnetic field lines and are reflected back between the magnetic poles acting as mirrors. Electrons reach energies of up to 7 MeV and protons up to 600 MeV. The energy of trapped heavy ions is less than 50 MeV. The trapped radiation is modulated by the solar cycle; proton intensity decreases with high solar activity, whereas electron intensity increases and vice versa.

The different types of radiation in space cause different amounts and kinds of biological damage per unit of absorbed dose. Therefore, the different types of radiation received in space have to be known and weighted using the quality factor Q. Figure 6 shows the contribution to the absorbed dose rate (Gy/d) and the dose equivalent rate (Sv/d) attributed to the various components of cosmic radiation. It is clearly seen that the total dose rate is about twice as high for MIR 92 than for IML-1 and the contributions of the different components of radiation to the total dose are quite different for the two missions. The reason for this difference is the higher altitude of the MIR orbit when compared to that of the IML-1 mission and a different period in the solar cycle.

While converting the radiation exposure of all different groups of radiation (however, in the absence of SPEs) to absorbed dose, the exposure during solar minimum conditions as example for the STS84 mission (orbit of the International Space Station) arrives at 132 μGy/d for the GCR and at 233 μGy/d for the radiation belt portion, in total at 365 μGy/d. For interplanetary space, slightly lower daily doses are expected behind comparable shielding thicknesses. The reason for this is the absence of the dose contribution of the radiation belt particles and an increase of the GCR part, due to the absence of geomagnetic shielding.

Absorbed dose, however, is an average quantity that does not precisely reflect the characteristics of energy deposition by a heavy ion of cosmic radiation. Heavy ions induce extremely high ionization densities in highly localized cylindrical volumes around their trajectory through matter, and therefore are capable of damaging a number of contiguous cells located along their trajectory. It is therefore necessary to determine the effect probability of the transversal of a heavy ion in dependence of its energy and charge. Some results are given later in this paper. The probability, within a three-year space mission, of a cell of the human retina (180 μm^2) or the human brain (60 μm^2) being hit by a heavy ion of $Z > 15$ is up to 0.24 or 0.08, respectively; and for ions of $Z = 26$ (iron) the numbers arrive at 0.07 and 0.02, respectively.

EFFECTS OF COSMIC RADIATION ON MICROORGANISMS

Inactivation

In space, microorganisms are exposed to the highly energetic type of radiation that may have severe consequences on their viability and the integrity of

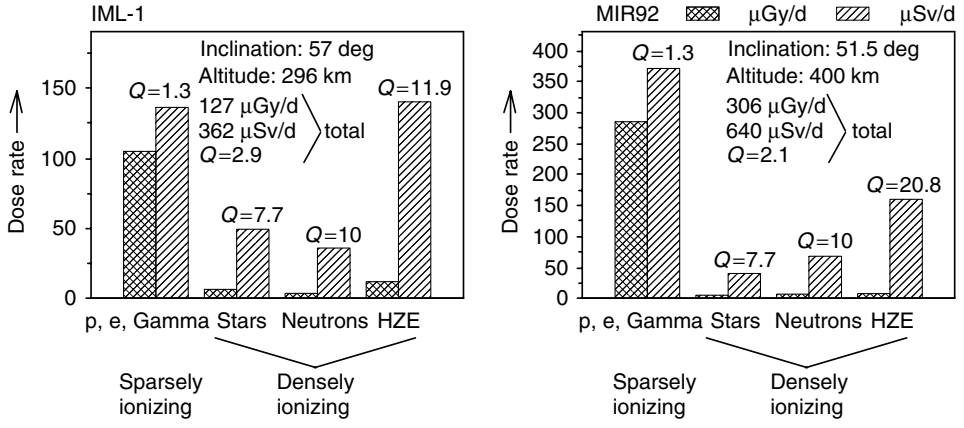

Figure 6. Absorbed dose rates (μGy/d) and equivalent dose rates (μSv/d) of the sparsely ionizing and the three densely ionizing components of the radiation field in LEO, determined from dosimetric measurements during the Spacelab mission IML-1 and the MIR'92 mission (29).

genetic information stored in their DNA. Among the ionizing components of radiation in space, the heavy primaries, the so-called HZE particles, are the biologically most effective species (30,31). To investigate the effects of single heavy ions on biological objects in a resting state (e.g., *Bacillus subtilis* spores), the Biostack concept was developed (32). In this system, biological systems are sandwiched between layers of nuclear track detectors and then exposed to the source radiation. This method helps (*1*) localize each heavy ion's trajectory in relation to the biological specimens (Fig. 7); (*2*) investigate the responses of each biological individual hit separately, with regard to its radiation effects; (*3*) measure the impact parameter (i.e., the distance between the particle track and the sensitive target); (*4*) determine the physical parameters (charge Z, energy E, and linear energy transfer LET); and finally, (*5*) correlate the biological effect with each heavy ion parameter. These studies provide important basic information on the attempts to assess the radiation risks for humans in space.

Bacterial spores, having a cytoplasmic core with a geometric cross section of 0.2 to 0.3 μm^2 are suitable test systems in HZE particle research, especially for sounding the biological effectiveness in dependence of the impact parameter for each particle's trajectory when applying the Biostack concept (Fig. 7). For this purpose, spores of *B. subtilis* (wild-type with regard to DNA repair) in suspension of 0.001% aqueous polyvinyl alcohol solution (PVA) were spread onto cellulose nitrate (CN) track detector sheets. After drying, a fixed contact of the spore monolayer with the track detector was achieved. These sheets, carrying the biological layer, were stacked between pure plastic detector sheets (32). The complete Biostack experiment package (about $10 \times 10 \times 10$ cm^3 in size) accommodated in a hermetically sealed aluminum container was stowed inside the spacecraft (Apollo or Spacelab) and exposed to cosmic radiation. Total absorption by the spacecraft walls was approximately 2.4 g/cm^2. The flux of heavy ion particles with LET $\geq$ 170 keV/μm was 2 to 3 particles/cm^2d.

After retrieval and disassembly, CN foils carrying a spore layer were etched (6N NaOH, 30 °C) only on the CN-side, resulting in an etch cone at the side opposite to the spore layer along the trajectory of an HZE particle. The procedure was followed by individual etching of each etch cone under microscopic control (pinpoint etching), until the tip of the etch cone approached the spore layer up to a few microns. By extrapolation of the etch cone, the target area in the spore layer could be determined. The target area was defined as an area of a radius of 5 μm off the point of intersection of an HZE particle with the spore layer. Spores of the target area were individually transferred onto nutrient agar by micromanipulation. During the subsequent incubation, germination, outgrowth, and growth were followed until the microcolony was formed. The original position of each spore relative to the HZE particle's trajectory (i.e., the impact parameter) was obtained from micrographs and after break through etching of the etch cone (33). The accuracy in determining the impact parameter — depending on the dip angle of the trajectory — was up to 0.2 μm, which is well below the size of a single spore. The physical parameters of the respective HZE particle, such as Z and LET, were obtained from the adjacent physical detector foils. Figure 8 shows the frequency of inactivated spores as a function of the impact parameter b. About 1,000 individual spores were analyzed. Spores within $b \leq 0.2$ μm were inactivated by 73%. The frequency of inactivated spores dropped abruptly at $b > 0.2$ μm. However, 15 to 30% of spores located within $0.2 < b < 3.8$ μm were still inactivated. Hence, spores were inactivated well beyond 1 μm, a distance that would approximately correspond to the dimensions of a spore. At a distance of 1 μm, the mean δ-ray dose ranges between 0.1 Gy and 1 Gy depending on the particle, and declines rapidly with increasing b (34). This value of 0.1 to 1 Gy is by several orders of magnitude below the D_{37} (dose reducing survival by e^{-1}) of electrons that amounts to 800 Gy. Therefore, the radial long-ranging effect around the trajectory of an HZE particle (up to $b = 3.8$ μm) cannot merely be explained by the δ-ray dose.

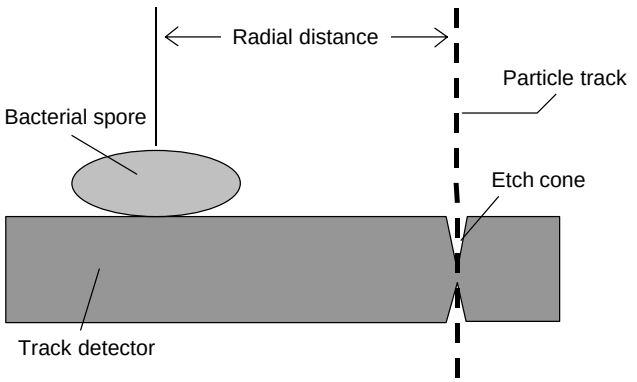

Figure 7. Biostack method to localize the trajectory of single particles (HZE particles) of cosmic radiation relative to individual bacterial spores in a spore monolayer (32).

Taking these results from the experiments in space, one can draw the following general conclusion: the inactivation probability for spores, centrally hit, is always substantially less than one. This means that heavy ions of even high LET might not necessarily kill a spore, even by a direct hit of the spore core. The effective range of inactivation extends far beyond the range of impact parameter, where inactivation of spores by δ-rays can be expected. This far-reaching inactivation of spores might reflect the so-called thindown effect at the end of the ion's path. The term is based on nuclear track detector analysis in which the track first increases in width to a maximum value and then thins down like a sharpened pencil (35), close to the stopping end of the path of a heavy ion. In this track regime, energetic δ-rays play a dominant role in the production of the cross section.

The dependence of inactivated spores from impact parameter points to a superposition of two different inactivation mechanisms: a short-ranged component reaching up to 1 μm may be traced back to the δ-ray dose and a long-ranged one that extends at least to somewhere between 4 and 5 μm off the particle's trajectory, for which additional mechanisms, such as shock waves, UV radiation, or thermophysical event (34), are conjectured.

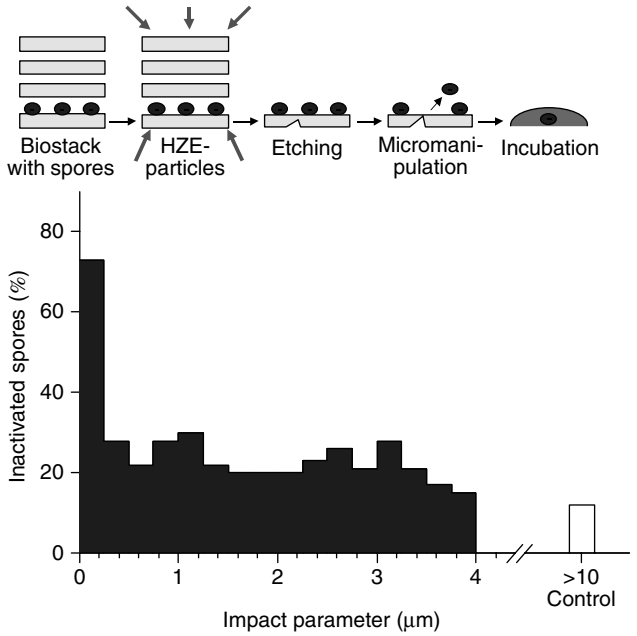

Figure 8. Results from Biostack experiments in space: inactivation probability of spores of *B. subtilis* as a function of the distance from the particles' trajectory (30). See color insert.

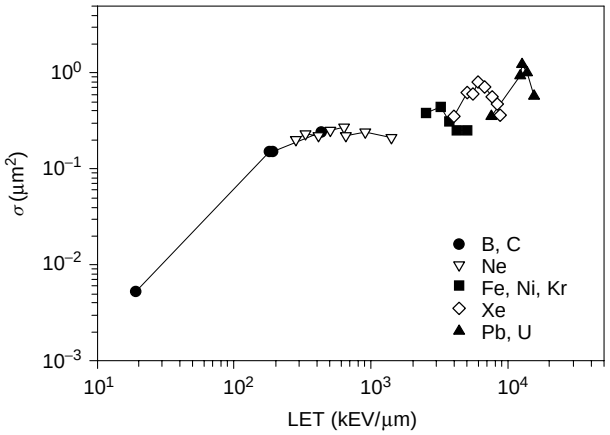

Figure 9. Inactivation cross-section σ of *B. subtilis* spores as a function of LET after irradiation of the spores with heavy ions from accelerators (36).

These results from space experiments were largely confirmed by experiments at heavy ion accelerators (36–38). The dependence of the inactivation cross-section σ of *B. subtilis* spores on the LET of the particles (Fig. 9) shows an increase of σ with increasing LET at LET $\leq$ 100 keV/μm, a saturation of σ at LET of 200–1,000 keV/μm and so-called σ-LET hooks at LET $>$ 2, 000 keV/μm. The saturation value of σ of 0.25 μm^2 that is identical for the different ions used is equivalent to the projected area of the spore core. This innermost part of the spore, containing the dehydrated cytoplasm and DNA, is most likely the sensitive site of the spore. The σ-LET hooks that occur at very high LET values are separate for each ion used and reflect the so-called thindown effect (see the preceding section for explanation). A comparable dependence of the inactivation cross-section on LET has been found for other microorganisms, such as cells of *E. coli* (38), of *D. radiodurans* (39), and of *S. cerevisiae* (40), as well as for mammalian cells (31). Double-strand breaks of the DNA (41) and bulk DNA lesions were the main cause of inactivation.

Mutation Induction

Mutagenesis is another important radiobiological end point because it directly reflects radiation damage to the DNA with the potential of severe consequences to biological diversity. Because cosmic radiation comprises heavy ions of a wide spectral range in mass and energy (Fig. 5), their mutagenic potential may vary with the physical properties of the ion under consideration. Experiments with microorganisms at heavy ion accelerations have shown that the cross-sections for mutation induction also show the "thindown" phenomenon (Fig. 10). The data are best interpreted by suggesting a "mutagenic belt" inside the track of a heavy ion that is restricted to an area, where the density of departed energy is low enough not to kill the cell (spore), but high enough to induce mutations (42,43). In this connection, due to their high inactivation potential, ions at very high LET values do not induce mutations (Fig. 10).

Repair of DNA Damage Caused by Heavy Ions of Cosmic Radiation

The involvement of DNA repair after irradiation with heavy ions reflects the cellular response to a radiation-induced DNA damage associated with the capacity to restore its DNA. It may lead to an enhanced survival of the affected microorganisms relative to those cells that are blocked in such a response. Comparing the inactivation cross-sections of spores of *B. subtilis* strains of different repair capacity, it was found that in most cases DNA repair enhanced survival after heavy ion irradiation (36). Repair based on recombination events was more efficient than repair based on repair replication. Repair is especially efficient in the extremely radiation-resistant cells of *D. radiodurans* (22,44), which therefore

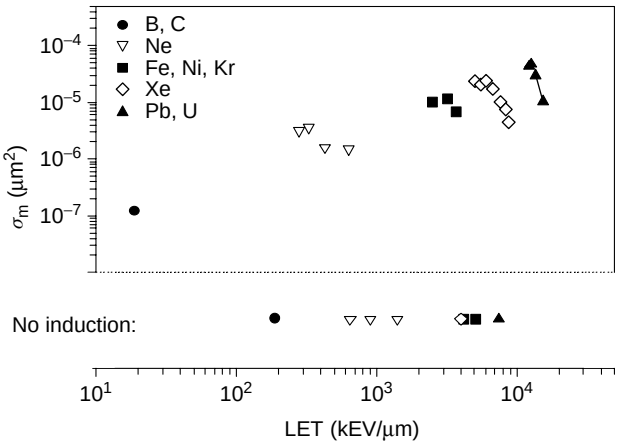

Figure 10. Mutation induction cross section into histidine prototrophy of *B. subtilis* spores as a function of LET after irradiation of the spores with heavy ions from accelerators (36).

exhibit an extraordinary ability to withstand damage induced by heavy ions (23,39).

RESPONSES TO COMBINED ACTION OF SPACE RADIATION AND MICROGRAVITY

Besides the unique radiation field in space, the cessation of the gravity stimulus that life on Earth has adapted to is another important source of potentially detrimental effects inevitably present during space flight. In response to microgravity, several essential cellular functions, such as signal transduction and gene transfer (45), are impaired [see also SPACE MICROBIOLOGY: EFFECTS OF IONIZING RADIATION ON MICROORGANISMS IN SPACE, this Encyclopedia]. In addition, synergistic interactions of radiation and microgravity have been observed in disturbances of the development of insect and plant embryos (2).

In attempts to explain these reported synergistic interactions of radiation and microgravity, it has been conjectured that microgravity might interfere with the operation of some cellular repair processes (46,47) that will result in an augmentation of the radiation response. Experimental support in favor of this hypothesis has been provided in a space experiment, utilizing a temperature-conditional repair mutant of *S. cerevisiae*, in which the extent of repair of DNA double-strand breaks (DSBs) was reduced by approximately a factor of two compared to the ground control at Earth's gravity (48). However, this observation could not be confirmed in a follow-up experiment (49). Examining several different repair pathways in different bacterial systems that were irradiated prior to the space mission, Horneck and coworkers provided evidence that in the microgravity environment, cells were able to repair radiation-induced DNA damage almost normally (50). Using the cell cultivation facility BIORACK of the European Space Agency ESA during the Spacelab mission IML-2, the following repair functions were investigated: (*1*) the kinetics of rejoining of radiation-induced DNA strand breaks in *E. coli* cells; (*2*) the induction of the SOS response in cells of *E. coli*; and (*3*) the efficiency of repair in spores of *B. subtilis* of different repair capacity. A comparison of cells that were allowed to repair in microgravity to those under gravity (one gravity reference centrifuge on board or corresponding ground controls) did not show any significant influence of microgravity on the enzymatic repair reactions studied (Fig. 11). The data suggest that the synergistic effects of microgravity and radiation in biological systems, which has been observed in several instances, probably cannot be explained by a disturbance of intracellular DNA repair in microgravity.

Therefore, other mechanisms have to be postulated for the synergistic action of microgravity and radiation: (*1*) at the molecular level, the consequences of a convection-free environment, (*2*) at the cellular level, an impact on signal transduction, on receptors, on the metabolic–physiological state, on the chromatin, or on the membrane structure, and (*3*) at the tissue and organ level, modification of self-assembly, intercellular communication, cell migration, pattern formation, or differentiation.

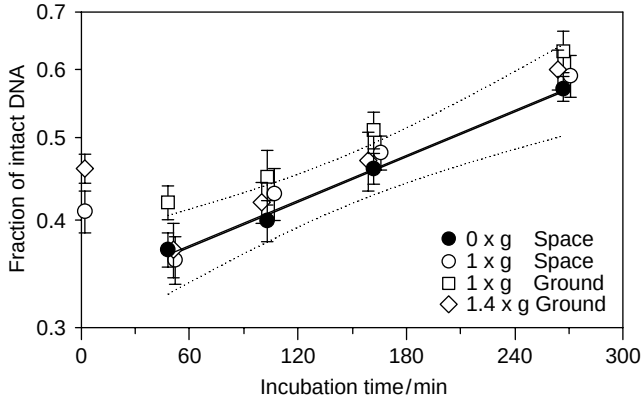

Figure 11. Repair of radiation-induced DNA damage under microgravity conditions: Rejoining of DNA-strand breaks in cells of *E. coli* B/r that have been irradiated by X-rays prior to the spaceflight at low temperatures, and incubated when in space [modified from (50)].

CHANCES OF INTERPLANETARY TRANSFER OF LIFE

The question of the chances of interplanetary transfer of life, initially termed "Panspermia" by S. Arrhenius (51), has recently received increased attention, especially since the detection of meteorites that originate from Mars. As shown earlier, *B. subtilis* spores can survive even a central hit of a heavy ion of cosmic radiation. Such heavy ions of cosmic radiation are conjectured to set the ultimate limit on the survival of spores in space because they penetrate even thick shielding. A spore's maximum time to escape a hit by an HZE particle (e.g., iron of LET > 100 keV/μm) has been estimated to be several hundred thousands up to a million years. This time span complies with estimates for boulder-sized rocks to travel from one planet of our solar system to another (e.g., from Mars to Earth) by random motion (4). However, it has been estimated that a few months are sufficient for an interplanetary transfer of microscopic particles (52).

Concerning shielding against radiation in space, a few micrometers of meteorite material are sufficient to give efficient protection against extraterrestrial UV, if the material is without cracks. Less than 0.5 g/cm^2 shielding is required to protect against the diffuse X-rays. Both the high-energy particles in SPEs and the GCR particles are more difficult to shield against because of their high penetration depth in material and because of the creation of secondary particles in nucleus–nucleus interactions. In fact, the dose increases with shielding depth before absorption becomes the dominant process.

On the basis of experimental data from accelerator experiments with *B. subtilis* spores (36), an estimated density of 3 g/m^3 for meteorite material (taken from data of Martian meteorites) and a NASA model on the HZE component of cosmic radiation (53), Mileikowsky and coworkers (54) have calculated the dose rate behind different thicknesses of shielding. The dose rate reaches its maximum value behind a shielding layer of about 10 cm; behind 130 cm it is about the same as that obtained without any shielding. The dose rate is significantly reduced only for higher shielding thicknesses (Fig. 12). The

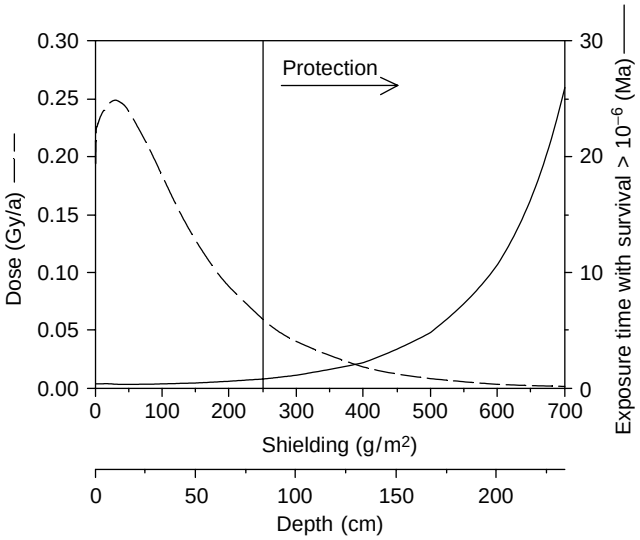

Figure 12. Shielding of bacterial spores against galactic cosmic radiation by meteorite material (54).

calculations also show that even after 25 million years in space, a substantial fraction of a bacterial spore population (10^{-6}) would survive the exposure to cosmic radiation if shielded by two to three meters of meteorite material. The same fraction would survive after about 500 thousand years without any shielding, and after 350 thousand years after one meter of shielding. However, one has to bear in mind that cosmic radiation is only one of the parameters of the hostile space environment. For a successful viable transfer throughout our solar system, microorganisms have to cope with the full matrix of all environmental stressors governing the space milieu.

ENVIRONMENTAL RADIATION AND PUTATIVE HABITATS ON MARS

There is growing evidence that the physical and chemical surface properties of early Earth and Mars were very similar (55) and that before 3.5 billion years ago and even sporadically in more recent time periods, the climate on Mars was wet and more temperate, allowing the presence of large quantities of water on its surface (56). At that time, life had already started on Earth. Under the assumption that life emerges at a certain stage of planetary evolution if the right environmental physical and chemical requirements are provided, it is legitimate to assume that conditions on early Mars were as favorable for life to emerge as on early Earth. A closer look at the radiation climate of Mars and its effectiveness on terrestrial model systems may provide clues for estimating the habitability of Mars, in early epochs or even today.

The radiation climate on the surface of Mars is governed by the following components: (*1*) solar UV radiation, including the UVC and UVB range ($\lambda >$ 200 nm); (*2*) charged particles of galactic and solar origin, as well as neutral secondaries; and (*3*) emissions from radionuclides of Mars itself. The biological effects caused by solar UV-radiation are considered elsewhere (57); this paper will concentrate on the ionizing components. Because of low shielding by the Martian atmosphere, 5 to 16 g/cm^2 depending on altitude, and the lack of a magnetic field, a substantial portion of cosmic radiation reaches the surface of Mars. In addition, highly energetic (up to several GeV) solar particle events consisting of protons, helium nuclei, and a small portion of heavier ions occur sporadically above all at the end of the solar maximum. Therefore, the biologically effective annual dose rate amounts to 0.1 to 0.2 Sv/a, depending on the altitude (58). The intensity of cosmic radiation is also a function of the direction of the incident particles: with increasing zenith angle, the amount of protection increases. With increasing depth, the regolith provides a certain radiation protection, although one has to consider the secondary radiation produced.

Although the radiation dose rate on the surface of Mars is about 100 times higher than that on Earth, it cannot be considered a limiting factor for microbial life on Mars. A terrestrial example is the most radiation resistant bacterium *D. radiodurans*. It can tolerate radiation doses up to 3,000 Gy without any significant inactivation (39,44) (Fig. 3). Thus, the annual dose rate on Mars is three to four orders of magnitudes lower and would not impair growth of microorganisms possessing potent DNA repair systems. Likewise, *B. subtilis* spores with a D_{37} of 600 Gy would be able to survive the radiation exposure on the Martian surface for extended periods. If microbial life once existed on Mars, spores could be suitable candidates to survive dry interim periods between two wet epochs that have been suggested to have occurred during Martian history (59).

SPACE MICROBIOLOGY: MICROGRAVITY AND MICROORGANISMS

DAVID M. KLAUS
University of Colorado
Boulder, Colorado

Both the opportunity and the need to characterize the effects of reduced gravity on living organisms accompanied the advent of manned spaceflight. In addition to studying how cosmonauts and astronauts fared, microbiological experiments were "piggybacked" on many of the early Soviet and U.S. missions. Zhukov-Verezhnikov and coworkers summarized the results of the "first microbiological experiments in space" by concluding that, "on flights similar to the orbit of the spaceship Vostok I, there is practically no effect from factors capable of primary action on isolated cells" (1). In fact, based on early theoretical analyses, many scientists did not expect to find any effect of microgravity on single cells smaller than about 10 microns (2). Despite this prediction, a general synopsis of the research over the past few decades reveals that many differences do occur in microbial growth and behavior as a result of spaceflight, presumably being due primarily to weightlessness. An overview of the literature also reveals inconsistencies in the findings reported by different investigators and in the interpretation of the data. Infrequent spaceflight opportunities, complicated by varying experimental conditions, add to the difficulty of establishing reproducible results and drawing consistent conclusions. As a result, the regulating mechanisms responsible for the changes observed in microbes caused by spaceflight remain largely unknown. The expanding volume of characterization data, however, is now paving the way toward hypothesis-driven research aimed at isolating variables and identifying causal factors.

Numerous microbial spaceflight experiments have been performed since the 1960s onward. Much of the earlier research has been previously documented in the following articles, cited here for reference (3–14). This current

summary focuses primarily on describing findings from literature published from the mid-1980s through the 1990s, and a short synopsis of the results is provided in Table 1.

GROWTH KINETICS AND MOTILITY

Microorganisms are highly dependent on intracellular and environmental parameters. Cellular movement within a liquid medium becomes important if one considers a microbe to be a point source, excreting metabolic waste products and consuming nutrients with a resulting sphere of molecular concentration gradients extending radially outward from the cell. The availability of nutrients and the removal of metabolic by-products in suspension cultures are, in turn, affected by various forces acting on the cell (sedimentation, diffusion, motility, etc.) as well as on the bulk fluid (diffusion, convection, etc.). To fully characterize the influence of gravity on living systems, it must be isolated and treated as an independent variable.

Gravity results in a constant sedimenting force on particles, dependent on density differences with the surrounding environment. Brownian motion, or diffusion, imparts random movement to particles due to thermal energy, and is independent of gravity. Brownian movement has been theoretically described as a counterbalancing force to sedimentation in the case of particles less than about 0.5 microns in diameter and below a density difference of about 0.03 g/cm^3 (15). On the basis of these criteria, nonmotile bacteria suspended in an aqueous medium fall just over the threshold into being capable of being influenced by gravity. Although random Brownian movement of the cells is still greater than that due to gravity at any given instant, the cumulative and unidirectional force of gravity progressively moves the cells toward the bottom of the container. Stirring the culture will, of course, also serve to maintain the cells

in a state of suspension as occurs in weightlessness, but as opposed to the quiescent environment encountered in space, stirring imparts additional motion to the cells and mixes the medium; thus consequentially adding variables, rather than helping to isolate them.

Theoretical prediction of the overall outcome of weightlessness becomes uncertain at the level of single cells on the threshold of gravity's influence. To attribute differences in cellular behavior to weightlessness, all aspects of gravity-driven phenomena must be considered. Gravity produces weight and/or sedimentation of the cell and/or its internal components. Gravity also causes changes in the external fluid environment (liquid or gas) surrounding the cells. The effects can largely be characterized as internal or external phenomena and are commonly referred to as *direct* and *indirect*, respectively. Delineation by primary (weight), secondary (sedimentation), and tertiary (environmental) effects is also sometimes used to describe various responses to gravity.

The majority of the investigations discussed later in this chapter deal with prokaryotes. The principal gravity-dependent factors governing the extracellular environment of bacterial cells can be expected to similarly affect eukaryotic microbes, but these larger and more complex organisms introduce added complexity associated with gravity-driven responses (including sensing) of intracellular components. Discerning the so-called internal (direct) from the external (indirect or environmental) variables presents unique challenges that are not fully explored in this review.

Early Spaceflight Bacterial Growth Experiments

Mattoni was the first to report that *Escherchia coli* growth in a liquid medium produced "significantly denser populations as a result of spaceflight than identical cultures on earth" (16). Speculation into what caused the increase was suggested to be related to altered nutrient transfer into and waste transport out of the cell as a result of the reduced gravity environment. Elaboration on this theory continues into the present era. This and other research, conducted during the 1968 U.S. Biosatellite II mission, were reported in a dedicated issue of BioScience (June 1968, Vol. 18, No. 6). Mesland summarized the results from the STS 61-A (Spacelab D-1) BIORACK experiments by noting that, "microgravity increases proliferation in bacteria and unicellular organisms" (17). This conclusion was termed "quite unexpected," with the underlying mechanisms remaining basically unknown.

Alpatov and coworkers discussed the results from several experiments performed on the biosatellite COSMOS-1887 and summarized the cellular biology goals as including "searching for gravity-dependent processes in the cells and nonspecific gravity sensors and identifying adaptive changes in the cell, occurring in weightlessness" (9). In the same journal volume, Parfenov presented the general conclusion that "individual one-celled organisms showed no signs of any gravity-dependent processes" (18). Seemingly, contrasting interpretations of data such as these exemplify the controversy currently surrounding the specific role(s) that gravity plays at the cellular level.

Regardless of the various primary experimental objectives and subsequent conclusions drawn from the data, the majority of investigations to date have indicated that weightlessness does appear to influence microbial growth and behavior. In an attempt to characterize the specific effects of spaceflight on microbial growth kinetics, each stage of growth — lag, exponential, and stationary — can be individually examined. Other factors, such as suspension versus agar cultures and motile versus nonmotile cells, should also be considered separately. Care should be taken to avoid interpreting reports of a higher "final population density" being reached to imply that a faster "growth rate" occurred, or vice versa. Ultimately, however, when attempting to establish cause-and-effect relationships, the common underlying biophysical parameters associated with reduced gravity must be consistently held accountable in governing all aspects of observed altered responses.

Transition from Lag to Exponential Phase in Suspension Cultures

Several investigations have indicated that spaceflight results in a shortened period of lag following on-orbit inoculation. A shortened lag phase on orbit (based on the observation that the maximal rate of increase in optical density occurred about five hours earlier in the flight unit compared to the ground control for *Bacillus subtilis* suspension cultures) was reported by Mennigmann and Lange (19), although a follow-on experiment failed to confirm the results. Mennigmann and Heise (20) later reported that the earlier finding may have been an artifact of specific test conditions.

Although not specifically reported as such, interpretation of the growth curve data presented for two other experiments using *E. coli* also indicated the possibility of a shorter lag phase having occurred on orbit (21,22). Through the use of on-orbit optical density recording, Klaus and coworkers observed the lag phase for suspended cultures of nonmotile *E. coli* to end four to eight hours sooner than for synchronized and comparably maintained ground controls (under conditions where the transition from lag to growth typically occurred 24 hours following inoculation) (23). Thévenet and coworkers also reported a shorter lag phase for suspended bacterial cultures on orbit, using a nonmotile strain of *E. coli* (24). In contrast, however, it was shown that lag phase was not affected in a complementary experiment using a motile strain of *E. coli*. This presents a significant observation, indicating that motile bacteria may be less susceptible to the indirect effects of sedimentation because of the overriding swimming motion.

Berg and Turner (25) showed that wild-type motile *E. coli* swim randomly at velocities of ~30 μm/sec, whereas the concurrent velocities driven by sedimentation and diffusion are calculated to be ~0.1 and ~0.5 μm/sec, respectively (23). As the movement of the cell due to sedimentation is estimated to be two orders of magnitude less than that of motility, it is presumed that the absence of gravity is unlikely to create noticeable

environmental (indirect) effects on a swimming organism. For a nonmotile bacterium, however, the absence of gravity limits cell motion to the forcing function of diffusion only, resulting in a less mixed extracellular fluid environment. Over time, this more quiescent state is suggested to alter the chemical gradients surrounding the organism and induce a corresponding physiological response. For example, one mechanism theorized to bring about the end of the lag phase is that excreted cofactors, such as enzymes, must reach a requisite concentration in the extracellular medium before the cells begin doubling (26). A decrease in net mass transport in the medium may allow these compounds to build up within a quasi-stable microenvironment surrounding the cell, given the absence of convection and sedimentation in weightlessness, thus signaling that the requisite concentration has been reached sooner than if the compounds were being further diluted throughout the bulk medium in normal gravity. This physical phenomenon is suggested to be the cause of the shortened lag phase duration in space (23). Thévenet and coworkers proposed that it is possible that the absence of gravity allows a small "cloud" of dissolved carbon dioxide to accumulate around the bacterial cell, which consequently allows it to come out of lag phase sooner than ground controls (24). This is consistent with laboratory studies that have shown that a lack of dissolved carbon dioxide in the medium can increase the lag phase (26). The proposed cascade of events described earlier in this section (removal of physical force due to gravity → altered chemical gradient around the cell → unique physiological response) exemplifies what are typically referred to as indirect effects of gravity.

Growth Rate and Final Population of Bacterial Suspension Cultures

The first observations of increased bacterial growth rate on orbit were made during the STS 61-A (Spacelab D-1) shuttle mission. Mennigmann and Lange reported an increase in both the rate of growth and in total final biomass yield of *B. subtilus* in space (19). In a follow-on experiment, Mennigmann and Heise reported the growth rate for *B. subtilis* on orbit was initially similar to that of ground controls, but later increased to about twice the growth rate observed in the controls (20). Other investigations have found the growth rate for *E. coli* on orbit to be similar to the ground controls (22) or statistically unaffected (but exhibiting a slightly slower trend) with the duration of the exponential phase on orbit, being two to five hours longer than the matched ground controls (23). Higher final cell population densities have been reported to occur for space grown bacterial suspension cultures reaching the stationary phase (16,19,23). Additional mention has also been made of a "stimulating effect on bacterial multiplication in space conditions" in other experiments not intended specifically to evaluate growth kinetics or population density per se (6,27–31).

Interestingly, similarities can be observed between the enhanced growth kinetics of *E. coli* batch cultures grown in space and specific bioprocessing characteristics achieved terrestrially through the use of a fed-batch glucose method. It has been demonstrated that using a controlled feeding technique (on earth) to limit the availability of glucose to the cells results in a slower, prolonged growth phase and a subsequent increase in final cell concentration (32,33). It is suggested that a reduction of extracellular mixing in the quiescent fluid environment experienced in the weightless environment of space may give rise to similarly reduced levels of glucose molecules being present in the (nonmotile) cell's immediate surroundings, albeit under normal batch conditions (34).

Data reported from an experiment performed on Biocosmos-2044, however, contradict the findings of increased growth rate and final yield. Bouloc and D'Ari found no differences between spaceflight samples and ground cultures in the growth yield per gram of carbon, in mean cell mass, or in the level of expression of the SOS response (35). Growth yield was not measured directly, but was determined using the relationship that mean cell volume increases proportionally to growth rates for *E. coli* (36). In drawing definite conclusions from these data, consideration needs to be given to several additional factors. Although growth rates were not directly reported here, it was stated that a minimal medium was used for this flight experiment. For growth rates less than one doubling per hour (as might possibly be expected using a minimal medium), the average cell mass tends to become constant (36). Therefore, if the flight and ground culture growth rates were different, but they were both undergoing near or less than one doubling per hour, that difference would presumably not be detectable based on cell volume alone. In addition to the potential of whether this may or may not have been taken into account, Manko and coworkers reported that *Proteus vulgaris* cells were shown to exhibit a slower growth rate on orbit (albeit on agar, further described later in the chapter), but the flight cells tended to be larger and showed a decrease in length-to-width ratio compared to the ground controls (37). This suggests that the normal ratio of cell volume to growth rate may be altered by other factors associated with spaceflight that could skew the otherwise predictable relationship referred to earlier in the chapter. Finally, gravity-dependent factors associated with hardware used to contain the samples may also influence growth kinetics, particularly of the ground controls. For example, bacteria grown in tall, vertical test tubes have further to sediment relative to otherwise comparably treated cultures grown in short, flat containers. The differing distances that cells are allowed to "fall" before reaching the container bottom may play a role in whether or not a cumulative response to gravity is realized. As such, a thorough description of the hardware used is integral to interpreting results from space research, but unfortunately, is not always provided in sufficient detail.

In a later study intended to examine the effects of microgravity on the microenvironment and membrane transducing pathways of the cell, Gasset and coworkers reported observing a doubling time of 46 minutes for *E. coli* on orbit versus 59 minutes on the ground (21). However, it was concluded that microgravity had no effect on the growth rate as the flight cells were not correspondingly larger in size as might be expected for

faster growing cells (36). Again, the final conclusion that no differences occurred may be debatable, depending on the factors described earlier in the chapter. Considering the potential for cell dimension changes, the doubling time measurement, which indicated that a significantly higher growth rate occurred on orbit, possibly provides a more accurate metric.

Bacterial Cultures Grown on Solid Substrate

Bacterial cultures grown on semisolid agar have similarly been reported to exhibit a shortened lag phase on orbit. In an experiment performed on Salyut-7, Manko and coworkers reported that all flight samples of the bacterium *Proteus vulgaris* cultivated on semisolid agar exhibited a considerably shorter lag phase, as well as a higher level of metabolic activity (37). Because the cells were grown on a solid substrate, the environmental effects of bulk fluid behavior were mitigated; therefore, it is presumed that the cells must have been "directly" affected by gravity. Swarming behavior was studied by inoculating cells onto meat peptone and monitoring the rate of ring-shaped colony formation with an increase in activity noted for the flight samples. As previously referred to, the authors also reported an increase in size of the flight cells, along with a gradual reduction in the ratio of length-to-diameter not seen on the ground. Interestingly, in the same journal volume it was concluded that although a number of experiments have shown that spaceflight does affect microorganisms, theoretical analysis maintains that gravity does not have a direct influence on individual cells smaller than 10 μm (38). Kacena and Todd also reported a shortened lag period, but no difference in growth rate on orbit for *E. coli* or *B. subtilis* when grown in space on an agar medium (39). Final population density for bacterial cultures grown on agar, however, does not appear to be increased by spaceflight (39,40), and may even be reduced (37).

Simulating Weightlessness by Clinorotation

A device called a clinostat can conditionally provide a state referred to as "simulated weightlessness" (41). For suspension cell cultures, this is achieved by rotating a cylinder completely filled with liquid medium (i.e., no air space) containing the cells at a constant velocity. After a brief start-up period, the rotational velocity of the container wall is transferred radially inward until no relative fluid motion exists. Therefore, although gravity remains present, the g-vector is continually being reoriented when the fluid and cells rotate together like a rigid body. Within mathematically defined constraints, the suspended cells can theoretically remain "motionless" with respect to their (rotating) fluid environment as they do in actual microgravity (42). However, the force of gravity still acts on cells in a clinostat, so the total effects of convection and sedimentation are reduced but not eliminated. The "direct" effects of gravity, presumably, causing events such as stress on the cellular membrane or internal organelle displacement, are still present, although in a constantly changing direction, which may, in fact, add additional stress on the organism.

Clinostat data pertaining to effects on bacterial growth generally appear similar to those from actual spaceflight (16,20,39,42), but this may not always be true for larger organisms having internal components with varying densities. Factors including gravity-threshold phenomena, nonlinear relationships and biophysical parameters must all be carefully considered in assessing the applicability of clinorotation to simulate weightlessness for a given system.

Eukaryotes

Not surprisingly, larger, more complex eukaryotic microbes have been shown to exhibit various responses that are perhaps more directly influenced by gravity. The ciliates *Paramecium* and *Loxodes* use gravity as an environmental stimulus governing orientation (gravitaxis) and swimming velocity (gravikinesis). Although these phenomena are well characterized in terms of their occurrence, the cellular mechanisms responsible for sensing gravity are not fully understood.

Planel and coworkers first reported an increase in the growth rate and cell volume of *Paramecium tetraurelia* cultivated onboard Salyut-6 (43). Factors such as temperature, launch acceleration and vibration, and cosmic radiation were ruled out through measurement and controls. Similar to the bacterial research, it was hypothesized that weightlessness would result in randomly distributed waste and nutrients that may indirectly serve to enhance the growing conditions of *Paramecia* in space. A second hypothesis was posed that the weightless condition may also play a more direct role by reducing the energy normally required for "upward" motility, thus allowing the metabolism to be directed more toward reproduction.

Using an onboard centrifuge (NIZEMI) to observe the swimming orientation of *Paramecia*, Hemmersbach and coworkers showed that a threshold for negative gravitaxis exists somewhere between 0.16 g and 0.3 g (44). In contrast to the *Paramecia*, *Loxodes* did not react to accelerations in space, although they exhibited typical graviresponses at hypergravity and normal gravity before and after flight. It was not clear if other factors affected the outcome. No indication of the microorganisms having adapted to the space environment was observed in these experiments, further corroborating previous "nonadaptive" findings for *Paramecia* (45,46), *Loxodes* (47), and *Euglena* (48). Studies of an acceleration sensitive contraction period exhibited by the *Myxomycete* (acellular slime mold) *Physarum polycephalum* indicated that a threshold of sensitivity exists for this organism at as low as 0.1 g, and that any acceleration above the threshold can induce the complete response-regulation process (49).

The indication of response thresholds further suggests that gravity-dependent processes are likely to be nonlinear, thereby complicating direct extrapolation of results among hypergravity, normal gravity, and hypogravity studies. Through the analysis of viscosity and density parameters of cellular components, clues may be found to help identify candidate gravisensors within the organism as functions of the specific levels of acceleration found to elicit the observed responses. The exact underlying mechanisms by which the reported gravity perception is brought

about, however, remain largely undetermined. Ultimately, other factors, such as launch acceleration, on-orbit vibration, and radiation, must also be taken into account to fully discern the influence of gravity on living organisms. Onboard centrifuge controls can also be useful in isolating the effects caused by these variables.

GENETICS

The effects of spaceflight on three basic mechanisms for genetic information exchange — conjugation (cell-to-cell), transduction (bacteriophage-to-cell), and transformation (free DNA fragment-to-cell) — have also been investigated by using *E. coli* on the STS 61-A (Spacelab D-1) shuttle mission (29). In the case of conjugation, although no differences were found in the rate of transmission of early markers (ile 0.8 min), later markers (arg 27.1 min, and pur 38.6 min) appeared to be transmitted more efficiently under microgravity conditions, with three to four times as many recombinants compared with ground controls and flight controls in an onboard 1 g centrifuge. The hypothesized explanation was that mating pairs of aggregates were less likely to be disrupted in the quiescent microgravity environment, thus giving rise to higher recombination frequencies for the later markers. Because transfer of early markers did not appear to be enhanced, it was assumed that the actual formation of mating pairs or aggregates was not impacted. No significant difference was noted for transduction and it was suggested that the bond between the cell and the phage is more stable and less sensitive to stresses. No conclusion was drawn from the transformation experiment because of the unexplained variations in viable counts and in the number of transformants. In addition to the specific reported test findings, an "increase in cell number" was observed under microgravity. Even taking into account the higher cell concentration, a difference in the transmission of the later characters was evident.

Although not directly within the purview of a microbial review, an interesting observation regarding gene expression in a steady state culture of human renal cortical cells has recently been reported (50). It was noted that more than 1,632 genes were changed in the microgravity environment. Whether or not similarly induced alterations might extend to microbial systems remains to be determined.

ANTIBIOTIC EFFECTIVENESS

Other investigations have shown that (in vitro) bacterial cultures grown in space are able to proliferate in the presence of normally inhibitory concentrations of antibiotics.

The Cytos-2 experiment flown on Salyut-7 in 1982 revealed that a fourfold increase in Minimal Inhibitory Concentrations (MIC) of colistin and kanamycin was necessary to stop the growth of in-flight *E. coli* samples compared to ground controls (6,27). The MIC for chloramphenicol and erythromycin was also higher in cultures of *Staphylococcus aureus* on orbit. No retention of the increased resistance was noted in postflight tests, however. A follow-on experiment was flown aboard the Spacelab D-1 mission in 1985. The MIC of colistin was twofold higher for the flight cultures (28,30,31). A 100-fold increase in the number of viable cells was also observed in the flight samples, which were given sub-inhibitory levels of antibiotics, compared with similar ground controls. In a third experiment conducted in 1992 on the Spacelab IML-1 mission, a higher MIC was again observed using dihydrostreptomycin for in-flight of *E. coli* cultures, and a higher growth rate was reported in cultures using a sub-inhibitory level of antibiotics (22). However, no difference was found in either experiment between onboard samples centrifuged at 1 g and those exposed to microgravity. Although this finding may be unique in suggesting that differences may be attributable to spaceflight factors other than gravity, it is important to point out that the 1 g flight controls were not placed on the centrifuge until five days (31) or eight days (22) after launch. Using the same equipment, Gasset and coworkers noted that because the "controls were not placed on the centrifuge during the long storage period they could have been [prematurely] influenced by possible microgravity effects" (21). Complementary ground-based studies of antibiotic resistance at three sub-inhibitory levels of hypergravity (2,5, and 10 g) showed no significant difference in growth rates of bacteria cultivated with or without sub-inhibitory concentrations of dihydrostreptomycin when compared to one gram controls (51). These findings suggest that differences observed in reduced-g are not likely to be linearly extrapolated into hyper-g regimes.

Juergensmeyer and coworkers exposed four species of bacteria to spaceflight for a four-month duration aboard the Mir space station and then tested postflight susceptibility to a suite of 12 antibiotics (52). The data indicated that each species responded differently to the antibiotics, frequently becoming less resistant, but occasionally more, with no discernible pattern identified.

Different theories have been proposed to explain the reduction of antibiotic effectiveness on orbit. Perhaps the simplest explanation is that the reduced antibiotic effectiveness observed on orbit is not so much a result of increased resistance by the microbe, but more a consequence of enhanced growth (30,31). Observations that in-flight cultures of *S. aureus* had "a very marked increase of the thickness of the cell wall" led to the theory that some antibiotics may be rendered less effective in space by the modifications in the cellular envelope (thickness or permeability); however, no change was found in the cell wall thickness of *E. coli* (6,27,30,53). More recent experiments have further indicated that no change occurred in the cell wall thickness of *E. coli* (22) or *B. subtilis* (20) in flight. A definitive explanation of how bacteria are able to proliferate in normally inhibitory levels of a drug on orbit has yet to be established.

CREW HEALTH AND LIFE SUPPORT

In addition to the in vitro antibiotic effectiveness studies, changes in the human–microbe interaction in space represent another critical, yet not well-understood phenomenon. Data exist to suggest that the human

immune system, both cell mediated and humoral, may be altered by spaceflight (54). Pierson and coworkers showed that the incidence and total counts of clinically significant bacterial isolates from urine samples collected from 144 astronauts, spanning 25 space shuttle missions, were somewhat greater postflight when compared with that in preflight baselines (55). Outbreaks of diarrheal illness have been reported onboard the U.S. shuttle and at least two life threatening infections, one Soviet and one United States, have occurred during space travel, with one case resulting in a long duration mission being terminated early because of an "acute inflammatory disease" (56). Dermatology concerns in space may also arise from the difficulties of bathing combined with the potential for facilitated microbial growth, and little is known about percutaneous delivery of pharmaceutical agents during spaceflight (57).

Isolation of individuals in an airtight environment presents a separate factor that must be considered in the spacecraft environment when studying drug resistance acquired via in vivo microflora exchange. Taylor and Zaloguev conducted an experiment during the Apollo-Soyuz Test Project to assess possible bacterial transfer in the confined capsule environment (58). The results of postflight incubation showed that microflora samples from crew members collected during the mission presented a higher resistance to antibiotics than the pre- and postflight samples. Il'lin reported that the majority of coliform bacterial cultures sampled postflight from the Salyut-7 crew were resistant to tetracycline, yet there had been no resistant strains in the preflight samples, suggesting that those found later had arisen from microbial and/or plasmid exchange with visiting crew members (59).

Finally, advanced human life support systems planned for long duration space habitation will probably utilize regenerative biological organisms to recycle air, water, and food. These systems will need to be monitored for functionality and pathogenicity. Wastewater treatment represents one such critical application that will potentially be highly dependent on microbial processes (60). Biofilm formation presents a related microbiological concern that has begun to be analyzed for effects arising from spaceflight. One experiment indicated that biofilms formed on orbit appeared to accumulate somewhat, but not statistically significant, higher bacterial areal densities than ground controls (61). It has also been reported that *Burkholderia cepacia* (61) and *Pseudomonas aeruginosa* (62) were able to grow and form biofilms in space in the presence of low concentrations of chemical disinfectants.

The unique environment encountered during spaceflight may significantly alter the normally stable, symbiotic relationship between humans and microbes, and also affect the likelihood, spread and treatment of pathogens throughout a closed spacecraft. Understanding and controlling these phenomena represent critical steps toward maintaining a healthy and sustainable habitat for long duration human exploration of space.

SPORULATION AND SECONDARY METABOLITES

Although most investigations into microbial behavior in space to date have sought to characterize the observed microbial responses as they pertain to fundamental gravitational biology questions and immunological concerns, applied research encompassing space biotechnology is beginning to gain momentum. In addition to the changes in general microbial growth and behavior reported to occur in space, altered sporulation patterns and specific productivity of secondary metabolites have also been observed. In theory, sporulation and secondary metabolite formation compete for common nutrients (63); therefore, unique or related changes observed in either process may give insight into if and how gravity alters the cellular metabolic pathways.

Mennigmann and Lange reported substantially reduced spore formation on orbit by *B. subtilis* when compared with ground controls (19). The number of spore-producing cells was also reportedly much lower on orbit. A follow-on experiment carried out by Mennigmann and Heise produced conflicting results, however, with 60% of the *B. subtilis* flight cells producing spores compared to only 15% in the ground controls (20).

A pilot study aimed at quantitatively assessing secondary metabolite production in space was carried out onboard STS-77 using the eukaryotic fungus *Humicola fuscoatra* to produce an antibiotic called *monorden* (64). Two different agar-based media, defined and complex, were used to grow the fungus. In both media, an equivalent amount of fungal biomass produced up to 190% higher specific yields of the antibiotic when cultured on-orbit than in controls maintained under similar conditions on Earth. As the fungus was grown on a semisolid agar medium, the increased antibiotic production in space could not be attributed to a lack of cellular sedimentation. Therefore, a direct effect of reduced gravity on the organism itself or physical alterations affecting other subcellular level processes pose more likely explanations (e.g., altered fluid uptake from the agar or convective currents at the surface). In addition, a disparity of results noted between the different types of media used (defined versus complex) further corroborates the theory that microbial response to spaceflight may be medium dependent (20).

Related antibiotic production investigations have been performed using a High-Aspect Rotating Vessel (HARV) bioreactor on the ground. This special bioreactor is similar to a clinostat in attempting to simulate certain facets of the microgravity environment through rotation. Fang and coworkers investigated the production of three antibiotics β-lactam, Microcin B17 and Gramicidin S, using *Streptomyces clavuligerus*, *E. coli* and *Bacillus brevis*, respectively, under simulated microgravity conditions using the rotating wall bioreactor (65–67). The production of β-lactam was inhibited in the rotating environment and Microcin B17 was found to accrue in the medium as opposed to its normal intercellular accumulation, but Gramicidin S production was unaffected. As with clinorotation, the ultimate ability of this system to accurately simulate spaceflight depends on multiple experimental parameters.

The mixed results reported thus far on sporulation and antibiotic production suggest that although the altered inertial environment experienced in space or with the HARV can affect cellular secondary metabolism, it does not

necessarily produce consistent responses between various microbial species and/or specific test parameters.

FUTURE OPPORTUNITIES

In summary, the majority of evidence to date indicates that the reduced gravity experienced during spaceflight affects microbes through mechanisms related to changes in the surrounding fluid environment, as well as or in addition to, and to responses driven by internal gravity-dependent actions in larger organisms. Specific test conditions, growth medium, and assay methods must be carefully taken into account when attempting to draw conclusions from the results. Hardware design and operational methods usually vary significantly between different space flown experiments. These in turn can affect both the independent and dependent variables, thereby complicating the process of generalizing findings and conclusions. In addition, it does not yet appear feasible to directly extrapolate findings between species, further limiting the availability of existing comparable studies. Reproducible and systematic evaluations are necessary to confirm the reported findings and to begin conclusively identifying the underlying causal factors. Ground-based studies utilizing clinostats, HARV bioreactors and centrifuges will certainly add critical insight into how gravity affects microorganisms, but the International Space Station (ISS) currently being assembled on orbit will ultimately provide the continuous presence of a space laboratory needed to fully enable the emerging field of gravitational biology.

STORAGE POLYMERS: ROLE IN THE ECOLOGY OF ACTIVATED SLUDGE

Mauro Majone

Activated sludge is a complex consortium of several populations of microorganisms, whose ecology is strictly dependent on wastewater composition and process conditions. In turn, process performance strictly depends on activated sludge metabolic behavior and composition (e.g., the presence of bacteria promoting bulking and/or foaming phenomena, hindering good separation of activated sludge in the secondary settler). (See Filamentous Bulking in Activated Sludge, Control of; Activated Sludge — Foaming)

Many microorganisms, even unrelated from a phylogenetic point of view, have the ability to transform substrates into polymeric materials (storage compounds), some being able to store more than one compound. The ability to store has a strong competitive advantage, and is a key factor in determining the ecology (i.e., the population dynamics) of activated sludge. According to the original definition (1), storage compounds have an energy-storage function: these compounds usually are produced when the supply of energy from external substrates is in excess of that required for cell growth and related processes. Once the supply of energy from external substrates is no longer sufficient for optimal growth or maintenance of the cell, the stored compounds can be used as internal substrates and this is advantageous in the struggle for existence over microorganisms that do not have a similar mechanism. The ability to store internal polymers has been reported for several microorganisms (1) including bacteria that are the most numerous and the most important population of activated sludge microorganisms (2).

The storage process basically consists of an imbalance between the time and extent to which the substrates are available in the medium and the time and extent to which the cells are able to use them for growth. These unbalanced growth conditions are often produced in activated sludge processes by deliberate process design and operation in order to exploit their potential in determining the activated sludge ecology. The aim is to select or enrich the activated sludge for microorganisms that are more favorable to the required process performance. (see ACTIVATED SLUDGE — THE MICROBIAL COMMUNITY.)

STORAGE POLYMERS

Cellular material is mainly composed of complex chemical components of polymeric nature (proteins, RNAs, and DNA) and most can be used by the cell as an endogenous source of energy for maintenance, when there is a lack of external substrates. So although most of these polymers can act as reserve materials, the definition of storage polymers has to be restricted to the specialized ones, that is, biopolymers specifically synthesized as carbon and/or energy reserves that are not basal components usually produced by the cells for growth.

In unbalanced growth conditions in which storage is likely, the substrate can also be removed quickly by accumulation (3), that is, the substrate is transported into the cell and maintained in an almost unchanged form or transformed into low-molecular-weight metabolic intermediates. Although accumulation is another mechanism for synthesis of reserve materials, this will cause unfavorable concentration gradients in the transport and the need for high osmotic pressure (2). Thus, accumulation is a less efficient mechanism than is storage in which the molar concentration of substrates or intermediates is reduced by their polymerization. In other words, storage acts also as a mechanism for preventing the accumulation of internal metabolites at toxic levels during the periods of nongrowth (4).

As an additional mechanism for preventing too high an accumulation, the release of solutes or extracellular polymers has also been observed. The production of extracellular polymers, mainly polysaccharide in nature, is frequently seen in bacteria, offering them other advantages including the formation of a protective slime or promoting floc formation (see ACTIVATED SLUDGE — THE FLOC). However, there is no evidence that these compounds are synthesized specifically as reserve materials.

According to the earlier definitions, the term *storage polymers* has to be used for a few particular compounds, namely, certain polysaccharides, lipids (polyhydroxyalkanoates), and polyphosphates (1). All these compounds are of relevance in activated sludge processes and are briefly described in the following text.

A more limited range of microorganisms can store other compounds, such as nitrogen (N) (the cyanophycins in cyanobacteria) (5) or sulfur (S) (as energy reserve in sulfur bacteria relevant to the activated sludge, in that it occurs in some microorganisms causing filamentous bulking, such as in *Thiothrix*) (6,7).

Polyhydroxyalkanoates (PHAs)

PHAs are linear polyesters of 3-hydroxyl fatty acid monomers, the carboxylic group of one monomer forming an ester bond with the hydroxyl group of another monomer. The most common PHA in activated sludge is poly-3-hydroxybutyrate (PHB, Fig. 1a), but other PHAs have also been found in activated sludge (e.g., 3-hydroxyvalerate, 3-hydroxymethylvalerate, etc.). PHB is also used for the production of biodegradable plastics (8) and is present in the cells as various-sized granules, with a high affinity for fat-soluble dyes such as Sudan black, that can be seen in bright field microscopy, or Nile blue, under epifluorescence microscopy (9).

Polyphosphates

Polyphosphates are known to be present in the cells as cyclic or linear forms of different lengths (Fig. 1b). The interest in this compound increased dramatically since the end of the 1970s when polyphosphate was suggested to play a key role as an anaerobic cellular energy source in activated sludge plants designed to stimulate enhanced biological phosphorus removal (EBPR) from wastewater. (see ACTIVATED SLUDGE — THE PROCESS; ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL)

Polyphosphates are present as large reserve granules inside cells and stain by many basic dyes such as toluidine blue, changing color from blue to red (metachromasy). In the activated sludge that performs EBPR, the polyphosphates are usually shown by Neisser staining, appearing as dark granules in the cells (6,10).

Glycogen

Glycogen is a polysaccharide of glucose units linked between carbon 1 and 4 in the α-orientation (Fig. 1c) with occasional α-(1 $\rightarrow$ 6) branch linkages (5). Glycogen normally is present in cells as granules smaller than PHAs and they are harder to observe by optical microscopy, giving only a weak reaction with diluted iodine.

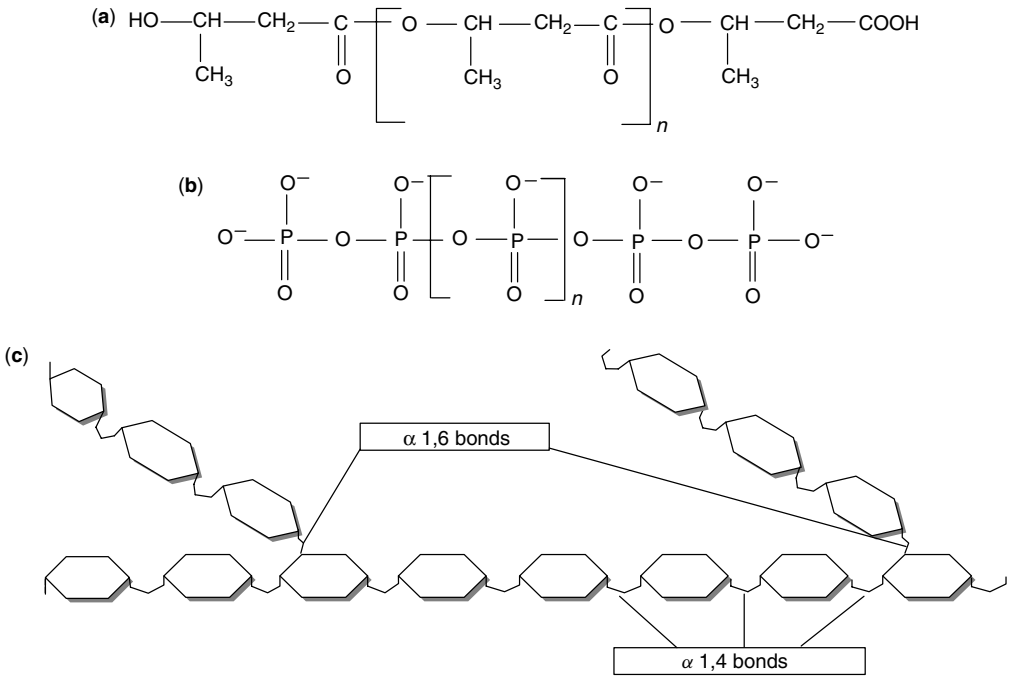

Figure 1. Structure of the main storage polymers: polyhydroxybutyrate (**a**), polyphosphate (**b**), glycogen (**c**).

STORAGE PROCESSES UNDER UNBALANCED GROWTH CONDITIONS

Although storage can occur under balanced growth conditions (11), it is observed more frequently under unbalanced growth conditions (12). As already stated, storage most often is present when some growth limitation prevents the cells from using the substrates for growth at the same rate at which they are transported into the cell and partially used to produce energy and reducing power and excess carbon (C) and energy are diverted into synthesis of storage polymers (1). Typically, this growth limitation can be caused by two different conditions that have been referred to (4) as metabolic (or external) induction and kinetic (or internal) induction.

Metabolic (External) Induction

In the case of metabolic induction, an excess of a readily usable carbon and energy source is available in a culture that is prevented from growing at its maximum rate by the absence or lack in the medium of some other essential component for cellular synthesis. A typical example is a deficiency of nitrogen with respect to carbon in the medium. Because most growth-associated components contain this element, overall growth is hindered, whereas carbon uptake and related energy production are not. Hence the energy available is used to transform excess carbon into storage compounds with no nitrogen content.

This metabolic (external) limitation is exploited for the production of commercial polymers (8,13,14) such as copolymers of 3-hydroxybutyric and 3-hydroxyvaleric acids (PHB/HV). The growth medium is typically designed to contain an excess carbon with respect to nitrogen, and the process is typically operated in two steps. First, the bacteria, usually *Ralstonia eutropha* (formerly known as *Alcaligenes eutrophus*), grow while the medium remains nutritionally well-balanced. Once the medium becomes nitrogen-deficient, the residual excess of carbon is stored until the cells almost totally consist of polymer (up to 80% as dry weight). Most of the available knowledge on physiology and biochemistry of PHA storage has been reviewed in this context (8,13). Similarly, polyphosphate can be stored in cells following sulfur or nitrogen starvation: again growth is hindered and the cells accumulate polyphosphate (15).

However, these conditions of nutrient deficiency rarely are reported for activated sludge processes treating municipal wastewater, although they might occur in the presence of wastes of industrial origin and eventually cause bulking problems (2,16).

The most frequent case of storage caused by external nutrition limitation in activated sludge processes is the storage of carbon source in the anaerobic phase of alternating anaerobic/aerobic processes (e.g., in processes for EBPR). Here, the limiting component is not an element to be used by the cell for growth but is the external electron acceptor necessary for energy production [molecular oxygen (O_2) or nitrate]. Apparently, in this situation, some microorganisms have the ability to use alternative sources of energy and reducing power in order to take up the substrate (usually acetate) and store it (as PHB) at rates and extent less than those when O_2 or nitrate is used in respiration. These include hydrolysis of polyphosphate as an energy source (17) and glycolysis of glycogen as both source of energy and reducing power (18–20). This anaerobic storage differs from that previously described, in that it seems to occur in

energy-poor instead of in energy-rich conditions. However, it is not clear whether cell growth is hindered due to such energy limitation or whether storage is the faster process in assimilating available substrates in the highly dynamic anaerobic/aerobic environment (see the following text). It is also noteworthy that during subsequent aerobic growth, internal reserves (polyphosphate and glycogen) are replenished, although no external or internal nutrition limitation is evident. Thus, this is an example of simultaneous growth and storage.

PHB accumulation can also be induced by oxygen limitation, in which PHB acts as a sink for excessively generated intracellular reducing power of electrons (1).

Kinetic (Internal) Induction

In the case of kinetic induction, no external limitation exists, that is, the medium contains all the substrates to allow cells to grow at their maximum rate. Nevertheless, the cells cannot immediately increase their growth rate to the maximum level because they have previously been under conditions of slow growth or maintenance, that is, they are deficient in the sufficient "synthetic machinery" needed for high growth rates (4). In other words, as a result of its previous growth and physiological conditions, the cell suffers an internal limitation. This is the case that is most likely to occur in activated sludge processes because of their highly dynamic conditions (21).

This internal limitation depends on the physiological adaptation of cells. When microbes are transferred to a different environment, fundamental changes occur in their composition (mainly their macromolecular composition, i.e., relative concentration of proteins, RNA, DNA, etc.) as it adapts to new conditions. This change in their macromolecular composition is known as *physiological adaptation*, and the macromolecular composition at a given time is referred to as the *physiological state* (22). When the environment is relatively steady, physiological adaptation produces a final physiological state that is optimum for cell growth in that environment, and no further adaptation is necessary. Growth of a well-adapted cell with no change in composition is also referred to as *balanced growth*, and growth in the presence of physiological adaptation (23,24) is referred to as *unbalanced growth*.

Bacterial cells in balanced growth synthesize all components (DNA, RNA, proteins, etc.) at the same relative rates. On transfer to different environmental conditions (e.g., higher carbon source concentration), the rate of RNA synthesis rapidly changes, whereas the rates of DNA, protein, and other compound synthesis and the rate of cell division only later follow the changes in RNA content (25,26).

When growth restriction is removed, the cell's ability to immediately increase substrate-removal rate is determined by its physiological state. Sometimes, particularly in activated sludge process, cells are not growing in a steady state but in fluctuating conditions, possessing an "extra synthetic machinery" and a limited ability to immediately increase their specific growth rate (available reaction potential, ARP, 27). However, the RNA usually is not sufficient to allow the culture to grow at its maximum specific rate and therefore the "synthetic machinery" level must be increased first (28). Hence, this will increase gradually with time, the specific growth rate will also increase and eventually reach the maximum value possible under the new conditions (the so-called growth response).

Consequently, when the culture experiences a sudden increase in available substrate and/or energy, it can adapt itself to the new conditions by storing the available substrate (storage response, phase I in Fig. 2a). Storage as well as growth, involves transport of substrates, oxidation of a portion for energy production, and use of another portion for synthesis. However, synthesis of storage polymers is simpler and faster than synthesis of all cellular components. In that sense, storage is a mechanism to maintain a more balanced situation inside the cell between energy production and energy utilization (21,29).

After being formed at high substrate concentrations, stored polymers are consumed as internal substrates for growth when external ones are at limiting concentration (phase II in Fig. 2a). It has been reported for *Paracoccus pantotrophus* (30), that the growth yield on acetate through formation and consumption of PHB is only 6% less than yield from direct growth on acetate under balanced conditions. This indicates that the storage response is quite efficient from an energetic point of view. Hence, microorganisms able to store substrates and reuse them for growth could have a competitive advantage, which is relevant when considering the selection of different populations in activated sludge.

For these reasons, storage response often prevails on the growth response during transient feeding conditions in activated sludge (12). Such prevalence is stronger when more of the substrate is in a form readily available to

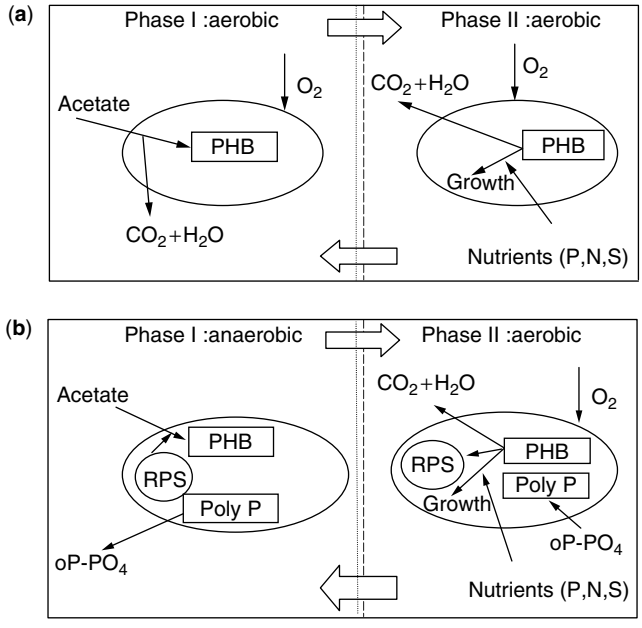

Figure 2. Storage response under different conditions. (**a**) Aerobic storage (phase I: storage phase, phase II: growth phase); (**b**) anaerobic/aerobic storage (phase I: anaerobic storage, phase II: aerobic growth and storage). RPS: reducing power source.

the cells (i.e., soluble, low-molecular-weight, and simple substrates such as volatile fatty acids and carbohydrates). On the contrary, for slowly biodegradable substrates, it is assumed that the storage is less important in transient conditions (4) as there is a need for their hydrolysis before they can become available to the cell.

AEROBIC STORAGE IN BULKING AND FOAMING CONTROL

Satisfactory performance of activated sludge processes implies that good separation and thickening of the sludge are obtained in the secondary settler. Unfortunately, activated sludge processes are often disturbed by numerous separation problems that include dispersed growth, viscous or filamentous bulking, pinpoint flocs, rising sludge, and foaming or scum formation. (see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF; ACTIVATED SLUDGE — FOAMING).

Usually, most of the problems are related to the presence of large amounts of filamentous microorganisms in the activated sludge; worldwide, 30–40% of traditional activated sludge plants suffer bulking and foaming problems. In particular, filamentous bulking is caused by the overgrowth of filamentous bacteria, which usually protrude from the flocs and interfere with sludge settling. Although more than 30 different filamentous microorganisms have been reported (10) in bulking sludges, their overgrowth has been explained according to some limited general physiological differences between the groups of so-called floc formers and filaments (2) (see FILAMENTOUS BACTERIA IN ACTIVATED SLUDGE: CURRENT TAXONOMIC STATUS AND ECOLOGY).

Storage is involved in controlling bulking phenomena in process configurations in which a substrate concentration gradient is created (corresponding to an F/M gradient). Figure 3 shows examples such as plug-flow configuration of the aeration tank (no longitudinal mixing because of the tank shape or compartmentalization, Fig. 3a), presence of a selector (a small tank receiving both the return sludge and the influent before the main one, Fig. 3b), and contact-stabilization configuration (similar to the previous one but with intermediate settling, Fig. 3c).

On the basis of empirical evidence that activated sludge from these configurations usually has better settling properties, two theories have been used to explain why the floc-forming bacteria are favored in the presence of a gradient (2), one based on balanced growth and the other based on unbalanced growth (i.e., storage) (see FILAMENTOUS BULKING IN ACTIVATED SLUDGE, CONTROL OF). The first approach assumes that floc formers usually have both higher specific maximum rate (μ_{max}) and semisaturation constant (K_s) than filaments. Hence, floc-formers have a μ_{max}-based strategy of competition, that is, they grow faster than filaments when substrate concentration is high, as in the presence of a concentration gradient, whereas filaments have a K_s-based strategy, that is, they grow faster than floc formers when substrate concentration is low, as in completely mixed reactors.

The second approach is based on the observation that in the presence of a substrate gradient, bacteria alternately

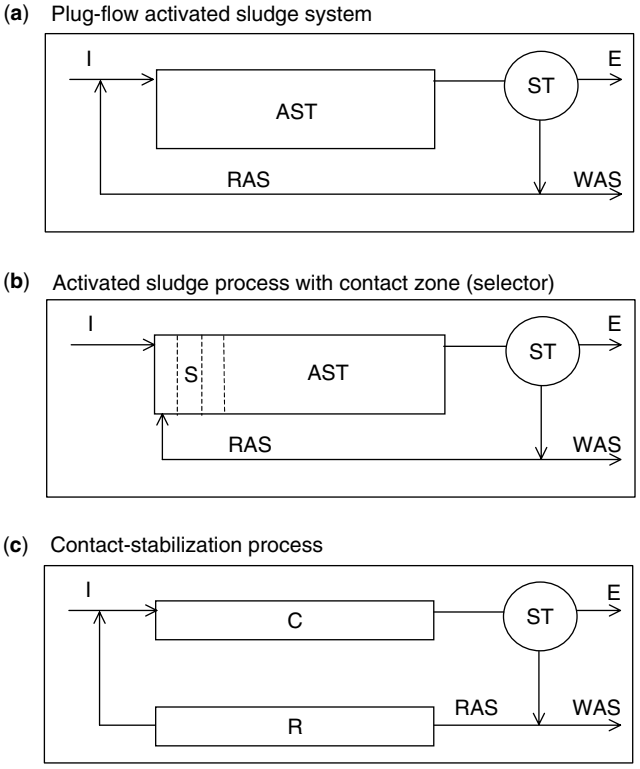

Figure 3. Activated sludge process configurations in which a substrate concentration gradient is created and storage is more likely to occur. I: influent, E: effluent, RAS: return activated sludge, WAS: waste activated sludge, AST: activated sludge tank, ST: settling tank, S: selector area, C: contact zone, R: regeneration zone.

experience high and low substrate concentration because they are circulated continuously through the plant. Because of this unbalanced condition (also called a feast and famine regimen), storage and accumulation are the main mechanisms for enabling fast substrate uptake when they arrive in the substrate-rich area coming from a substrate-limiting situation (31,32). Thus, selection is based not only on an ability to quickly accumulate or store the substrate but also on an ability to subsequently reuse it for growth. According to the accumulation-regeneration theory (3), the use of accumulated or stored compounds during growth is also necessary to regenerate their limited accumulation or storage capacity. The better settling performance obtained in configurations with substrate concentration gradients seems to indicate that floc formers have this type of competitive advantage over filaments (2).

Although these approaches are not mutually exclusive, it is widely accepted that storage plays a relevant role in competition between floc formers and filaments, at least in highly dynamic processes and in the presence of readily biodegradable substrates (3,12,21). Nevertheless, very little experimental confirmation has been published on full-scale plants or at least with real activated sludges and wastewater. Most of the knowledge comes from pure or mixed culture studies under aerobic conditions (12), as briefly summarized in the following section.

Pure Culture Studies

Studies have been carried out on floc formers such as *Arthrobacter globiformis* (33,34) and *Zoogloea ramigera* (11); on typical filaments such as *Sphaerotilus natans* (33,34), Type 021N (11), and *Gordona amarae* (35), and on other bacteria such as *Pseudomonas putida* (22,36), *Aquaspirillum autotrophicum* (37), and *Paracoccus pantotrophus* (38).

Although not all these studies explicitly consider the storage, they all investigate the transient response of a biomass (harvested from a continuous steady state culture) to a pulse addition of an excess of substrate (short-term batch tests). As already mentioned, once substrate limitation is removed from earlier culture conditions, a rapid increase of substrate-uptake rate (SUR) usually occurs and the related "observed yield" is often high (here, observed yield has to refer to the formation of biological suspended solids, independently from their composition, so also including stored compounds). In the absence of direct determination of storage polymers, the high rates and "observed yields" have often been taken as evidence of storage. In some cases (11,33), SUR and "observed yield" were higher in batch tests than under unrestricted balanced growth (i.e., maximum values obtained in the parent chemostat). This trend could only be due to growth and confirms the presence of storage as a fast and high-yield response. When directly determined, the observed amount of polymer formed per unit of substrate removed ranges from 0.32 to 0.79 COD of formed polymers/COD of removed substrate (12), often representing most of the overall "observed yield."

Figures 4 and 5 summarize pure culture studies performed using acetate as the sole carbon source (11,35,38). Specific SUR (Fig. 4a) and observed yield (Fig. 5a) in batch tests are reported as functions of dilution rates D (growth rate) in the parent chemostat. It is quite evident that both specific SUR and "observed yield" depend on the previous D and that in a "theoretical" situation, different microorganisms could dominate at different D. This indicates that the previous physiological state of the biomass can be the key factor in the kinetic selection of different microorganisms in mixed cultures. Figures 4b and 5b report the same data shown in Figures 4a and 5a, except that D has been normalized with respect to the maximum growth rate of each microorganism. A general trend can be observed for the different bacteria. The transient response seems to decrease as D either becomes very similar or very low with respect to the μ_{max}. In all studies, the transient response at D near μ_{max} tends to correspond to the steady state behavior. For microorganisms in which transient SUR presents a maximum as a function of D, the authors (11) assume that this corresponds to the maximum storage capacity. Inconsistent to the SUR, the observed yield seems to show a constant trend: it slightly decreases as D increases, which seems to indicate that storage also decreases; accordingly, direct measurement of storage yield and storage capacity confirmed that both tend to increase as D decreases (30).

Little attention has been given to substrates other than acetate. *Arthrobacter* sp. and *Sphaerotilus natans*, grown at one D ($1\ d^{-1}$) in glucose-limited conditions, have storage responses under transient conditions (33,34). However, glucose-uptake rate for *Arthrobacter* sp. was more than twice that for *S. natans*, and the ratios of stored polymer to the substrate taken up were 0.7 and 0.3 COD/COD, respectively, thus showing that the floc former has a higher storage response than the filament. A higher storage response is clearly advantageous to the floc former *Arthrobacter* sp., with respect to the filament *S. natans*, when competing under transient conditions. A storage response has also been observed for *A. autotrophicum* on pyruvate (37) although only 12% of removed substrate was recovered as stored polymer. In experiments performed on *P. putida* cultivated in an L-lysine-limited feed (22) at a dilution rate less than $0.3\ \mu_{max}$, the oxygen-uptake rate (OUR) under transient conditions was faster than

Note: Original units of most data from authors of this entry.

that under steady state conditions, whereas the rate of synthesis of growth-associated macromolecules remained unchanged. Hence, the available surplus of energy under transient conditions could probably be used for synthesis and accumulation of intermediary metabolites, whereas storage polymers were not identified.

Very few studies have been performed on pure cultures grown under periodic feeding conditions. A comparison was made of the transient responses of both *Arthrobacter* sp. and *S. natans* grown under continuous versus intermittent feed of glucose (34). For both microorganisms, growth under periodic conditions increased storage response with respect to steady state culture.

It has to be stressed that the range of D investigated so far (usually $>1\ d^{-1}$, corresponding to culture age <1 d) does not correspond to growth conditions that are most typical of activated sludge processes (in which the sludge age is usually much higher). Hence, there is still a lack of knowledge on the dynamic response of pure cultures growing at high sludge age (low growth rate).

Mixed Culture Studies

Studies with mixed cultures (31,34,39–44) have been related more directly to bulking control. These studies have been typically performed by comparing the transient response of sludges exposed to continuous feeding (usually bulking sludges) with that of sludges with intermittent feeding regimens or with the presence of a selector (usually well-settling sludges). It has to be stressed that in the case of mixed cultures, the effects of different growth conditions include significant change of both the physiological state of microorganisms and the distribution of microbial population in the sludge.

Well-settling sludges typically presented faster substrate uptake and higher "observed yields," which have been usually interpreted as indirect evidence for more relevant storage response. The importance of a storage response has been confirmed by direct determination of polymers in sludges storing glucose mainly as glycogen (34,42) or storing acetate as PHB (29,43), and confirms that the more the bacteria are able to store substrates during imposed transients and subsequently reuse them for growth, the more they are likely to have a competitive advantage. Predominance of such microorganisms will increase the transient response of the sludge.

As an exception, it has also been shown (44) that although intermittent feeding always causes a storage response, a bulking sludge can also be selected. The authors showed that this was due to high storage response of an unusual filamentous bacterium that eventually became dominant in the sludge. They also investigated the effects of different dilution rates in an intermittently fed reactor and showed (45) that increase in D from 0.33 to 2.64 d^{-1} caused an increase and then a decrease in the transient response (because of the corresponding trend in the storage response). This behavior is in qualitative agreement with studies reported earlier on pure cultures (11).

By studying the effects of temperature (15–35 °C) on the settleability of sludges, storage contribution to external substrate removal (acetate) appeared to decrease as temperature increased (29). Accordingly, the sludge settleability decreased (i.e., the sludge volume index) as the temperature increased.

Activated Sludge Studies

Lack of detailed studies on real wastewater and sludges is due to practical difficulties and simultaneous presence of many different phenomena such as sorption, accumulation, storage, and growth on soluble substrates and enmeshment and hydrolysis of particulate. Some data are available from respirometric batch experiments in which typically a known amount of a selected substrate is added to a sample of activated sludge. In these conditions, it

has been shown that the respirometric curve (i.e., OUR as function of time) presents two different phases, at high and low OUR (both higher than the endogenous OUR). Because a single and readily biodegradable substrate is used, the presence of the second phase at low OUR has been attributed to the consumption of the stored product, indicating the presence of storage during the first phase (46). Recently, it was confirmed experimentally (47) that PHB was formed when mixing domestic wastewater and activated sludge. Moreover, more PHB was formed than that possibly coming from acetate present in the wastewater, thus suggesting that PHB storage also was due to other organic compounds present in the wastewater.

ANOXIC STORAGE IN NITROGEN REMOVAL PROCESSES

Activated sludge processes for biological nitrogen removal are characterized by the presence of an "anoxic" tank (here anoxic refers to the absence of oxygen in the presence of nitrate) where the nitrate reduction (denitrification) takes place. (see ACTIVATED SLUDGE — THE PROCESS; ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Storage under anoxic conditions has been studied much less than that under aerobic or anaerobic conditions, although it is likely that it also is important in nitrogen-removal processes (21,48) in which the removal of the major fraction of organic substance occurs when nitrate is present as the only electron acceptor.

Storage can be relevant when, in a system with pre-denitrification, the anoxic tank has a plug-flow configuration or contains a selector (so introducing a feast and famine regimen). Similar to aerobic selectors, storage under anoxic conditions can be a key factor of microbial competition for the substrate. Literature evidences of a positive effect of storage phenomena on settling properties of sludge has been reported widely under aerobic conditions (see previous section) and the same selection of floc-forming biomass therefore is expected under anoxic conditions. Moreover, such selection also should be stronger under anoxic conditions because most of the reported filaments are not able to denitrify (2). However, a recent study showed that, although filaments are less able than floc formers to store substrate into PHA, they nevertheless can grow and proliferate in an anoxic-aerobic SBR fed with a mixture of readily and slowly biodegradable substrates (49).

The presence of storage can be enhanced when an external source of readily biodegradable COD (RBCOD) has to be added to increase the denitrification rate. In this regard, it is important to observe that the external substrate often is the effluent of a fermentative process (50,51) and therefore is rich in volatile fatty acids, the favorite substrate for PHA storage. Besides storage under anoxic conditions, denitrification on the stored products also can be important in increasing "endogenous" denitrification rate. As an example, an aerobic contact-anoxic stabilization process has been proposed (52) in which a higher "endogenous" denitrification rate is achieved in the anoxic tank as a result of previous biosorption and storage of COD in the aerobic one.

The formation and/or consumption of storage products in the anoxic zone will affect the overall "observed yield" and therefore the COD/N ratio (i.e., the amount of COD that is needed to reduce 1 unit of nitrate nitrogen to molecular nitrogen). As already stated, storage requires less energy than growth that corresponds to a lower amount of oxidized substrate per unit of removed substrate. Theoretical calculations, considering acetate as substrate (48), show that maximum biomass yield is 0.58 COD/COD when acetate is only stored into PHB, whereas it is 0.36 COD/COD when it is used directly for growth. These different values correspond to 6.8 and 4.5 mg COD/mg reduced N-NO_3, respectively. On the other hand, growth through formation and consumption of PHB will require more energy (maximum yield 0.31 COD/COD corresponding to 4.1 mg COD/mg reduced N-NO_3) than direct growth on acetate. So the overall "observed yield" and related COD/N ratio will vary depending on relative extent of storage of external substrates and consumption of internally stored ones in the anoxic tank.

With regard to experimental evidences of anoxic storage, recent studies (48,49,53,54) have shown that anoxic storage of PHB occurs under transient conditions by using acetate or ethanol as carbon source. From the reported studies, it is clear that storage mechanisms under anoxic conditions are basically the same as those under aerobic conditions: storage response is induced by feast and famine conditions. Kinetics of PHB storage under anoxic or aerobic conditions also has been compared. By using biomass cultivated under fully anoxic conditions, different evidences were found: some authors (54) showed that acetate uptake rates were almost similar when switching from anoxic to aerobic conditions; on the contrary, other authors (48) reported a three times higher acetate uptake rate under aerobic conditions with respect to anoxic ones. However, in both studies the amount of stored polymer per amount of removed acetate was quite similar and almost independent of the type of electron acceptor present.

More limited are the studies of glycogen storage under anoxic conditions. Storage of carbohydrates (probably glycogen) under anoxic conditions has been shown when glucose was the carbon source (49): in that case, formation of internal carbohydrates accounted for the whole "observed yield" (overall formation of biological solids).

ANAEROBIC/AEROBIC STORAGE IN EBPR PROCESSES

During the 1970s an important observation was made in activated sludge plants: sometimes in treatment plants with an anaerobic zone at the head of the plant, phosphorus (P) was removed to an increased extent in the aerobic zone. The aerobic sludge presented a higher phosphorus content and consequently the effluent a lower phosphorus level, (<1 mg/L). Many large treatment plants began to be built on the basis of this new process (17), named EBPR (see ACTIVATED SLUDGE — THE PROCESS).

Intense research (55,56) since then has tried to elucidate the microbial basis of the phenomenon. The common information obtained from both full-scale and pilot plants are as follows:

- In the anaerobic zone there is a P-PO_4 release, (see , corresponding to an uptake of the carbon source.
- Carbon sources are not equally efficient and the best are simple molecules and monomers, such as short-chain fatty acids (SCFA), and particularly acetate, widely selected for research studies as the preferred anaerobic substrate. In real plants the role of other classes of compounds has to be considered.
- Substrate assimilated is converted simultaneously into polymers reserve material, including PHAs, such as not only PHB but also PHV′3 methyl PHV′, etc., when SCFA different from acetate are fed.
- In the aerobic zone, oxidation of stored PHAs occurs with growth of the biomass and reconstitution of the polyphosphate reserves. The final result is that a sludge with a higher phosphorus content is produced, and can be disposed of (17).
- The EBPR sludges microscopically look quite different from ordinary activated sludge, with large clamps of bacteria, cocci in shape, which, if sampled in the aerobic reactor, strongly stain with Neisser stain because the cells are full of polyphosphate (57).

To explain these observations, the existence of bacteria possessing a peculiar metabolism was proposed. These bacteria would have the capacity to anaerobically use their polyphosphate as energy source, allowing them to transport substrates and synthesize PHA. These bacteria would have a mixed metabolism (Fig. 2b) involving anaerobic storage of the carbon source using energy from polyphosphate (Phase I in Fig. 2b) and aerobic growth and storage of polyphosphate (Phase II in Fig. 2b). Crucial is the involvement of internal-storage carbohydrate reserves for production of reducing power ($NADH_2$ probably) necessary for the anaerobic synthesis of PHB from acetate. The term *poly P bacteria* was used to describe organisms with this ability.

Twenty-five years have not been sufficient to clarify the metabolism of these poly P bacteria and identify them (55,58). A pure culture of a poly P bacterium performing the chemical transformation depicted in Figure 2b has never been obtained. Nevertheless, the existence of such poly P bacteria is the only way to explain adequately the observations repeatedly made with EBPR.

EBPR represents one of the most intriguing cases of storage because all the three main classes of storage compounds are involved and mutually interconnected: PHAs, polyphosphates, and carbohydrates polymers. Full-scale EBPR plants currently are used in many countries but uncertainties still exist with the process. Sometimes the plants fail to reach expected performances and the required low phosphorus level in the effluent; this explains why many of them have a tertiary chemical-physical treatment for phosphorus removal, to cope with unexpected failures.

Some of the reasons given to explain the failures include

- The unsuitability of the organic carbon sources in the anaerobic zone. Basically, SCFA are thought to promote EBPR. Carbohydrates can be fermented to SCFA by other heterotrophs, so acting in favor of the metabolism shown in Figure 2b. However, the energy derived from carbohydrate fermentation can also be used for directly storing carbohydrates (55). As outlined in the following, this is a competing metabolism with respect to the one shown in Figure 2b. Very little is known about the role of proteins as substrates for poly P bacteria under anaerobic conditions.
- Use of suitable carbon sources by denitrifying bacteria can occur if too much nitrate and nitrite are circulated back into the anaerobic zone from the aerobic one.
- The existence of bacteria competing in the anaerobic zone for SCFA, without involving polyphosphate. Basically, these would use the internal stored carbohydrates as energy source. Also, the existence of these bacteria has been supposed; they have been indicated as GAOs (56). Even though G-bacteria (60) were formerly assumed to behave as GAOs, this has not been demonstrated yet (see ACTIVATED SLUDGE — THE "G-BACTERIA").

EBPR certainly is a complex process in which the bacteria alternate under different conditions: the microbiology of these processes is not explained and a proper study of these systems represents a good challenge for the future.

It is important to underline that the phenomenon also is complicated by the involvement of chemical and physical phenomena, because of the presence of cations such as calcium and magnesium in the wastewater. Calcium and magnesium phosphates have a very low solubility product and it is possible that precipitate formation and dissolution can occur in different environments (61). EBPR in some cases may be a biologically mediated physical-chemical phenomenon.

Detailed characterization of the storage processes in EBPR sludges are available mainly on pilot plants; complete sets of data concerning the substrates and polymers involved (acetate, phosphate, polyphosphate, PHB, and carbohydrates) are available.

An activated sludge in a traditional aerobic plant shows neither appreciable anaerobic acetate uptake nor PHB synthesis. Sludges grown in alternating anaerobic/aerobic conditions on wastewater containing appropriate amounts of phosphate (high enough to allow storage of polyphosphate) and suitable carbon sources (containing or suitable for producing SCFA) show the typical turnover of the polymers depicted in Figure 2b.

The following points can be highlighted (62–64):

- The values for anaerobic acetate uptakes are variable (12.2–73.8 mg/g SS h) but are lower compared with aerobic processes (at least 1 order of magnitude less).
- The amount of PHB formed per acetate taken up depends on the experimental conditions and the reducing power source (e.g., 1.3 Carbon mole PHB/Carbon mole acetate at pH 7.4).
- The anaerobic phosphate releases are quite variable, between 3.7 and 60.9 mg P/g SS h and also are strongly influenced by the pH value.

- Total carbohydrates usually decrease in the anaerobic conditions and increase again during the aerobic phase. The amount used is variable in comparison to polyphosphate turnover.
- Aerobic uptakes rates of phosphate are lower than the release rates.
- The phosphate released/acetate uptake ratio ranges from 0.24 to 0.80 P-mole/C-mole, and is strongly influenced by pH.
- EBPR sludges may contain up to 10% P and only part of it is released anaerobically.

It may be concluded that anaerobic storage involving PHAs, polyphosphates, and probably glycogen, is a process occurring slower than under aerobic conditions, as far as the PHAs synthesis is concerned (12). The key point is to allow the poly P bacteria cells to use properly their storage materials to accumulate more phosphate than they need, leaving a minimum level in the final effluent.

Moreover, there is evidence that microorganisms other than poly P bacteria and GAOs can take up soluble organic compounds in the anaerobic step of EBPR processes, by using different energy sources and by producing different storage compounds. In particular, the fermentation of carbohydrates (namely to lactic acid, 59,65), has been shown to be an alternative way for facultative heterotrophic bacteria to obtain the energy necessary for the storage of organic substrates (namely as glycogen) and possibly for growth itself. Provided fermentable substrates are present, storage is quite likely to occur because bacteria undergo both metabolic and kinetic limitations (alternating anaerobic and aerobic conditions and alternating high and low substrate levels, respectively).

CONCLUSION

Present knowledge on the storage of carbon source by bacteria under aerobic conditions is based mainly on using synthetic media with a limited range of carbon sources (practically only acetate and glucose) and using empirically selected cultured bacteria and sludges approaching the conditions under which real plants operate. In these cases, when the process imposes a kinetic pressure on the biomass (i.e., the concentration gradient of the carbon sources), a storage response usually is established without any necessity of other external limitations (e.g., lack of nutrients or electron acceptors). Under such conditions, storage often is the main mechanism for substrate removal, although other mechanisms also can contribute, depending on the previous physiological state of the biomass. There is no evidence that storage is restricted to just a few particular microorganisms and both filamentous and floc former ones have been reported to be able to store carbon sources.

Floc formers appear to have a higher ability to store than filamentous microorganisms, that is, they have a competitive advantage under conditions of unbalanced growth. In general, laboratory-scale studies on pure and mixed cultures seem to confirm the importance of storage on population dynamics in activated sludge. However, there still is a lack of knowledge both at a basic and applied level. At a basic level, pure culture studies on transient response have been based mainly on bacteria that have been grown

- Under balanced growth (steady state) conditions.
- At low solid retention time (high D).
- On synthetic media with a single carbon source.
- Using once a single disturbance.
- By focusing separately on a single transient mechanism (usually growth or storage response).

To improve knowledge on how different process conditions can affect the type and extent of the transient response, more representative conditions and a wider range of phenomena should be investigated. For example, studies should look at using

- Solid retention times typical for activated sludge processes.
- Periodic conditions of cultivation (that also means more operating variables have to be considered, namely cycle and feed length).
- Substrates other than acetate and glucose, and mixtures of them.
- Focusing on several phenomena (sorption, accumulation, and release).

Moreover, process conditions and transient responses should be linked to each other through the description of the physiological state (internal composition) of the microorganisms, by also using advanced experimental techniques such as labeled substrates and nuclear magnetic resonance (NMR) studies (20,66,67).

Similarly, there is a lack of data about storage processes under conditions of nitrate respiration in anoxic reactors (see ACTIVATED SLUDGE — MICROBIOLOGY OF NITROGEN REMOVAL). Systematic studies need to address the identity and kinetics of the bacteria mainly responsible.

The microbiology of EBPR is complex with several bacterial populations, some not yet identified, carrying out different reactions; it is hoped that soon the definitive clarification of the groups able to synthesize anaerobically PHAs from acetate, either poly P bacteria or their competitors will be accomplished. Then it will be possible to elucidate their identity, physiology, and biochemistry. Particular attention has to be focused also on the fermentative bacteria because their activities in anaerobic conditions is crucial for directing the fermentation of wastewater in the anaerobic reactor to supply suitable substrates for the poly P bacteria in EBPR.

STREAM MICROBIOLOGY

Laura G. Leff
Kent State University
Kent, Ohio

Streams differ from other environments in several ways, such as the presence of a constant flow of water. These differences influence the nature of the stream microbiota and the role of microorganisms in ecosystem function. Generally, microbial processes in streams are dominated by benthic processes (those in biofilms and sediments) and microorganisms play a central role in the food web. Specifically, bacteria and fungi act on the detrital pool, making this major pool of organic carbon available to higher trophic levels. Streams are also vital to humans as sources of drinking water and conduits for carrying away wastes. Such activities are associated with the occurrence of specific types of viruses, bacteria, and protozoa that are detrimental to human health and adversely affect water quality. In addition, streams are greatly influenced by the land around them and microorganisms from the terrestrial surroundings may enter into streams, especially after flooding. Overall, streams are important to the function of human societies, and microorganisms play an underappreciated part in stream ecology

Streams present their microbial inhabitants with a unique set of physical and chemical features unlike other aquatic ecosystems. These environmental conditions influence the ecology of the microorganisms and their roles in the food web. Moreover, stream microorganisms tend to be less well studied than microorganisms in other types of aquatic ecosystems (1,2).

PHYSICAL FEATURES OF STREAMS

Perhaps the most obvious feature of streams is the flow of water. On the one hand, this flow ensures that microorganisms are continuously supplied with dissolved nutrients and organic carbon (3,4). On the other hand, this limits their ability to form stable planktonic (meaning "free floating" organisms in the water) communities. These two different effects of water flow combine to ultimately create an environment for microorganisms unlike other aquatic ecosystems, such as lakes.

The two effects of flow, provision of dissolved compounds and the need to maintain position (and not be swept away by the flowing water), makes streams benthos (from the Greek word for "bottom") dominated systems (3,4). Unlike lakes, where the water column features a diverse and important planktonic community (including bacterio-, phyto- and zooplankton), stream microorganisms seldom can sustain self-supporting, planktonic communities except in large rivers. Only in rivers with suitable discharge, light levels, and other environmental features, do planktonic communities and associated food webs develop (5). Thus, for example, bacterioplankton (i.e., bacteria in the water column) do not contribute as much in terms of secondary production to a stream as benthic bacteria (6). In these streams with limited microbial production in the water column, it is thought that microorganisms present in the water are primarily derived from the benthos or other substrata, washed in from the surrounding drainage basin, or derived from reservoirs and backwaters (6,7,8).

Occupancy of benthic biofilms by microorganisms can minimize the loss of cells because water moves through the stream and can help concentrate dissolved materials (9). Thus, biofilms coat the surfaces or substrata in streams and play a major role in microbial ecology. These biofilms consist of an intermingled array of bacteria, algae, protozoa, and fungi embedded in an extracellular polysaccharide matrix.

The connection between the stream water and the biofilms extends through the top layer of sediment into the hyporheos (3). The hyporheos (meaning under the flow) lies beneath the surface sediments where the surface water mixes with groundwater. This provides a unique (but rather unstudied) habitat for microorganisms and a potent site for diverse biogeochemical processes because of differences in oxygen concentrations, redox potentials, the presence of various inorganic compounds containing N, Fe, or S, and patterns of water movement.

STREAMS AND THEIR WATERSHED

Streams are intimately and directly connected to the terrestrial world, thus inputs of inorganic and organic compounds and microorganisms from the surrounding terrestrial environment (or catchment, watershed) are important (3). This has important water quality implications because undesirable microorganisms can be washed into the streams from septic systems, feedlots, and combined sewer overflows or carried into streams by animals. This also means that the microbial community in a stream naturally contains both autochthonous (from inside the stream) and allochthonous (from outside the stream) cells that are intermingled and may play very different roles. However, distinguishing between allochthonous and autochthonous-derived cells is problematic.

The strong connection between streams and their surrounding catchment highlights another manner in which streams differ from most other ecosystems: they are an important natural resource commonly used as sources of drinking water and that also fill the role of carrying away wastes from human activities (10). Some wastes are directly discharged into streams, such as sewage effluents, which may harbor allochthonous microorganisms that can be detrimental to human health. In addition, various nonpoint sources of pollution, such as runoff from agricultural and residential areas, add dissolved chemicals (such as nutrients from fertilizer, pesticides, etc.) to streams that can affect the microbiota. Allochthonous microorganisms originating in surrounding regions can also be carried into the stream water, particularly during times of high rainfall.

STREAM FOOD WEBS

Because of the influence of the catchment and the impact of the flowing water, the food webs of streams and the

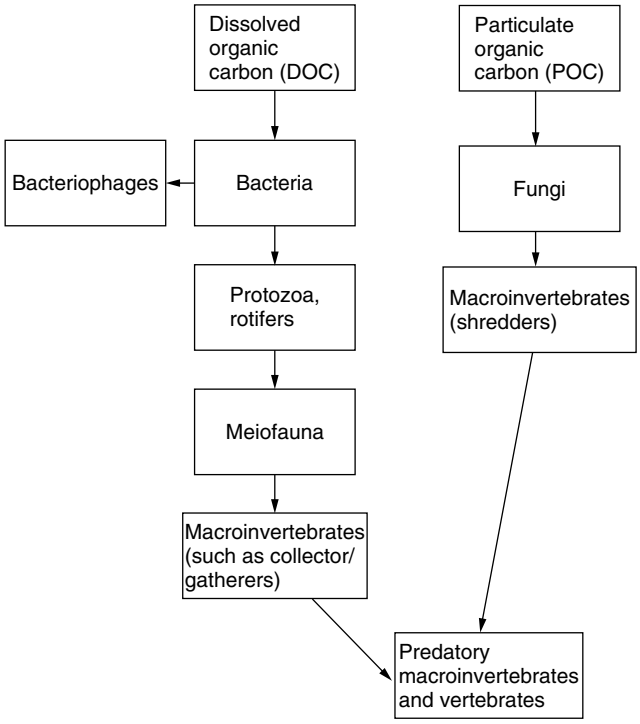

Figure 1. Simplified detritus-based stream food web.

roles of microorganisms differ from those found in other systems (11; Fig. 1). Typical streams that are encountered and studied throughout much of the world are shaded by vegetation (called riparian vegetation) that grows along their banks. This means that light is limited and thus primary production within the stream channel is also limited. Exceptions to this tendency are found in places where the growth of trees in the riparian zone is limited by climatic conditions, such as in desert streams that have minimal shading and abundant primary production in the stream channel (12). Also, reservoirs, lakes, and backwater areas may contribute algae directly to streams and rivers.

In shaded, small, headwater streams (also called low order streams; a first-order stream has no tributaries, a second-order stream occurs when two first-order streams join, and so on) input of leaf litter represents a main source of organic carbon (13). As described in the river continuum concept, the features of a stream change as it grows larger and draws from a progressively larger drainage area (14). As the channel broadens and the order of the stream increases, the riparian vegetation no longer fully shades the stream providing an opportunity for in-stream primary production. This pattern of change in primary production with increasing order is complicated by nutrient inputs, temperature, and hydrology (12). As the lotic (flowing water) ecosystem grows to be a river or joins a river, turbidity, and depth ultimately may limit light and primary production.

In streams, throughout their lengths, dissolved organic carbon (DOC) is a dominant form of organic carbon (15,16). The various forms of detritus, such as dissolved organic matter, and fine particulate organic matter, coarse particulate organic matter, are utilized by stream microorganisms that help make this resource available to higher trophic levels. Furthermore, often (based on the in-stream primary production) streams are heterotrophic, meaning that they rely on organic compounds from outside the system (17). Another way of describing the base of the food web is that streams tend to be detritus-based (detritus refers to all the organic matter not tied up in living organisms or biomass). The importance of DOC and the reliance on detritus means that, in streams, microorganisms play a very central role in the food web (Fig. 1; 11).

The various components of the microbial community in streams are discussed below and each play a different role. These roles are complementary and the depth of knowledge about a particular component is quite variable. In addition, to the basic ecology of microorganisms in streams, microbial aspects of stream water quality are also discussed.

VIRUSES

Aquatic microbial ecologists have in the past few years placed a new emphasis on the role of viruses in aquatic systems (18). Studies of planktonic viruses suggest that in lakes and oceans they are a major source of bacterial mortality. It is quite possible that viruses are also important in streams but the number of stream viral ecology studies is extremely limited (19). In one such study, Lemke and coworkers (19) found that viral numbers in stream water (determined based on staining with the Molecular Probes stain YO PRO and examination with epifluorescence microscopy; 20) averaged 2×10^7 ml^{-1} and greatly exceeded the number of bacteria. However, the number of bacteria was similar to or greater than viral numbers in sediments and leaf biofilms. Viral numbers in streams seem to be comparable to those found in other systems but there have been few studies so generalities cannot be drawn.

Advances in staining and detection of viruses have made enumeration of the total number of viruses in streams a more simple undertaking compared with earlier methods involving plaque assays or electron microscopy (Table 1; 20,21). Counts obtained via staining of nucleic acids (YO PRO is commonly used) provide accurate numbers based on comparisons to electron microscopy-based enumeration. However, information about total viral numbers is not particularly useful, in some ways, because the identities of the viruses are unknown. In streams, specifically, the presence of certain types of viruses is a significant health concern, so efforts have focused on detecting specific kinds of viruses.

Because of the importance of viruses to microbiological aspects of water quality, more information is available for streams concerning specific kinds of viruses (compared with viral ecology studies) that are not naturally produced in water but that can be found in streams (Table 2). For example, viral human pathogens in stream water can be an important water quality issue. Streams can be contaminated with a variety of viral pathogens through the introduction of untreated fecal waste (22). Initial efforts concerning aquatic environmental virology

Table 1. Commonly Used Methods in Stream Microbial Ecology

Microorganism	Total Number	Biomass	Production
Viruses	EM, EFM with nucleic acid stains (such as YO PRO)	image analysis	tritiated thymidine incorporation into DNA
Bacteria	EFM with nucleic acid stains (such as DAPI/Acridine Orange)	image analysis	tritiated thymidine incorporation into DNA, tritiated leucine incorporation into protein
Protozoa	EFM with stains such as DAPI or primulin, light microscopy of live specimens or progartol staining	image analysis	—
Fungi	indirect, conidia enumeration	ergosterol content	^{14}C acetate incorporation into ergosterol
Algae	light microscopy	chlorophyll *a* content	^{14}C bicarbonate uptake

Note: See text for references and more details; EM stands for electron microscopy and EFM stands for epifluorescent microscopy.

Table 2. Selected Human Pathogens Encountered in Water (for references and details, see text)

Group	Types
Viruses	Hepatitis A and E viruses, enteroviruses, caliciviruses, rotaviruses, astroviruses, and Norwalk-like viruses
Bacteria	*Campylobacter jejuni*, *Salmonella, Shigella*, some strains of *Escherichia coli*, *Yersinia, enterocolitica*, misc. opportunistic pathogens
Protozoa	*Giardia*, *Cryptospordium*, *Entamoeba histolytica*
Fungi	None
Algae	None

focused on polioviruses; today enteric viruses are a major concern and the most common consequence of infection is gastroenteritis (23). Viruses of concern include hepatitis A and E viruses, enteroviruses, caliciviruses, rotaviruses, and astroviruses (24). Norwalk-type viruses are among the major causes of waterborne illnesses (22) and present special methodological concerns.

Traditionally, viral pathogens in water have been detected/enumerated using cell culture-based methods (24). However, viruses isolated from the aquatic environment may not readily grow under such conditions and thus must be detected using other means (note: this same type of phenomenon also is widespread for bacteria and is discussed in a subsequent section). Another limitation is that the number of viruses of a given type in water can be quite low (22). Often, polymerase chain reaction (PCR)–based methods (in which viral nucleic acids are amplified) can be used to detect specific types of viruses, including those that are not amenable to growth in the lab or that are present in low numbers (23,24). The Norwalk-like viruses illustrate the advantages of using molecular biology techniques: these small, fastidious viruses defy laboratory cultivation and thus must be detected and identified using other methods (25).

Freshwater ecosystems can also play important, indirect roles in the ecology of viral pathogens by serving as hosts for viral vectors, such as mosquito and blackfly larvae (22). This same role is important for some bacterial and protozoan parasites, as well. Streams are generally not suitable for mosquito larvae because of the flowing water but backwater areas and reservoirs can be habitats for the growth of the juvenile mosquitoes (26). Thus, the role of streams as hosts for viral disease vectors is somewhat limited. However, other stream residents (i.e., blackfly larvae) are vectors for significant parasitic (nonviral) diseases including river blindness (Onchocerciasis caused by a filarial parasite; 27).

Viruses in streams can also be used as indicators; specifically, examination of coliphages has been used as an indicator of fecal contamination (28). Bacteriophages used as indicators of water quality do not multiply in the aquatic environment and may be more abundant in wastewater discharges than viral pathogens of humans (22). Traditionally, the abundances of specific bacteriophages are determined using plaque assays in which phages are detected by the formation of plaques (cleared areas) on lawns of bacteria on agar plates. It seems likely that such culture-based methods suffer from the same limitations that are encountered when enumerating human pathogens.

BACTERIA

Bacteria play a particularly important role in streams because they convert the dominant organic carbon source (DOC) into bacterial biomass; this results in an increase in the size of the organic carbon resource making it available for consumption by higher trophic levels (such as protozoa and small invertebrates; Fig. 1; 11). Because of this role, bacteria are more well studied, in some ways, than are some of the other microbial residents of streams. However, bacteria are typically lumped together as a single unit (or "black box") and most studies typically report values relevant to the full bacterial community but ignore the underlying populations.

Bacterial populations in streams, in many ways, can transcend "normal" habitat boundaries (29). In other words, bacteria are likely to readily immigrate between the benthos and water column, between the stream channel and the riparian zone, and between the hyporheos and the surface water. Thus, boundaries, such as the banks of the stream, may not represent the limits or edges of a stream bacterial population.

Bacteria are thought to move through a stream in a spiral fashion (29,30) in a manner analogous to the movement of nutrients (31). Spiraling of materials through streams is described by the nutrient spiraling concept that models release of nutrients, transport downstream, and subsequent uptake (31). In other words, nutrients "cycle" between the benthos and the water column as in any aquatic ecosystem but in streams the flow of water displaces these cycles resulting in a spiral. Thus, nutrients travel some distance (the spiraling length) downstream before they are taken up again. Leff and coworkers (29) speculated that bacteria exhibit this same tendency; in that, they are released from biofilms by a variety of different mechanisms, and are then transported downstream some distance before they reattach to a surface. This process was termed information spiraling and subsequently researchers have attempted to measure the information spiraling length (32). It is thought that the information spiraling length is influenced by factors such as: the presence of bacterivorous invertebrates, substrate type, and retentive structures in the stream (such as debris dams).

Bacterial community level measurements commonly reported in streams include total numbers, number of active cells, biomass, and production (Table 1). Numbers are typically based on treating cells with nucleic acid–specific stains (such as Acridine Orange and DAPI, 4′-6-diamidino-2-phenylindole) and viewing them under epifluorescence microscopy (reviewed by 33). Biomass determinations are often made after staining, based on sizes determined manually or by using an image analysis system. Production is typically measured based on incorporation of tritiated thymidine into DNA or tritiated leucine into protein (34).

Like many other environments, a small percentage (typically less than 1%) of bacteria in streams that can be detected by microscopy are culturable (2). Because of this low culturability, widely used methods rely on molecular biology–based approaches. Some of these methods are as simple as determining total numbers based on staining with nucleic acid-specific stains, whereas others that are aimed at examining bacterial species composition or diversity are more involved.

Examination of the bacterial community as a whole has revealed several general trends. The number of bacteria in stream water ranges over several orders of magnitude from 0.01 to 100×10^6 ml^{-1} (8,35–49). Within a given stream, total numbers typically do not vary more than one order of magnitude over the course of a year (41,42,50–53). Changes within a stream are often correlated with physical variables, such as turbidity, discharge, and rainfall (8,41,42,54), although a variety of other relationships have also been detected (39,55). Overall, bacterial numbers in water are often correlated with discharge or precipitation, suggesting that inputs of allochthonous cells during rain events and scouring of cells from the benthos are important (8). In other cases, are correlated with temperature bacterial numbers in the water (36,44).

Bacterial numbers in stream sediment also vary greatly among streams (ranging from 0.002–7.21x 10^9 g^{-1}; 8,47,56,57). Organic matter content tends to be highly correlated with bacterial number in the sediments.

Leaves in streams often represent a major source of detritus, which is readily colonized by bacteria and fungi (as discussed in a subsequent section). Microorganisms use these leaves both as a surface and as a source of organic matter, making the leaves, as described in the section on fungi, more palatable for invertebrates. One focus of studies on bacterial responses to leaves in streams is the use of leaf leachate by stream bacteria (58,59,60). Collectively, these studies have demonstrated that the response of bacteria to leachate depends on the nature of the leachate (concentration, source) and the composition of the bacterial community.

Epifluorescent examination of stream bacteria has been coupled with activity determination in some studies. One commonly used approach is the INT (2-[p-iodo-phenyl]-3-[p-nitrophenyl]-5-phenyl tetrazolium) method. With this method, respiring cells are detected by reduction of INT by the electron transport chain that causes the formation of a red deposit in active cells (61). In Australian rivers, Boon (55) found that typically less than 25% of planktonic bacteria were active. In a stream in Alabama (U.S.A.), Johnson and Ward (62) found that 15 to 26% of benthic bacteria were active, whereas only 2 to 7% of planktonic bacteria were active. Higher activity within benthic habitats suggests that these locations are sources of planktonic bacteria that then become inactive when they enter the water column. An alternative explanation is that the water column contains higher numbers of inactive cells derived from allochthonous sources.

Other methods have been used to detect activity; fluorescein diacetate (FDA) hydrolysis has been used in some freshwater environments (63) but has not been applied frequently in stream studies. Nalidixic acid, an antibiotic that inhibits cell division, is also used in activity determinations; active cells become abnormally large because cell division does not occur (64). Buchanan-Mappin and coworkers (35) found using this approach that, in stream water, 34.6% of cells were active. Results obtained with the INT method have been shown to be similar to those from the nalidixic acid method (65).

Bacterial production in streams is less commonly measured than bacterial number and is also quite variable among streams. In the water column, production ranges from 0.002 to 70 μg C l^{-1} h^{-1} (39,55,66–69) and water column production is typically lower than benthic production, which ranges from 0.04 to 140 mg C m^{-2} h^{-1} (6,39,67,70–74) and varies among sediment types. Differences are most likely related to the organic matter content of the sediment (65,69,70). For example, Findlay and coworkers (70) found that production in backwater sediments was more than 20 times higher than production

in the sandy mid-channel of the Ogeechee River (Georgia, U.S.A.). Also, Kaplan and Bott (75) found diel variation in benthic bacterial production that was related to temperature and concentrations of algal exudates. There is also considerable intrasite variability in production perhaps resulting from spatial heterogeneity (76).

Examinations of "natural" bacterial populations of specific species or higher taxa in streams are less common in the ecological literature than those dealing with whole bacterial communities. However, a large body of research has been conducted on the occurrence of indicator species (most notably *E. coli*) and pathogens (such as *Salmonella* and *Shigella*) that are not necessarily present naturally and often cannot reproduce in streams (22). The presence of such organisms is a significant water quality issue.

Perhaps the greatest effort aimed at enumerating bacteria in stream water has been on determination of the numbers of *E. coli*, fecal coliforms, or fecal streptococci as indicators of fecal contamination. Such bacteria are transients in the stream and are generally present because of inputs attributable to human activities (77). Typically, such bacterial indicators of fecal contamination are monitored based on enumeration following specific cultivation protocols.

Widely used protocols for enumeration of bacterial indicators are primarily based on cultivation of the bacteria. One commonly used approach is to concentrate bacteria from water samples by filtration (membrane filtration or MF) and to then incubate the filters on various types of selective media (such as Endo medium; 77). Most probable number (MPN) techniques are also used. Some methods that do not rely on culturing, such as nucleic acid-based detection or fluorescent antibodies, are also suitable and have the advantage of detecting cells that are not culturable.

Survival of *E. coli* has been studied in freshwater because it is a widely used indicator species and some are pathogenic. Several studies have examined survival of *E. coli* in lakes and found that mortality rates are generally high but survival is enhanced in the presence of sediment or other particles (78,79). In streams and rivers, survival of *E .coli* is also limited and is related to light and predation by protozoa (80,81).

Native populations of stream bacteria have rarely been examined and our knowledge of bacterial population ecology in streams is quite limited compared with what is known about lakes and oceans (2). Approaches that have been used to characterize the composition of the stream bacteria community (without attempting to cultivate the bacteria) include fluorescent in situ hybridization (FISH) (43,51,82) and amplification of 16S rDNA from DNA extracts (these PCR products can then be examined using, for example, denaturing gradient gel electrophoresis, 83).

Perhaps the most significant trends to emerge from these studies of stream bacteria population ecology are that (*1*) bacterial population dynamics are not reflected in the overall bacterial number, and (*2*) bacterial populations exhibit pronounced seasonal changes (43,51,53,82). In some cases, protozoan grazing, DOC pool composition, and anthropogenic disturbance appear to potentially be related to spatial changes in population sizes of particular species (43,49,51,53,82). The effect of these factors appears to vary among bacterial species; for example, *Acinetobacter calcoaceticus* populations vary spatially in a South Carolina (U.S.A.) stream in a manner that appears to be related to changes in anthropogenic disturbance; other bacterial species examined in this stream do not exhibit this same tendency (49,51).

Other studies of stream bacteria have focused on processes mediated by bacteria, such as denitrification and nitrification. Denitrification, a process mediated by heterotrophic bacteria under anaerobic conditions, has been documented in lotic ecosystems (84). The importance of denitrification varies among streams, depending on nitrate concentrations and the extent of anaerobic zones in the sediment (85). Rates of denitrification in stream sediments range from 0 to 345 $\mu mol\,N\,m^{-2}$ and are highest in anthropogenically disturbed systems (84). Although some estimates suggest that 7 to 35% of nitrogen input into rivers is lost by denitrification (84), Cooper (86) found that denitrification accounted for less than 15% of nitrate depletion in a New Zealand headwater stream. Nitrification also occurs in streams with some biofilms providing suitable environments for the ammonia-oxidizing bacteria, *Nitrosomonas* (87).

Bacteria are made available to higher trophic levels through consumption by protozoa as described in the next section. In contrast, the direct role of bacteria as food for macrofauna, specifically macroinvertebrates, is less well established and less widespread among different invertebrate taxa. The feeding method and mouth parts of the macroinvertebrate greatly influences their ability to eat bacteria.

Filter feeders, such as blackfly larvae, are capable of directly consuming planktonic bacteria and bacteria attached to small particles (54). Blackflies are able to rapidly digest bacteria (88); however, planktonic stream bacteria are smaller than cultivated bacteria so they cannot be captured as efficiently (54). In a field experiment, Hall and coworkers (32) demonstrated that blackflies accounted for 91% of bacterial ingestion in a small stream.

Bivalves are another important filter feeder that can consume bacteria. Laboratory studies have shown that both native unionid mussels and exotic species, such as *Corbicula*, can clear water of bacteria (89,90). In addition, *Corbicula* can use pedal-feeding to supplement filter-feeding and directly affect benthic bacterial abundance (91). In the laboratory, disruption of the sediments by *Corbicula* may shift bacterial population distribution (92). However, McEwen and Leff (93) found that unlike other types of invertebrates studied, guts of *Corbicula* were not readily colonized by ingested bacteria.

Other macroinvertebrates, called collector/gatherers, ingest bacteria associated with benthic particles. Austin and Baker (94) examined the gut flora of the mayfly nymph, *Ephemera*, and found it to be dominated by gram-negative rods, including *Acinetobacter* and *Flavobacterium /Flexibacter*. Mayfly nymphs were not selective in consumption of bacteria of different species but different bacteria were digested to different extents. In contrast, Baker and Bradnam (88) found that two other mayfly

nymphs, *Baetis,* and *Ephemerella*, were not able to digest bacteria.

Shredders are a functional group of macroinvertebrates that consume bacterial and fungal cells on leaf particles yet bacterial carbon appears not to be important in meeting their energy needs (95). Specifically, bacterial biomass was not a major source of carbon for the isopod *Lirceus* (96) and accounted for less than 1% of the carbon respired by a stonefly nymph, *Peltoperla*, and a cranefly larvae,*Tipula* (97). Although direct consumption of bacteria may have limited importance for shredders, the activity of microbial fermenters in the hindguts provides an alternative source of organic carbon and aids in digestion (98).

Another pathway of carbon transfer from bacteria to higher trophic levels is through meiofauna (including interstitial animals), such as rotifers, copepods, and nematodes. It has been found that copepods consumed 22% of bacterial production per day (99). Also, chironomid larvae (the aquatic larvae of a group of small flies) and copepods preferentially assimilate bacterial carbon compared with fine particulate organic matter (95). However, the extent of predation by meiofauna may not have the intensity to alter bacterial standing stocks unless certain taxa (i.e., rotifers) are particularly abundant (100).

Bacterial carbon transfer to higher trophic levels also occurs by the consumption of extracellular materials, particularly polysaccharides (101). Rounick and Winterbourn (102) found that stream invertebrates were able to readily assimilate heterotroph-dominated biofilms (including the living cells and extracellular matrix). In addition, blackfly larvae assimilated extracellular polysaccharide from a bacterium with 80 to 90% efficiency and the carbon content of the extracellular material was nine times greater than the bacterial biomass (103). Within the stream sediments, hyporheic biofilms may provide food for interstitial meiofauna (104).

Macroinvertebrates can also have indirect, more subtle effects on bacteria in streams (29). Specifically, macroinvertebrates can enhance the detachment of bacteria from stream biofilms because they feed and move across surfaces (92,105). Also, macroinvertebrates are rapidly colonized by a wide variety of bacteria, and bacteria are abundant on exoskeletons, cases of caddisfly larvae, and in the invertebrate guts (93,105). Some bacteria appear to survive gut passage and are deposited in the feces of the invertebrates (93). Colonization of invertebrates by bacteria enhances bacterial dispersal and can affect the distribution of bacteria among different habitats (93,105,106). Studies have shown that invertebrates are potent vectors of bacterial transport (93,105) and that bacteria ingested by stream insect larvae can persist in the gut into adulthood (93).
