
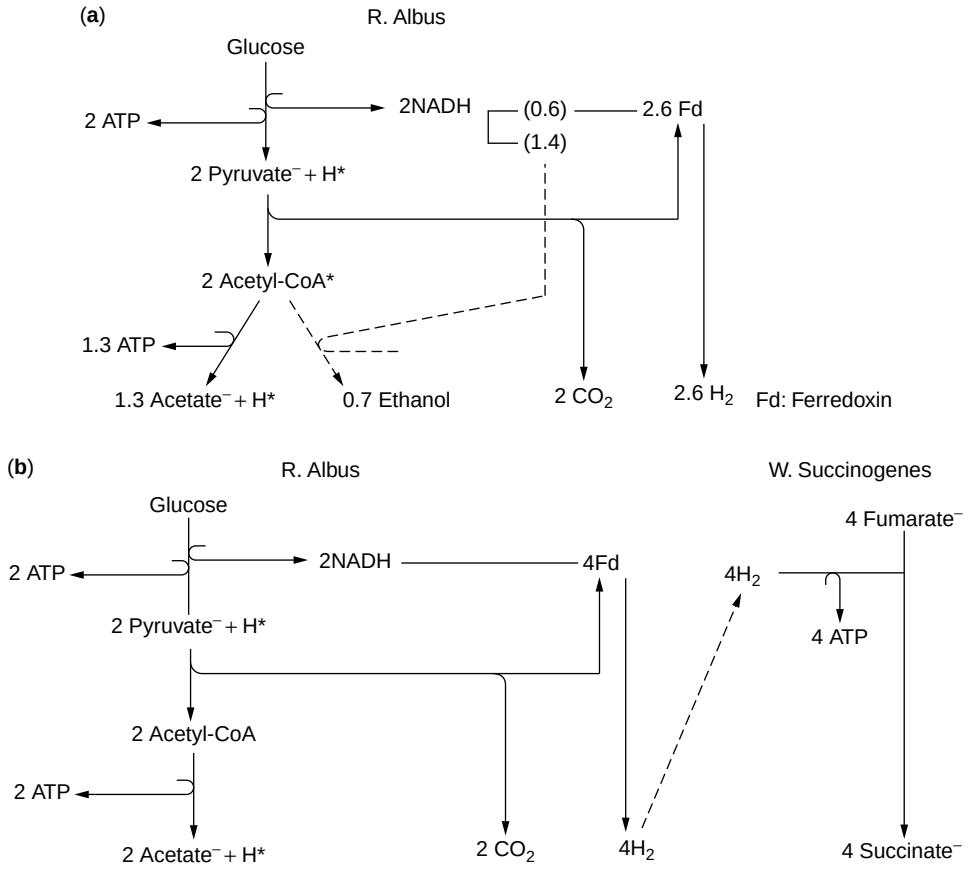

Figure 3. Sugar fermentation by *R. albus* in pure culture and in mixed culture, with a hydrogen-utilizing anaerobe.

$$2Fd_{(red)} + 2H+ \rightarrow 2Fd_{(ox)} + H_2 \quad \Delta G^{0'} = +3.1\ kJ$$

$$NADH + H^+ \rightarrow NAD^+ + H_2 \quad \Delta G^{0'} = +18.1\ kJ$$

The oxidation of reduced ferredoxin is relatively easily coupled to H_2 formation, while H_2 formation from NADH is only possible at a lower H_2 partial pressure. At a H_2 partial pressure of 1 Pa, which can be maintained by hydrogenotrophic methanogens the $\Delta G^{0'}$ of the two conversions is around -26 and -11 kJ, respectively. In the course of the fermentation by a pure culture of *R. albus*, H_2 accumulates, and consequently the organism is no longer able to couple the oxidation of NADH to the reduction of protons. As an alternative, acetyl-CoA or acetaldehyde is used as an electron sink to form ethanol. In the coculture, hydrogen is removed efficiently and ethanol is not produced. Because the organism forms ATP during acetate formation from acetyl-CoA, but not if ethanol is produced, the ATP yield per glucose is higher in the coculture than in the pure culture. Similar effects have also been observed with other sugar-fermenting microorganisms, which dispose off reducing equivalents by formation of reduced organic compounds such as ethanol, lactate, succinate, butyrate, or propionate (38–43). In general, the effect of the presence of hydrogenotrophic methanogens is that relatively fewer of these reduced organic compounds and more of the methanogenic substrate acetate are formed.

Mineralization of Amino Acids:

Proteins are composed of about 20 structurally different amino acids, which require different biochemical pathways for degradation. Therefore, anaerobic degradation of amino acids by the mixed methanogenic consortia is even more complex than described above for sugars. This degradation involves oxidation and reduction reactions of one or more amino acids. Some amino acids are degraded preferentially via reduction, others via oxidation. The combined oxidation and reduction of sets of amino acids (Stickland reaction) is a well-known way for many clostridia species to degrade amino acids (28). Table 5 shows some oxidative and reductive reactions involved in the anaerobic degradation of amino acids. In the Stickland reaction, an oxidative reaction with one amino acid is coupled with the reductive degradation of another. A classical and well-known Stickland mixture is alanine and glycine. Other couples that have been described are leucine, isoleucine valine, phenylalanine, and tryptophane, which are oxidized to 3-methylbutyrate, 2-methylbutyrate, 2-methylpropionate, phenylacetate, and indolacetate, respectively, and proline, phenylalanine, tryptophane, and leucine, which are reduced to 5-aminovalerate, phenylpropionate, indolpropionate, and 4-methylvalerate, respectively. Besides these other couples have been found or may occur. Some amino acids can be degraded both oxidatively and reductively (Table 5). This may result in fermentative growth of microorganisms on single amino acids. For example, trypthophane can be fermented to indoleacetate and indolepropionate, phenylalanine to phenylacetate and phenyl propionate, and leucine to isovalerate and 4-methylvalerate. Also, other compounds and intracellular intermediates may act as terminal electron acceptors in the degradation of amino acids. Leucine oxidation can be coupled to the reduction of acetate to butyrate as described for *Clostridium acetireducens* (44). A similar reaction takes place in the classical glutamate fermentation by, for example, clostridia, in which reducing equivalents formed

Table 5. Oxidative and Reductive Reactions Possibly Involved in the Anaerobic Conversion of Amino Acids

Oxidative Reactions:

1) $Serine + 2H_2O \rightarrow Acetate^- + HCO_3^- + NH_4^+ + H^+ + 2[H]$
2) $Alanine + 3H_2O \rightarrow Acetate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
3) $Leucine + 3H_2O \rightarrow Isovalerate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
4) $Isoleucine + 3H_2O \rightarrow 2 - Methylbutyrate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
5) $Valine + 3H_2O \rightarrow Isobutyrate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
6) $Phenylalanine + 3H_2O \rightarrow Acetate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
7) $Tryptophane + 3H_2O \rightarrow Indolacetate^- + HCO_3^- + NH_4^+ + H^+ + 4[H]$
8) $Histidine + 3H_2O \rightarrow Glutamate^- + HCO_3x^- + NH_4^+ + H^+ + 4[H]$
9) $Glutamate^- \rightarrow Propionate^- + 2HCO_3^- + NH_4^+ + H^+ + 4[H]$
10) $Glutamate^- \rightarrow 2Acetate^- + HCO_3^- + NH_4^+ + H^+ + 2[H]$
11) $Aspartate^- \rightarrow Acetate^- + 2HCO_3^- + NH_4^+ + H^+ + 2[H]$
12) $Glycine \rightarrow 2HCO_3^- + NH_4^+ + H^+ + 6[H]$
13) $Threonine \rightarrow Propionate^- + NH_4^+ + H^+ + 2[H]$

Reductive Reactions

14) $Glycine + 2[H] \rightarrow Acetate^- + NH_4^+$
15) $Proline + 2[H] \rightarrow 5 - Aminovalerate$
16) $Leucine + 2[H] \rightarrow 4 - Methylvalerate^- + NH_4^+ + H^+$
17) $Phenylalanine + 2[H] \rightarrow Phenylpropionate^- + NH_4^+ + H^+$
18) $Tryptophane + 2[H] \rightarrow Indolpropionate^- + NH_4^+ + H^+$
19) $2HCO_3^- + H^+ + 8[H] \rightarrow Acetate^-$
21) $Acetate + HCO_3^- + 6[H] \rightarrow Propionate^-$
22) $2\ Acetate^- + H^+ + 4[H] \rightarrow Butyrate^-$
23) $2[H] \rightarrow H_2$
24) $HCO_3^- + 2[H] \rightarrow formate^-$

in the conversion to acetate are used to form butyrate from acetate (45,46). However, in this case no externally supplied acetate is needed for growth.

In methanogenic environments amino acid degrading microorganisms may also dispose off their reducing equivalents by formation of hydrogen and formate (47,48,28). This means that methanogens can take over the function of the reductive conversions listed in Table 5. There are several examples of syntrophic degradation of amino acids by methanogenic consortia. Nagase and Matsuo (49) observed that in mixed methanogenic communities the degradation of alanine, valine, and leucine was inhibited by inhibition of methanogens, while Nanninga and Gottschal (50) could stimulate the degradation of these amino acids by the addition of hydrogen-scavenging sulfate-reducers. *Clostridium sporogenes* (51,52), *Eubacterium acidaminophilum* (53), *Acidaminobacter hydrogenoformans* (54), and *Selenomonas (Thermanaerovibrio) acidaminovorans* (55) are examples of bacteria, which can grow syntrophically on one or more of the amino acids aspartate, alanine, leucine, isoleucine, or valine.

The initial step in the degradation of alanine, valine, leucine, and isoleucine is an NAD(P)-dependent deamination to the corresponding ketoacid. The $\Delta G^{0'}$ of this reaction when coupled to hydrogen formation is about +60 kJ/mol. Thus, methanogens are needed to pull this reaction in a fashion similar to that described for sugar fermentations. The ketoacid is converted further probably by a ferredoxin-dependent oxidative decarboxylation to a fatty acid, a reaction that energetically is much more favorable (the $\Delta G^{0'}$ is about −50 kJ/mol). Aspartate probably is not directly oxidized to oxaloacetate, but via fumarate and malate. In this conversion malate oxidation to oxaloacetate is most unfavorable; the $\Delta G^{0'}$ of this reaction is +47.7 kJ/mol.

The fermentation of glutamate to acetate and butyrate is well-known. The anaerobic oxidation of glutamate to acetate and propionate as shown in the following reactions is carried out by *A. hydrogenoformans* and some other glutamate-degrading microorganisms:

$$\text{Glutamate}^- + 3H_2O \rightarrow 2\text{acetate}^- + HCO_3^- + H^+ + NH_4^+ + H_2\Delta \quad G^{0'} = -33.9\text{kJ}$$

$$\text{Glutamate}^- + 4H_2O \rightarrow \text{propionate}^- + 2HCO_3^- + NH_4^+ + H^+ + 2H_2 \quad \Delta G^{0'} = -5.8\text{kJ}$$

These fermentations are less known, but in anaerobic environments with a high methanogenic activity, in particular, these glutamate degradation pathways seem to be rather common.

Mineralization of Nucleic Acids

Hydrolysis of RNA and DNA results in the formation of C5-sugars ribose and deoxyribose, respectively, and purines and pyrimidines. Purines and pyrimidines are easily fermented under anaerobic conditions (Gottschalk, 1986). Guanine, adenine, and a number of other heterocyclic compounds such as hypoxanthine, urate, and xanthine can be fermented by *Clostridium* strains, including *C. acidiurici*, *C. purinolyticum*, and *C. cylindrosporum* (56,57). The fermentation of these compounds is selenium-dependent and a glycine-reductase plays a key-role (58). A number of bacteria can ferment pyrimidines, although they are not as readily degraded as purines. Uracil is converted to β-alanine, CO_2, and ammonium by *C. glycolicum* and *C. uracillum*, while *C. sporogenes* can transform cytosine and thymine (59). So far no research has been conducted to investigate the influence of methanogens on the anaerobic degradation of purines and pyrimidines.

Mineralization of Fats

Fats are cleaved into glycerol and long-chain fatty acids. Glycerol is easily fermentable, and in a few enzymatic steps can be converted to intermediates of the glycolytic pathway. Therefore it may be fermented in a similar fashion as sugars. However, it should be noted that the carbon in glycerol is more reduced than the carbon in sugars. As a result, more reduced organic products are formed from glycerol than from sugars. For example, if glycerol is fermented by propionic acid bacteria, it mainly yields propionate.

Long-chain fatty acids are degraded via so-called beta-cleavage (47). In a series of reactions acetyl groups are cleaved off yielding acetate and hydrogen in the case of even-numbered fatty acids, while uneven-numbered fatty acids are degraded to acetate, hydrogen, and propionate. The biochemical mechanism is that oxidation of long-chain fatty acids is first activated to a CoA derivative before further conversion takes place:

$$R{-}CH_2{-}CH_2{-}CH_2{-}COO^- + ATP + HS{-}CoA \rightarrow R{-}CH_2{-}CH_2{-}CH_2{-}CO{-}SCoA$$

$$R{-}CH_2{-}CH_2CH_2{-}CO{-}SCoA \rightarrow R{-}CH_2{-}CH = CH{-}CO{-}SCoA + 2[H]$$

$$R{-}CH_2{-}CH = CH{-}CO{-}SCoA + H_2O \rightarrow R{-}CH_2{-}CHOH{-}CH_2{-}CO{-}SCoA$$

$$R{-}CH_2{-}CHOH{-}CH_2{-}CO{-}SCoA \rightarrow R{-}CH_2{-}C = O{-}CH_2{-}CO{-}SCoA + 2[H]$$

$$R{-}CH_2{-}C = O{-}CH_2{-}CO{-}SCoA + HS{-}CoA + H_2O \rightarrow R{-}CH_2{-}CO{-}SCoA + CH_3{-}CO{-}SCoA$$

The smallest fatty acid that is degraded with such a mechanism in butyrate. The energetics of this conversion is discussed later. Oxidation of long-chain fatty acids to acetate and hydrogen is energetically difficult and can only occur by syntrophic consortia of hydrogen-producing acetogens and methanogens. Microorganisms that degrade long-chain fatty acids generally are also able to grow with butyrate.

Syntrophic Degradation of Propionate, Butyrate, and Other Fatty Acids

Propionate and butyrate are important products of sugar fermentation, while branch-chain fatty acids

are formed during amino acid degradation. The fatty acids are degraded by obligate syntrophic consortia of bacteria.

The existence of obligately syntrophic degradation by interspecies electron transfer was recognized for the first time by Bryant and coworkers (60). It was observed that the originally believed pure culture of the ethanol-degrading *Methanobacillus omelianskii* consisted of two bacterial species, the S-organism that degraded ethanol to acetate and the methanogen strain M.o.H. However, as mentioned earlier, ethanol can also be fermented in other ways. Also, degradation of propionate and butyrate requires the syntrophic cooperation of acetogenic bacteria and hydrogenotrophic and aceticlastic methanogens.

Boone and Bryant (61) described *Syntrophobacter wolinii*, an organism that can only grow in syntrophic cooperation with methanogens or sulfate-reducing bacteria. Since then several other *Syntrophobacter* species have been described (62,63). Recently, *Smithella propionica* has been described (64). This organism forms butyrate during propionate degradation. The pathway of propionate degradation in this microorganism is different from the pathway in *Syntrophobacter* species (65).

McInerney and coworkers (48) enriched and characterized *Syntrophomonas wolfei*, a bacterium that degraded butyrate and some other short-chain fatty acids syntrophically. Several other butyrate-oxidizing bacteria such as the spore-forming bacterium *Syntrophospora bryantii* (former *Clostridium bryantii*) (66,67) and *Syntrophomonas sapovorans* (68) were described. The latter bacterium can oxidize butyrate and saturated and unsaturated long-chain fatty acids.

During propionate and butyrate degradation, methanogens are needed to remove the products, which negatively affect the energetics of their oxidation to acetate and hydrogen (Fig. 4).

$$\text{Propionate}^- + 3H_2O \rightarrow \text{Acetate}^- + HCO_3^- + H + 3H_2$$

$$\Delta G^{0'} = +76.1 \text{ kJ}$$

$$\text{Butyrate}^- + 2H_2O \rightarrow 2\text{Acetate}^- + H^+ + 2H_2$$

$$\Delta G^{0'} = +48.1 \text{ kJ}$$

$$4H_2 + 2HCO_3^- + H^+ \rightarrow \text{acetate}^- + 4H_2O$$

$$\Delta G^{0'} = -104.6 \text{ kJ}$$

$$\text{Acetate}^- + H_2O \rightarrow HCO_3^- + CH_4 \quad \Delta G^{0'} = -31.0 \text{ kJ}$$

The pathways of propionate and butyrate oxidation by *Syntrophobacter* and *Syntrophomonas* species have been resolved (27,28). During propionate oxidation via the so-called methylmalonyl-CoA pathway, reducing equivalents are formed in the oxidations of succinate to fumarate, malate to oxaloacetate, and pyruvate to acetyl-CoA; these reducing equivalents are formed at the level of $FADH_2$, NADH, and ferredoxin. Butyrate is oxidized via β-oxidation. In this pathway reducing equivalents are formed at the level of $FADH_2$ in the oxidation of butyryl-CoA to crotonyl-CoA and at the level of NAD in the oxidation of 3-hydroxybutyryl-CoA to acetoacetyl-CoA. In particular, coupling the oxidation of $FADH_2$ to proton reduction is energetically problematic in these organisms. The redox couple of $FADH_2$/FAD is -220 mV. The Gibbs free energy change of $FADH_2$ oxidation coupled to proton reduction is $+37.4$ kJ.

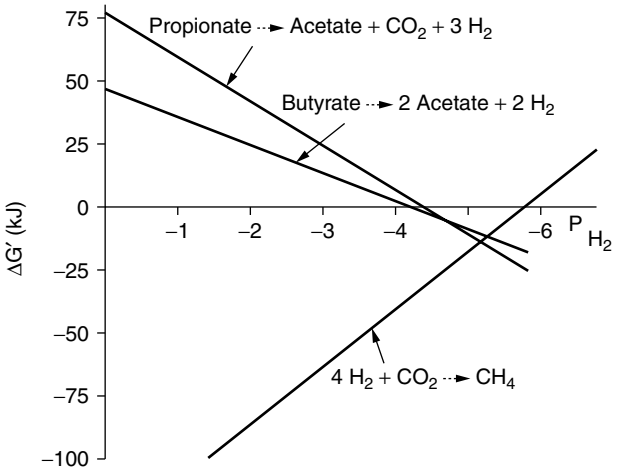

Figure 4. $\Delta G'$ values of propionate and butyrate oxidation and methanogenesis from $H_2 + CO_2$ at different PH_2 values.

$$FADH_2 \rightarrow FAD + H_2 \quad \Delta G^{0'} = +37.4 \text{ kJ}$$

Even at a hydrogen partial pressure of 1 Pa, a value which can be created by methanogens, this reaction is not feasible. The Gibbs free energy change is still positive. Therefore, propionate and butyrate-oxidizing bacteria have to invest metabolic energy to push this reaction. The biochemical mechanism involved has been explained later in detail (27,28).

Branched chain fatty acids such as isobutyrate and isovalerate are degraded by syntrophic consortia as well. The thermodynamic principles are the same as those described for butyrate, and the same types of microorganisms are involved in their degradation (66).

THE ROLE OF CELL DEATH AND CELL LYSIS DURING THE METHANOGENIC DIGESTION OF ACTIVATED SLUDGE

For anaerobic digestion of activated sludge, an additional factor has to be included because hydrolysis is preceded by the death and lysis of the aerobic biomass. This is illustrated by the conceptual model, which was proposed by Pavlostathis (69; Fig. 5), in which the biomass in activated sludge consists of viable and nonviable cells. When the cells are viable, the particulate and soluble biological oxygen demand (BOD) that resides in these cells, proteins, carbohydrates, and nucleic acids are not available for hydrolysis. Upon death of the cells the soluble BOD is either immediately released into the bulk fluid or leaks slowly from the cells by diffusion. This soluble BOD probably contains macromolecular components that require hydrolysis before they can be converted by acidogenic bacteria. However, the hydrolysis of soluble macromolecular components is very fast and in the model, soluble BOD is considered directly available for the acidogenic microorganisms. The particulate BOD

either is hydrolyzed intracellularly by the cell's own enzymes or is released to the bulk fluid where it is then hydrolyzed.

Because the conceptual model (Fig. 5) is very complex and difficult to verify it has been simplified (69,70; Fig. 6). For verification of this model Pavlostathis and Gossett (70) used a "biological" sludge. This "biological" sludge was generated in a fill-and-draw activated sludge reactor fed with synthetic wastewater. The wastewater contained nutrients and trace elements, and glucose and peptone were the carbon source. The reactor was operated at a sludge loading of approximately 0.25 ggCOD/g VSS/day, 20 °C, a hydraulic retention time of two days and a sludge retention time of 10 days. Several continuous and batch experiments were conducted with this sludge (69,70).

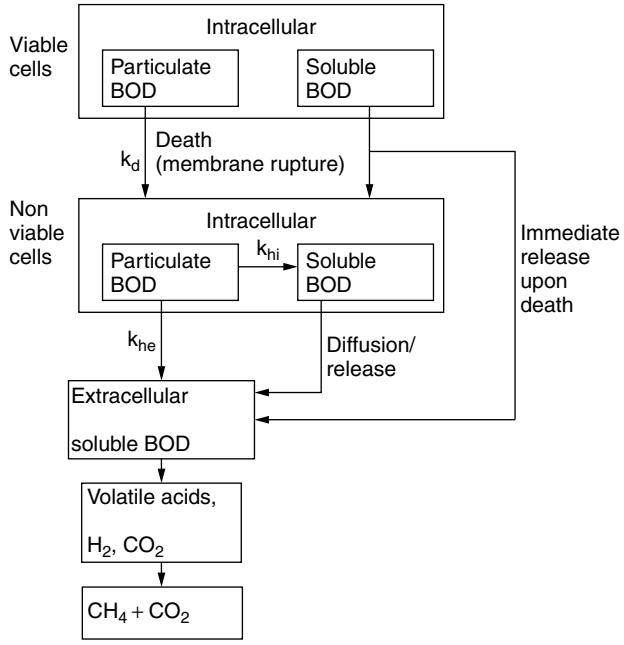

Figure 5. Conceptual model for activated sludge digestion (69).

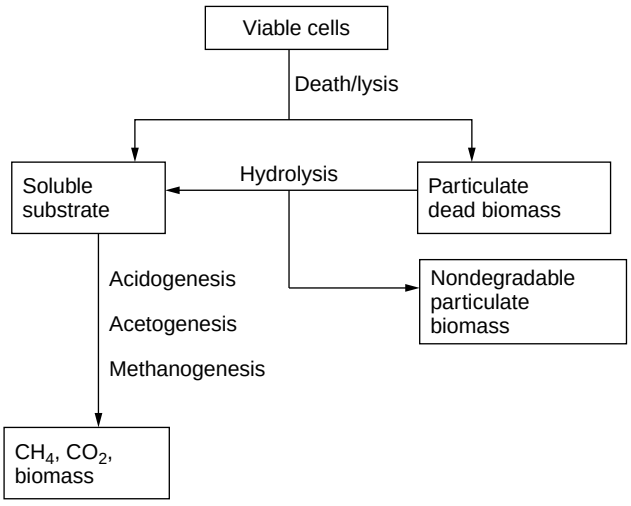

Figure 6. Simplified model for activated sludge digestion (70).

During continuous digestion of the sludge at 35 °C and a solid retention time of 1 to 23 days, degradability of the sludge was low. Only a maximum of 35% of the sludge could be converted to biogas. Moreover, from the validation of the model, it was shown that death/lysis (Fig. 6) was the rate-limiting step during the conversion of the biodegradable part of the sludge. Because the sludge was generated with a wastewater that it, all contained no refractory components it can be concluded that the refractory part of the waste activated sludge is formed during the activated sludge process. Incorporation of refractory material from the influent of the activated sludge plant into activated sludge seems to be of less importance.

During anaerobic digestion or anaerobic storage of activated sludge changes also occur with respect to the structure of activated sludge. Rasmussen and coworkers (15) observed an increase of divalent calcium ions in the water phase during the anaerobic storage of activated sludge. Moreover, Nielsen and coworkers (17) observed a decrease in the amount of capsular and slime polymers from 369 to 299 mg polymer/g volatile solids during a 12-day storage of activated sludge under anaerobic conditions at 20 °C. As the polymers and Ca^{2+} are believed to form the matrix that serves as the backbone of the activated sludge floc, it appears that the floc structure falls apart during anaerobic storage or digestion.

IMPROVING BIOGAS YIELDS

The usually applied one-stage mesophilic digestion of waste-activated sludge gives only a low biogas yield. Because most of the refractory material in activated sludge from low loaded WWTPs (Table 2) seems to be inactive, except unlysed biomass, attempts to improve the biogas yield have focused on lysis of this biomass. To destroy the cell wall of bacteria, different methods are used. Mechanical methods such as sonication and high-pressure homogenization, stirred ball mill or shear-gap homogenizer (71). Chemical pretreatment methods such as alkaline treatment (72) and thermal pretreatment have also been the topics of several investigations (73,74). Often combinations of chemical, mechanical, or thermal pretreatment have been investigated (75,72). Moreover, some authors report that a two-stage digestion might also improve the biogas yield from WAS, in which the low pH in the first stage (acidic) is believed to improve the death and lysis of the bacteria (76,77).

Mechanical Pretreatment

Müller and coworkers (71) investigated several mechanical disintegration methods to improve lysis of biomass in activated sludge. The specific energy input and the disintegration rate of a stirred ball mill, a high-pressure homogenizer, an ultrasonic homogenizer and a shear-gap homogenizer were compared. The specific energy input was defined as the amount of mechanical energy that disrupts a certain amount of sludge (in kJ/kg dry solids). The disintegration rate was defined as the oxygen consumption rate of the pretreated sludge relative to its consumption by an untreated sludge sample. Muller and

coworkers (71) reported that all disintegration methods, except the shear-gap homogenizer, gave a disintegration rate of more than 80% (this implied that more than 80% of the active biomass in the WAS was disintegrated efficiently). The high-pressure homogenizer and the stirred ball mill were selected as the most economical methods as they required the lowest specific energy input to achieve more than 80% disintegration.

All experiments were conducted with WAS with a sludge age of 3 and 13 days. After disintegration the WAS was digested at 35 °C in continuous flow experiments with a (HRT) of 2 to 23 days. The results of the digestion are depicted in Table 6. At a sludge age of three days the degradation of the disintegrated WAS was 8 to 10% higher than the untreated WAS, irrespective of the HRT of the reactor. At a HRT time of 17 days 55% and 63% of the WAS were hydrolyzed for the untreated and pretreated sludge, respectively.

The maximum degradation of the WAS with a sludge age of 13 days was much lower. The untreated and pretreated WAS both reached a maximum hydrolysis of approximately 48% at HRTs of 23 and 17 days, respectively. Moreover, the effect of the disintegration was dependent on the retention time of the digester. At a hydraulic retention time of 2.5 days the degree of degradation of the treated sludge was 15% higher than that of untreated sludge, but at a HRT of 17 days the effect of the disintegration was negligible. This indicated that, although mechanical disintegration destroys the active biomass in the activated sludge, most of the biomass still remains refractory.

Thermal Pretreatment

Pretreatment of the WAS at high temperatures can be applied to enhance death and lysis of the WAS. The method that has received most attention is the exposure of the WAS for short periods (20–60 min) to high temperatures (60–225 °C) and subsequent digestion at mesophilic temperatures.

Haug and coworkers (74) treated WAS for 30 minutes at 100 to 225 °C and subsequently digested it in a CSTR at 35 °C, organic loading rate 2.6 g/l.d, and an SRT of 15 days. At 175 °C, the highest WAS conversion was reached; a 56% higher degree of degradation was found than with the untreated WAS. At pretreatment temperatures higher than 175°C, methane production was inhibited, probably by toxic compounds from the pretreated sludge. Brons (73) investigated the effect of pretreatment at 80 to 175 °C on the batch digestion at 30 °C. After 32 days of digestion the highest gas production was observed in the digester with the WAS pretreated at 145 °C; 60% more methane was produced than that for untreated WAS. At 175 °C, gas production was only 51%, probably because of the same toxic effect as observed by Haug and coworkers (74) Hiroaka and coworkers (20) investigated lower pretreatment temperatures. After treatment of the WAS at 60 to 100 °C the sludge was digested at 35 °C. The highest methane production from WAS was gained at a pretreatment temperature of 60 °C, at which 30% more methane was formed, compared with untreated WAS. Hiroaka and coworkers concluded that at pretreatment temperatures below 100 °C, gas production from WAS was enhanced by a higher gas yield from the biodegradable fraction of the WAS. At pretreatment temperatures above 100 °C an increase in biodegradability of the sludge increased methane production.

Chemical Pretreatment

Alkaline pretreatment can be performed by sodium hydroxide or lime. It was reported that sodium hydroxide

Table 6. Results of Different Pretreatment Methods on the Solubilization and/or Subsequent Hydrolysis During the Anaerobic Digestion of WAS

Reference	Sludge	Pretreatment Method	Solubilization (%)	Digestion Conditions	Hydrolysis During Digestion (%)
71	WAS (age 3 d)	HPH or SBM		35 °C	55 to 60% (3d)
	WAS (age 13 d)			HRT 17 days	48% (13d)
74	WAS	175 °C, 30 minutes		35 °C	56% higher than untreated
				HRT 15 days	
73	WAS	145 °C,		30 °C, batch	60% higher than untreated, after 32 days
20	WAS	60 °C		35 °C	30% higher than untreated
72	1% WAS	40 meq/L NaOH	28 to 42		
		40 meq/L NaOH + Ultrasound*	70 to 89		
74	WAS	60 meq/L NaOH	15		
		115 to 150 °C, 5 minutes	15		
		180 °C, 5 minutes	30		
		34 meq/L NaOH +130 °C, 5 minutes	45		

*120 Watt, 20 KHz, 13.5 to 14.4 sec/ml.

Note: HPH = high-pressure homogenizer, SBM = stirred ball mill.

yields a greater solubilization efficiency than lime (78). A 12 to 24 hour pretreatment of 1% WAS with 40 meq/L NaOH resulted in a soluble COD over a total COD ratio of 28 to 42%. However, combined with a mechanical method, such as Ultrasound (120 W, 20 KHzKHz13.5 to 14.4 sec/ml) the solubilization of WAS could be enhanced to 77.9 to 89.0% (72).

DEWATERING OF ANAEROBICALLY DIGESTED ACTIVATED SLUDGE

In general, the two main reasons for digestion of excess sludge from WWTPs are stabilization and volume reduction. For volume reduction, it is assumed that not only is the amount of solids reduced but digestion also has a positive effect on the dewatering characteristics of the sludge. However, this assumption only seems to hold for the digestion of primary sludge. Lawler and coworkers (2) digested several mixtures of primary and activated sludge in CSTRs at a retention time of 10 days at 25 °C. The results indicated that the dewaterability, measured as the specific capillary suction time, became worse when the amount of activated sludge increased above 40% of the digester influent (Fig. 7). Lawler and coworkers (2) attributed this to the occurrence of particles between 2 and 9 μm. Increase of Ca^{2+} concentration in the water phase and degradation of the exopolymers are indications of the disintegration of the structure of the activated sludge floc (15,17). Because of the formation of small aggregates or suspended bacteria the flow of free water from the sludge during filtration tests, such as the measurement of the capillary suction time, is obstructed. Moreover, the results of Palmgren and coworkers (79) indicate that during oxygen-limiting circumstances the surface of the activated sludge becomes less hydrophobic. This effect could increase the amount of *vicinal* water in the sludge and as this cannot be removed by mechanical dewatering techniques. An increase in the amount of sludge will result in a lower dry weight of the sludge after dewatering.

When the activated sludge is pretreated before the digestion, the cells are lysed, the floc structure is destroyed, and numerous small particles arise. Kopp and coworkers (80) and Muller and coworkers (71) investigated

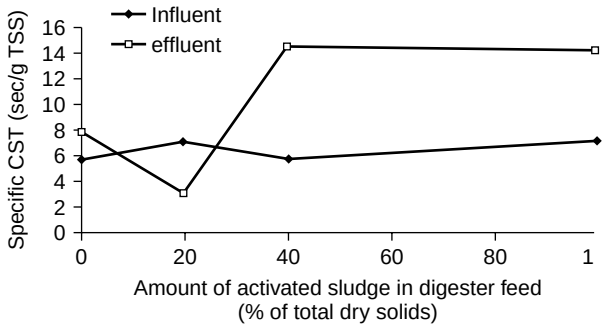

Figure 7. Effect of the fraction activated sludge in the digester feed on the dewatering characteristics of the digested sludge. (D. F. Lawler, Y. J. Chung, S. –J. Hwang, B. A. Hull, J. WPCF 58(12), 1,107–1,117 (1986)).

the relation among the degree of disintegration, the dry matter content of the dewatered sludge, polymer demand, and anaerobic digestion. They showed that sludge age of the WAS affected disintegration and subsequent digestion and the dewatering characteristics of the sludge. In experiments with WAS of 13-day sludge age, the dry matter content of the centrifuge cake decreased with increasing degree of disintegration. Moreover, more synthetic polymer was needed to obtain the maximum dry matter of the centrifuge cake. However, this negative effect of the disintegration decreased with increasing retention time in the digester. At an SRT of 17 days in the digester (35 °C) the dry matter content for both the untreated and disintegrated sludges became equal, although the disintegrated sludges still required twice as much synthetic polymer as the untreated sludge to reach maximum sludge concentration. Results obtained with three-day-old sludge were different from those obtained by using 13-day old sludge. With the former, a much higher dry solids content of the centrifuge cake could be obtained by disintegration. Immediately after disintegration, a dry solid content of about 5.2% could be achieved for the untreated sludge. For sludge that was pretreated by a high-pressure homogenizer, a dry solid content of about 9.5% could be obtained, although this required almost 10 times as much synthetic polymer (42 g/kg SS, Zetag-87 Allied Colloids). This trend persisted even when the sludge was digested, although these were fewer differences between untreated and disintegrated sludges became smaller. After 15 days of digestion, the dry solids content of the centrifuge cake was about 6% and 6.8% for the untreated and pretreated sludge, respectively. Polymer demand of pretreated sludge decreased dramatically, resulting in a demand of 10 g/kg SS and 15 g/kg SS for untreated and pretreated sludge, respectively.

CONCLUSION

In the anaerobic decomposition of waste activated sludge (WAS) microbial cells form the substrate of anaerobic methanogenic consortia. This process is applied to stabilize primary and secondary sludge from wastewater purification plants. Additionally, in this process a major part of the chemical COD is converted into biogas, which can be applied to operate the purification plant.

Technologically, key factors in this digestion process are the death and lysis of the cells, and the dewatering capacity of the sludge. Much of this depends on the sludge age of the activated sludge, as the viable fraction of the biomass seems to decrease with increasing sludge age (Table 2). The death and lysis of the biomass can be increased by chemical and mechanical disintegration of the sludge before the digestion. However, this pretreatment will result in a higher polymer demand during dewatering of the digested sludge.

Microbiologically, the decomposition of WAS is intriguing. In this methanogenic process complete degradation of organic biopolymers is achieved by a concerted action of a mixed microbial community consisting of fermentative bacteria, proton-reducing acetogenic bacteria, and methanogenic archaea. These microorganisms act in a

syntrophic food web. Metabolic interactions by means of interspecies hydrogen transfer are important in anaerobic digestion. Hydrogen consumption by hydrogenotrophic methanogens affects the metabolism of those sugar- and amino acid-fermenting anaerobes, which have the ability to dispose reducing equivalents as molecular hydrogen. In addition, the anaerobic oxidation of propionate, butyrate that are formed by fermenting bacteria, and the oxidation of long-chain fatty acids can only be carried out by hydrogen-producing acetic bacteria in coculture with hydrogenotrophic anaerobes. Stabilization of WAS is an important part of the conventional purification of municipal wastewater. It seems that in the near future aerobic purification of municipal wastewater remains the main purification process. However, in the long term it might be that other wastewater purification systems become more important. For the purification of industrial wastewater and for the treatment of municipal wastewater in tropical regions, an anaerobic treatment followed by an aerobic posttreatment seems the most appropriate technology.

BIOSURFACTANTS: TYPES, SCREENING METHODS, AND APPLICATIONS

Adria A. Bodour
Raina M. Maier
The University of Arizona
Tucson, Arizona

This article discusses biosurfactants and bioemulsifiers, microbially produced molecules that either reduce surface or interfacial tension, or act as emulsifying agents, or have both of these properties. Whereas certain physicochemical properties are shared among biosurfactants, this group of compounds exhibits great variety and uniqueness with respect to structure and properties. This combined with their environmental compatibility has created an interest in biosurfactants for application to many facets of the surfactant industry ranging from biotechnology to environmental cleanup. Currently the surfactant industry, which exceeds $ 9 billion per year, markets predominantly synthetic surfactants. Biosurfactants and bioemulsifiers are produced by a number of bacteria, yeasts, and fungi when cultivated on different carbon sources. The type of carbon source utilized ranges from simple sugars or

hydrocarbons, such as glucose or hexadecane, to complex mixtures, such as petroleum. It is important to point out that both substrate and growth conditions dictate the quantity and structure of biosurfactant/emulsifier obtained from a microorganism. In this article, we define the terms biosurfactant and bioemulsifier, and then discuss the types produced, methods used for screening and purification, synthesis, and potential industrial and biotechnology applications.

DEFINITION OF BIOSURFACTANTS AND BIOEMULSIFIERS

Biosurfactants

All biosurfactants have amphiphilic structures, containing at least one hydrophilic and one hydrophobic moiety. The hydrophilic moiety can be an ester, hydroxyl, phosphate, carboxyl, or carbohydrate group and is either neutral or negatively charged. There have been no cationic biosurfactants reported, presumably because cationic surfactants are quite toxic. The hydrophobic moiety is a fatty acid ranging in size from 8 to 18 carbons.

Because of their amphiphilic nature, surfactants tend to accumulate at interfaces (air–water and oil–water) and surfaces. As a result, surfactants reduce the forces of repulsion between unlike phases at interfaces or surfaces and allow the two phases to mix more easily. Specifically, surfactants can reduce surface (liquid–air) and interfacial (liquid–liquid) tension. For example, a proficient biosurfactant can reduce the surface tension between pure water and air from 73 to less than 30 mN/m. As surfactant monomers are added into solution, the surface or interfacial tension will decrease until the surfactant concentration reaches what is known as the critical micelle concentration (CMC). Above the CMC no further reduction in surface or interfacial tension is observed. At the CMC, surfactant monomers begin to spontaneously associate into structured aggregates such as micelles, vesicles, and lamellae (continuous bilayers) (Fig. 1). These aggregates form as a result of numerous weak chemical interactions between the polar head groups and the nonpolar tail groups, including hydrophobic, van der Waals, and hydrogen bonding. The CMC for any surfactant is dependent on the surfactant structure as well as the pH, ionic strength, and temperature of the solution. Further, the aggregate structure is dictated by the polarity of the solvent in which the surfactant is dissolved. For example, in an aqueous solution, the polar head groups of a micelle will be oriented outward toward the aqueous phase and the hydrophobic tails will associate in the core of the micelle (oil-in-water micelle). In contrast, in oil the polar head groups will associate in the center of the micelle, whereas the hydrophobic tails will be oriented toward the outside (water-in-oil micelle).

Bioemulsifiers

An emulsion is a stable mixture of two liquids. Normally an oil and water mixture forms separate phases. However, if the mixture is shaken vigorously, the oil will disperse into the water phase. When the shaking is discontinued, the phases quickly separate. One way to achieve a stable mixture or emulsion is to add a surfactant. The two most common types of emulsions are oil-in-water and water-in-oil. For an oil-in-water emulsion, the water phase is continuous whereas the oil phase is composed of discrete droplets. Since emulsions represent large interfacial areas,

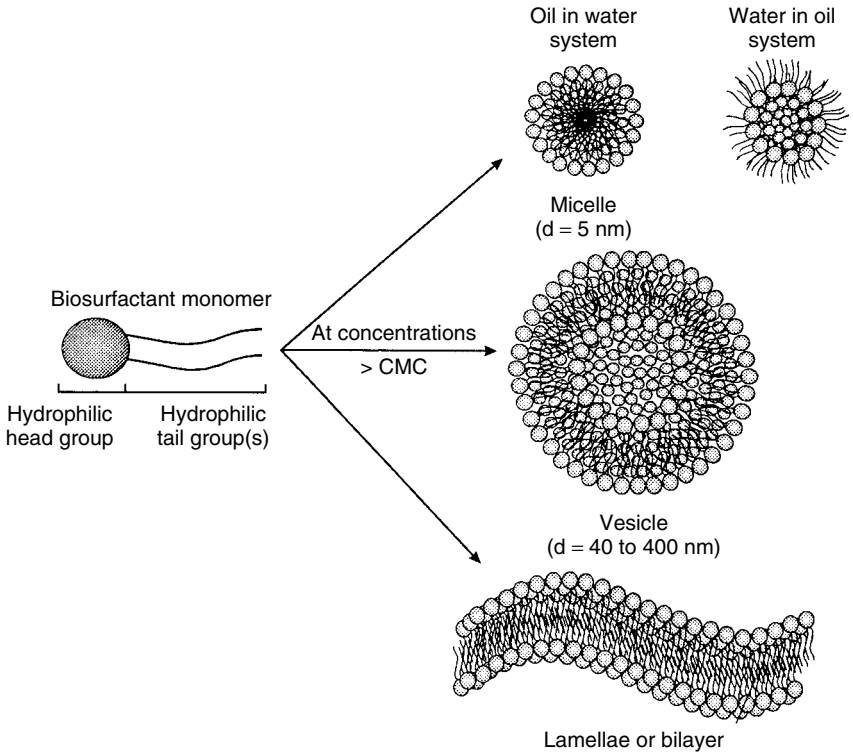

Figure 1. The types of aggregates formed by biosurfactants.

any reduction in interfacial tension caused by addition of a surfactant will promote stability of the emulsion. Although some bioemulsifiers decrease interfacial tension, others have little impact on interfacial tension. These emulsifiers are effective because they form films on the surface of the oil droplets in the aqueous phase. Once these films are formed, it is difficult to eject the emulsifier from the surface and therefore the oil droplets cannot coalesce, allowing a stable emulsion to be maintained. The length of time that an emulsion remains stable reflects the effectiveness of the emulsifier. After some period of time, the droplets in most emulsions will flock together and coalesce, ultimately causing separation of the two phases.

TYPES OF BIOSURFACTANTS AND BIOEMULSIFIERS

Biosurfactants and bioemulsifiers are classified based on their major structural features and the organism that produces them. The major groups include: (*1*) glycolipids; (*2*) phospholipids, neutral lipids, and fatty acids; (*3*) lipopeptides and lipoproteins; and (*4*) polymeric biosurfactants. There are many reviews of biosurfactants, including several recent ones (1–3).

Glycolipids

The most widely studied biosurfactants are the glycolipids. Glycolipids have a carbohydrate group attached to one or more long-chain aliphatic acid or hydroxy-aliphatic acid groups, and range in molecular weight from 500 to 1,500. The best-studied glycolipids include rhamnolipids, trehalose lipids, sophorolipids, and a new group, mannosylerythritol lipids. Other types of glycolipids, such as cellobiose lipid (4), glucose lipid (4,5), glycoglycerolipid (6), sugar-based bioemulsifiers (7–9), and many different hexose lipids (10–14), have been reported in the literature. These glycolipids are produced by a wide variety of microorganisms.

Rhamnolipids. The best-studied glycolipid is rhamnolipid (Fig. 2). Rhamnolipid was isolated from *Pseudomonas aeruginosa* 141 and characterized by Jarvis and Johnson in 1949 (15). Edwards and Hayashi (16) elucidated the rhamnolipid structure by identifying the α-1,2-linkage between adjacent rhamnose moieties. Rhamnolipid is a glycolipid that has been shown to have up to six different anionic forms ($pK_a \sim 4.6$) (7). The most abundant are the R1 and R2 forms, which contain one and two rhamnose sugars, respectively, and have two β-hydroxy fatty acid tail groups, most commonly β-hydroxydecanoic acid (18). Much less abundant are R1 and R2 forms with three β-hydroxy fatty acid tail groups (19). The R3 and R4 forms contain only one β-hydroxy fatty acid tail group (20–22). In addition to these anionic forms of rhamnolipids, there have been reports of neutral or methylesters of these rhamnolipid forms (23–25). Rhamnolipids reduce surface tension to less than 30 mN/m, and reduce interfacial tension to 1 mN/m in hexadecane/water (25–28). The CMC of rhamnolipid varies depending on the mixture of rhamnolipids produced, ranging from 20 to 100 mg/L. The average

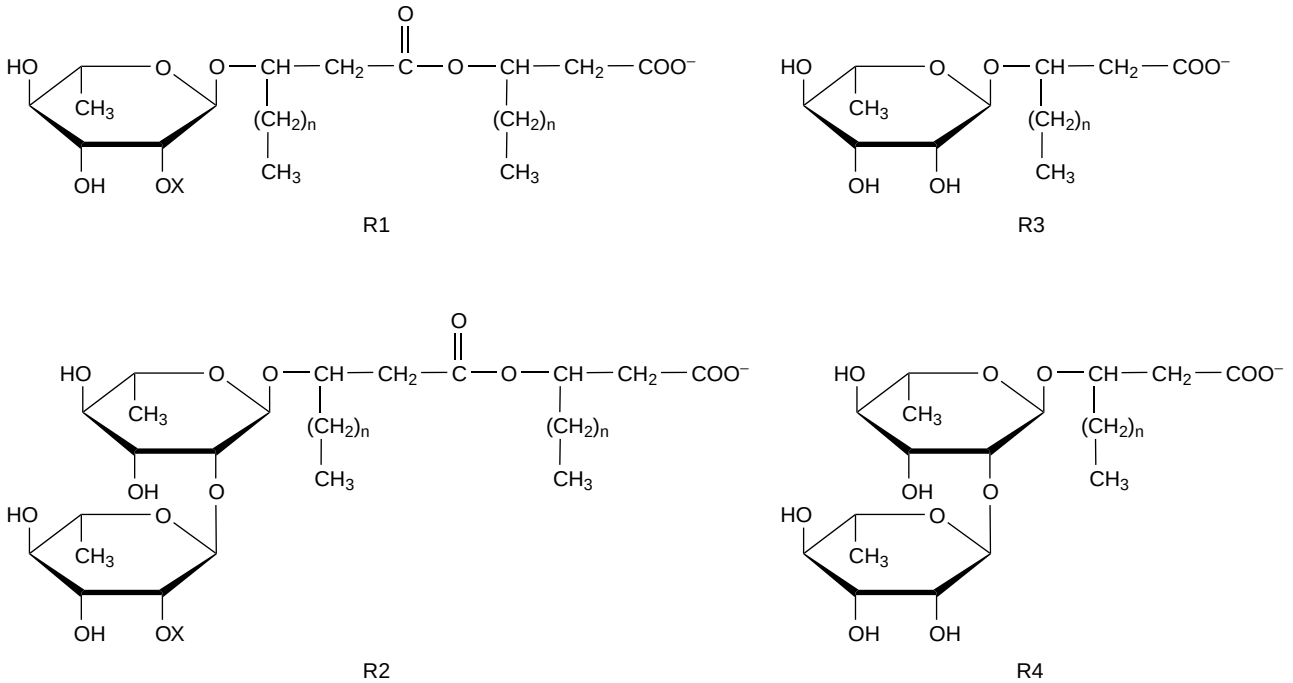

Figure 2. The six major types of rhamnolipid produced by *P. aeruginosa*. Most common are R1 (rhamnosyl-β-hydroxydecanoyl-β-hydroxydecanoate) and R2 (rhamnosyl-rhamnosyl-β-hydroxydecanoyl-β-hydroxydecanoate) where $\mathbf{X} = \mathrm{H}$. There are two much less common forms of R1 and R2 wherein $\mathbf{X} =$ hydroxydecanoate. R3 and R4 are also less common, where R3 is rhamnosyl-β-hydroxydecanoate and R4 is rhamnosyl-rhamnosyl-β-hydroxydecanoate (29). In all cases $n = 4$ to 8.

molecular weight of rhamnolipid mixtures varies between 400 and 700 g/mol.

Rhamnolipid production is limited to *P. aeruginosa* strains. There are a few early reports that state that other *Pseudomonas* species produce rhamnolipid; however, it is likely that at the time these isolates were not accurately identified to the species level. Rhamnolipids are produced during the late log and stationary phases on a variety of carbon sources, including glucose (30–32), molasses (33), ethanol (34,35), vegetable oils (13,36,37), glycerol (21,38), *n*-alkanes (20,39–42), polyaromatic hydrocarbons (43,44), and mixtures of the above (45). Limiting addition of inorganic nutrients, including phosphate, nitrogen, and iron, has been reported to increase production of rhamnolipid (30,46,47). Reported yields of rhamnolipid range from 0.25 to 100 g/L (35,48). The highest yields have been obtained with continuous batch-fed or fermenter systems using mixed carbon sources such as glucose and hexadecane (35). Currently, rhamnolipid is commercially available from Jeneil Biosurfactant Co., LLC (Saukville, Wisconsin).

Parts of the rhamnolipid biosynthetic pathway and its regulation have been described (49,50). Rhamnolipid (R1) is formed from deoxy-thymidine-diphospho-L-rhamnose (dTDP-L-rhamnose) and β-hydroxydecanoyl-β-hydroxydecanoate (β-H) (Fig. 3). It is thought that the *algC* and the *rml* genes used to produce dTDP-L-rhamnose for the O-antigen in lipopolysaccharide (LPS) are also responsible for formation of dTDP-L-rhamnose used in rhamnolipid synthesis. The *rhlG* gene, which is homologous to reduced nicotinamide adenine dinucleotide phosphate–dependent ketoacyl reductase, is responsible for obtaining fatty acid precursors from the normal fatty acid biosynthetic pathway for synthesis of the β-H component of rhamnolipid (50). It is not yet clear how the *rml* and *rhlG* genes are regulated with respect to rhamnolipid synthesis. The *rhlA* and *rhlB* genes encode the enzyme rhamnosyl transferase I, which catalyzes the addition of dTDP-L-rhamnose to β-H forming R1. Rhamnosyltransferase II, encoded by the *rhlC* gene, adds a second dTDP-L-rhamnose to the R1 molecule to form R2. It is currently not known how *rhlC* is regulated or where RhlC is located in the cell.

The synthesis of R1 is under the regulation of the RhlR-RhlI quorum-sensing system (Fig. 4) which is coordinately regulated at both the transcriptional and posttranslational levels with a second quorum-sensing system, LasR-LasI (51,52). Together, these two quorum-sensing systems are responsible for expression of a number of genes at high cell density and in response to stress. Other exoproducts produced include alginate, elastase, exotoxin A, protease, and pyocyanin. Clearly, the genetic regulatory network involved in the production of rhamnolipid is very complex and a full understanding of the regulation of rhamnolipid production remains to be determined.

Trehalose Lipids. Trehalose lipids exhibit great structural diversity. They can be nonionic or anionic and contain two to eight sugar groups and one to two mycolic acids. The molecular weight of these compounds ranges from 800 to 3,000. The three major types of trehalose lipids are α-trehalose-6-monomycolate, α,α-trehalose-6,6′-dimycolate, and trehalose-2,3,4,2′-tetraester (Fig. 5). However, a mixture of trehalose structures and/or other glycolipid structures are normally produced depending on substrate source and growth conditions (54). *Rhodococcus erythropolis* trehalose mycolates are among the best studied of the trehalose lipids. Nonionic trehalose lipids from this species reduce surface tension to 36 mN/m and interfacial tension to 16 mN/m against hexadecane. However, when this isolate is grown in nitrogen-limiting conditions, it produces anionic trehalose tetraesters, which further reduce surface tension to 26 mN/m and interfacial tension to less than 1 mN/m (55–58). The CMC for trehalose lipids ranges from 3 to 15 mg/L (58,59).

Trehalose lipid structures have been isolated from several bacterial genera, including *Rhodococcus* (now separated into *Gordona* and *Tsukamurella*), *Mycobacterium*, *Arthrobacter*, *Nocardia*, *Brevibacterium*, and *Corynebacterium* (60–68). Trehalose lipids can be secreted from the cell as is the case for some *Rhodococcus*, but are often found as an important constituent of the cell wall in genera such as *Mycobacterium*. In *Mycobacterium*, α,α-trehalose-6,6′-dimycolate (Fig. 5) also known as cord factor, is found at the cell wall surface and causes the microbe to grow in serpentine cords. In this organism, the cord factor has been implicated in virulence, wherein the presence of cord factor is related to the ability of the organism to protect itself against macrophages and to induce delayed-type hypersensitivity (69,70).

Trehalose lipids are produced during growth on hydrocarbons, including alkanes or vegetable oils, such as sunflower oil. Yields for trehalose lipids range from 2 to 40 g/L, somewhat less than yields reported for other glycolipids (17,57,67,68,71–74). Yield is dictated by the carbon source used for growth, nutrient availability, the method of production, and the microbial isolate used for production. For example, the highest yield reported (40 g/L) was obtained using *Rhodococcus* sp. strain SD-74 with *n*-hexadecane as a carbon source in a jar fermentor. The following seven parameters were optimized in this system: hexadecane concentration, ionic strength, phosphorous concentration and form, nitrogen concentration and form, metal ion concentration (e.g., iron), temperature, and aeration (17,71,72). Increased yields are still needed to make trehalose lipids economically competitive with synthetic surfactants. However, trehalose lipids have the potential for a variety of applications under a wide array of conditions. For instance *Tsukamurella* sp. 26A produces trehalose lipids with good emulsification activity, and this biosurfactant is stable over a wide pH and temperature range (67).

Sophorolipids. Sophorolipids were first isolated from the yeast *Torulopsis mangnoliae* (75). Since then the taxonomical classification of *Torulopsis* has changed and several *Torulopsis* species now belong to the genus *Candida*, including *T. bombicola*, *T. magnoliae*, *T. apicola*, and *T. gropengiesseri*. Other species of *Candida* known to produce sophorose lipids include *C. apicola*, *C. magnolia*, and *T. petrophilum* (76–78). The chemical structure of sophorolipid is a sophorose sugar dimer linked to one of several fatty acids (Fig. 6). The molecular

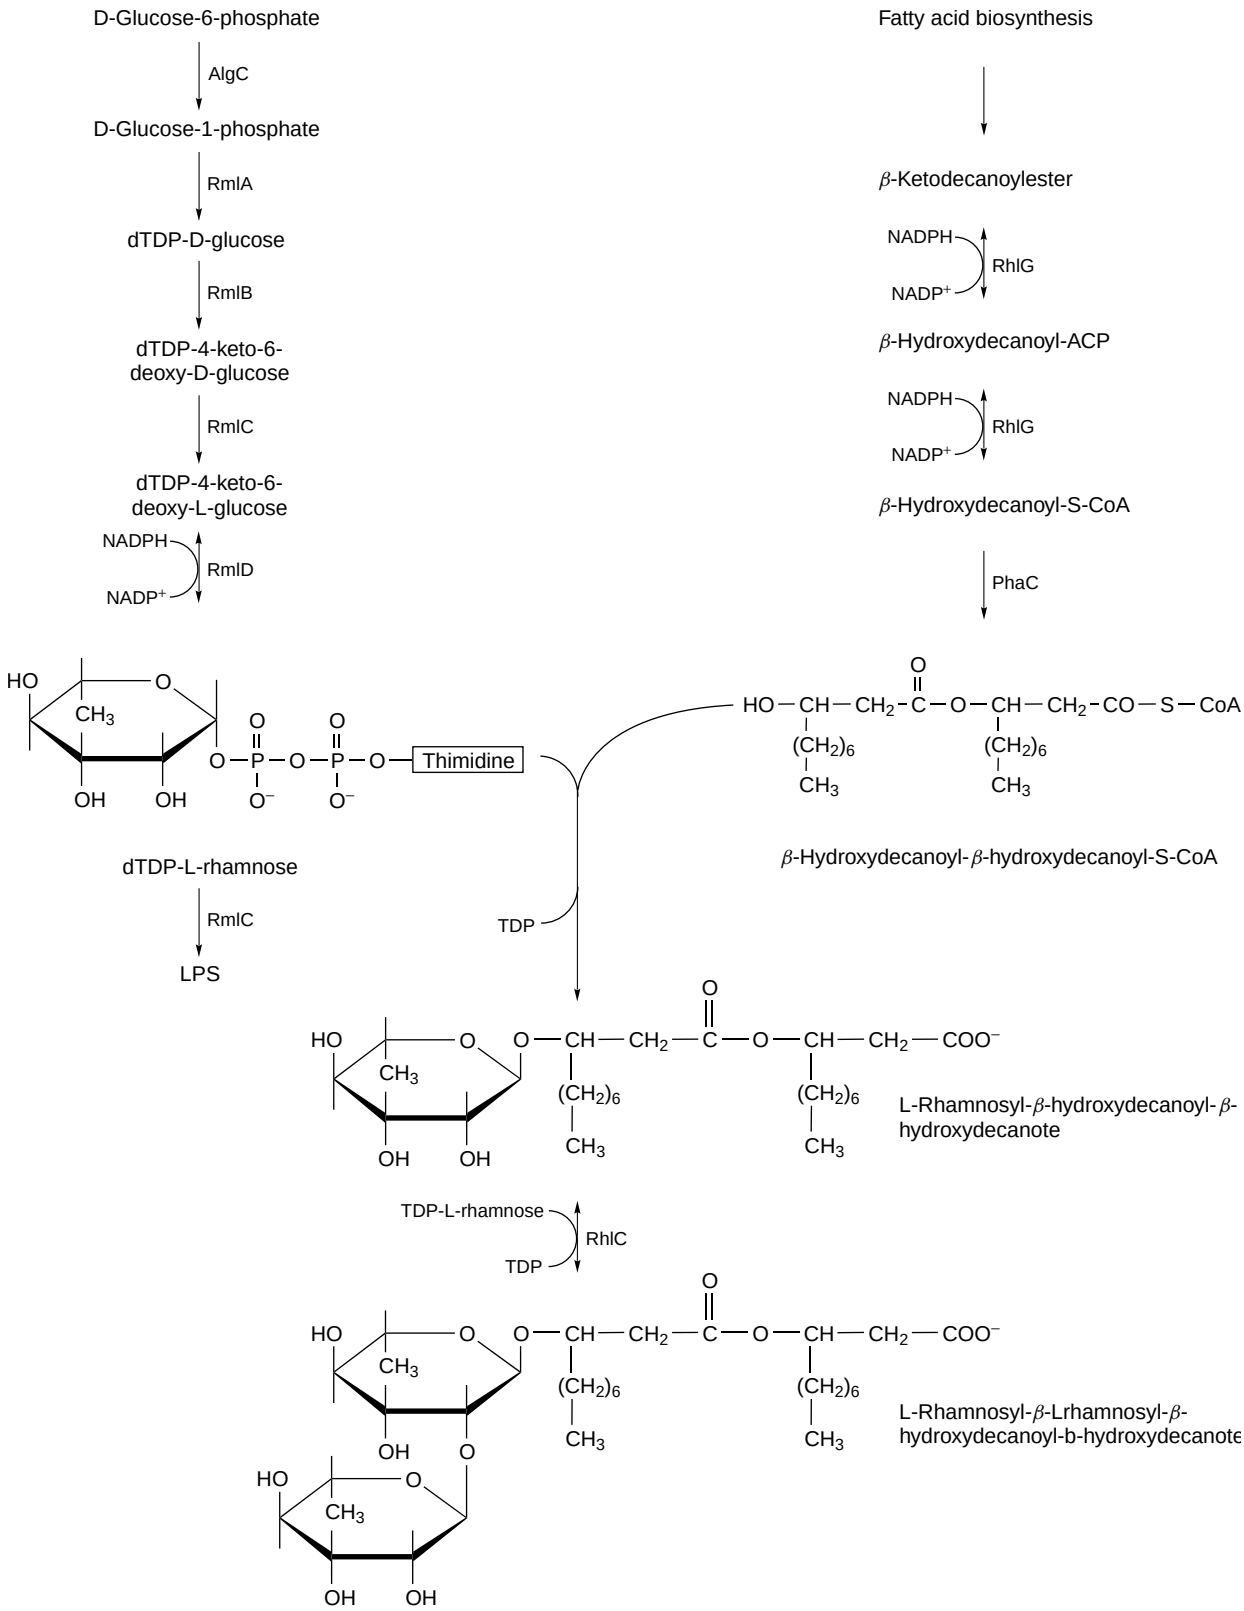

Figure 3. The rhamnolipid biosynthetic pathway. PhaC is polyhydroxyalcanoate synthase, AlgC is a phosphomannomutase that catalyzes the second step in the alginate biosynthetic pathway, the *Rml* genes are involved in synthesis of dTDP-L-rhamnose for LPS and rhamnolipid synthesis, and the *Rhl* genes are involved in synthesis of rhamnolipid (50).

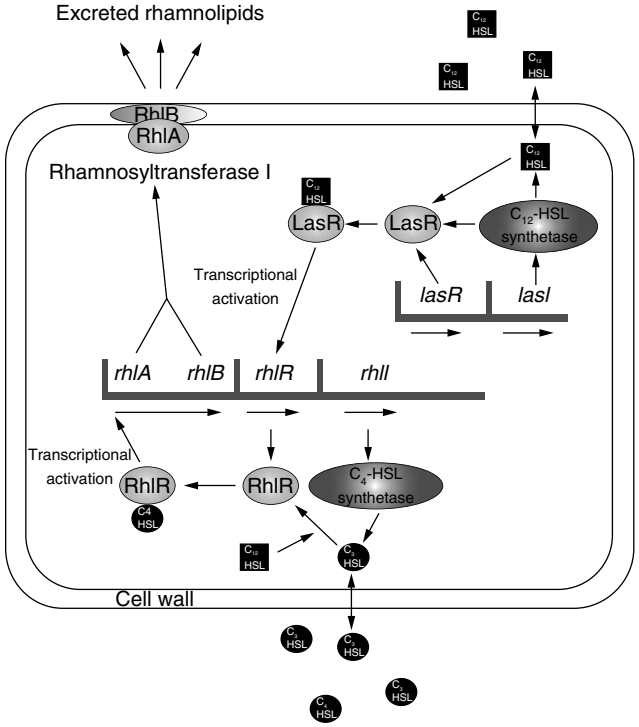

Figure 4. Quorum-sensing regulation of rhamnolipid (R1) synthesis. Rhamnosyltransferase I is composed of two subunits: RhlA, an inner membrane bound protein, and RhlB, a periplasmic protein. Together these catalyze the addition of dTDP-L-rhamnose to β-hydroxydecanoyl-β-hydroxydecanoate to form R1, which is then excreted from the cell (53). There are two signal molecules involved in R1 synthesis. The first is *N*-butryl homoserine lactone (C_4-HSL) encoded by *rhlI*. The C_4-HSL binds to the RhlR regulatory protein, and the HSL-RhlR complex causes transcriptional activation of the *rhlA* and *rhlB* genes that encode rhamnosyltransferase I. The second signal molecule is *N*-(3-oxododecanoyl)-L-homoserine lactone (C_{12}-HSL), which controls rhamnolipid synthesis in two ways. The C_{12}-HSL binds to the LasR protein, and the HSL-LasR complex causes transcriptional activation of the *rhlR* gene. However, at the posttranslational level, it has been shown that the C_{12}-HSL prevents binding of the C_4-HSL to RhlR and thereby prevents transcription of *rhlA* and *rhlB*. Pesci and coworkers (51) suggest that the latter control is more important at low cell density.

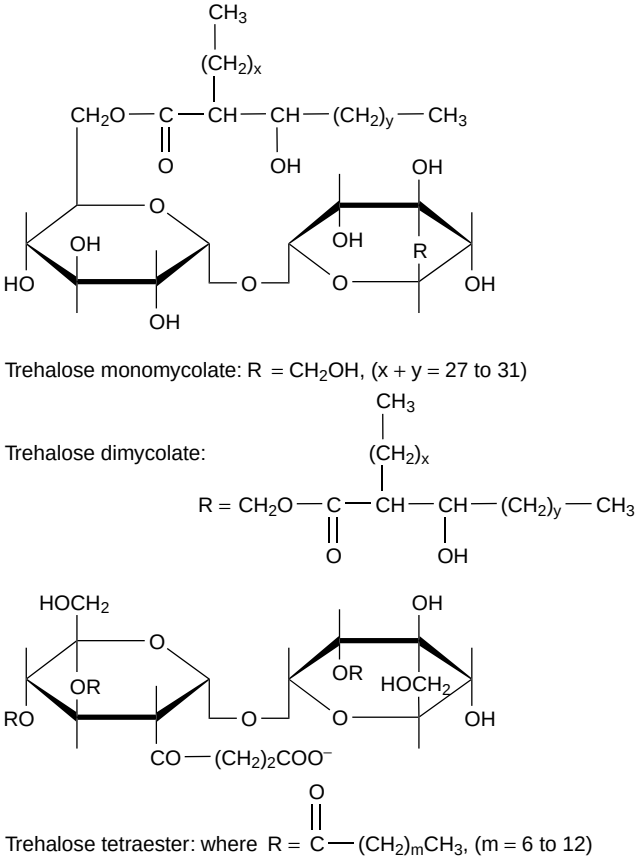

Figure 5. Structure of trehalose lipids produced by species of *Rhodococcus* (now separated into *Gordona* and *Tsukamurella*), *Mycobacterium*, *Arthrobacter*, *Nocardia*, *Brevibacterium*, and *Corynebacterium*. Nonionic trehalose monomycolate (56) and dimycolate also known as cord factor (55), and anionic trehalose tetraester (57).

weight of sophorolipids ranges between 460 and 705. Sophorolipids can reduce surface tension to less than 33 mN/m and interfacial tension between hexadecane and water from 40 to less than 1 mN/m (1,79). In contrast, they are generally poor emulsifying agents (77).

Growth conditions, including pH, temperature, resting cells versus growing cells (81), substrate(s), and method of cultivation (batch versus fed-batch), have been optimized for production of sophorolipids by *Candida bombicola* (82). As a result, yields of up to 250 to 300 g sophorolipid/L have been achieved (83). In general, the highest sophorolipid yields were obtained by fermentation using a continuous feed of a substrate combination containing a carbohydrate (glucose) and a lipid (rapeseed ester rich in C18 : 1 and C18 : 0 fatty acids) (83,84). Other carbon sources have been investigated, such as glucose, lactose, sucrose (85), canola oil, vegetable oil, deproteinized whey (86), sunflower oil, oleic acid, hexadecane, dodecanol with the hydroxyl group in the 1,2,3, or 4 position (87), and a mixture of the above. The substrate used dictates the composition of the sophorolipid fatty acid moieties as well as the number of sugars (83,84,88). Kim and Kim (89) determined that the carbon to nitrogen ratio impacts production yield for *C. bombicola*. Specifically, it was shown that nitrogen-limiting conditions are needed for good production. Finally, some sugars inhibit the production of sopohorose lipids even if a hydrocarbon is present (78).

The largest reported yield of sophorolipid is 422 g/L (86). This was obtained using a two-stage cultivation method. The first stage used *Cryptococcus curvatus* ATCC 20509 to deproteinize a whey substrate. In the second stage the deproteinized whey substrate was inoculated with *C. bombicola* ATCC 22214 and fed continuously with rapeseed oil. The high yields reported for sophorolipids make commercial production competitive with synthetic surfactants.

Mannosylerythritol Lipids. Mannosylerythritol lipids have been reported to be produced by several strains of the yeast *Candida* (90–93) and by the smut fungus Ustilago

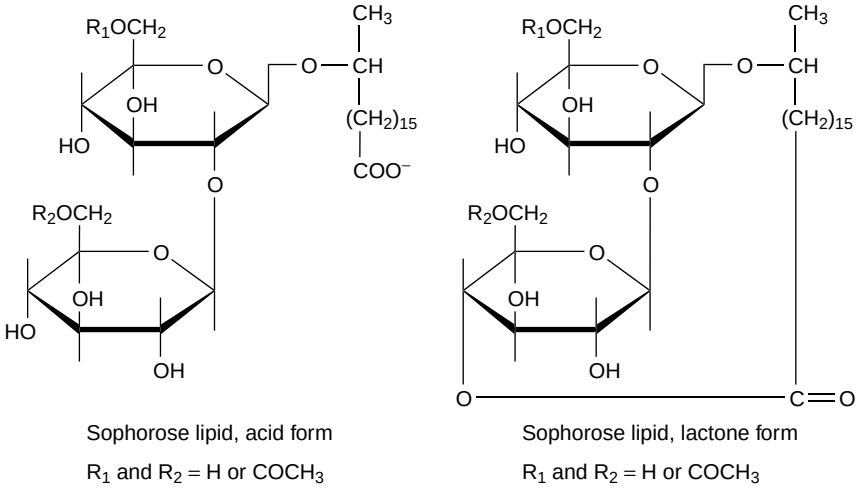

Figure 6. Structure of sophorose lipids produced by *Candida* sp. (80).

maydis (4). Mannosylerythritol lipids are anionic, with a structure that consists of a mannose sugar monomer linked to two fatty acids. There are three major forms of mannosylerythritol lipids reported, MEL-A, MEL-B, and MEL-C (Fig. 7). The molecular weight of this biosurfactant ranges from 577 to 745.

The mannosylerythritol lipid isolated from *Candida* sp. SY16 (MEL-B form) reduces surface tension to 29 mN/m and reduces interfacial tension against kerosene to 0.1 mN/m (93). The CMC of this surfactant was 10 mg/L. Reported yields of mannosylerythritol lipids from *Candida* sp. range up to 80 g/L. In this case high concentrations of resting cells were used with peanut oil as the carbon source (94). No nutrients (other than the peanut oil) or buffer were required in this system. Growing cells have also been reported to produce high levels of mannosylerythritol lipids (30 to 46 g/L) on a variety of carbon sources, such as soybean oil (90,95) safflower, coconut, cottonseed, corn, and palm oils (91), olive oil, triolein, and several long-chain alcohols (94). *Ustilago maydis* produces a surfactant

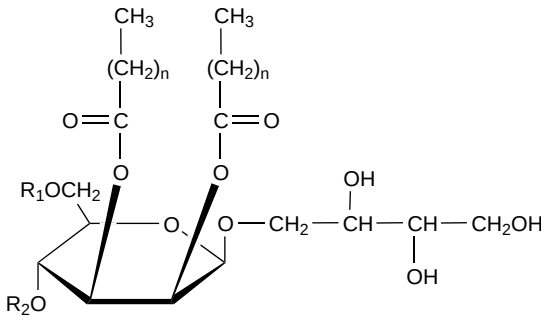

Figure 7. Structure of mannosylerythritol lipids produced by *Candida* and *Ustilago* (4).

mixture composed of mannosylerythritol and cellobiose lipids. Carbon and nitrogen sources dictate the mixture composition with oil-based substrates, favoring formation of mannosylerythritol lipids regardless of nitrogen source (ammonia or urea). In contrast, sugar-based substrates favor production of cellobiose lipids in the presence of urea and mannosylerythritol lipids in the presence of ammonia (4).

Other Glycolipids. A number of other glycolipids have been characterized, although information about these molecules and their properties is more limited. The fact that numerous different glycolipids have been identified illustrates the great structural variety possible in biosurfactants. This variety is especially important from the perspective of potential biosurfactant applications.

Several microorganisms have been reported to produce glucose lipids, including the yeast *Candida antaria* T-34 (4,91), the smut fungus *U. maydis* DSM 4500 and ATCC 14826 (4), and the bacteria *Alcanivorax borkumensis* (14,96,97), *Alcaligenes* sp. MM1 (98), and *Alcaligenes* sp. MM7 (99). Glucose lipids can reduce surface tension to less than 25 mN/m and interfacial tension against hexadecane to less than 5 mN/m (97). They have been shown to enhance the degradation of the polychlorinated biphenyl mixture Aroclor 1248 (14).

A number of bacteria can produce other glycolipids either singly or in mixtures. In some instances, the carbohydrate portion of the molecule can be dictated by the carbon source used. In particular, when a resting cell culture is used, it is possible to influence the glycolipid produced (100). The variety of glycolipids reported includes mannose, cellobiose, maltose, maltotriose, sucrose, fucose, galactose, and altrose lipids. The producing organisms include *Arthrobacter* sp., *Brevibacteria*, *Corynebacterium, Nocardia*, and *Rhodococcus* (12,100–103).

Phospholipids, Neutral Lipids, and Acidic Lipids

There are several lipid-containing molecules integral to cell structure that are also surface active and have activities normally associated with biosurfactants. These include phospholipids, acidic lipids such as fatty acids, and

neutral lipids such as triacylglycerol. For example, Beebe and Umbreit (104) isolated a mixture of phospholipids and neutral lipids from *Thiobacillus thiooxidans*, which was capable of wetting elemental sulfur. Phospholipid-rich and LPS-rich vesicles, produced by *Acinetobacter* sp. HO1-N during growth on hexadecane, were shown to function in enhancing the solubility of hexadecane (105). Similarly, *Arthrobacter paraffineus* KY 4303 produces a primary fatty alcohol when grown on paraffin that coats the paraffin in the medium (106). The surface-active compound produced by *Nocardia erythropolis* ATCC 4277 during growth on 4% hydrocarbon was determined to be a neutral lipid. This biosurfactant was able to reduce surface tension to 34 mN/m and interfacial tension against hexadecane to less than 1.0 mN/m (107,108).

One acidic lipid that is not integral to the cell structure is spiculisporic acid, a tricarboxylic acid produced by *Penicillium* (Fig. 8). Spiculisporic acid is produced during growth on glucose and yields of up to 110 g/L have been achieved (109). Whereas the surface activity of spiculisporic acid is low, derivatives of this molecule have good surface activity. For example, a disubstituted *n*-hexylamine salt of the S-form reduced surface tension to 27 mN/m (110).

Lipoproteins

Lipoproteins, also referred to as lipopeptides, have a hydrophilic protein moiety attached to a hydrophobic fatty acid. The protein moiety can be neutral or anionic and the amino acids are arranged in a cyclic structure. As a group, the lipoprotein biosurfactants are perhaps best known for their antibiotic activities. For example, gramicidin S is produced by *Bacillus brevis* (112) and the polymyxins are produced by *Bacillus polmyxa* (113). Both are cyclic lipopeptide antibiotics that have notable surface activity. The best-characterized lipoproteins, including surfactin, iturin, fengycin, and lichenysin, are those produced by *Bacillus* sp. These have molecular weights ranging from 1,000 to 1,500.

Surfactin, Fengycin, and Iturin. Surfactin is produced by *Bacillus subtilis*. The peptide sequence of surfactin's seven amino acids and β-hydroxy fatty acid were first characterized by Kakinuma and coworkers (114,115), and since then several isoforms have been detected and described. These isoforms vary in the composition of the anionic heptapeptide as well as the length and branching of the fatty acid tail (116,117) (Fig. 9). In many cases, the biosurfactant produced by *B. subtilis* is a mixture composed of surfactin and two other similar lipoproteins, iturin and fengycin (118,119). Iturin differs from surfactin in that an amino fatty acid is attached to the heptapeptide (120). Fengycin differs in that the β-hydroxy fatty acid is attached to a peptide containing 10 rather than seven amino acids (121). Like surfactin, there are isoforms of iturin and fengycin that vary in the amino acid composition of the peptide ring and in the length and composition of the fatty acid moiety (Fig. 8).

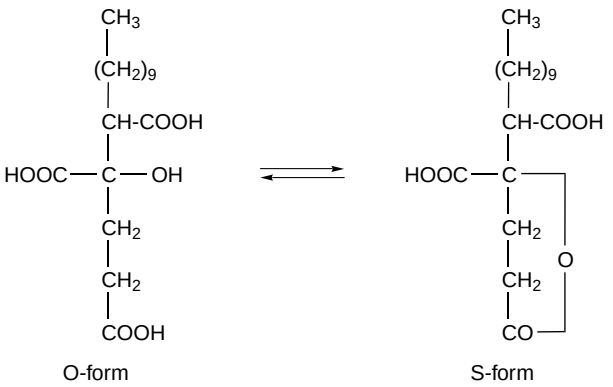

Figure 8. Structure of spiculisporic acid produced by *Penicillium* (111). Spiculisporic acid comes in two forms, the S or spiculiosporic form, and the O or open form.

Surfactin is a highly surface active molecule. It can reduce surface tension to 27 mN/m and interfacial tension against hexadecane to 0.1 mN/m (123–125). The reported CMC for surfactin is 10 mg/L, and the reported CMC values for iturin and fengycin are 20 and 11 mg/L, respectively (126). Efforts have been made to produce lipoproteins in high amounts for commercial use. The normal yield of lipoprotein is 0.1 to 0.4 mg/L. Cooper and coworkers (124) reported a doubling of surfactin yield to 0.8 g/L from *B. subtilis* strain ATCC 21332 using glucose as a carbon source. A fermentor was used for growth, and the surfactant was harvested continuously from the fermentor as a foam. Mulligan and coworkers (46) were able to increase surfactin yield to 1.1 g/L using a mutant *B. subtilis* strain. Iron enrichment was used to enhance surfactin production to 3.5 g/L (127). However, the highest reported yield, 7 g/L, was obtained under oxygen-limiting conditions (128). Surfactin has also been produced on unconventional carbon sources such as potato waste (129) and under extreme conditions. *Bacillus subtilis* is able to produce surfactin at 45 °C, under a wide range of pH (4.5 to 10.5) and at salt concentrations as high as 4% NaCl (130).

Surfactin biosynthesis and regulation have been recently reviewed (49,118). Thus far, three proteins have been identified as necessary for surfactin synthesis. One protein is surfactin synthetase, a complex multifunctional protein encoded by the *srfA* operon. The *srfA* operon contains four open reading frames, ORF1 (*srfA-A*), ORF2 (*srfA-B*), ORF3 (*srf A-C*), and ORF4 (*srfA-D*). These open reading frames encode the four subunits of surfactin synthetase, E_{1A}, E_{1B}, E_2, and a thioesterase thought to be involved in the lactonization of the molecule (Fig. 10). Subunits E_{1A}, E_{1B}, and E_2 are responsible for addition of surfactin's seven amino acids to the β-hydroxy fatty acid (131). E_{1A} and $E_{1B}$are multifunctional subunits that each add three amino acids to the β-hydroxyacylpeptide. E_2 adds the seventh amino acid. The second protein required for surfactin synthesis is the acyl transferase responsible for the initial transfer of the β-hydroxy fatty acid to surfactin synthetase. The gene encoding the acyl transferase has not yet been characterized. The third protein required is Sfp, a phosphopantetheinyl transferase that is required to activate the surfactin synthetase by posttranslational modification. The gene encoding Sfp is located several kilobases downstream of the *srfA* operon.

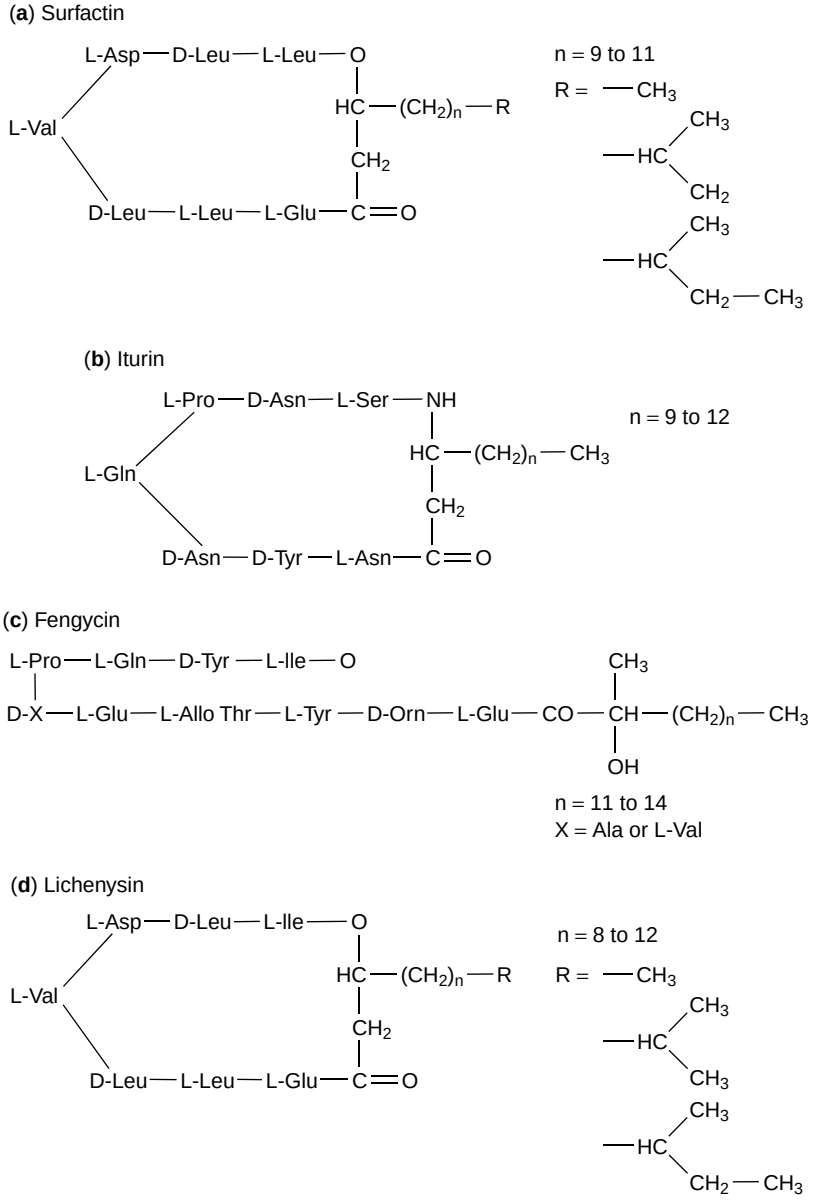

Figure 9. Structure of the lipopeptides surfactin, iturin, fengycin (produced by *B. subtilis*), and lichenysin (produced by *B. licheniformis*) (122). Surfactin and lichenysin are the best characterized of these surfactants. Both the fatty acid and peptide moieties can vary in structure. For example, for lichenysin, the amino acids shown in bold can be Gln or Glu (amino acid 1), Asn or Asp (amino acid 5), Ile or Leu (amino acid 7).

The synthesis of surfactin is under the regulation of the *com* operon, an operon required for development of competence of *Bacillus* (Fig. 11). This is because the *comS* gene, which is needed for competence, is embedded in the *srfA* operon. Therefore, in a quorum-sensing system similar to that described for rhamnolipid, a signal peptide, ComX, accumulates at high cell density and is responsible for initiating transcription of the *srfA* operon. Specifically, ComX interacts with a membrane bound protein, ComP. ComP then phosphorylates ComA, and ComA-P binds to the promotor of *srfA*. There is a second signal peptide, competence stimulating factor (CSF), which also influences *srfA* expression. CSF is the product of *phrC*, and it is processed into the active form of CSF as it is excreted through the cell wall (132). At low concentrations of CSF, such as the concentration present in midexponential phase (2 to 5 nM), CSF acts to stimulate expression of *srfA*. CSF stimulates *srfA* by preventing the phosphatase RapC from interacting with ComA-P (ComA-P $\rightarrow$ ComA). At stationary phase levels of CSF (approaching 100 nM), expression of *srfA* is inhibited. Currently the mechanism of inhibition is unknown.

Biosynthesis of fengycin is similar to that of surfactin. In this case, the operon responsible for synthesis of

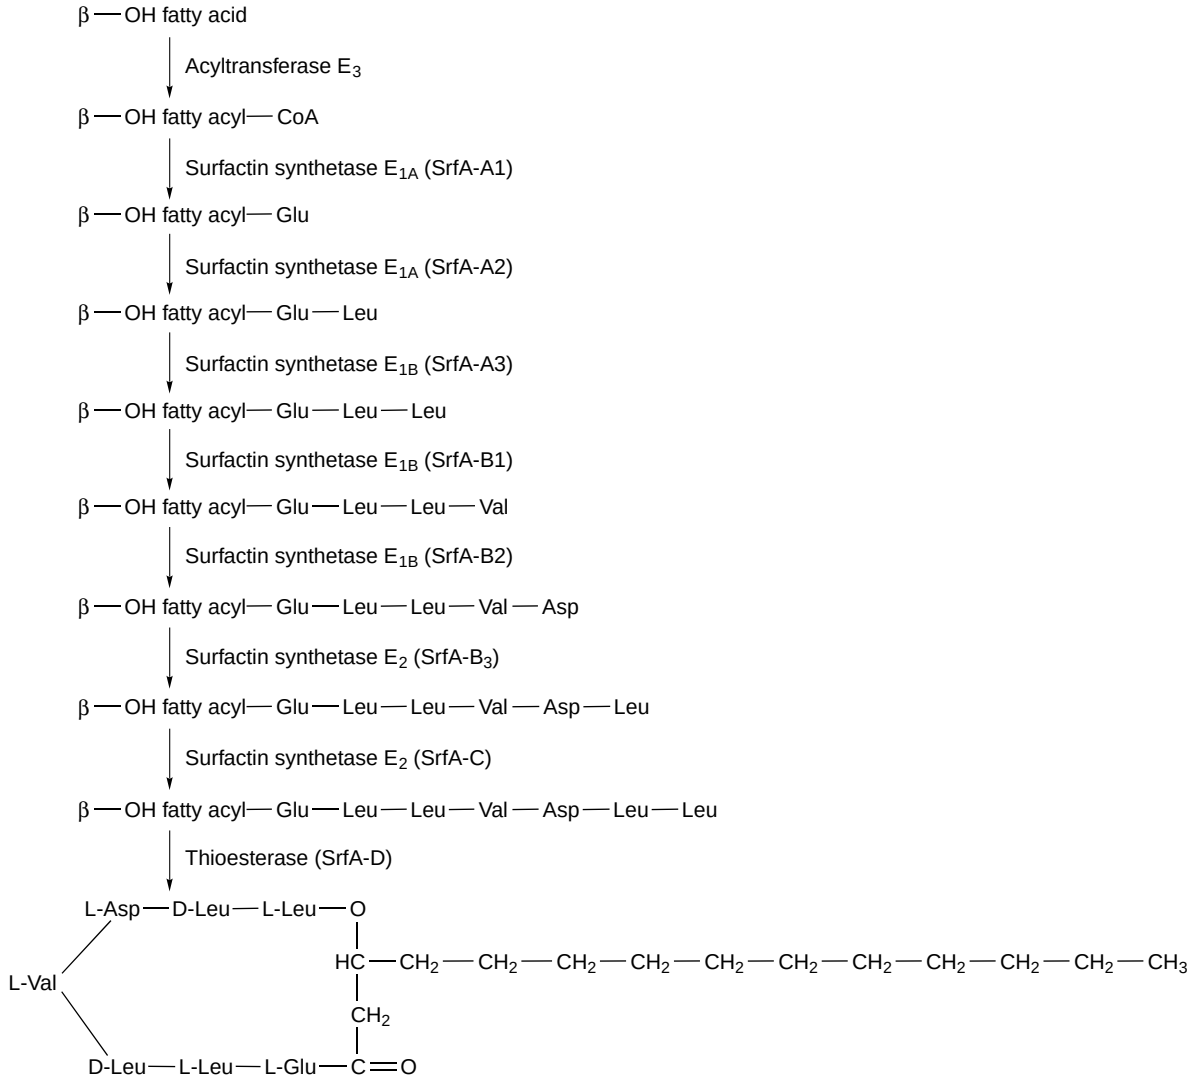

Figure 10. The surfactin biosynthetic pathway. An acyl transferase (E_3) activates and delivers β-hydroxy fatty acid to the surfactin synthetase complex. This complex is encoded for on the *srfA* operon, which contains four open reading frames (*srfA-A*, *srfA-B*, *srf A-C*, and *srfA-D*). SrfA-A is a multifunctional subunit of surfactin synthetase that adds the first three amino acid residues. SrfA-B is a multifunctional subunit that adds the next three amino acid residues, SrfA-C (E_2) adds the final amino acid and SrfA-D is a thioesterase involved in the lactonization of the molecule (131).

the peptide portion of the molecule is the *pps* or *fen* operon. There are five multifunctional peptide synthetases associated with fengycin (121). The *fen1, fen2*, and *fen3* genes encode three proteins of similar size (fengycin synthetase), which activate the first six amino acids of fengycin. The *fen4* gene encodes a multifunctional enzyme, which activates three additional amino acid residues. The *fen5* gene product activates the final amino acid, isoleucine, and is also involved with lactonization of the peptide.

Lichenysin. Lichenysin is a lipopeptide produced by *Bacillus licheniformis*, which is very similar in structure and properties to surfactin (Fig. 9). As described for surfactin, the peptide and the β-hydroxy fatty acid moieties are variable depending on growth conditions and the producing isolate (122,133–137). Lichenysin, depending on the isoform tested, can reduce surface tension to 27 mN/m and interfacial tension against hexadecane to 0.36 mN/m in a 4% salt solution (138). The reported CMC values are as low as 10 mg/L (138). Lichenysin is produced under both aerobic and anaerobic conditions during growth on a glucose medium containing 0.1% yeast extract and 0.1% sodium nitrate (139).

The biosynthesis of lichenysin is similar to that discussed earlier for surfactin and fengycin (137). The lichenysin operon is 26.6 kb and contains three open reading frames: *licA* and *licB* (both multifunctional subunits), and *licC*. All three open reading frames encode peptide synthetases. The *licTE* gene encodes a thioesterase that is homologous to the *srfA-D* gene.

Other Lipoproteins.. A surfactin-like lipoprotein with high hemolytic activity is produced by *Bacillus pumilus*,

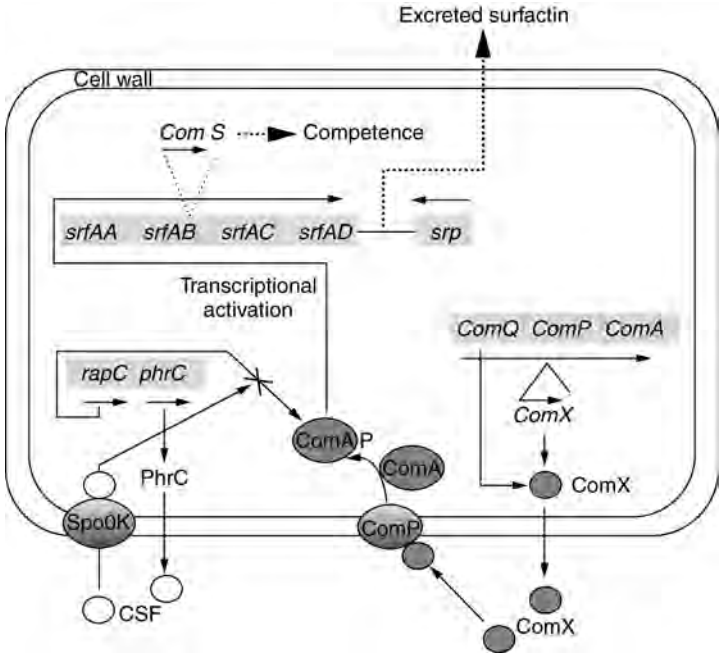

Figure 11. Regulation of surfactin synthesis is controlled by two quorum-sensing signal peptides, ComX and CSF (competence stimulating factor). ComX interacts with a membrane-bound protein, ComP, which phosphorylates ComA. ComA-P binds to the promotor of *srfA* and initiates transcription. CSF is the product of *phrC* and is activated as it is excreted through the cell wall. At low concentrations of CSF, expression of *srfA* is stimulated because the phosphatase RapC is prevented from interacting with ComA-P (ComA-P → ComA). This results in increased expression of *srfA* (132).

Table 1. Lipoproteins Produced by Genera Other Than *Bacillus*

Producing Organism	Lipoprotein	Remarks	Reference
Actinoplanes friuliensis sp.	Friulimicin β-Hydroxy-decenoyl-Asn-Dab[a]-Pip[b]-Me-Asp-Asp-Gly-Asp-Gly-Dab-Val-Pro-lactone	Antibiotic	141
Arthrobacter	Arthrofactin 3-Hydroxydecanoyl-D-Leu-D-Asp-D-Thr-D-Leu-D-Leu-D-Ser-L-Leu-D-Ser-L-Ile-L-Ile-L-Asp-lactone	S.T. = 24 mN/m	142
Pseudomonas fluorescens	Viscosinamide or viscosin β-Hydroxy-decanoyl-L-Leu-D-Gln-D-Allo-Thr-D-Val-L-Leu-D-Ser-L-Leu-D-Ser-L-Ile-lactone	Cell associated S.T. = 25 mN/m, CMC = 4 mg/L in phosphate buffer	143–145
Pseudomonas fluorescens	Tensin β-Hydroxy-decanoyl-D-Leu-D-Asp-D-Allo-Thr-D-Leu-D-Leu-D-Ser-L-Leu-D-Gln-L-Leu-L-Ile-L-Glu-lactone		146
Pseudomonas syringae	Syringomycin, nine amino acid residues	Phytotoxin	147
	Syringopeptin, 22 to 25 amino acid residues	Phytotoxin	147
Serratia marcescens	Serrawettin		148
Serratia rubidaea	Rubiwettin		148

[a] Diaminobutyric acid.
[b] Pipecolinic acid.

an organism associated with marine sponges (140). This lipoprotein is called bacircine. In addition, there are a number of lipoproteins similar to those shown in Figure 9 that are produced by genera other than *Bacillus*. These are summarized in Table 1.

Polymeric Biosurfactants

The polymeric biosurfactants are characterized by their high molecular weight, which ranges from 50,000 to greater than 1,000,000. These polymers can be carbohydrate- or protein-based, and in addition usually contain lipids. In some cases, the polymer may be a mixture of carbohydrate, protein, and lipid. These compounds, noted for their emulsification abilities, are produced by a number of bacteria, Archea, and yeast. Of great interest commercially is the fact that each polymeric biosurfactant has different hydrocarbon specificities with respect to degree of emulsification. In general, the polymeric biosurfactants do not lower surface or interfacial tension significantly (149). These polymers are quite heterogeneous and therefore have been difficult to categorize as precisely as the low molecular weight biosurfactants.

Emulsan. The best characterized of the polymeric biosurfactants is emulsan, produced by *Acinetobacter calcoaceticus* RAG1. The structure of emulsan is a heteropolysaccharide linked to fatty acids through *o*-ester and amide bonds. The fatty acid component comprises 15% (dry weight) of the polymer with average lipid molecular weight of 231. Three major sugars have been identified: *N*-acetyl-D-galactosamine (*20 to 30% dry weight of polymer), *N*-acetylgalactosamine uronic acid (*33% dry weight of polymer), and diamino deoxyhexosamine (*5% dry weight of polymer) (49,150). There is also a protein associated with this polymer, which is required for emulsification activity. A number of other *Acinetobacter* sp. produce polymers similar to emulsan, which also require a separate protein component for emulsification activity. These include *A. calcoaceticus* MM5 (151) and BD4 (152).

Emulsan is an effective emulsifier at concentrations of 0.001 to 0.01%. It initially accumulates on the cell surface as a capsule and is then released as the cells enter stationary phase. It emulsifies petroleum-like hydrocarbon mixtures best, showing little activity toward pure alkane, aromatic, or alicyclic compounds (3). All of these emulsifiers act to coat hydrocarbon droplets in solution, thereby stabilizing the oil-in-water emulsion. It is thought that the protein component associated with the polymer is required for mediating the initial association of the polymer with hydrocarbon droplets. Emulsan can reduce surface tension to 52 mN/m (153). Emulsan is commercially available from the Petroferm Company (154).

The biosynthesis and regulation of emulsan has been recently reviewed by Sullivan (49). Thus far two enzymes, an esterase and a lipase, have been identified as having a role in emulsan production. However, loss of their activity does not completely inhibit emulsan production. The esterase is an outer membrane-bound esterase encoded by the *est* gene, and is thought to have a role in releasing emulsan from the surface of the cell (155). The lipase is encoded by the *lip* operon and is involved in addition of fatty acids to emulsan. Specifically, a mutant in the lipase chaperone gene (*lipB*) was found to be defective in lipase activity. This mutant produces an emulsan that has a lower fatty acid content and reduced emulsification activity (155,156).

Other Polymeric Biosurfactants. There are quite a few other microorganisms that have been identified as polymeric biosurfactant producers (Table 2). These are of interest because they differ substantially from emulsan in their ability and specificity to emulsify hydrocarbons.

Table 2. Polymeric Biosurfactants from Representative Microorganisms

Producing Organism	Biosurfactant	Remarks	Reference
Acinetobacter radioresistens KA-53	Alasan	Anionic, MW = 9×10^5; complex polysaccharide covalently bound to alanine; emulsification ability is activated by heat treatment; emulsifies *n*-alkanes and aromatics separately	157,158
Acinetobacter calcoaceticus A2	Biodispersan	Anionic, MW = 51, 400; contains glucosamine, 6-methylaminohexose, galactosamine uronic acid, an amino sugar	159,160
Bacillus stearothermophilus VR-8		Contains protein (46%), carbohydrate (16%), and lipid (10%), emulsifies over wide pH, salt, and temperature range	161
Candida albicans		Contains 26% carbohydrate and 1% protein, minimum surface tension = 51 mN/m, increased yeast cell adherence to human intestinal epithelial cells and decreased adherence to buccal epithelial cells	162
Candida lipolytica ATCC 8662/IA 1055	Liposan	83% Sugar (glucose, galactose, galactosamine, galacturonic acid) and 17% protein, emulsifies between pH 2 and 5	163–165
Halomonas S-30	EPS	Salt tolerant, contains 41% carbohydrate, 5% protein, and 9% uronic acids	166
Methanobacterium thermoautotrophicum		Emulsifies over wide pH and temperature range	167
Phormidium J-1	Emulcyan	Cyanobacterium, MW greater than 1×10^5, polymer of sugar, protein, and lipid	168
Pseudomonas fluorescens 378	Protein/carbohydrate	MW = 1×10^6, CMC = 8 mg/L in 0.9% NaCl; minimum surface tension = 30 mN/m; interfacial tension against hexadecane = 0.7 mN/m	153
Pseudomonas maltophila CSV89	Biosur-Pm	Contains 45 to 50% protein and 12 to 15% carbohydrate; minimum surface tension −53 mN/m, CMC = 50 mg/L; demonstrates substrate specificity for 1-naphthaldehyde	169
Pseudomonas marginalis	PM factor	MW > 10^6, contains protein, LPS, and phospholipid (60 to 80% protein, 20 to 30% lipid, 3 to 7% polysaccharide)	170
Saccharomyces cerevisiae	Mannoprotein	44% Mannose and 17% protein, emulsifies over broad range of pH, produced in high yield (8% of wet weight)	171

Some of these microorganisms come from extreme environments, and their associated emulsifiers have activity under a broad range of pH, temperature, and salt conditions. Finally, some of these microorganisms, for example, *Saccharomyces cerevesiae*, are already used in the food industry and presumably emulsifiers from such organisms would have wide application in the food industry.

SCREENING FOR SURFACTANT AND EMULSIFICATION ACTIVITIES

Biosurfactants have a wide range of physical and chemical properties and there is little homology in the genes encoding various types of surfactants. Therefore, normal biochemical or molecular screening techniques are of little use. This has led to the development of several screening assays based upon either reduction of surface or interfacial tension or on emulsification ability.

Screening for Surface or Interfacial Tension Reduction

Drop-Collapse Test. A qualitative drop-collapse test was first developed by Jain and coworkers (172) and later modified by Bodour and Miller-Maier (173) so that it can be either qualitative or quantitative. In the test, a 5-μL droplet of culture is added to an oil-coated surface. If the droplet remains beaded, the sample contains no biosurfactant; if the drop collapses, the sample contains biosurfactant. The use of Pennzoil® as the coating oil allows this assay to be quantitative as long as a reference sample of the surfactant is available. A standard curve is constructed by measuring the diameter of a series of droplets containing known concentrations of the surfactant using 15x magnification. The advantages of this test are that it is rapid, requires very little sample, and uses no specialized equipment. Further, it can be used to give qualitative information.

Tilted Glass Slide. A qualitative tilted glass slide technique was used to screen *Pseudomonas* and *Vibrionaceae* sp. for surfactant production (174). In this test, the organism is first grown on agar plates. A colony is mixed with a droplet of 0.9% (w/v) NaCl on one end of a glass slide and the glass slide is tilted. If a biosurfactant is present, the droplet will travel down the slide when tilted. If the droplet remains motionless, the sample has no detectable biosurfactant. This test has the advantages that it is rapid, simple, and requires no specialized equipment. A potential disadvantage of this method is that in some cases an agar-grown colony can produce false negative results.

Hemolysis of Red Blood Cells. Some biosurfactants are known for their ability to lyse red blood cells (RBC), including the lipoproteins and some of the glycolipids (175). Singer (176) used this ability as the basis for a qualitative screening test for such biosurfactants. Commercial blood agar plates were used to screen a number of known biosurfactant producers as well as nonproducing isolates. Results were evaluated in terms of whether zones of hemolysis formed around colonies on the blood agar plates. In this study, zones of hemolysis were observed only with isolates that produced surfactants. Whereas this screening assay is simple to perform, the author notes that its use is limited to screening for microorganisms that produced water-soluble, diffusible, low molecular weight biosurfactants during growth on a complex medium (blood agar).

Axisymmetric Drop Shape Analysis by Profile. A modified axisymmetric drop shape analysis by profile (ADSA-P) technique was used by van der Vegt and coworkers (177) to assess cell-associated biosurfactant production by 11 *Streptococcus* strains. Of these 11 isolates, two were positive controls known to produce cell-associated surfactant, and two were negative controls that did not produce surfactant. Each isolate was grown overnight, harvested, and washed twice with potassium phosphate buffer. The cells were resuspended in buffer to a final concentration of 5×10^9 cells/mL. A 100-μL droplet of the resuspended cells was placed on a teflon surface, and the shape of the drop surface was digitized using ADSA-P for a 2-hour period. ADSA-P is a program that was developed to determine interfacial tension and contact angles from droplet profiles (178). Noordmans and Busscher (179) modified input and output terms of ADSA-P to incorporate parameters such as density, gravity, and magnification factors (input terms) and surface tension, contact angle, and droplet volume (output terms).

The results showed that the ADSA-P analysis predicted that the two positive controls were surfactant producers and the two negative controls were not. Of the remaining seven isolates, three were positive for cell-associated surfactant production according to the ADSA-P analysis. This technique can accurately predict surfactant production and most likely could be used to evaluate extracellular biosurfactant production as well. The disadvantage of this technique is that it requires video monitoring equipment that is interfaced with the ADSA-P program, which is not routinely available in most labs.

Colorimetric Assay. A colorimetric plate assay has been developed that is specific for anionic biosurfactants (180). This technique was originally developed to screen for rhamnolipids, but can be used to screen for any low molecular weight anionic biosurfactant. Mineral salts agar plates containing a carbon source (2%) and cetyltrimethylammonium bromide (CTAB)-methylene blue are prepared. Carbon sources that have been tested include glucose, mannitol, glycerol, peptone, succinate, and citrate. As the biosurfactant is produced it forms complexes with the CTAB-methylene blue. As a result, any colony that produces biosurfactant develops a dark blue halo.

Screening for Emulsification Activity

Emulsion Index. Cooper and Goldenberg (125) developed a simple technique to screen for emulsification activity based on the emulsion index (E_{24}). This index is obtained by adding a culture to kerosene in a 1 : 2/3 (vol/vol) ratio. The solution is vortexed for two minutes and allowed to stand. After 24 hours, the height of the emulsion (the layer between the aqueous and kerosene layers) is measured and used to calculate the emulsion index (E_{24}) using the following equation:

Emulsification ability can be expressed as an emulsion index but is also often expressed as activity units. For example, Trebbau de Acevedo and McInerney (167) expressed emulsifying activity as units per milligram where one unit of emulsifying activity was defined as the amount of emulsifier that gave an emulsification index of 20.

Turbidity Assay. An emulsification assay based on turbidity measurement was reported by Rosenberg and coworkers (149) and modified by Neu and Poralla (181). A 10-mL sample of the culture is filtered and the filtrate dried. The dry filtrate is added to 1.5 mL Tris-Mg buffer and the optical density (OD) measured at 446 nm. Hydrocarbon (0.2 ml) is added, the sample is vortexed for two minutes, allowed to stand for 10 minutes, and the OD is measured again. The emulsification activity is the difference between the initial and final OD reading. It is difficult to compare emulsification activities reported in the literature since emulsifiers show selectivity and a standard hydrocarbon is not always used. Therefore, it is important that both negative and positive controls be performed with this assay. As an example, the reported emulsification value for emulsan is 1.58 for corn oil (154). In this study, negative controls had values of approximately 0.1.

INDUSTRIAL AND BIOTECHNOLOGY APPLICATIONS

Some biosurfactants, for example, rhamnolipid, sophorolipid, and spiculosporic acid, can be commercially produced at levels exceeding 100 g/L (29,109,182). At this level, the cost of producing biosurfactants becomes competitive with the cost of producing synthetic surfactants. As the production cost becomes competitive and as the commercial availability of biosurfactants increases, one can expect the commercial use of biosurfactants to grow. It is important to note that only two biosurfactants have been studied extensively. However, the analytical and molecular tools now available make the tasks of identifying new biosurfactants, and understanding how and why biosurfactants are produced, more feasible and rapid. The following sections explore various uses of biosurfactants that have been proposed in the scientific literature.

Bioremediation

Bioremediation is the use of microorganisms and/or plants to aid in the cleanup of sites contaminated with organics, metals, or in some cases with a mixture of these two types of contaminants. According to a recent National Research Council report (183), the estimated cleanup cost for the United States alone exceeds $1 trillion. As a result, interest in cleanup alternatives, such as bioremediation, is increasing. Surfactants, both synthetic and biological, have been explored for their bioremediation potential, and show promise for application to sites impacted by both organic and metal contaminants. Biosurfactants have several potential advantages over synthetic surfactants for bioremediation applications. These advantages include low toxicity, better specificity for some applications, and the potential for in situ production of biosurfactants.

Biodegradation of Organics. There is an extensive body of literature documenting the effects of biosurfactants on biodegradation of hydrocarbons, both aliphatic and aromatic. The majority of research has involved glycolipids. Glycolipids can enhance solubility and biodegradation of a variety of alkanes, including hexadecane, octadecane, lubricating oil waste, and *n*-paraffins, as well as phenanthrene in solution or pure culture (25,31,40,42,66,80,184–190). Further, glycolipids have been shown to enhance degradation in soil systems containing hexadecane (191–193), tetradecane (191), pristane (191), creosote (194), a hydrocarbon mixture (195), crude oil (196), chlorinated phenols (65), and polychlorinated biphenyls (13,14). Polymeric biosurfactants have also been tested. Alasan (197) and the emulsifier produced by *A. calcoaceticus* MM5 (198), have been shown to enhance solubilization and biodegradation of polyaromatic hydrocarbons. Heptadecane uptake rate was increased by an unidentified emulsifier produced by *Pseudomonas nautica* (199).

While the success of biosurfactants is clearly documented, there are also reports involving both pure culture and soil systems, which suggest that the addition of biosurfactant can inhibit biodegradation. Whether biodegradation is enhanced or inhibited in pure culture seems to be dependent on the degrading genus, wherein the biosurfactant-producing genus is more likely to be stimulated than other genera (40). However, even biosurfactant-producing strains vary in their response to biosurfactant addition (185,193). For soils, it is unclear why biosurfactants cause inhibition, although recent findings suggest that biosurfactants can serve as a preferred carbon source (200–202).

Both low and high molecular weight biosurfactants enhance biodegradation. The mechanism of enhancement depends on the surfactant concentration. At high concentration (>CMC) low molecular weight biosurfactants increase the aqueous solubility of a contaminant by either incorporating the contaminant into a micelle (Fig. 1) and increasing the apparent solubility of the contaminant, or by increasing the rate of desorption of the contaminant from soil surfaces (42,203). High molecular weight biosurfactants similarly increase contaminant availability but they do so by increasing the available surface area through emulsification. At low concentrations (<CMC) low molecular weight biosurfactants induce alterations in cell surface properties to allow better contact between the cell and the contaminant (31,193,204). A recent study examined the interaction of the low molecular weight biosurfactant, rhamnolipid, with degrading cells. Results showed that rhamnolipid caused a loss of LPS, an important hydrophilic component of the gram-negative cell surface (204). Loss of LPS resulted in an increase in cell hydrophobicity, which in turn increased the interaction of the cell with the hydrocarbon, and ultimately increased the biodegradation rate. As cell surface changes occur at very low surfactant concentrations, there are several reasons for taking advantage of this phenomenon

for hydrocarbon bioremediation. First, because rhamnolipids are biodegradable, they can serve as a preferred carbon source in a mixed population. In this case, addition of high amounts of rhamnolipid will suppress degradation of hydrocarbons until a substantial portion of the rhamnolipid is degraded. Second, sub-CMC levels of rhamnolipid will not cause mobilization of hydrocarbons, which can result in undesirable spreading of a contaminant plume (192). Third, in situ production of sub-CMC levels of biosurfactant may be achievable (whereas it is unlikely that super-CMC levels can be produced in situ). Finally, if the biosurfactant is exogenously added to a contaminated site, it will be more economical to add sub-CMC levels.

Biodegradation of Organics in Metal-Organic Cocontaminated Systems. It is estimated that 40% of sites contaminated with organics are also contaminated with metals (205). The presence of toxic metals, such as lead, cadmium, or arsenic, can cause inhibition of biodegradation of organic compounds (206–208). Rhamnolipids have been demonstrated to enhance hydrocarbon degradation in systems cocontaminated-contaminated with organics and toxic metals. This has been shown both in pure culture with cadmium and naphthalene (205) and in two soils amended with cadmium and phenanthrene (201). In the soil tests, it was found that rhamnolipid biodegradation occurred over 8 to 12 days. Therefore, rhamnolipid was added in several pulses to each soil such that phenanthrene biodegradation in the cadmium-containing microcosms reached levels similar to the microcosms that contained no cadmium.

Biosurfactants as a Flushing Agent — Organics. Biosurfactants have been studied for their potential as soil washing or flushing additives for organics. In some instances, where biodegradation processes are too slow or infeasible, it may be necessary to remove organics from soil using ex situ soil washing or in situ soil flushing, also known as pump and treat. This pertains to two types of organic compounds: nonaqueous phase liquids (NAPL) (e.g., petroleum or chlorinated solvents), and solid phase organics (e.g., polyaromatic hydrocarbons [PAH]). In both cases the low aqueous solubility of the organic constrains removal by water alone. Additives that can enhance organic solubility have been researched including the use of surfactants.

For NAPL, addition of a surfactant to a flushing solution can enhance flushing efficiency by either mobilization of NAPL, which results from a decrease in interfacial tension between the NAPL and the surfactant solution, or by an increase in solubilization of the NAPL. Thus, to be effective, a surfactant must have a good solubilization capacity and/or be able to reduce interfacial tension. Rhamnolipid has been shown to have a solubilization capacity (expressed as a molar solubilization ratio [MSR]) for the model NAPL hexadecane, which is 20 times greater than the MSR for hexadecane-alkyl benzyl sulfonate (209). In studies examining the use of rhamnolipid for removal of residual hexadecane from soil, it was shown that rhamnolipid (20% removal) was more effective than either sodium dodecyl sulfate (SDS) (negligible removal) or Tween 80 (6% removal) (210). This experiment compared the surfactants on an equal mass basis (500 mg/L) and for an equal number of flushings (100 pore volumes). It was further shown that NAPL removal could be optimized by altering pH and ionic strength to achieve a maximum reduction in interfacial tension. Thus, in the same system, under conditions of pH 6 and 320 mM sodium, rhamnolipid removed 60% of residual hexadecane in only two pore volumes (211). A *Rhodococcus* biosurfactant has also been examined for its efficacy in removal of oil from sand (196). Crude biosurfactant extracts from 10 different *Rhodococcus* strains were tested with four different oils. Each strain performed slightly differently in terms of oil removal, with overall removal ranging between 9.8 and 98.0% (in comparison to the removal by water alone which ranged between 1.9 and 31.3%).

Similar promising results are reported for rhamnolipid solubilization of solid phase materials. Specifically, the rhamnolipid-octadecane MSR (203) was 10-fold higher than the MSR for Triton X-114-octadecane and fivefold higher than the MSR for Corexit 0600-octadecane (212). The MSR for rhamnolipid-phenanthrene ranged from 1.7 times higher to 2.8 times lower than that for 13 different synthetic surfactants that have been tested with phenanthrene (188,213,214). In a comparison of removal of a hydrocarbon mixture from soil, it was found that rhamnolipid performed more effectively than either Triton X-100 or Tween 60 for all hydrocarbon components. The hydrocarbon mixture contained undecane, pentadecane, hexadecane, octadecane, pristane, naphthalene, phenanthrene, and pyrene (215). Rhamnolipid-enhanced removal of phenanthrene (216,217), pyrene (218), polychlorinated biphenyls, and a variety of PAH (216) from soil have also been demonstrated.

Rhamnolipid as a Flushing Agent — Metals. Sites may be contaminated with metals alone or may be cocontaminated with metals and organics. In either case, in some instances it may be necessary to remove the toxic metals from the site. There are a variety of agents that have been shown to form complexes with metals. While the strength of the metal complexation is important, it is also requisite that these materials are environmentally compatible. The strength of the complexation is quantified by determining stability constants for the metal-organic ligand in question. Table 3 compares the stability constants for several different organic ligands that have been proposed for metal remediation. Whereas synthetic materials such as NTA, ethylenediamine tetraacetic acid (EDTA), and DTPA are extremely effective at metal complexation, as indicated by their high stability constants, their use in the field is questionable because of potential toxicity effects. NTA is a Class-II carcinogen (219) and DTPA is a potential carcinogen (Sigma Chemical Co., St. Louis, Missouri). Both EDTA and DTPA are toxic, as measured by invertebrate toxicity tests (220,221). These effects are suggested to be caused by formation of chelates with biologically important trace metals such as manganese, iron and zinc. Thus, these materials are such effective metal chelates that they remove required as well as toxic metals from the soil. A further concern is biodegradability.

Table 3. Stability Constants for Various Organic Ligands with Cadmium (Cd) and Lead (Pb)[a]

Organic Ligand	Naturally Occurring or Synthetic	Stability Constants[b]	
		Cadmium	Lead
DTPA	Synthetic	19.00	18.66
EDTA	Synthetic	16.36	17.88
NTA	Synthetic	9.78	11.34
Rhamnolipid	Naturally occurring	6.89	8.58
Oxalic acid	Naturally occurring	2.75	4.00
Citric acid	Naturally occurring	2.73	4.08
SDS	Synthetic	1.95	N.D.[c]
Acetic acid	Naturally occurring	1.56	2.15

[a]From Maier and Soberón-Chávez (50).
[b]Stability constants are expressed in log values. All stability constants are from Martell and Smith (223), except for those of rhamnolipid (224) and SDS (D. Gage and R. M. Maier, unpublished data).
[c]N.D. = not determined.

EDTA is a decontamination agent that was used in nuclear facilities and routinely buried with radioactive wastes. EDTA's limited biodegradability in the environment is demonstrated by its presence in groundwater near these nuclear facilities (222). These examples illustrate the importance of choosing environmentally compatible alternatives.

Sophorolipid is one such alternative. A 4% sophorolipid solution in 0.7% HCl has been used to remove copper (50%) and zinc (100%) from soil. This level of removal was achieved after several washings (225). Rhamnolipids have also been tested and show selectivity for metals of concern, including cadmium, copper, lanthanum, lead, and zinc (224,226,227). Rhamnolipid-facilitated metal removal was demonstrated in bench-scale column experiments for both cadmium (228) and lanthanum (D. Gage and R. M. Maier, unpublished data). Rhamnolipids were also used to demonstrate removal of zinc and copper from a contaminated soil with a 12.6% oil and grease content (229). Polymeric biosurfactants are also effective at metal complexation. Emulsan was found to bind up to 240 μg uranium (UO_2^+)/mg emulsan (230). Fatty acids have also been investigated for removal of metals from water. Tannic acid was able to remove both cadmium (99%) and lead (96%) from water samples (231).

Industrial Processes

A number of industrial applications have been investigated for biosurfactants. Helle and coworkers (232) report the use of sophorolipid and rhamnolipid to enhance the heterogeneous enzymatic hydrolysis of cellulose and steam-exploded wood. In this study, sophorolipid was capable of increasing the hydrolysis of steam-exploded wood by 67% and also decreased the amount of cellulase adsorbed onto the cellulose.

Another application proposed for biosurfactants is as an additive for microbially enhanced oil recovery (MEOR) and cleaning oily sludges from storage tanks. In a thorough review of this topic, Banat (233) describes several MEOR field trials that have been performed. In general, the results of these field trials are positive, with increases in oil production ranging from 11 to 250% following injection of microorganisms and nutrients. Similarly, injection of a combination of kerosene and biosurfactant resulted in a 500% increase in oil production. However, as Banat points out, it is difficult to provide controls for field studies that isolate each parameter tested. Therefore, it is difficult to conclusively say that addition of biosurfactants or biosurfactant-producing microbes were the cause of the increased oil recoveries observed. More recently, several groups have noted that isolates with emulsifying abilities can be isolated from environments that are extreme with respect to temperature, salinity, or pH (161,167). Such isolates may be applicable to MEOR as well as well bore and oil tank cleanups. As the price of petroleum continues to increase and petroleum reserves shrink, enhanced oil recovery will receive more attention. Clearly, the use of MEOR is an attraction option that will be worth pursuing in the future.

Fouling of heat exchanger plates in the dairy industry is a problem that can result in contamination of pasteurized milk. Busscher and coworkers (234) have studied the thermophilic dairy organism, *Streptococcus thermophilus*. This organism produces a mix of biosurfactants during growth, which seem to have a role in detachment of the organism from surfaces. Following detachment, a surface coating is left behind, which seems to prevent attachment of closely related isolates to the surface. The authors suggest that this ability could be used to retard colonization of heat exchanger plates in pasteurizers.

Medicine

Biosurfactants, in particular the lipoproteins, are known to have antibiotic properties. In some cases, this property has potential for medical research. For example, Vollenbroich and coworkers (235) showed that surfactin has antimycoplasma properties useful for protecting cell cultures from mycoplasma infection. Others have reported the antiviral activity of surfactin (236,237). In this case, surfactin effectiveness was dependent on its structure. Surfactin with fatty acid chains of 14 or 15 carbons inactivated an enveloped virus, whereas surfactin with a fatty acid chain of 13 showed little antiviral activity. Kim and coworkers (238) describe an anti-inflammatory effect of surfactin. This effect occurs through the selective inhibition of cytosolic phospholipase A_2 (PLA_2). The PLA_2s are a family of enzymes that catalyze the hydrolysis of the fatty acid ester bonds of membrane phospholipids. The result of the hydrolysis is the formation of inflammatory mediators such as prostaglandins and leukotrienes.

Busscher and coworkers (239) report that biosurfactants produced by *S. thermophilus* can be used to coat silicone rubber of voice prostheses and prevent adhesion of *Candida albicans*. Under normal conditions, colonization by *C. albicans* limits the life of the prostheses to 3 to 4 months. In this study, a single exposure to *S. thermophilus* prevented colonization by *C. albicans* for 4 hours. The authors suggest that regular consumption of this probiotic in yogurt could significantly extend the lifetime of the prosthesis.

The activity of seven different biosurfactants, including MEL-A and MEL-B, polyol lipid, rhamnolipid,

sophorolipid, succinoyl trehalose lipids 1 and 3, against human promyelocytic leukemia cell line (HL60) was investigated (240). Results showed that each of these biosurfactants, except rhamnolipid, inhibited the proliferation of HL60 cells.

Production of Fine Chemicals

Biosurfactants and chemically modified biosurfactants are being investigated as alternatives to high-value synthetic chemicals whose use may have toxic environmental impacts. For example, Ishigami and Suzuki (241) report the synthesis of a pyrenacylester of rhamnolipid (R-PE) for use in monitoring the polarity and fluidity of solid surfaces and the attendant impact of coatings on these surface properties. The R-PE was synthesized to facilitate the use of pyrene, which is one of the most effective fluorescent probes in monitoring the micropolarity and microfluidity of surfaces. However, pyrene alone is difficult to use in aqueous systems because of its extremely low aqueous solubility and its propensity to bind to hydrophobic surfaces.

Rhamnolipids are also a source of stereospecific L-rhamnose, a compound used commercially in the production of high-quality flavor compounds and as a starting material for synthesis of some organic compounds (242). Rhamnose can be obtained from a variety of sources, including quercitrin from oak bark, naringin from citrus peels, or rutin which is found in a variety of plants. Rhamnose can also be obtained from rhamnose-containing polysaccharides produced by either plants or microorganisms. However, processing rhamnose from these materials is difficult. Plant sources of rhamnose are bulky and generate unwanted waste products. Rhamnose in polysaccharides must be separated from other sugar components. An alternative to these rhamnose sources is the use of rhamnolipid produced by *P. aeruginosa*. Rhamnolipids are excreted by *Pseudomonas* in the late log and stationary phase allowing easy separation from cells. Once isolated, rhamnolipid can be hydrolyzed to produce a mixture of L-rhamnose and the fatty acid 3-hydroxydecanoic acid (242).

The cosmetic and health care industries use large amounts of surfactants for a wide variety of products, including: insect repellents, antacids, acne pads, antidandruff products, contact lens solutions, hair color and care products, deodorants, nail care products, lipstick, eyeshadow, mascara, toothpaste, denture cleaners, antiperspirants, lubricated condoms, baby products, foot care products, antiseptics, shaving and depilatory products, and moisturizers (243). Biosurfactants in general are considered to have some advantages over synthetic surfactants, the predominant type of surfactant used in this industry. These advantages are low irritancy or anti-irritating effects and compatibility with skin (243). Sophorolipids and rhamnolipids in particular are being used as cosmetic additives (1,244, Iwata Chemical Co., personal communication). There are currently patents for use of rhamnolipids to make liposomes (245) and emulsions (246), both of which are important in the cosmetic industry. Similarly, there are patents for the use of sophorolipid as a humectant in cosmetics (247,248).

Surfactants and emulsifiers are routinely used in the food industry. Torabizadeh and coworkers (249) found the mannoprotein emulsifier produced by *Saccharomyces cerevisiae* could be used as a mayonnaise additive. This emulsifier is found in the cell wall and can be obtained cheaply and in high yield (80 to 100 g/kg (g/g) wet cells). In addition, it is stable from pH 3 to 11, and the by-products can be used as animal feed supplements.

Biological Control

There are several reports on the efficacy of biosurfactants in biological control. Rhamnolipids have been shown to have activity against zoosporic plant pathogens, specifically *Pythium aphanidermatum*, *Phytophthora capsici*, and *Plasmopara lactucae-radicis*. In a study reported by Stanghellini and Miller (53), mono- and dirhamnolipid were found to cause loss of motility and lysis of zoospores in less than one minute. Effective concentrations ranged between 5 and 30 mg/L, depending on the rhamnolipid tested. The same group also demonstrated the efficacy of rhamnolipid in a near-commercial hydroponic recirculating cultural system. In this system, the recirculating tubs were inoculated with a *Pseudomonas* strain isolated from the greenhouse system and received inputs of olive oil as a substrate for growth. Therefore, rhamnolipids were produced in the system. Though positive results were observed, it was noted that results were not consistent in performance and/or sustained control.

Research indicates that surfactin and a similar lipopeptide, iturin A produced by *B. subtilis* RB14, play a role in the suppression of damping-off disease of tomato seedlings caused by *Rhizoctonia solani* (250). This group compared the effect of RB14 with a RB14 mutant, R*1, deficient in production of surfactin and iturin A, on prevention of damping off. Results showed that the wild type suppressed *R. solani* and prevented damping-off, whereas the mutant did not. This result was further confirmed using a transformant of R*1 in which the production of iturin A was restored and the production of surfactin was partially restored. This isolate was able to prevent damping off. Further, this group provides evidence that iturin A is stable in soil for one to two weeks and surfactin is stable for even longer periods of time.

CONCLUSION

Demand for new specialty chemicals in the agriculture, cosmetic, food, pharmaceutical, and environmental industries is steadily increasing. As these chemicals must be both effective and environmentally compatible, it is natural to turn to the microbial world to try to meet this demand. Microbes offer a largely unexplored variety of chemicals, such as biosurfactants, which have exciting potential for industrial application. However, to realize the application of any new chemical product is difficult. First and foremost, demonstrations of product efficacy have to be obtained. Then the new microbial product must be produced at an economical scale and yield, as well as regulatory testing requirements need to be met.

This article documents the types of biosurfactants that have been identified thus far, methods for screening for surfactant and emulsifying activities, and potential industrial and biotechnology applications for biosurfactants. Biosurfactants, including rhamnolipid, sophorolipid, and spiculisporic acid, can now be produced at high yield in large-scale fermenters and are becoming economically competitive with synthetic surfactant alternatives. Therefore, it seems likely that in the future, biosurfactants will be competitive for certain industrial and medical applications currently employing synthetic surfactants.

BIOTERRORISM

TIMOTHY J. SHEERAN
Department of Defense
Washington, D.C.

The views expressed in this article are those of the author and do not reflect the official policy or position of the Department of Defense or the U. S. Government.

History has illustrated the utility of biological agents as weapons of war. Although at least ten countries are suspected to have offensive biological warfare programs at the national level, the threat of biological attack from state and non-state-sponsored terrorists is a growing concern. Biological warfare may be defined simply as the use of a biological organism or biologically derived toxin or other substance to cause lethal or incapacitating effects. Agents may be used to target humans, crops or livestock, or nonliving but economically vital material such as an oil supply. An act of biological terrorism may be employed in a multitude of scenarios ranging from a small-scale attack on a restaurant salad bar incapacitating tens to hundreds, to the covert aerosolization of smallpox virus in a crowded auditorium that would kill an estimated 15,000 people causing confusion, hysteria, and civil unrest (1). Understanding the threat of bioterrorism is crucial in developing proper procedures and countermeasures to provide an effective response to an attack.

This article focuses mainly on the technical aspects of biological warfare as they apply to a terrorist attack. A history of biological warfare, employment scenarios, agent characteristics, aspects of dispersion, and countermeasures are covered in this review. Because of the sensitivity of this topic, some areas are covered more generally than others, so as not to provide helpful information to a would-be terrorist.

HISTORY OF BIOLOGICAL WARFARE

Early Development

Humans have known of the utility of biological organisms and toxins as weapons of war well before the germ theory of disease was understood. One of the first recorded events in which a biological agent was used in war was the siege of Kaffa, which occurred in the fourteenth century in what is now Feodosia, Ukraine. The attacking Tartar force took advantage of a plague outbreak among their ranks by catapulting bodies of their deceased into the city to create a plague epidemic. The ensuing spread of plague led to the fall of Kaffa to the Tartar force (2,3). For centuries to follow, diseased animals and humans were used to contaminate the water supplies of would-be aggressors in the hope of creating an epidemic that would affect the outcome of the battle. During the French and Indian war in 1763, the British successfully used smallpox-infected blankets to create epidemics among the native American tribes opposing the British (3).

World War I

Advances in microbiology through the nineteenth century allowed the isolation and identification of disease-causing microorganisms, which could be used to attack with some degree of specificity. World War I saw the use of biological agents to attack livestock. Strong evidence exists indicating that Germany used *Bacillus anthracis* and *Burkholderia mallei*, the causative agents of anthrax and glanders, to infect livestock during transshipment. Anthrax and glanders agents were reportedly used by Germany to infect Romanian sheep being transported to Russia. Additionally, German covert operators also may have used glanders to infect 4,500 mules in Mesopotamia and horses in France. They were also used in operations in the United States targeting horses bound for allied forces in Europe (2).

Extensive use of chemical weapons during World War I prompted the creation of the Geneva protocol of 1925, which called for the prohibition of the use in war of asphyxiating, poisonous or other gases, and of bacteriological methods of warfare. Although the Geneva Protocol prohibited the use of biological weapons, it did not prohibit research and development, production or storage of biological weapons. Many countries, while signing the protocol, maintained the right and capability to respond in kind to a biological attack. These countries included Belgium, Canada, France, Great Britain, Italy, the Netherlands, Poland, and the Soviet Union (2).

World War II

During World War II, Japan conducted extensive biological weapons (BW) research from 1932 to 1945 (2). The focal point of the Japanese BW program, called Unit 731, was located near the town of Pingfan and had a staff of over 3,000 scientists working in over 150 buildings and five satellite camps. Unit 731 conducted at least 12 biological weapons field trials and utilized prisoners of war as their test subjects (2). Agents tested include *B. anthracis, Neisseria meningitidis, Shigella species, Vibrio cholerae*, and *Yersinia pestis*. Japan used biological weapons on at least 11 Chinese cities during World War II. The tactics used in these attacks included contamination of food and water supplies as well as tossing cultures directly into homes and spraying agents from aircraft. The Japanese allegedly

used fleas fed on plague-infected rats to drop from aircraft over Chinese cities. As many as 15 million fleas were used per attack to infect the population with plague (2).

The use of biological weapons by the Japanese during World War II also made clear the dangers to the attacking force if they employed biological weapons. A biological attack on Changteh in 1941 led to a reported 10,000 Chinese casualties and 1,700 deaths among Japanese soldiers. Japan stopped field trials in 1942, but basic research in biological warfare continued until the end of the war (2).

The U.S. Program

The United States Biological Warfare Program began in 1942, and included a research and development facility at Camp Detrick (now Fort Detrick), Maryland, test sites in Mississippi and Utah, and a production plant in Terra Haute, Indiana. Experiments were performed on potential biological agents such as *B. anthracis* and*Brucella suis*. Experiments were also performed using nonpathogenic simulants such as *Serratia marcescens* and *Bacillus globigii* to test production, storage, and aerosolization methods for biological warfare agents (2). The United States also collaborated with its allies, including Canada and Great Britain, on biological warfare applications. Live fire tests by the allies in 1943 were conducted using anthrax bombs at Gruinard Island off the coast of Scotland. These experiments led to long-term contamination of the island due to the persistence of the anthrax spores tested. In 1986 and 1987 the island was successfully decontaminated using formaldehyde and was handed over to its original owners in May 1990 (2,4).

Expansion of the U.S. program during the Korean War included construction of a new production facility in Pine Bluff, Arkansas, and a countermeasures program for biological defense, which began in 1953. Animal studies using live agents were also carried out at Camp Detrick, remote desert sites, and on barges in the Pacific Ocean. Human tests were begun in 1955 using military and civilian volunteers to evaluate the effects of aerosol exposure to *Francisella tularensis* and *Coxiella burnetti* (2). By the late 1960s the United States had developed a substantial biological arsenal that comprises bacterial and toxin agents for antipersonnel use. This arsenal included both lethal and incapacitating agents such as *B. anthracis*, *F. tularensis*, *Brucella suis*, *C. burnetti*, botulinum toxin, and Staphylococcal enterotoxin B. The United States also developed plant pathogens as biological weapons, which would be used to target an enemy's food supply. These agents included rice blast, rye stem rust, and wheat stem rust (2).

In 1969 President Richard M. Nixon terminated the U.S. biological weapons program. Because of the already robust stockpiles of conventional, chemical, and nuclear weapons, it was believed that a biological weapons arsenal was not needed as a strategic deterrent. Furthermore, because of ethical and public health reasons, the true potential of biological weapons could not be tested. For this reason, BW was considered unproven as well as unpredictable and uncontrollable thus making them potentially hazardous to the attacking party (2,3). All stockpiles of biological weapons were destroyed by 1973, but research related to defense against biological warfare agents continues.

Former Soviet Union

The Soviet biological warfare program, which reportedly began during the early 1900s, was the largest of all national programs. After the signing of the Biological Weapons Convention in 1972, the Soviet biological weapons program continued under a clandestine organization called Biopreparat. Biopreparat operated over 40 research and production facilities scattered across the Soviet Union, employing up to 55,000 scientists. Many government agencies were involved in the BW program, including the Ministries of Defense, Agriculture, and Health, the Soviet Academy of Sciences, the Central Committee to the Communist Party, and the KGB (5).

The Soviet BW program considered scores of lethal bacteria, toxins, and viruses for use in its biological program, including anthrax, plague, ricin, ebola, marburg, and smallpox. Hundreds of tons of anthrax and dozens of tons of plague and smallpox were stockpiled for use against the United States and its allies (5). The Soviet Union also reportedly used biological agents as assassination weapons. For example, ricin toxin weaponized into a small pellet in an umbrella gun was reportedly used by the secret service of the Soviet Union to assassinate Georgi Markov, a Bulgarian defector living in London (2,5).

In April 1979, an outbreak of inhalational anthrax occurred in the city of Sverdlosk in Russia, which caused at least 77 clinical cases and 66 deaths. Persons working and living within 4 km from the suspected source were affected, whereas livestock were affected up to a distance of 50 km from the facility. Although an initial cover-up by the Soviet government claimed that the epidemic was caused by infected meat, suspicions that an accident occurred at a secret Soviet anthrax facility in Sverdlosk were prevalent (2,6). In 1992, Russian President Boris Yeltsin admitted that the outbreak at Sverdlosk was caused by the accidental release of anthrax spores from an offensive biological warfare production facility, specifically from the inadvertent removal of air filters on the exhaust stacks at the portion of the plant were the anthrax agent was dried (1,5). Since the fall of the Soviet Union, Russia claims that it has shut down all remaining remnants of its offensive biological warfare program.

Iraq

Before the Persian Gulf War, intelligence reports indicated that Iraq was engaged in an extensive offensive biological warfare program. When the Gulf war ended, the United Nations Special Commission on Iraq (UNSCOM) obtained information that confirmed these reports. Iraqi officials admitted to having an offensive biological warfare program, which included basic research on anthrax, rotavirus, camelpox, aflatoxin, and botulinum toxins, as well as T-2 mycotoxin, and the anticrop agent wheat cover rust (2). Some of these agents were reportedly weaponized in missile warheads and bombs. The Iraqi government claims to have destroyed its

biological arsenal after the war, and some research and production facilities were destroyed under the supervision of UNSCOM in the mid-1990s (2). The United Nations Monitoring and Verification Commission (UNMOVIC) is positioned to reenter Iraq and resume the monitoring and verification of the destruction of Iraq's weapons of mass destruction programs. UNMOVIC will replace the UNSCOM inspection regime, which was ousted by Iraq in late 1998. Iraq has not yet given permission to allow UNMOVIC to re-enter the country, and thus the status of the Iraqi biological warfare program remains unknown.

Aum Shinrikyo

Although the Aum Shinrikyo cult is most famous for its March 20, 1995 Sarin attack on the Tokyo subway system, subsequent investigations indicate that the cult was also involved in biological terrorism as well. In addition to producing chemical agents, Aum Shinrikyo reportedly performed research on botulinum toxin, anthrax, cholera, and Q fever. In 1992, a team of Aum cult members was detected in Zaire on an alleged medical mission; whereas the actual purpose of the trip was to obtain samples of the Ebola virus. Cult members also reportedly launched three biological attacks in Japan using botulinum toxin and anthrax, which were unsuccessful. Although many of the cults leaders are either in jail or still on trial, the Aum may still be capable of carrying out future attacks using biological agents (7).

BIOLOGICAL AGENT CHARACTERISTICS

Biological Versus Chemical Weapons

Although the terms "biological" and "chemical" weapons are used synonymously, there are profound differences between these two types of weapons of mass destruction. The most obvious difference is that chemical agents are nonliving poisons made by humans, whereas biological agents are infectious living entities that reproduce inside the host to cause incapacitating or fatal disease. Biologically derived toxins such as botulinum toxin or ricin share characteristics of both chemical and biological agents (8).

With regard to biological agent use, the phrase, "a little goes a long way" has direct meaning. Pathogenic organisms multiply within the host to cause disease, meaning that relative to chemical agents small quantities of biological agent, if properly disseminated through the air, have the ability to inflict casualties over a large area (8,9). The inhaled infectious doses for biological organisms are measured from tens to tens of thousands of cells depending on the organism (Table 1). "Weight for weight, biological and toxin weapons are hundreds to thousands of times more potent than the most lethal chemical warfare agents" (8). Figure 1 illustrates the lethal dose range in terms of quantity of agent for chemical, biological, and toxin weapons (8). Even a small-scale operation only producing a few hundred grams or agent may be sufficient to cause significant casualties. Some biological agents such as *Yersinia pestis* and Variola major (smallpox) have the added characteristic of being easily contracted from human-to-human contact. Thus, unlike chemical agents, biological agents have the potential to spread through human transmission from the area immediately affected to produce casualties of epidemic, or possibly pandemic proportions.

On a small scale, production of biological agents does not require a large amount of specialized equipment. All equipment necessary for production of biological agents is commercially available and procedures for their production are readily available in the scientific literature and require little specialized expertise outside of a basic knowledge of microbiology. Comparatively, some processes required for production of chemical agents are more complex and may require special knowledge

Table 1. Infective Doses (Aerosol) for Commonly Considered Biological Warfare Agents (10)

Agent	Infective Dose (Aerosol)
B. anthracis	8,000–50,000 spores
Brucella species	10–100 organisms
V. cholerae	10–500 organisms
Burkholderia mallei	Assumed low
Yersinia pestis	100–500 organisms
Francisella tularensis	10–50 organisms
Coxiella burnetti	1–10 organisms
Smallpox virus	Assumed low (10–100 organisms)
Venezuelan Equine Encephalitis Virus (VEE)'	10–100 organisms
Viral hemorrhagic fevers	1–10 organisms
Clostridium botulinum toxin	0.001 μg/kg in humans for *C. botulinum* type A toxin
Staphylococcus aureus enterotoxin B	0.03 μg/person for incapacitation
Ricinus communis toxin	3–5 μg/kg is the lethal dose for mice
Trichoethecene mycotoxins	Moderate

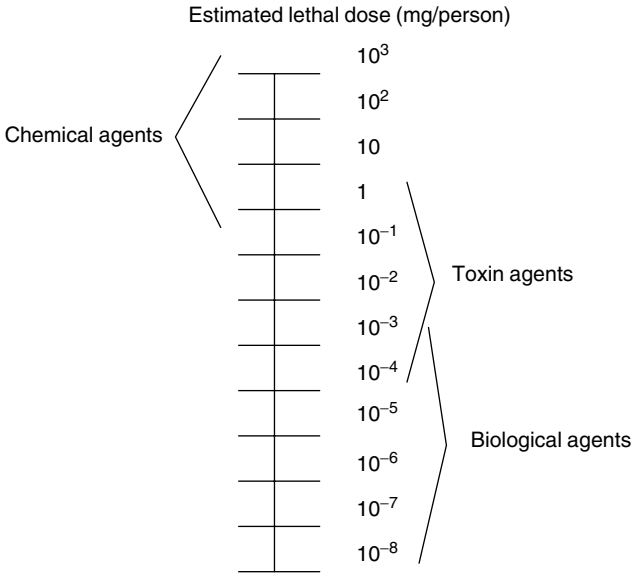

Figure 1. Toxicity of chemical and biological agents (8).

and equipment. Furthermore, production of chemical agents requires the procurement of some specialized and controlled precursor chemicals, which are not readily available (8). Because the production of biological agents does not require large amounts of chemicals or equipment, facilities used for production on a terrorist scale may be relatively easy to hide.

Although the production of biological agents appears relatively simple compared with that of chemical agents (Table 2), some obstacles exist. First only a small amount of pure starter culture is required, however, it may be difficult to acquire. Until recently, many infectious agents were accessible through commercially available culture collections and were fairly easy to obtain. Cases such as that of Larry Wayne Harris, who was arrested after obtaining cultures of *Yersinia pestis* through mail order in May 1995 and again in February 1998 after obtaining a *B. anthracis* strain have prompted tighter governmental regulation of those organisms that could be used as biological warfare agents (Table 3). Additionally, working with biological and toxin agents does pose a significant health risk to the operator if agents are not handled properly. Production of highly infectious or toxic biological agents will probably require some sort of personal protection or containment to be handled safely (8).

Table 2. Key Low-Technology Production Techniques for Biological and Toxin Weapon Agents (8)

Type of Agent	Low-Tech Production
Bacteria	Batch fermentation, production in animals
Rickettsiae and viruses	Cultivation in eggs, mouse brains, or tissue culture
Protein toxins	Batch fermentation and purification of a bacterial toxin, or extraction of toxin from a plant or animal source
Nonprotein toxins	Extraction from plant or animal source

Another major difference between biological and chemical weapons use is the timescale in which an attack may be detected. Generally, chemical agents produce symptoms of exposure in less than a minute to a few hours. These agents may have an acrid smell or taste, produce a colored smoke, or a burning sensation on the skin, lungs and mucous membranes (8). These factors combined will most probably lead to a relatively quick determination that a toxic chemical was involved. This was illustrated during the March 1995 Sarin gas attack on the Tokyo subway system by the Aum Shinrikyo cult, which killed 12 and injured almost 3,800. Authorities were able to assess within a short time that a chemical attack had occurred and were raiding Aum Shinrikyo facilities within 48 hours (7); however, this would have not been the case if this attack had been performed covertly with anthrax or plague.

The onset of symptoms from exposure to biological agents may vary from less than minutes to a few hours for toxin agents, to a range of a few days to weeks for

Table 3. CDC List of Critical Biological Agents (11)

Category A — high priority agents include organisms rarely seen in the United States. These agents pose a risk to national security because they can be easily disseminated or transmitted person-to-person, cause high mortality, with potential for major public health impact, might cause public panic and social disruption, and require special action for public health preparedness	Variola major (smallpox) *Bacillus anthracis* (anthrax) *Yersinia pestis* (Plague) *C. botulinum* toxin (Botulism) *F. tularensis* (tularemia) Ebola virus Marburg virus Lassa virus (Lassa fever) Junin virus (Argentine hemorrhagic fever) and related viruses
Category B — second highest priority agents include those that are moderately easy to disseminate, cause moderate morbidity and low mortality, and require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance	*Coxiella burnetti* (Q fever) Brucella species (brucellosis) *Burkholderia mallei* (glanders) *Venezuelan equine encephalomyelitis* virus (VEE) *Eastern equine encephalomyelitis* virus *Western equine encephalomyletis* virus *Ricinus communis* toxin (ricin) *Clostridium perfringens* epsilon toxin *Staphylococcus aureus* enterotoxin B
Category B subset — includes pathogens that are food and waterborne.	These pathogens include but are not limited to: *Salmonella* species Shigella dysenteriae *Escherichia coli* O157 : H7 *V. cholerae* *Cryptosporidium parvum*
Category C — Third highest priority agents include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, potential for high morbidity and mortality and a major health impact	Nipah virus Hantaviruses Tick-borne hemorrhagic fever viruses Tick-borne encephalitis viruses Yellow fever virus Multidrug-resistant Tuberculosis

infectious agents. Furthermore, for infectious biological organisms, and most biological toxins, the agent cloud is odorless, colorless, and produces no immediate sensation upon contact with the skin, lungs, or mucous membranes. These factors increase the chances that a biological agent may be covertly employed in a terrorist scenario with little or no warning until symptoms appear.

Biological agents used in a terrorist scenario may be endemic or exotic to a particular environment. A biological attack that utilizes a common or indigenous organism may be difficult to attribute to a terrorist attack because of the commonality of the organism, which was used. This was the case in a September 1984 outbreak of salmonellosis caused by a strain of *Salmonella typhimurium* in the community of Dalles, Oregon, which affected 751 people. Followers of the religious commune Bhagwan Shree Rajneesh, evaluated the use of *S. typhimurium* as an incapacitating biological agent in an attempt to influence a community vote affecting the construction of their new international headquarters. At least ten restaurants were affected in two phases spanning a total period of approximately four weeks (12). Although the *S. typhimurium* infections comprised the largest outbreak of food-borne disease reported to the Centers for Disease Control (CDC) in 1984, it took over a year after the outbreak had occurred to acquire sufficient evidence to attribute the unusual outbreak to the Rajneesh commune. Because salmonellosis is a common food-borne pathogen, the intentional nature of the outbreak in Dalles went initially unrecognized. An extensive epidemiological investigation was required to rule out the hypothesis that the outbreak occurred from "other factors" (12).

A biological attack that utilizes an exotic or nonendemic organism may be easier to identify as unusual once identified, however, a different set of problems exist regarding diagnosis. The initial symptoms of infection are similar for many pathogens, both lethal and nonlethal. Fever, chills, headache, fatigue, persistent cough, nausea, and vomiting comprise many of the initial symptoms of exposure to a biological agent by inhalation or ingestion. These symptoms are also prevalent in common, non-life-threatening illnesses such as respiratory infection, common cold, or influenza. Because they are similar to those of common illnesses, initial symptoms of exposure to a biological agent may not be properly diagnosed until symptoms appear that would discern from a common illness. The delay in proper diagnosis also causes delays in treatment and prophylaxis that may mean the difference between patient-survival and death. This is illustrated clearly when looking at the symptomology of inhalational anthrax exposure. Initial symptoms of anthrax exposure include fever, malaise, fatigue, cough, and mild chest discomfort. These symptoms are followed by respiratory distress and other severe symptoms. Shock and eventual death usually occur within 24 to 36 hours after onset of these severe symptoms and treatment at that point is largely ineffectual (6).

All of the factors that describe the nature of a biological terrorist event indicate that the emergency response may not be immediate, unlike the Aum Shinrikyo Sarin attack on the Tokyo subway. Because of the delayed onset of discerning characteristics of a biological attack, the first responders will probably not be hazardous materials teams, fire departments and police, but instead will be health care professionals working in emergency rooms, health clinics, and doctors offices. In the event of a biological attack, pressure will be placed on these individuals to have the ability to recognize a biological attack by symptomology and frequency of cases (13). Pressure will also be placed on the clinical laboratories to maintain the equipment, assays, and expertise to detect and characterize exotic or uncommon infectious agents rapidly and decisively. Moreover, disease surveillance and communication systems are required to quickly collate and analyze epidemiological data to recognize an outbreak of disease that may be attributable to a biological attack (13).

There are hundreds of biological organisms and toxins that can be used in a terrorist scenario to cause incapacitating or lethal disease, or produce toxic effects. The following comprises some of those that are most commonly considered biological warfare agents.

Bacteria

Anthrax (*B. anthracis*). *Bacillus anthracis*, the causative agent of anthrax is a gram-positive, spore-forming, rod-shaped, bacterium that is found primarily in herbivores. Cattle, sheep, goats, and horses are common domestic animal hosts. The disease may be contracted by humans from eating infected and improperly cooked meat, introduced through cuts or abrasions in the skin, or possibly by flies. Inhalational anthrax may be contracted by handling contaminated animal materials such as blood, flesh, hides, and bones (9,10). Anthrax was employed by both the United States and Russia as a biological warfare agent (5,10). Iraq has also admitted to performing research on weaponized anthrax before the Gulf War (9). *B. anthracis*, in its spore form is extremely resistant to environmental stresses. The sporulated form can survive for years in water and soil, and is also resistant to heat and ultraviolet light. This allows it to maintain viability during long-range travel through the air (9,14). Although the infectious inhaled dose for *B. anthracis* is higher than that of other biological agents (Table 1), its durability makes it desirable as a biological agent. The incubation period for anthrax varies from one to six days depending on the inhaled dose, and human-to-human transmission is rare. Initial symptoms include fever, malaise, fatigue, cough, and mild chest discomfort followed by severe respiratory distress, shock, and death (10). An effective FDA licensed vaccine does exist and inhalational anthrax is treatable with antibiotics. However, once the onset of severe symptoms has occurred, treatment is largely ineffective (9). In humans, the mortality rate of untreated cutaneous anthrax ranges up to 25%; in inhalational and intestinal cases, the mortality rate in untreated patients is virtually 100% (10).

Brucellosis (*Brucella* spp.). There are four organisms in the genus *Brucella* that are pathogenic to man. Although closely related, these bacterial organisms primarily infect different animal hosts (9). *Brucella melitenis* infects goats,

B. suis infects swine, *B. abortus* infects cattle and *B. canis* infects dogs. The severity of human disease from these organisms also varies with *B. melitensis* being the most severe followed by *B. suis*, *B. abortus*, and *B. canis*. Organisms of the *Brucella* species are small, slow-growing, gram-negative coccobacilli that are susceptible to heat and most disinfectants, but may survive for several weeks in dust, soil, or water. Most human infections are caused by contact or ingestion of contaminated raw meat or dairy products, and person-to-person transmission is rare (9,10).

The United States weaponized *B. suis* in the 1950s but stopped offensive work on this organism a decade later (9). Although *Brucella* species are non-spore-forming and may be considered relatively fragile, these organisms are extremely infectious by the aerosol route. It is estimated that as few as 10 to 100 inhaled bacteria are sufficient to cause infection in humans. The incubation period is highly variable ranging from 5 to 60 days and the symptoms are nonspecific. Symptoms include irregular fever, chills, headache, sweating, depression, and mental health changes (10). Respiratory symptoms may also occur in about 20% of those infected (9). The mortality rate for untreated brucellosis in humans is approximately 5%, and it is primarily considered a disabling or incapacitating type of disease (10).

Cholera (*V. cholerae*). *Vibrio cholerae* is a waterborne pathogen affecting multiple animal species. Cholera is usually contracted through ingestion of contaminated water and is endemic to many third world countries where poor sanitation and overcrowding are common. A recent and extremely large cholera outbreak in Peru produced over 250,000 symptomatic cases in Peru alone and spread to surrounding countries as well (9). *V. cholerae* affects multiple animal species including humans but is not readily transmitted from host to host. *V. cholerae* is easily killed by desiccation, steam and boiling, and is not viable in pure water. However, the organism may survive up to 24 hours in sewage and as long as six weeks in water containing organic, matter including sewage (10,14). *Vibrio cholerae* was reportedly considered by some countries for use as a biological warfare agent, however, because the amount of agent required to produce mass casualties is high, the organism is not considered to be effective. The use of *V. cholerae* on a small scale may still be effective in producing casualties in a terrorist scenario. *V. cholerae* is a short, motile, gram-negative, non-spore-forming rod. Two serotypes, O1 and O139, have been associated with disease in humans (10). The incubation period ranges from four hours to five days depending on the amount ingested and the ratio of symptomatic to asymptomatic cases is approximately 1 : 400. Symptoms include vomiting, headache, and intestinal cramping followed by severe and painless diarrhea that may produce fluid losses of 5 to 10 liters per day. Death may occur from severe dehydration, decreased amount of blood in the body, and shock. The mortality rates in humans for untreated cholera may be as high as 50%. Treatment includes continuous administration of fluids and electrolytes, as well as antibiotics. A licensed vaccine is available, but only provides 50% protection for as long as six months (10).

Glanders (*Burkholderia mallei*). *Burkholderia mallei*, the causative agent of glanders, is a gram-negative rod, which produces disease primarily in horses, mules, and donkeys. Human cases of glanders historically have been associated with veterinariansas well as horse and donkey caretakers. Although reports of human infection are rare, laboratory cultures of *B. mallei* have shown to be extremely infectious via the aerosol route. Because of the lack of a vaccine and effective therapy to treat the infection, *B. mallei* can be considered a potential biological agent (10). *B. mallei* was reportedly used during World War I to infect large numbers of horses and mules supporting allied operations in Russia. The Japanese also used *B. mallei* on horses, civilians, and prisoners of war during World War II. The United States and Russia also reportedly considered *B. mallei* as a biological warfare agent during the World War II era (2,10).

Glanders may occur in four forms in humans; an acute localized form, a septicemic and rapidly fatal form, an acute pulmonary form, and a chronic form. No form of glanders is readily transmissible from person to person. Aerosol infection may produce any of these four forms of glanders, or a combination of several. Incubation periods range from 10 to 14 days after exposure. Symptoms from inhalational exposure to *B. mallei* include fever, rigors, sweats, myalgia, headache, chest pain, swelling in the lymph nodes, and pustular eruptions. The mortality rate for septicemic infection is almost 100% if untreated. Recovery may occur for the chronic form, although this form may also turn septicemic (10).

Plague (*Y. pestis*). *Yersinia pestis*, the causative agent of plague is a nonmotile, gram-negative, non-spore-forming rod, which exists naturally as a zoonotic disease of rodents (rates, mice, and ground squirrels). Human plague is most commonly caused by bites from fleas, which live on infected rodents. Transmission to human by fleas produces the common bubonic form of the disease. Naturally occurring inhalational plague in humans is extremely rare. Although both the United States and Russia considered *Y. pestis* as a biological agent, only Russia chose to weaponize it. The Japanese Unit 731 reportedly inflicted heavy casualties by releasing plague-infected fleas of China during World War II (2,9). *Y. pestis* may remain viable in water and some moist environments for several weeks, and may survive for months to years at near freezing temperatures, but is susceptible to heat and ultraviolet light. Although *Y. pestis* is a relatively fragile organism, its low infectious dose and ability to spread from person to person make it a desirable biological agent capable of causing massive casualties if released in the aerosol form. The incubation for the pneumonic or inhalational form of plague in humans is two to three days. Symptoms include high fever, cough, chills, headache, and bronchial hemorrhaging, which progresses rapidly causing death by respiratory failure and circulatory collapse. The incubation time for the bubonic form of plague is approximately 2 to 10 days. Symptoms include fatigue, high fever, and tenderness in the lymph nodes, liver, and spleen (9,10). The bubonic form may also produce skin lesions and pustules containing virulent plague bacteria, and may spread spontaneously

to the blood stream, the central nervous system, lungs, and other organs. Although a licensed vaccine is available, it is not effective against exposure to plague through the aerosol route. The mortality rate for untreated pneumonic and bubonic forms of plague are 100 and 50%, respectively (10).

Tularemia (*F. tularensis*). *Francisella tularensis*, the causative agent of tularemia is a small, gram-negative, non-spore-forming cocco-bacillus. The disease is primarily zoonotic, and human cases are usually caused by contact with tissue or fluids from infected animals, or from the bites of infected insects. Human cases caused by inhalation or ingestion of *F. tularensis* are less common (9,10). Exposure by aerosol route, typical of a biological attack, would produce a pneumonic tularemia (10). The United States weaponized *F. tularensis* during its biological warfare program during the 1950s and other countries are suspected of its use as well. *F. tularensis* is easily killed by heat and disinfectants, but may remain viable for weeks in water, soil, carcasses and hides, and for months in freezing temperatures (10). As few as 10 to 50 organisms are sufficient to produce disease in man, which makes *F. tularensis* a desirable biological warfare agent. The incubation period for tularemia is 2 to 10 days depending on the dose. Characteristics of pneumonic tularemia include fever, headache, fatigue, weight loss, and pneumonia with nonproductive cough. The nonspecific symptoms of the pneumonic form of tularemia make it difficult to diagnose initially. Tularemia is treatable with antibiotics and an investigative live vaccine is available. The mortality rate for untreated pneumonic tularemia is approximately 35%. (9,10).

Viruses

Smallpox (Variola major and minor). Variola virus, the causative agent of smallpox occurs in at least two strains; variola major and minor. The last reported case of smallpox occurred in Somalia in 1977. In 1980, the World Health Organization (WHO) declared that smallpox has been eradicated from the planet (9,10). No animal reservoir for smallpox is known to exist, although monkeys are susceptible to infection (9). Although only two laboratories in the world (The Centers for Disease Control in Atlanta, Georgia and The Vector State Research Center of Virology and Biotechnology in the Novisibirsk region of Russia) are WHO-approved repositories for the variola virus, concerns still exist that the virus may be used as a biological weapon. The aerosol infectivity, stability, high mortality rate, contagiousness, and lack of vaccinated population would make the variola virus a desirable biological agent in a terrorist scenario (9). Russia reportedly weaponized and stockpiled smallpox as part of its biological arsenal (5). The average incubation period for smallpox is approximately twelve days. Initial symptoms from aerosol exposure include malaise, fever, rigors, vomiting, headache, and backache. Fifteen percent of patients also develop delirium (9,10). Approximately two to three days after initial symptoms appear, eruptions in the mucous membranes appear with a rash about the face, hands, and forearms. Lesions or pox, formed in the mucous membranes produce infectious secretions during the first few days of illness and are the primary means of transmission from person to person (9). The rash then spreads to the lower extremities, and finally to the trunk, producing lesions that progress to pustules. From 8 to 14 days after onset of initial symptoms, pustules progress to form scabs that may contain live variola virus. Currently, there is no effective treatment for smallpox virus. Although a live vaccine does exist, vaccinations for the general population were stopped in the early to mid-1970s leaving a large portion of the U.S. population susceptible (10). Furthermore, the smallpox vaccine, a live *Vaccinia* virus strain, may complicate vaccination because of its negative effects on immunocompromised patients (9). The mortality rate for smallpox in vaccinated and unvaccinated personnel is 3 and 30% respectively (10).

Venezuelan Equine Encephalitis Virus (VEE). Venezuelan Equine Encephalitis virus is an arthropod-borne alphavirus that is endemic to many areas in North and South America. Of the eight distinct viruses in the VEE complex that have been associated with human disease, the two most significant are variants A/B and C of the 1 subtype (10). Natural infections are caused by mosquito bites. and can also cause severe disease in horses, mules, burros, and donkeys. These animals serve as the host to VEE and are responsible for transmission of mosquito-borne infections. VEE was weaponized by the United States during its biological warfare program during the 1950s, and other countries may have also considered VEE as a biological agent (9,10). Besides being transmitted by mosquitoes, VEE is also highly infectious by aerosol, surviving best at low temperatures and relative humidity, but is easily killed by heat and disinfectants (10,14). The incubation time for VEE ranges from two to six days. Symptoms include malaise, spiking fever, rigors, headache, and light sensitivity. These symptoms may be followed by nausea, vomiting, cough, sore throat, and diarrhea. These symptoms may persist for 24 to 72 hours and full health is usually regained in one to two weeks. Four percent of children and few adults develop neurological complications because of infection. An investigational vaccine exists for VEE, and antiviral treatments have proven effective in postexposure treatment in animals, but clinical data do not exist to assess its efficacy on humans (10). The mortality rate for VEE is less than 1%, but is higher in the very young and very old (10). VEE is considered an incapacitating agent because of its low mortality rate.

Viral Hemorrhagic Fevers (Ebola and Marburg Viruses). Although the viral hemorrhagic fevers are caused by a number of virus families, Ebola and Marburg that are part of the *Filovirus* family are two of the most dangerous and have been considered for use as biological warfare agents in the past (5,9). The first cases of Ebola virus were recognized in Sudan and Zaire in 1976. These two outbreaks produced mortality rates of 53% and 92%, respectively (9). Subsequent outbreaks have occurred in Sudan in 1979 and in Zaire in 1995, which have produced a large number of casualties. In 1989, a strain of Ebola

determined to be nonpathogenic to humans was found in a monkey quarantine facility in Reston, Virginia. Marburg was first recognized in 1967 in Germany, where it produced 31 cases and 9 deaths. Human infection from these RNA viruses seems to be associated with contact with monkeys; however, the reservoir for these viruses in nature is not known. Human-to-human transmission of these viruses is not fully understood, but they definitely spread from direct contact with infected bodily fluids and organs (10). Russia reportedly performed extensive research and development on the production and weaponization of Ebola and Marburg (5). The high mortality rate, low infective dose, and lack of effective treatment would make these agents desirable for use as a biological warfare agent. The incubation times for viral hemorrhagic fevers may range from 4 to 21 days (10). Symptoms include fever, muscular pain, headache, vomiting, and diarrhea. Viral hemorrhagic fevers produce vascular damage, and changes in the permeability of the vascular system. Full blown viral hemorrhagic fever evolves into shock and hemorrhaging from the mucous membranes, and may be accompanied by neurological or pulmonary difficulties, or hemorrhaging on the skin (9,10). The mortality rate for Ebola may range between as high as 50 and 90%, depending on the strain. No vaccine or effective treatment is available for the Ebola and Marburg viruses, however, recent research is ongoing to develop a DNA vaccine for the Ebola using genes coding for virus proteins (9).

Toxins

Botulism (*C. botulinum* toxin). *Clostridium botulinum* toxin, the causative agent of botulism is comprised of seven related neurotoxins, A through G, which are produced from the anaerobic, gram-positive, spore-forming bacillus *C. botulinum*. The most common form of botulism in humans is caused by ingestion of contaminated foods and canned goods. However, the symptoms caused by food-borne exposure to *C. botulinum* toxin are very similar to those produced by aerosol exposure. *C. botulinum* toxin in extremely small amounts also has medicinal uses in treating muscle spasms and wrinkles. *C. botulinum* toxin has been researched by numerous countries for use as a biological weapon. Iraq admitted to The United Nations that it had performed research on and weaponized at least 100 munitions with *C. botulinum* toxin before the Persian Gulf War (9,10). The time from inhalation of botulinum toxin to onset of symptoms ranges from 24 to 36 hours to several days depending on the inhaled dose. Symptoms include bulbar palsies, blurred vision, and sensitivity to light. This is followed by skeletal muscle paralysis, which descends down the body as it progresses. Death is usually caused by respiratory failure caused by paralysis of respiratory muscles. With proper respiratory assistance, mortality rates due to exposure to *C. botulinum* may be less than 5% (9). The time taken from onset of symptoms to respiratory failure may be as little as 24 hours in food-borne botulism (9,10). An investigational vaccine is available for *C. botulinum* toxin types A through E, and has been shown to be effective in preventing botulism and in the treatment of botulinum exposure. Botulinum toxins are among the most toxic substances known (Table 1), and are 100,000 times more toxic than sarin gas, a well-known chemical warfare agent (10). Although it is not an infectious organism, the high toxicity and availability of *C. botulinum* would make it an effective agent in a bioterrorist attack.

***Staphylococcus aureus* enterotoxin B(SEB).** *Staphylococcus aureus* is a gram-positive cocci that produces a number of exotoxins including enterotoxin B. Exotoxins comprise those toxins that are released outside of the cell. The term enterotoxin indicates that the primary effects of the toxin occur in the intestines (9,10). SEB intoxication is caused by ingestion of improperly handled foods, and is extremely common, however, inhalation of SEB produces a distinctly different set of symptoms (10). Although SEB exposure through ingestion or inhalation does not normally produce death, 80% of those exposed may be incapacitated for 1 to 2 weeks (9,10). Symptoms may occur from 3 to 12 hours after inhalation. These symptoms include sudden onset of fever, headache, chills, muscular pain, and a nonproductive cough. Severe cases may also experience shortness of breath and chest pain. Inadvertent ingestion of the toxin may also produce nausea, vomiting, and diarrhea. Symptoms from SEB inhalational exposure are similar to those for common respiratory pathogens, which may complicate the diagnosis. Although several SEB vaccines are under development, no human vaccine is available, and treatment is supportive in nature, designed to alleviate the symptoms (10).

Ricin Toxin (*R. communis*). Ricin toxin is produced by the *R. communis* or castor plant, which is grown worldwide for the production of castor oil that is extracted from the castor bean. The waste product from castor oil production may contain as much as 5% ricin toxin by weight. The toxin is fairly persistent in the environment and is extremely toxic when inhaled, ingested, or injected (10). A few countries are suspected of performing research on ricin to be used as a biological weapon. Ricin injected from a specially designed umbrella gun was allegedly used to assassinate the Bulgarian exile Georgi Markov in London in 1978 (5,10). Because of its large availability and relative ease of production, ricin toxin could be used in a terrorist attack. Onset of symptoms may occur within 18 to 24 hours after exposure. Symptoms from inhalation of ricin toxin vary depending on the dose inhaled, but may include fever, chest tightness, cough, shortness of breath, nausea, and joint pain. Although data on human exposure to lethal doses of ricin are not available, animal models indicate that destruction of cells in the respiratory system may be sufficient to cause death if sufficient toxin is inhaled. Ricin toxin may cause severe gastrointestinal symptoms, followed by vascular collapse, and death when ingested, and circulatory and multiple organ failure when injected (10).

No human vaccine is available for Ricin exposure, and treatment is given to attempt to alleviate the symptoms (10).

Yellow Rain (trichoethecene mycotoxins). The trichoethecene of T-2 mycotoxins are low molecular weight

compounds produced by several types of filamentous fungi including *Fusarium*, *Myrotecium*, *Trichoderma*, and *Stachybotrys*. Mycotoxins may produce casualties when inhaled, ingested, or from contact with the skin, making them unique in that they are one of the only dermally active biological agents. Controversial reporting indicates that mycotoxins may have been used in biological attacks in Laos, Kampuchea, and Afghanistan during the 1970s and the early 1980s, producing an estimated 8,300 deaths resulting from exposure (10). The term "yellow rain" is derived from the characteristic yellow cloud that is created from aerosolization of the toxin in the liquid form. These toxins are resistant to inactivation by ultraviolet light, and are only destroyed by heat when exposed to temperatures of 1,500 °F for 30 minutes. Because of their stability in the environment and toxicity, the T-2 mycotoxins would be an effective biological agent for use in a terrorist scenario. The onset of symptoms may begin minutes after exposure and include burning skin pain, redness, and blistering. In lethal cases, blackening and sloughing of the skin occurs. Nasal contact from inhalation of T-2 mycotoxins produces pain, itching, sneezing, and nasal discharge. Lung exposure produces symptoms of shortness of breath, wheezing, and coughing, and ingestion produces symptoms of anorexia, nausea, vomiting, and bloody diarrhea. Because of the similarity in symptomology, exposure to T-2 mycotoxins may be misdiagnosed as a chemical weapon attack from an agent such as mustard gas. No vaccine, antidote, or therapy is available for exposure to mycotoxin and treatment is designed to alleviate the symptoms (10).

DISPERSION METHODS

As previously indicated, biological agents can be employed in a terrorist scenario using several different methods. These methods vary in levels of difficulty and effectiveness, but dispersion through aerosolization proves to be the most useful.

Waterborne and Food-Borne Application

History has shown that contamination of a water source can be an effective dispersion aerosol attack, contamination of a water source may provide a centralized means to reach a population and cause disease when ingested. Many bacterial agents have potential for use as a waterborne threat because of their stability in an aquatic environment. For instance, *B. anthracis* spores have been shown to survive for up to two years in pond water (14). *Vibrio cholera*, one of the most noted aquatic pathogens can survive for as long as six weeks in aquatic environment containing organic matter, and *F. tularensis*, primarily an epizootic disease of animals can survive for months in water or mud and may even multiply during that period (14). The viral diseases that are considered potential biological warfare agents, except the enteric viruses and possibly smallpox, have virtually no utility as waterborne threats (14). Toxin agents are fairly stable in aquatic environments, and given sufficient quantities, may be useful as potential waterborne threats. Although numerous biological agents may be suitable for waterborne contamination in a terrorist scenario, advances in water purification technology have significantly decreased the threat. Early use of biological agents to contaminate water sources proved effective primarily because of the absence of effective water treatment systems. A well-designed and well-operated water treatment system can be expected to remove significant amounts of bacteria and toxins from the water supply. Furthermore, disinfection of potable water using chemical additives such as chlorine decreases the threat of waterborne contamination (14). It should be noted that gaps do exist in the evaluation of the susceptibility of potable water supplies to biological attack, however, the dose of any biological warfare agent required to cause adverse affects is directly related to the proximity of the contamination to the consumer and the size of the body of water to be contaminated. Contamination of large bodies of water such as reservoirs would be impractical because of the immense magnitude of the agent required to produce disease (14). An effective biological attack through contamination of water sources would be most effective on small localized areas.

Similar to a waterborne attack, biological agents may also be applied to food sources to produce human disease. Contamination of food with the intent of infecting the consumer is a kind of terrorist scenario that has proved effective in the past. Advancements in food safety standards and packaging of food products will increase the chance that these attacks will be insignificant because of the need to place the agent in close proximity to the consumer, as was done in the Dalles Oregon incident. Intentional contamination of feed supplies to infect livestock and poultry may have serious economic consequences (15).

Vector-Borne Transmission

Vectors facilitate the transmission of disease from one species to another and apply mainly to zoonotic or epizoonotic diseases. Examples of natural vectors include deer flies and fleas with *F. tularensis and Y. pestis*, respectively. The use of plague-infected fleas by the Japanese illustrates the usefulness of vector-borne biological attacks (2). Although not attributed to biological terrorism, the August 1999 outbreak of West Nile virus in New York and its spread to points south in 2000 is a modern-day example of the affects of a vector-borne outbreak on a large population. West Nile virus taxonomically belongs to the Japanese encephalitis subgroup and is readily transmitted by mosquitoes, through which it can infect a wide variety of vertebrates including humans (16,17). During the period of August 23 (when the first case of West Nile Virus was identified), to September 28, 1999, there were 17 confirmed human cases, 20 probable cases, and 4 deaths in New York City and the surrounding counties of Westchester and Nassau (17). Although the incidence of infection is insignificant compared with the millions of people living in the affected areas, the outbreak sparked widespread fear in the population and necessitated extensive aerial and ground application of mosquito adulticides and larvacides. Other control measures that were instituted included the distribution of 300,000 cans

of mosquito repellent, and 750,000 public health leaflets with personal protection information. Local radio and TV networks, and newspapers were also used to distribute information (17). The New York City West Nile virus telephone hotline, set up on September 3, 1999 to address public inquires regarding the outbreak and pesticide applications, received more than 130,000 calls in a 25-day period (17). The West Nile virus outbreak may be considered an indicator of the public response that could be expected from a mild biological attack on a large population.

Aerosolization

Airborne infection has long been known to be a major factor in the spread of disease. The utility of aerosol spread of disease was readily illustrated in the investigation of respiratory disease experienced in recruit barracks at armed services training centers during World War II. This investigation showed that increasing the space between bunks substantially decreased the incidence of disease because the infectious aerosol particles had a further distance to travel to infect the adjacent individual (18).

Dissemination of biological agents via the aerosol route is the most effective means of dispersion in a biological attack. Dispersion of biological agents through aerosol dissemination has the potential to affect the largest area compared with waterborne, food-borne, or vector-borne dispersion methods. Biological agents that are disseminated as bioaerosols using a spray or explosive device in a terrorist scenario have the capability to travel long distances through the air covering large areas indiscriminately. For example, the hypothetical human health impact of 50 kg of anthrax sprayed by an aircraft along a 2 km-line upwind of a population of 500,000 would result in 95,000 dead, 125,000 incapacitated, and have a downwind travel distance of more than 20 km (15). Similar tests performed by the United States off the coast of San Francisco during the 1950s using *B. globigii*, an anthrax simulant, also illustrated the large area coverage potential for aerosol dissemination of biological organisms (1,19). Because of the nonspecific nature of an aerosol release of biological agent, the effects may be more widespread than other dispersion mechanisms. For example, an outdoor aerosol attack targeting a human population with anthrax may also kill livestock, contaminate food supplies, or cause vector-borne transmission to occur, as well as cause contamination inside buildings and homes because of transport of contaminated air. Additionally, biological attacks that occur indoors may also produce a large number of casualties because of modern-day heating ventilation and air conditioning (HVAC) systems that recirculate indoor air, requiring a smaller amount of "clean" makeup air from the outdoors (19). Decontamination of such a large area is also problematic, especially in the case of environmentally persistent spore-forming bacteria such as *B. anthracis*. For example, anthrax spores exploded on Gruinard Island from allied biological warfare testing during World War II, survived for at least 40 years in the soil before the area was decontaminated (4).

Some of the environmental factors that govern the effectiveness of an outdoor aerosol dissemination are wind patterns, turbulence, atmospheric conditions, temperature, and humidity (20). Another factor includes the efficiency of the dissemination device, which determines the size and amount of the particle disseminated. The dissemination device also produces shear forces during dispersion, which may damage the organisms to the point of nonviability. Other factors that affect the viability of the organism are ultraviolet radiation, atmospheric oxygen, and environmental pollutants such as ozone and other synthetic chemicals (21). The size of the particle disseminated is also an important factor as it controls the ability of the biological agent to travel downwind. For example, the sedimentation velocity for a 5-μm particle is 0.75 cm/s compared with 7.28 cm/s for a 50-μm particle (22). The increase in particle size leads to a decrease in the ability of a particle to remain airborne for an extended period, thus reducing its coverage area.

Particle size also plays a substantial role in infectivity. Small size particles (1 to 10 μm), if inhaled can penetrate into the distal bronchioles of the lung and alveoli to cause infection (9). Studies performed in the late 1950s using *B. anthracis* spores showed that the concentration of spores in the 12 micrometer particle size range required to infect 50% of exposed animals was 17-fold greater than those spores in the 5-μm size range. This relationship of particle size to infectivity is a consequence of the shape and structure of the upper and lower respiratory system (19). Larger particles are impacted onto the walls of the upper respiratory tract and are removed with the help of ciliated membranes and mucosal secretions in the lining of the nasal-pharyngeal region. Smaller particles evade the natural defenses of the respiratory system and deposit in the terminal alveoli of the lung where the infection occurs (8,19)

AGROTERRORISM: THE BIOLOGICAL THREAT TO PLANTS AND ANIMALS

Although one usually thinks of the threat to humans when considering a bioterrorist scenario, a vulnerable target remains in the plant and animal industry. The United States, like many developed nations is vitally dependent on its cash crops, livestock, and poultry to sustain its quality of life and provide economic stability. The utility of a biological attack on plants and animals was realized during the early 1900s and continued through the Cold War (2). Although the initial purpose of these weapons was to render crops or animals unfit for consumption, the terrorist threat is also motivated by economic factors (23). An outbreak of disease in livestock or cash crops not only renders it unfit for use but also has the added implication of industry restrictions on international trade and disruption of internal distribution caused by eradication efforts (23). Procedures for disease eradication in plants and animals may be severe. For example, an outbreak of avian influenza in Eastern Pennsylvania in 1984 almost eliminated the poultry population. Although 40 to 60% of these animals would

have survived the epidemic, containment procedures mandated that they be destroyed. Examples of antiplant and animal agents include: rice blight, corn blight, wheat stem rust, tobacco mosaic virus, foot and mouth disease of cattle, rinderpest or cattle plague, and Newcastle disease of poultry (24). Unlike most human biological warfare agents, many plant and animal pathogens are contagious and may be spread from host to host (15). The spread of a contagious disease among livestock may be amplified by large-scale, high-density husbandry methods, transportation practices, and centralized feed supply systems. Furthermore, many of the agents pathogenic to livestock have been eradicated from the United States, and vaccinations are not required, leaving the animal population increasingly susceptible to infection (15). Plant and animal pathogens may be dispersed in the same ways as those utilized for an attack on a human population. Although not attributed to a terrorist attack, the recent foot and mouth disease outbreak Great Britain illustrates the devastating nature of a widespread agricultural epidemic.

ENVIRONMENTAL SAMPLING

With regard to a bioterrorist scenario, environmental sampling may serve numerous purposes similar to those in an epidemiological, environmental, or public health investigation; its primary function is to identify the disease-causing biological agent. Sampling may be performed in response to a perceived attack, or in response to an unusual outbreak of disease. Sampling may be used to determine the source of exposure, determine the area of coverage, or to render an area free of contaminants, or determine if remediation is required. Types of sampling may include air, water, soil, or surface swipes. Methods of analysis may include live cultures, polymerase chain reaction (PCR), or immunoassays and vary depending on the organism being sought after, the sampling method, and the circumstances surrounding the event. Environmental sampling of air and water, for example, may also be used for continuous monitoring of the environment to serve as an alarm system for immediate notification that a biological attack has occurred. Detailed information on sampling methods and techniques used in environmental monitoring and detection directly applicable to the topic of bioterrorism, and are covered in other entries in this encyclopedia.

COMBATING BIOTERRORISM

The threat of domestic bioterrorism has captured the concern and attention of the American public and government officials alike. Concern for this issue is further amplified by the widespread belief that at the current time, the United States is not well prepared to respond to a biological attack on its own soil. Without considering the likelihood that an attack will occur, the social, economic, and public health consequences of a biological attack are severe enough to warrant a comprehensive plan to respond to a bioterrorist event. As the national center for disease control and prevention, the Centers for Disease Control (CDC) has been given the responsibility by the U.S. Department of Health and Human services to coordinate and lead efforts to upgrade national public health capabilities at the local, state, and national levels to effectively respond to a biological attack (25). The CDC has outlined five major areas that make up a comprehensive bioterrorism response plan.

1. *"Detection (Surveillance)."* An essential part of the response plan is recognition of unusual and unexplained illnesses. If an attack can be detected early, those exposed may receive prophylaxis, vaccination, or other medical treatment to minimize loss of human life (25).

2. *"Rapid Laboratory Detection."* Rapid diagnosis of unexplained and unusual outbreaks is dependent on the ability of diagnostic clinical laboratories to detect and characterize pathogenic agents that are likely to be used in a biological attack. The CDC is working with metropolitan health departments to enhance their capability to identify biological threats, as well as creating a "rapid response and advanced technology laboratory" to provide local and state health departments and bioterrorism response team analytical support 24 hours a day (25).

3. *"Epidemiological investigation and implementation of control measures."* Epidemiologists at the local and state levels will have the responsibility for investigating unusual disease occurrences to identify sources of exposure and route of transmission. The CDC is providing training at the state and local level to ensure that biological threat agents are considered when investigating an unusual outbreak (11).

4. *"Communication."* As in any large-scale domestic emergency, rapid and secure communications are critical in achieving a prompt and organized response as well as providing emergency-related guidance to the public through the media. The CDC is working to develop a national health alert network linking local health departments to each other, the CDC, other federal agencies, and local health care providers to ensure the efficient transmission of crucial information regarding a bioterrorist incident. (25).

5. *"Preparedness Planning and Readiness Assessment."* The CDC has enhanced its capabilities including new hires, pertinent training, and enhanced interagency collaborations to ensure that it is prepared to respond to a bioterrorist incident. The CDC is also providing support to state and local governments to develop similar public health response plans (25).

Other initiatives involved in developing a response to a biological attack include the creation of a national pharmaceutical stockpile for use in response to mass casualties from a bioterrorist incidents that overwhelm the local health systems. This program would provide the area affected with rapid access to vaccines, antitoxins, and therapeutic drugs used to treat a large number of biological casualties (25).

CONCLUSION

Biological warfare has shown its utility in causing disease, hysteria, and death, and is not limited to military applications or targeting only humans. The multitude of agents available for use and the variety of dispersion mechanisms that can be utilized increase the complexity in identifying and treating the intentional use of biological agents as weapons of mass destruction. Furthermore, the relative ease of obtaining and producing biological agents increases the chances that they will be used as a terrorist weapon targeting humans, plants, or animals.

BIOTRICKLING FILTERS FOR AIR POLLUTION CONTROL

MARC A. DESHUSSES
HUUB H. J. COX
University of California
Riverside, California

Biological treatment of contaminated air is an emerging technology in air pollution control. The principle is relatively simple: a contaminated airstream is passed through a porous packed bed on which pollutant-degrading cultures are immobilized. Like all biological treatment processes, air biotreatment relies on microbial reactions for the degradation of waste compounds. Bioreactors used in air pollution control have found most of their success in the treatment of dilute, high flow waste gas streams containing odors or volatile organic compounds (VOCs). Under optimum conditions, the volatile or gaseous pollutants can be degraded completely to carbon dioxide, water, and excess biomass. In the case of contaminants such as H_2S, reduced sulfur compounds, or biodegradable chlorinated compounds, harmless sulfates or chlorides are additional by-products. Bioreactors for air pollution control are promising and could treat many contaminants in a wide spectrum of applications. The technology has a niche in commercial and industrial applications in which high airflows and low pollutant concentrations are encountered (Fig. 1). It offers several advantages over traditional technologies such as incineration or adsorption. These include lower treatment costs, reduced environmental impact, an absence of the formation of by-products such as nitrogen oxides (NO_x) or spent activated carbon, low energy demand, a lack of the need for fossil fuel burning, and low temperature treatment.

The two most promising bioreactors for air pollution control are biofilters and biotrickling filters. Biofiltration has been reviewed recently (1); hence, this article is only concerned with biotrickling filters.

- *Biofilters* work by passing a humid stream of contaminated air through a damp packing material, usually compost mixed with wood chips or any other bulking agent on which pollutant-degrading bacteria are naturally immobilized. Biofilters are simple and cost- effective. They require low maintenance and are particularly effective for the treatment of odor and volatile compounds that are easy to biodegrade and for compounds that do not generate acidic by-products. Biofilters are increasingly used in industrial applications. (See BIOFILTRATION and BIOFILTRATION AND BIOODORS).
- *Biotrickling filters* work in a similar manner to biofilters, except that an aqueous phase is trickled

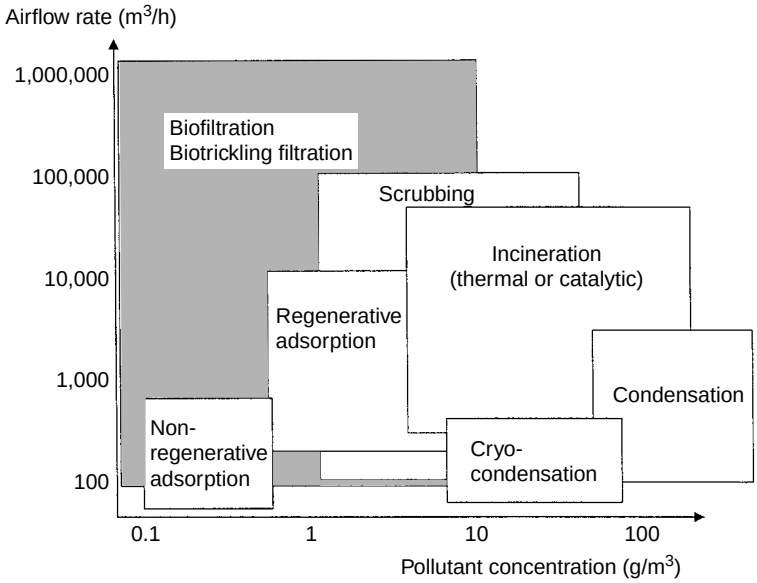

Figure 1. Applicability of the various air-pollution-control technologies based on airflow rates and concentrations to be treated (updated from reference 2).

over the packed bed and the packing is usually made of some synthetic or inert material, such as plastic rings, open pore foam, lava rock, and so on. The trickling solution contains essential inorganic nutrients such as nitrogen, phosphorous, potassium, and so on and is usually recycled. Biotrickling filters are more complex than biofilters but are usually more effective, especially for the treatment of compounds that generate acidic by-products such as H_2S. They can be built taller than biofilters. Biotrickling filters are more recent than biofilters, and have not yet been fully deployed in industrial applications.

BIOTRICKLING FILTRATION PRINCIPLE

The principle of biotrickling filtration is schematically explained in Figures 2 and 3, and typical characteristics of biotrickling filters are listed in Table 1. Biotrickling filters are biological scrubbers. At a first glance, the mechanism appears to be relatively simple: contaminated air is contacted with an immobilized culture of pollutant degrading organisms in a packed bed. A more detailed examination of the processes involved (Fig. 3) reveals that elimination of the pollutant is the result of a combination of physicochemical and biological phenomena. Understanding these phenomena is a key to the successful deployment of the technology.

In biotrickling filters, contaminated air is forced through a packed bed, either downflow or upflow. The packed bed is generally made of an inert material such as a random dump or structured plastic packing, or less often, an open pore synthetic foam or lava rocks. The packing provides the necessary surface for biofilm attachment and for gas-liquid contact. During treatment, an aqueous phase is recycled over the packing. It provides moisture, mineral nutrients to the process culture, and a means to control the pH or other operating parameters. The system is continuously supplied with essential mineral nutrients such as nitrogen, phosphorus, potassium, and

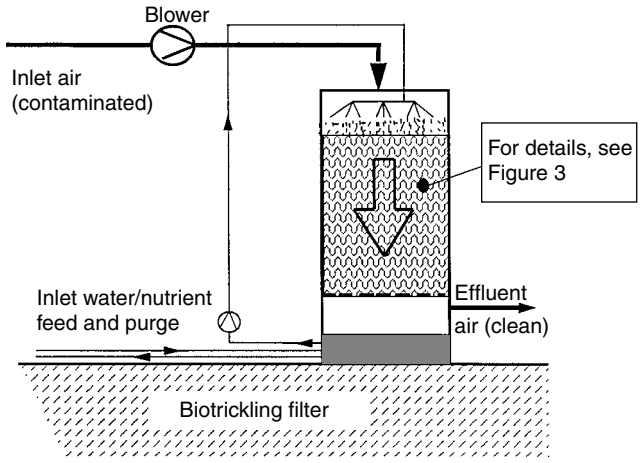

Figure 2. Schematic principle of biotrickling filtration; the cocurrent operation is shown here.

trace elements via a liquid feed. In general, most of the pollutant is biodegraded in the biofilm, but a part may also be removed by the suspended microorganisms in the recycle liquid (3). Possible biodegradation metabolites will leave the system via the liquid purge along with small amounts of biomass. Usually, less than 10% of the carbon pollutant entering the system leaves via the purge (3).

Biotrickling filters work because of the action of the pollutant degrading microorganisms. In the case of the removal of hydrocarbon vapors, the primary degraders are aerobic heterotrophic organisms that use the pollutant as a source of carbon and energy. For the removal of hydrogen sulfide or ammonia, the primary degraders are autotrophs, which will use the pollutant as a source of energy and use carbon dioxide as a source of carbon for growth. The removal of compounds such as dimethyl sulfide or dimethyl disulfide will require both autotrophs and heterotrophs to be present. In any case, the biotrickling filter will host a wide variety of microorganisms, similar

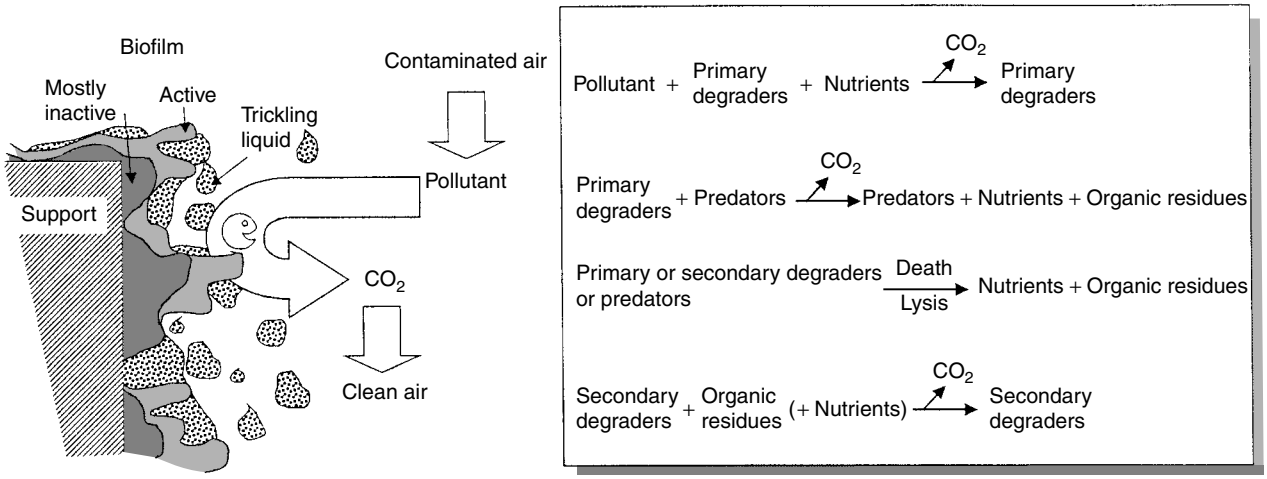

Figure 3. Mechanism of pollutant removal and the main biological processes involved in biotrickling filters.

Table 1. Typical Characteristics of Biotrickling Filters

Biotrickling filter bed height	1–5 m
Biotrickling filter cross section area	1–3,000m^2
Airflow treated	100–1,000,000 $m^3\,h^{-1}$
Packing void volume[a]	
— Plastic rings, foam, random or structured packing	90–95%
— Lava rock	~50%
Empty bed gas retention time[b]	2–60 s
Pressure drop	<1 cm of water column per meter of bed depth
Operating temperatures	15–50 °C
Trickling rates[c]	0.01–10 $m\,h^{-1}$
Liquid dilution rate[d]	0.1–2 per day
Usual pH of the recycle liquid	
— removal of VOCs or compounds difficult to degrade	~7
— removal of H_2S	1–2
Inorganic nutrient supply (N, P, K, traces)	Usually 0.05 to 1 times the amount calculated using biodegradation stoichiometry
Inlet pollutant concentration	
— VOCs	0.01–10 $g\,m^{-3}$
— Odors	500–50,000 odor units
Typical pollutant removal efficiencies	60–99.9+%

[a]Value at reactor start-up; over time, biomass growth will decrease bed porosity, typically by 10–30%
[b]The empty bed gas retention time (EBRT) is defined as the bed volume/airflow
[c]Trickling flow rate/bed cross-section area
[d]Liquid feed rate/recycle liquid volume.

to those encountered in wastewater-treatment operations. The microorganisms responsible for pollutant removal in biotrickling filters are usually aerobic because biotrickling filters are well-aerated systems. However, it has been proposed that the deeper parts of the biofilm (Fig. 3), where anaerobic conditions probably prevail, can be utilized to perform anaerobic biodegradation (e.g., reductive dechlorination, or NO_x reduction) for the treatment of pollutants that are otherwise recalcitrant under aerobic conditions (4). Anaerobic treatment in aerobic biotrickling filters is still an experimental area.

As illustrated in Figure 3, a major fraction of the biofilm becomes inactive (mostly because of mass transfer limitations) as the biofilm grows, and active primary degraders only constitute a minor fraction of the total population in the biofilm. Secondary degraders feeding on either metabolites, biopolymers, or predators feeding on the primary degraders include bacteria, fungi, and higher organisms such as protozoa, rotifers, even mosquito or fly larvae, worms, or small snails. The importance of higher organisms in the overall process should not be underestimated. They have been shown to play an important role in reducing the rate of biomass accumulation and in recycling essential inorganic nutrients (5,6). In fact, comparison of traditional mineral growth media with biotrickling filter

recycle liquid composition reveals that most biotrickling filters are operated under various degrees of inorganic nutrient limitation. The relationship between nutrient supply and biomass growth is discussed further in this article.

BIOTRICKLING FILTER PERFORMANCE

Definitions and Factors Affecting Performance

Operation and performance of biological reactors for air pollution control is generally reported in terms of removal efficiency, pollutant elimination capacity as a function of pollutant loading, or the gas empty bed retention time (EBRT). These terms are defined in Equations 1 to 4:

$$\text{Removal} = \text{RE} = \frac{C_{\text{in}} - C_{\text{out}}}{C_{\text{in}}} \times 100(\%) \quad (1)$$

$$\text{Pollutant Elimination Capacity} = \text{EC} = \frac{(C_{\text{in}} - C_{\text{out}})}{V} \times Q(\text{g m}^{-3}\,\text{h}^{-1}) \quad (2)$$

$$\text{Empty Bed Retention Time} = \text{EBRT} = \frac{V}{Q}(\text{s or min}) \quad (3)$$

$$\text{Pollutant loading} = \text{L} = \frac{C_{\text{in}}}{V} \times Q(\text{g m}^{-3}\,\text{h}^{-1}) \quad (4)$$

where C_{in} and C_{out} are the inlet and outlet pollutant concentrations (usually in g m^{-3}), respectively, V is the volume of the packed bed (m^3), and Q is the airflow rate ($\text{m}^3\,\text{h}^{-1}$). Pollutant concentrations are usually reported as mass per volume; conversion of volumetric to mass concentrations is done using the ideal gas law that reduces to Equation 5 at room temperature:

$$\text{Concentration}(\text{g m}^{-3}) = \frac{\text{Concentration}\,(\text{ppm}_v) \times \text{molecular weight of pollutant}\,(\text{g mol}^{-1})}{24,776} \quad (5)$$

It should be stressed that the elimination capacity and the loading are calculated using the volume of the packed bed and not the total volume of the reactor. Depending on the reactor design, the volume of the packed bed will be about 40 to 90% of the total reactor volume. In addition, the EBRT is calculated on the basis of the total volume of packed bed (Equation 3). The actual gas residence time will be lower depending on the porosity of the packing, the dynamic liquid holdup, and the amount of biomass attached to the packing. The porosity of packing ranges from about 50% (lava rock) to 95% (all random or structured packings), the liquid holdup is usually less than 5% of the bed volume, and biomass may occupy 5% to 30% of the bed volume. Hence, the actual gas residence can be less than half the EBRT.

A typical elimination capacity versus pollutant loading curve is shown in Figure 4. It is usual to report the performance as a function of the load, that is, inlet concentration × airflow, rather than the concentration. This enables comparison of systems of different sizes operated under different conditions. One underlying assumption is that the performance depends only on the pollutant load, hence, that low concentrations-high flow rates lead to similar elimination capacities as high concentrations-low flow rates. This assumption is generally valid because the pollutant concentrations commonly encountered in biotrickling filters are high enough for the microkinetics to be of zero order. This is no longer true at very low pollutant concentrations (typically below $0.05-0.1\ \text{g m}^{-3}$), particularly for pollutants with high Henry's law coefficients, because first-order kinetics will prevail in the biofilm, resulting in a reduction of the maximum elimination capacity.

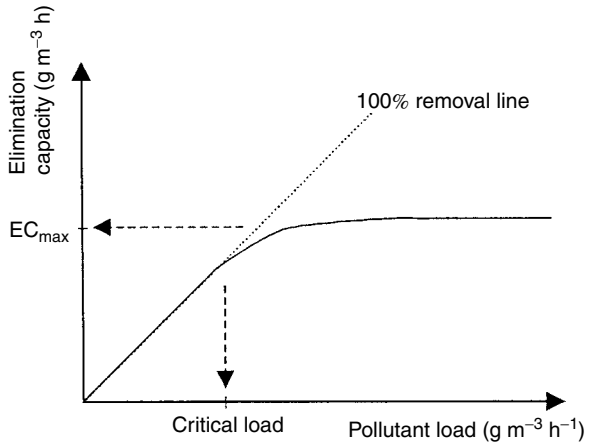

Figure 4. Schematic of a typical elimination capacity versus the load curve for a biotrickling filter.

Examination of Figure 4 reveals that there are essentially three operating regimes:

1. Low loading, also called first-order regime. The elimination capacity and the loading are identical and the pollutant is completely removed. The biotrickling filter is operated well below its maximum elimination capacity. The performance increases proportionally with the loading.
2. Intermediate range, where breakthrough of the pollutant occurs. With higher inlet concentration or higher airflow rates, the elimination capacity increases, but to a lesser extent than the loading.
3. High loading, also called zero-order regime. The biotrickling filter is operated at its maximum elimination capacity. Increases in pollutant concentration or the airflow rate do not result in further increases in elimination capacity. However, the removal efficiency decreases.

For the evaluation of biotrickling filter performance, both the maximum elimination capacity and the removal efficiency should be considered. For practical reasons, academic research is mainly concerned with the maximum elimination capacity or with high performance, which occur at relatively high pollutant concentration and often less than approximately 90% removal efficiency. On the other hand, reactor design for industrial application often needs to meet a certain discharge requirement or

achieve a high removal percentage. Thus, there might be some challenges in extrapolating research data for reactor design. In this context, the critical load defined as the maximum loading before the removal deviates significantly from the 100% removal line (Fig. 4) is a valuable parameter. Nevertheless, there are limitations to the use of the critical loading. It is relatively sensitive to the pollutant inlet concentration, thus extrapolation of low flow-high concentration to high flow low-concentration should be avoided.

Examples of Biotrickling Filter Performance

Research over the past 10 years has greatly broadened the range of pollutants that can be treated in biotrickling filters, including volatile organic compounds (VOCs), chlorinated hydrocarbons, reduced sulfur compounds, and compounds containing nitrogen. Typical examples are presented in Table 2.

Maximum elimination capacities generally are in the range of 5 to 200 $g\,m^{-3}\,h^{-1}$. Although many factors influence performance, a few general comments can be made. As biotrickling filters rely on microorganisms as the catalysts for pollutant conversion, biodegradability of the pollutant is of prime importance. Decreasing biodegradability causes lower elimination capacities and/or longer periods of adaptation. The use of specially acclimated or enriched microorganisms may be considered in these cases. Equally important is the accessibility of the pollutant to the microorganisms. The overall rate of pollutant removal may be limited by the mass transfer rate of the pollutant into the biofilm, which depends mainly on the pollutant's air-water partition, which is in turn best described by the Henry coefficient. Mass transfer limitation leads to a biofilm not completely saturated with the pollutant, hence pollutant concentrations in the biofilm are below those required for maximum biological activity. Means to improve the overall mass transfer rate in biotrickling filters include the selection of packing materials with a high specific surface area and intermittent trickling to reduce the thickness of the water film on the biofilm (Fig. 3).

As illustrated in Table 2, many different types of packing materials have been used in biotrickling filters, and research in this area is still in progress. The packing should combine a high porosity to minimize the pressure drop across the reactor and a high specific surface area to maximize biofilm attachment and pollutant mass transfer. Other factors to consider for a packing include water holding capacity, structural strength, surface properties, weight, stability over time, and cost.

Reaction conditions in the biotrickling filter can be optimized by controlling the pH, the concentrations of nutrients, and the metabolic end products in the recycle liquid. Many biotrickling filters are equipped with a pH control, with automatic water or nutrient addition to control ionic strength. The optimum pH depends on the process culture. Most VOC-removing biotrickling filters are operated at a near neutral pH. On the other hand, H_2S-oxidizing microorganisms such as *Thiobacillus* sp. are acidophilic and show maximum activity at low pH. In biotrickling filters treating H_2S vapors, pH values as low as 1 to 2 are common. Treatment of sulfur and chlorinated compounds will result in the accumulation of sulfate and chloride in the recycle liquid, respectively. These salts will inhibit biodegradation if certain concentrations are exceeded. Frequent supply of freshwater and purging of the recycle liquid are required to prevent accumulation of inhibitory concentrations. The dilution rate can be controlled by continuous measurement of the conductivity of the recycle liquid or by using ion selective electrodes.

BIOMASS GROWTH IN BIOTRICKLING FILTERS

Growth Kinetics

Clogging of biotrickling filters by growing biomass is one factor that has markedly slowed down the implementation of biotrickling filters at the industrial scale. A better understanding of biomass growth in biotrickling filters is warranted. In general, pollutants are used by the primary degraders to produce new biomass and to generate energy for its maintenance (Fig. 3). These processes have been extensively investigated in batch or continuous monocultures. The situation is much more complicated in biotrickling filters in which a complex ecosystem exists. In a first approximation, neglecting heterogeneities and mass transfer effects, it could be said that the rate of pollutant degradation depends on the intrinsic growth rate of the active fraction of the primary degraders (X_1) and their maintenance requirements as in Equation 6:

$$\mathrm{EC} = \left(\frac{\mu}{Y_{X/S} + m}\right) \times X_{1(\text{active fraction})} \tag{6}$$

where μ is the specific growth rate of the primary degraders, $Y_{X/S}$ is the biomass yield, m is the maintenance energy requirement, and $X_{1(\text{active fraction})}$ is the biomass content of active primary degraders per volume of reactor.

The specific growth rate of the active fraction of the primary degraders can be expressed using a modified Monod type equation:

$$\mu = \frac{\mu_{\max} \times S}{Ks + S} \times \frac{N}{Ks_{\mathrm{N}} + N} \times \frac{\mathrm{O}}{Ks_{\mathrm{O}} + \mathrm{O}} \times \frac{I}{1 + \dfrac{I}{K_{\mathrm{I}}}} \tag{7}$$

where S is the pollutant and substrate, N is any nutrient, O is the oxygen, and I is any inhibitor, and Ks, Ks_{N}, Ks_{O}, and K_{I} are the respective half-saturation and inhibition constants.

A similar equation can be written for all the species (or group of species) present in the system. Each will have one or several specific substrates, specific kinetic constants, and thus a specific growth rate. The overall rate of biomass accumulation is the sum, for all the different species, (designated by the indices i) of the growth rate minus death and lysis (d term), the predation by other species and the washout via the recycle liquid purge. This is expressed in Equation 8:

$$\text{Rate of biomass accumulation} = \sum_{\mathrm{i}} ((\mu_{\mathrm{i}} - d_{\mathrm{i}}) \times X_{\mathrm{i}} - \text{Predation}_{\mathrm{i}} - \text{Wash out}_{\mathrm{i}}) \tag{8}$$

Table 2. Laboratory Studies on Removal of Different Pollutants in Biotrickling Filters

	Methanol (7)	MTBE (8)	Hexane (9)[c]	Dichloromethane (10)	H_2S (11)	Nitrobenzene (12)

-Inlet concentration ($g\,m^{-3}$)	1.5	0.4–1	0.4		0.4–1.4	

Equations 6 to 8 are highly simplified since they do not take local heterogeneities into account. Still, they define a number of parameters that are impossible to determine. A possible solution is to split the process culture into large classes of organisms, such as primary degraders, secondary degraders, predators, and so on, and use lumped kinetic parameters. This is an area of current research. Even so, Equations 6 to 8 reflect the fact that the pollutant elimination and the observed biomass growth are interrelated in a complex manner. The equations further allow development of biomass control strategies for biotrickling filters. This is discussed in the next section.

Strategies for Controlling Biomass Growth

Examination of Equations 6 to 8 suggests several possible approaches to controlling biomass growth. Attempts can be made to reduce the overall rate of biomass accumulation (Equation 8) by either reducing the specific growth rate or increasing death and lysis. Several means have been investigated. Other options include increasing predation, washing-out or otherwise periodically removing the excess biomass. These are briefly discussed.

The first option to prevent clogging is the reduction of the biomass accumulation rate or of the specific growth rate (Eq. 7). The challenge is to reduce biomass accumulation while maintaining a high pollutant removal rate (Eq. 6) as growth and pollutant elimination are often tightly linked. This can be achieved by reducing the biomass yield coefficient ($Y_{x/s}$) and/or increasing the maintenance requirements (m). Growth, biomass yield, death and lysis, and activity and maintenance are interrelated parameters reflecting general cell metabolism and are as difficult to influence independently.

Table 3 reports various attempts to reduce the specific growth rate in biotrickling filters. These include limiting the supply of nutrients essential for growth (N or K), the use of nitrate as a nitrogen source instead of ammonium, the addition of compounds such as NaCl in concentrations that partially inhibit microbial growth, and so on. In general, these strategies also result in a reduction of microbial activity, thereby lowering reactor performance. Hence, larger reactors will be required to treat the same volume of waste gas, which will increase the capital costs. An interesting option is the use of organisms with lower biomass growth rates and yields, such as fungi. Interestingly, under similar conditions, fungi have shown a higher removal rate and a lower biomass accumulation rate than bacteria in toluene-degrading biotrickling filters operated under nutrient-limiting conditions (13).

The second option is to stimulate predation of the process culture by higher organisms such as protozoa (5), possibly even larger organisms such as larvae, small snails, or other biomass-eating organisms. This is a promising approach since it will not lead to a reduction in the performance, nor result in excess biomass to be disposed off, as per the methods discussed in the following paragraph. The challenge is that higher organisms may be difficult to control and/or to maintain in the biotrickling filter. This is an area of development, and advances are expected in the near future.

The last option to prevent clogging is to remove the excess biomass. This is usually done periodically rather than continuously, because shearing by the trickling liquid during normal operation is not sufficient to remove substantial amounts of attached biomass (20). Hence, the recycle liquid only contains a low concentration of biomass and increasing blow-down does not wash out much biomass. When periodic removal of biomass is chosen, the biotrickling filter is best operated at a high elimination capacity, and biomass is allowed to accumulate up to a given point where remedial action is required. From a cost perspective, the capital costs will be lower because a smaller reactor will suffice, but clogging will necessitate frequent cleaning, thus increasing operating costs (21). Removal of biomass can be done either physically or chemically (Table 4). Physical removal of biomass relies on biofilm detachment by high shearing forces. This can be done by backwashing the reactor, or by periodical stirring of the packed bed. Although these techniques result in prolonged, stable biotrickling filter operation, certain drawbacks exist (Table 4). Chemical removal of biomass is a simpler operation, as no major changes of the reactor configuration are required. In this procedure, a chemical solution is recycled over the packing using the existing system for liquid recycling. A stable toluene-degrading biotrickling filter was obtained by periodic washing of the packing with a NaOH solution for three hours (13). Posttreatment with HCl was needed to restore the pH to a neutral value. Other chemicals such as sodium hypochlorite and hydrogen peroxide may be more effective in removing biomass, but they are also more toxic to the microbial population (22). This could potentially slow down the restart of the reactor.

Unfortunately, all biomass control strategies have only been investigated in the laboratory and no experience is

Table 3. Options for Reduction of the Biomass Growth Rate in Biotrickling Filters

Option	Principle	Reference
Nutrient limitation	Reduction of the biomass yield	
— Nitrogen		13,14,15
— Phosphate		16
— Potassium		16
Use of $N\text{-}NO_3^-$ instead of $N\text{-}NH_4^+$	Reduction of the biomass yield	17,18
Use of specific microbial species	Selection of low biomass yield species	13
Addition of growth inhibitors	Reduction of the specific growth rate	17,19

Table 4. Options for Removal of Excess Biomass in Biotrickling Filters. Note that all methods were only tested at relatively small scale

Option	Advantages	Disadvantages	Reference
Backwashing	• Mild treatment • Possibly redistributes packing and may thus avoid formation of preferential paths or short circuits	• Requires larger reactors (+40% for packing fluidization • Requires packing that can be fluidized	18,23
Periodic stirring	• Probably low cost to perform • Easy to automate	• Complicated reactor design and construction • Higher capital costs • Not feasible with all packings	24,25
Chemical washing	• Effective removal of biomass • Does not require reactor modification	• Toxicity to microorganisms • Secondary waste	13,22

available from industrial-scale biotrickling filters. This is because most full-scale biotrickling filters have been designed for applications with low potential for clogging. In the future, design and operation of biotrickling filters will need to find the optimum between operation of large, low-performance biotrickling filters that do not require biomass removal and small, high-performance biotrickling filters with high potential for biomass accumulation (21). The perspective for progress in controlling biomass growth in biotrickling filters suggests that the latter option will be preferred.

BIOTRICKLING FILTRATION COSTS

Capital Costs

Capital costs for biotrickling filters vary a great deal depending on the size of the biotrickling filter and the material of construction. The size of the biotrickling filter is a function of the airflow, the nature and concentration of the pollutant treated, and the required removal efficiency. The presence of corrosive gases (e.g., H_2S) or solvent vapors will influence the choice of the construction material (polyethylene, fiberglass, steel, or concrete). The cost of the biotrickling filter will be further influenced by the presence of dust or fine particles, by excessively high or low temperatures, by highly fluctuating pollutant concentrations, and so on. Controls and ducting can also be a significant expense. Hence, before reactor design and construction, extended problem definition that includes a detailed characterization of the exhaust air is required.

Deshusses and Cox (21) have recently proposed a simple relationship (Eq. 9) to estimate the capital cost of a biotrickling filter on the basis of the volume of the bed. The costs include basic instrumentation (pumps, level switch) but no ducting and are for a simple biotrickling filter constructed out of inexpensive materials. For expensive materials such as stainless steel, a multiplication factor should be used. The cost obtained by Equation 9 is a rough estimation, with ±20% accuracy.

$$\text{Biotrickling Filter Capital Cost (\$)} = 13,000 \times \text{Bed Volume}^{0.757} \quad (9)$$

This equation covers bed volumes ranging from 5 to 1,000 m^3, where the reactor volume is in m^3. On the basis of the concentration of the pollutant, the target removal efficiency, and the airflow to be treated, the bed volume can be determined. Equation 9 is then used to estimate the capital cost (Table 5). Of course, vendor quotes are more appropriate for a detailed economic evaluation of the final installed costs.

Table 5. Estimated Costs, Footprint, and Treatment Capacity of Biotrickling Filters of Various Sizes

Bed Volume (m^3)	Capital Costs (Equation 1) (\$)	Approximate Footprint[a] (m^2)	Approximate Airflow That Can Be Treated[b] ($m^3\,h^{-1}$)
5	\$45 k	1–2.5	300–3,600
10	\$75 k	2–5	600–7,200
20	\$125 k	4–10	1,200–14,400
50	\$250 k	10–25	3,000–36,000
100	\$425 k	20–50	6,000–72,000
200	\$720 k	40–100	12,000–144,000
500	\$1.4 m	100–250	30,000–360,000
1,000	\$2.4 m	200–500	60,000–720,000

[a]Estimated using a 2- to 5-m bed height; to convert to sq. ft, multiply by 11.
[b]Calculated using EBRT of 5 s to 1 min; to convert to cfm, multiply by 0.59

Operating Costs

The determination of the cost of operating a biotrickling filter should include (*1*) nutrients and water expenses, (*2*) electricity for the blower and the recycle pump and miscellaneous electrical equipment, (*3*) maintenance, (*4*) costs associated with controlling the growth of biomass, and (*5*) capital costs (amortization). A detailed discussion of each of these costs is beyond the scope of this article. Specialized literature and vendor information can be referred to for more details (21). Even so, in general, the following applies:

- Nutrients, chemicals (e.g., for pH control), and water are usually a relatively small fraction (10–30%) of the total operating costs.
- Electricity for the blower is often a major fraction of the total operating expenses.
- Maintenance of biotrickling filters is minimal. A reasonable estimate is 2 to 4 hours per week. It is important is to inspect spray nozzles for possible clogging that would result in inadequate bed-wetting.
- If the biotrickling filter is likely to get clogged, the costs associated with controlling the growth of biomass must be included. These can be significant (21), up to half of the total operating costs. As discussed in the previous section, various approaches to control biomass growth exist. Unfortunately, there is only limited experience at the industrial scale. Careful evaluation of the various options is recommended.
- Since biotrickling filter operation is relatively inexpensive, capital cost amortization will be significant compared to other costs. An average fraction, assuming a plant life of 10 to 20 years, is between 20 and 40% of the total treatment costs. This stresses the importance of proper sizing and careful selection of the materials to minimize the actual capital costs.

A convenient way to compare the operating costs of biotrickling filters is to report the cost per thousands of cubic meter of air treated, that is, to divide the yearly costs incurred by the volume of air treated in a year (in thousands of m^3). Usual values for the operating costs range from \$0.05 to \$1.5 per 1,000 m^3 of air treated, not including capital costs, and from \$0.1 to \$3 per 1,000 m^3 when capital amortization is included. The wide range reflects the variety of possible applications and sizes of biotrickling filters. Typically, large biotrickling filters tend to be more economical per unit volume of air treated than small biotrickling filters.

CASE STUDIES

In this section, four cases of biotrickling filtration are presented. These case studies are reported to the best of our knowledge. Their description in this article does not constitute an endorsement of the design or of the vendor. Note also that the methods for calculating the treatment costs may be different from case to case. Hence, treatment costs may not be directly comparable. Nevertheless, they are included for information purposes, as an indication of the potential economic value of the technology.

H_2S and VOC Treatment at a Wastewater Treatment Plant in Los Angeles, California

Wastewater treatment plants have to control various odors and VOC emissions. The odor is generally from H_2S and from reduced sulfur compound emissions. Usually, the H_2S concentration is in the 3 to 100 ppm_v range and reduced sulfur compounds are in the ppb_v to ppm_v range. Some VOCs (aliphatics, aromatics, and some chlorinated) are also emitted, usually in the ppb_v range. Biotrickling filters have been proposed as one promising alternative treatment to the present use of chemical scrubbers. A pilot study was conducted in 2000 by the University of California, Riverside, at the Hyperion Treatment Plant in Los Angeles to evaluate the efficacy of biotrickling filters for the treatment of contaminated air from the headworks. The Hyperion plant treats domestic and industrial wastewater from the Los Angeles Basin. Odor nuisance and the growing concern about the potential toxicity of individual compounds require removal of H_2S as well as VOCs such as benzene and chlorinated compounds such as methylene chloride and chlorobenzenes. The main objective of this feasibility study was to evaluate combined treatment of H_2S and VOCs in a single-stage biotrickling filter. A particular emphasis was placed on determining the effect of pH on the elimination of the trace VOCs. The reactor used for this demonstration was a well-instrumented pilot unit (26) that included two vessels, but only one was used in this project (Table 6 and Fig. 5). The air was in an upflow mode and secondary effluent water ($2.2\ L\ m^{-3}_{reactor}\ h^{-1}$) was used as a nutrient source for microbial growth and to wash out sulfate. Despite great variations of the H_2S inlet concentration over the day (10–50 ppm), greater than 95% removal efficiency was continuously observed. Removal of VOCs and chlorinated compounds depended on their biodegradability, which was much higher at a near neutral pH than at a low pH (pH of 1–2). Moderate fractions of common VOCs (e.g., toluene, benzene) were removed. Typical results are presented in Figure 6.

Figure 5. Picture of the UCR biotrickling filter installed at Hyperion Wastewater Treatment Plant in Los Angeles.

Table 6. Characteristics of the UCR Biotrickling Filter Tested at Hyperion

Owner and present location	University of California, Riverside/Hyperion Treatment Plant, Los Angeles, California
Builder	University of California at Riverside and Environmental Biosystems
Type of airstream	Exhaust air from the primary headworks (slip stream taken prior to chemical scrubbing)
Year of construction	1996
Packing type and volume	3.87 m^3 of COOLdeck PVC Munters 12060 structured packing.
Height and number of layers of packing	7 layers of 0.30 m on top of each other. Total bed height is 2.1 m.
Biotrickling filter construction type	304 stainless steel cylindrical reactor of 1.5-m diameter and a total height of 3.35 m. The lower plenum of 0.77 m contains 800 L of recycle liquid and 0.30 m of void space. The upper plenum for liquid distribution is 0.45 m high. The reactor is mounted on a trailer.
Airflow rate	650 m^3/h (380 cfm), upflow. Airflow is variable depending on the application
Empty bed residence time	21 seconds
Pressure drop	4–8 mm of water gauge
Average bed temperature	15–35 °C
Pollutants treated	Hydrogen sulfide: 15–70 mg/m^3 (10–50 ppm_v); VOCs and chlorinated compounds 0–150 ppb, depending on the species
Biotrickling filter controls	Initial construction included 28 parameters monitored or controlled. Unit has been simplified since then to include only pH control and low-level switch. At Hyperion, pH control is either by purging sulfate with secondary effluent or by automatic addition of caustic soda to pH 7–8. Monitoring of various operational and performance parameters is by grab samples.
Biotrickling filter design and acceptance criterion	None. This is a feasibility study. The objective is removal of hydrogen sulfide to below 1 ppm and significant reduction of target VOCs and chlorinated compounds
Approximate investment costs	Estimated at $175,000 for the R& D unit, the cost include two reactors of 3.87 m^3 and many control and analytical devices for scientific purposes.
Approximate treatment cost per 1,000 m^3 off-gas treated	Electricity costs (recycle pump only): $0.02 per 1,000 m^3 of off-gas treated; pH control cost $0–0.04 per 1,000 m^3 of off-gas treated. Water costs: insignificant.
Typical performance	Reduction of hydrogen sulfide down to 0.25–0.5 ppm (i.e., about 98% removal efficiency), 50–70% removal of VOCs (toluene, benzene, xylenes), removal of chlorinated compounds is currently being studied.

H_2S and CS_2 Treatment in Monterrey, Mexico

Grupo Cydsa S. A. de C. V. is a large Mexican corporation with in-house needs for inexpensive air pollution control, mostly for treating H_2S and CS_2 emissions from cellophane film and rayon fiber manufacturing. After evaluating several technologies, a unique expertise was developed in the design and operation of biotrickling filters. So far, Cydsa has installed at least four full-scale biotrickling filters for the control of sulfur odors. The reactors usually use an inexpensive structured plastic packing of the type sold by Munters. They include a nutrient supply, a blow-down for the oxidized sulfur, and a pH control. The biotrickling filters have been very successful. The characteristics of one of their biotrickling filters are listed in Table 7 and a picture is shown in Figure 7.

Odor Treatment from Cigarette Manufacturing in Berlin, Germany

M + W Zander Facility Engineering GmbH (Germany) installed a large biotrickling filter for the treatment of odors at a tobacco company in Berlin. Several air pollution control technologies were evaluated, and biotrickling filtration was selected for its cost-effectiveness.

M + W Zander used open pore polyurethane foam as a packing material (27). The foam was very light (20 kg m^{-3}), had a large interfacial area for bacterial attachment (about 600 m^2 m^{-3}), and its open pore structure resulted in low pressure drops. Pilot tests were performed prior to the design of the full-scale unit to ensure that odor removal was satisfactory, and that no clogging of the bed occurred within a reasonable time frame. In the full-scale biotrickling filter, a small flow of water containing nutrients is recycled intermittently over the support. The pattern adopted in this case was sprinkling 5 to 15 minutes every hour. Thus, in a sense, this biotrickling filter was operated as a biofilter for most of the time. The reactor was remote controlled from an operator room via a modem. The characteristics of the system are reported in Table 8.

Start-up of the full-scale biotrickling filter required a two-month acclimation period, after which odor removal was continuously higher than 90%. Typical inlet and outlet odor levels were 5,400 and 400 odor units, respectively, and removal was consistently more than 90%. Because of the low pollutant loadings and the limited supply of nutrients, clogging of the filter bed was not an issue. The pressure drop was low and stable around 2 to 4 cm of water gauge.

Odor and VOC Treatment at a Naval Air Station

As part of a technology development or technology demonstration program, Envirogen, Inc. operated a small pilot biotrickling filter and then designed a full-scale biotrickling filter for the removal of low concentrations of VOCs from contaminated air vented from wastewater treatment tanks (28). The contaminants

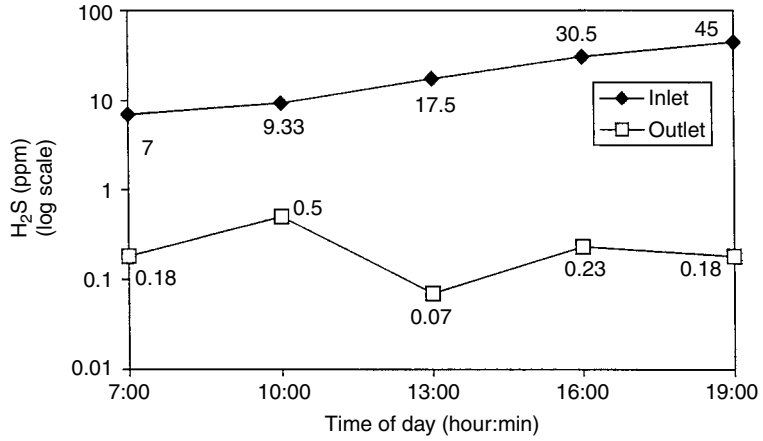

Figure 6. Typical performance of H_2S removal in the biotrickling filter. Note the fluctuating inlet concentration during the day (7 to 45 ppm). The labels show the measured H_2S concentrations in ppm_v.

Table 7. Characteristics of the Biocyd Celorey Biotrickling Filter

Owner and location	Grupo Cydsa S.A. de C.V. Ruiz Cortines Cydsa Industrial Complex, Celorey plant. Monterrey, NL. Mexico
Builder	DICOTEC (Design and Construction), a subsidiary of the Environmental Division of Grupo Cydsa.
Type of airstream	Exhaust air from a cellophane plant (viscose process).
Year of installation	1994
Packing type and volume	51 m^3 of PVC structured packing. Each layer is composed of a series of corrugated PVC sheets hot-welded together at an angle.
Height and number of layers of packing	Two sections of 2.44-m high on top of each other, separated by a 1-m air plenum. Each section is composed of 8 layers of corrugated PVC.
Biotrickling filter construction type	Cylindrical shape of 3.66-m diameter and 11.5-m total height. The bottom 3 m is used for waste gas distribution, for the foundation, and as a liquid reservoir; there is a 1 m of air plenum between the two beds and 2.5 m of space for water distribution an air exhaust above the top bed. The vessel is constructed of fiberglass reinforced plastic (FRP) that is coated on the inside and the outside with resin.
Airflow rate	Waste air from four production lines (viscose process), total flow of 44,200 $m^3\,h^{-1}$ (26,000 cfm), upflow
Empty bed residence time	4–10 seconds
Pressure drop	10 cm of water gauge of total pressure drop. 25 cm of water gauge when the maximum elimination capacity is reached.
Average bed temperature	18–34 °C
Pollutants treated	Carbon disulfide: 35–100 $mg\,m^{-3}$; hydrogen sulfide: 85–213 $mg\,m^{-3}$ (60–155 ppm_v)
Biotrickling filter controls	Continuous monitoring (gas flow rate, recycle liquid temperature, pressure drop, recycle flow rate and pH), no automatic control is performed, except for pH, which is maintained between 4 and 5 by the addition of a slurry of magnesium hydroxide.
Biotrickling filter design and acceptance criterion	The biotrickling filter was designed for odor control. Most of the odor comes from hydrogen sulfide, so the biotrickling filter was designed for 90% removal efficiency for hydrogen sulfide. There was a design criterion for carbon disulfide removal.
Approximate investment costs	$525,000
Approximate treatment cost per 1,000 m^3 off-gas treated	Yearly electricity and chemical costs are about $43,000; various indirect costs (personnel, various equipment maintenance) are $20,000. Total is $63,000 per year or about $0.18 per 1,000 m^3 of off-gas treated
Typical performance	Hydrogen sulfide is easy to degrade, and usual hydrogen sulphide removal efficiencies are in the range of 85–99%. Carbon disulfide–removal efficiency depends on the concentration of hydrogen sulfide. When the concentration of hydrogen sulfide is low, i.e., in the range of 100–150 $mg\,m^{-3}$, good removal of carbon disulfide is observed. At higher hydrogen sulphide concentrations, the removal of carbon disulfide decreases. Usually, carbon disulfide removal ranges from 40 to 70%. The combined elimination capacity for hydrogen sulfide and carbon disulfide is usually around 310 $g\,m^{-3}\,h^{-1}$

Table 8. Characteristics of the Reemtsma Biotrickling Filter

Owner and location	Reemtsma, Berlin, Germany
Builder	M + W Zander Facility Engineering GmbH, Nürnberg, Germany
Type of airstream	Cigarette production off-gas, odor treatment
Year of installation	1995
Packing type and volume	Polyurethane foam (cubes of 4 cm), total volume: 500 m^3.
Height and number of layers of packing	1 layer, 2.5-m high
Biotrickling filter construction type	6 container units.
Airflow rate	160,000 $m^3\,h^{-1}$, downflow
Empty bed residence time	11 seconds
Pressure drop	2–4 cm water gauge
Average bed temperature	40 °C
Pollutants treated	Odors: 800–1,200 OU.
Biotrickling filter controls	Continuous monitoring of temperature and pressure drop, water level is controlled.
Biotrickling filter design and acceptance criterion	90% odor removal or outlet air odor lower than 100 OU.
Approximate investment costs	4.3 million DM (1995, approximately $3.05 m) including ductwork cooling towers and heat exchangers.
Approximate treatment cost per 1,000 m^3 off-gas treated	Operating costs of 160,000DM per year ($93,000 per yr), i.e., 0.114 DM per 1,000 m^3 of off-gas treated (1997, $0.066 per 1,000$m^3$ of off-gas treated)
Typical performance	>90% odor removal

of concern were common volatile paint solvents (ranging individually from 7 to 520 ppm_v), together with low concentrations (1–2 ppm_v) of H_2S resulting from sulfate reduction by anaerobic bacteria in the water tanks. The total VOC concentration in the air has relatively large fluctuations over the day, typically from 150 to 350 ppm_v (as methane equivalents).

The biotrickling filter design consisted of both air and water downflow operation through two media beds in series. A computer and various data loggers were

Table 9. Characteristics of the North Island Naval Air Station Biotrickling Filter

Owner and location	Naval Air Station-North Island (San Diego, CA)
Builder	Envirogen, Inc. (Lawrenceville, NJ)
Type of airstream	Effluent from industrial and oily wastewater treatment tanks
Year of installation	1999
Medium type, and volume of¡w¿medium	Random, dump packing. Approximately 31 m^3 (1,100 ft^3).
Height and number of layers of medium	Two beds in series, each 2.1 m (7 ft.) in height. Air is downward flow.
Biotrickling filter construction type	3.0 m (10 ft.) in diameter, 9.0 m (30 ft.) tall, cylindrical in shape, cast in fiberglass resin polymer.
Airflow rate	2,970 $m^3\,h^{-1}$ (1,750 scfm)
Empty bed residence time	37 seconds
Pressure drop	12.7 cm (5 inches) total of water column across both beds
Average bed temperature	18–27°C (65–80 °F) for recirculating water phase
Pollutants treated	Total sulfur compounds: 1–3 mg sulfur m^{-3} Total organic compounds: 75–175 mg carbon m^{-3} Identified compounds were hydrogen sulfide, benzene, toluene, xylene, trimethylbenzenes, acetone, methyl ethyl ketone, methyl isobutyl ketone, methylene chloride, heptane, cyclohexane, and numerous other aliphatics at lower concentrations
Biotrickling filter controls	Continuous monitoring of air and water flow, air and water temperature, pressure drop, and pH. All data is logged into a PLC for trend analysis. System conditions are monitored through the PLC. The PLC terminates system operation when alarm conditions occur (i.e. low airflow)
Biotrickling filter design and acceptance criterion	Design based on pilot-test studies on a site treating similar compounds, acceptance criterion: 80% removal of odor-producing compounds
Approximate investment costs	Not available
Approximate treatment cost per 1,000 m^3 of off-gas treated	Costs for water and chemicals were estimated at about $5,000 per year, i.e., $0.19 per 1,000 m^3 of off-gas treated. Electricity and maintenance costs were not available¡w¿but were estimated to be similar to those of a carbon adsorption system that would otherwise be used if the biotrickling filter was not available.
Typical performance	Greater than 99% removal of hydrogen sulfide Greater than 90% removal of aromatics Greater than 95% removal of ketones

used to monitor and control the reactor's operation (Table 9). The liquid recirculation rate was kept manually constant using butterfly valves. Approximately 230 to 380 L (60–100 gallons) of recycle liquid was removed from the system daily by a timer on a discharge valve located at the bottom of the reactor. Fresh water and nutrients were added automatically when the water level inside the system dropped below a specified height. The pH was controlled automatically. At reactor start-up and during initial operation, a large quantity of commercial microorganisms, cultured microbes from an in-house laboratory, and some activated sludge were used to inoculate the system. Which inoculum source proved to be most efficient is not known.

CONCLUSION

There is no doubt that reducing pollutant emissions at the source should always be attempted. However, zero emission is not always technically or economically feasible. For many of these cases, end-of-pipe treatment in biotrickling filters appears to be a promising alternative to conventional treatment technology. It is effective, environmentally friendly, and does not have many of the drawbacks of conventional treatment technologies. The field of biotrickling filtration is maturing. The number of full-scale biotrickling filters is rapidly increasing, and continuous research helps understand the fundamental principles of biotrickling filters. All together, this speaks for a rapid increase in the use of biotrickling filters in the twenty-first century.

BOTTLED WATER, MICROBIOLOGY OF

FRED A. ROSENBERG
California Lutheran University
Thousand Oaks, California

"In all advanced ancient cultures water, especially running water, was associated with mythological ideas. Water was worshipped as a life-giving fluid of particular efficacy. Even in these days the Kastalia spring at Delphi is said to donate health and beauty to a great age. Both in religious thinking and in natural philosophy, water plays an important role. The spring is invariably the place of mysterious birth" (1). Since the majority of individuals no longer obtain their water at the source, the bottling process has replaced the journey to the spring. By 1999, bottled water sales in the United States alone exceeded 5.2 billion. Worldwide, the industry accounted for 35 billions in sales (2). In the United States, 54% of Americans regularly drink bottled water, although the cost of drinking bottled rather than tap water may be anywhere from 240 to 10,000 times more per gallon (3).

WHY DO PEOPLE DRINK BOTTLED WATER?

Many people drink bottled water because they are concerned about the quality of their tap water. In developing countries, the lack of quality-controlled tap water has led to the substitution of bottled water. Other individuals prefer the taste of bottled water to that of tap water. In general, bottled water drinkers believe that the water they drink, when compared with tap water, is free of microbes. This is, however, a misconception. Source springs are associated with soil formations, and the latter contain indigenous bacteria. The numbers of these organisms may be minimal, but they have the ability to proliferate during storage, that is, once the water has been bottled.

WHERE DOES BOTTLED WATER COME FROM?

Many of the older European springs that have served as source waters for hundreds (if not thousands) of years tend to have their distinct bacterial flora. In fact, Frenchmen have been known to believe that the taste of specific waters is dependent on the types of "normal" bacteria present, much as is the case with cheeses. Much of the bottled water that is purchased in the United States does not, however, come from springs. Springwater may be

defined as water that flows naturally to the surface of the earth from an approved underground source. Many bottlers obtain their water from boreholes, which may or may not be located in the proximity of natural springs, but which are actually wells dug into the ground. Twenty-five to 40% of bottled water is actually bottled tap water from municipal sources, which may or may not be subjected to additional treatment. Bottled municipal water actually has the added advantage of being regulated by the Environmental Protection Agency (EPA), as well as by the Food and Drug Administration (FDA). If any of these sources becomes contaminated, or if potential pathogens enter the water during the manufacturing process, the product has the potential of causing illness in the user. Although, with one exception (4,5), bottled water has not been implicated in confirmed outbreaks of disease, it is unlikely that incidents of gastroenteritis or related illnesses would tend to be reported by the consumer or be attributed to the water.

REGULATION OF BOTTLED WATER

In the United States bottled water is considered to be a food product and, as such, is regulated by the FDA. The quality of tap water, on the other hand, is overseen by the EPA. The rationale for this arrangement is mandated by the fact that bottled water may be purchased by choice, whereas access to tap water is a right, if not a requirement. EPA tap water regulations are identical in all states. FDA Regulations cover only bottled water sold in interstate commerce, so that unless a state has adopted its own standards and regulatory procedures, bottled water sold in-state may be totally unregulated. FDA rules also exempt many types of what the consumer would consider "bottled water," to wit, those labeled as "water," "carbonated water," "disinfected water," "filtered water," "seltzer water," "sparkling water," or "soda water." These are not considered "bottled water" by the FDA.

In the United States, microbial standards are based on total coliforms and the presence of either *Escherichia coli* or fecal coliforms. Coliform bacteria are referred to as "indicator" organisms since they indicate the presence of fecal contamination and thus the possible presence of pathogenic organisms, which may cause intestinal disease, although they themselves may not be disease producing.

There are other organisms that fall within the classification of "coliforms" as this type of organism is classified by biochemical tests. These may originate from the soil, rather than from the intestinal tract of humans or other warm-blooded animals. For this reason a differentiation is made between *E. coli* (which is a coliform organism characteristically found in the intestinal tract) and fecal coliforms, as opposed to coliforms in general. The EPA Tap Water standards do not allow for the presence of *E. coli* or fecal coliforms in drinking water. FDA standards, on the other hand, note that up to 1 of 10 bottles tested may contain one per 100 mL by the membrane filter technique of any type of coliform (6).

Coliforms have been used as indicators of water quality in the United States since the early twentieth century. They are correlated neither with the presence of certain viruses nor with *Giardia* or *Cryptosporidium*, which are waterborne intestinal parasites. In the United States "bottled water" is typically a flat water that may originate from a number of different sources. In Europe, individuals tend to drink *mineral water*. European regulations for these waters are considerably stricter than those promulgated by the FDA. In the United States mineral water is defined as "bottled water containing not less than 250 ppm total dissolved solids, coming from a source tapped at one or more boreholes or springs, and originating from a geologically and physically protected underground water source. Mineral water is distinguished from other types of water by its constant level and relative proportions of minerals and trace elements at the point of emergence from the source. No minerals may be added to this water" (7). There are few true mineral water springs in the United States. In the European Union (EU), mineral water typically comes from well-known springs that have, in some cases, been used since Roman days. The water must be officially approved. No disinfectant of any type may be added to the water for the removal of microorganisms (6). The EU regulations stipulate that, at the source, natural mineral water must be free of disease-producing organisms. This includes the total absence, in 250 mL samples of the water, of *E. coli*, coliforms, fecal streptococci, or *Pseudomonas aeruginosa*. Moreover, 50 mL samples may not contain sulfite-reducing, spore-forming anaerobic organisms (8). The normal habitat of fecal streptococci is the gut of humans and animals. *Pseudomonas aeruginosa* is an opportunistic pathogen, that is, although it is generally not pathogenic for a healthy population, it is typically problematic in immunocompromised patients. It has been shown responsible for the deaths of infants drinking water contaminated with the organism (9), although an effect of this severity is not typical. The organism is included in the microbial standards because it typically indicates contamination occurring somewhere during the bottling process. Spore-forming anaerobes are also common inhabitants of the intestinal tract, which on their elimination from the host, have the ability to produce spores, or protective structures, allowing for a long-term resting stage.

EU mineral water regulations also impose strict limitations on the number of colonies (populations of bacteria arising from a single cell) of normally-occurring springwater organisms present at the source and after bottling. Specifically, at source, water may contain no more than 20 colonies/ml when incubated for 72 hours at 20 to 22 °C and 5 colonies/ml when incubated for 24 hours at 37 °C. After bottling, the total colony count may not exceed 100 colonies/ml when incubated at 20 to 22 °C and 20 colonies/ml if incubated at 37 °C for 24 hours. Total colony count must be determined within 12 hours after bottling, with the water being maintained at 3 to 5 °C during this period (8).

GROWTH MEDIA FOR BACTERIA IN BOTTLED WATER

The twentieth edition of *Standard Methods for the Examination of Water and WasteWater* (10) defines

bacterial plate-count procedures for water, including the membrane filter technique, which allows for sampling volumes of water greater than 1 ml. It permits the use of a nutrient medium specific for the growth of organisms in the presence of low concentrations of organic matter. This is the so-called R2A medium, developed by Reasoner and Geldreich (11). The medium is specifically devised to allow for the growth of organisms that are oligotrophic or require only minimal amounts of organic matter. Heterotrophic plate count (HPC) measures those organisms that are normally found in springwaters. It is also used to quantify bacteria in the finished product and to determine the increase in numbers after bottling. There is no definitive limit placed on the numbers of HPC organisms in bottled waters, although suggested limits are generally on the order of not more than 500 per milliliter, which is in accordance with EPA limits. Individual states may set their own guidelines. Rhode Island, for example, had set a limit of 200 organisms/ml, which was subsequently dropped since it was legally unenforceable. Concern about high numbers of HPC organisms is based on the possibility of their masking disease-producing microbes in the water as well as indicating a problematic source water or contamination during the bottling process. In the United States, where disinfection is permitted, HPC may also indicate the effectiveness of the agent used and its extended effectiveness in the bottle. In the European Union, no disinfection is permitted.

TYPES OF BACTERIA NORMALLY FOUND IN SOURCE WATERS

Waters derived from springs typically contain a low number of autochthonous, or indigenous, organisms. These are generally gram-negative and capable of existing in environments with low nutrient levels, such as are characteristic of spring waters. Their origin is undoubtedly associated with the substrata from which the water arises. Most studies describing the qualitative presence of these organisms have concerned themselves with European mineral waters. Typically found are the group of organisms classified as pseudomonads. These bacteria are distributed through a number of different genera. They are widespread in nature, being found in soil and water environments, and are known for their ability to use an unusually large number of nutrient sources, many in trace quantities. Most of them are harmless, but a few are opportunistic pathogens, a term denoting the ability to cause problems in immunocompromised individuals. *Pseudomonas aeruginosa*, which can infect almost any body site, is one of the most problematic of the pseudomonads. It is rarely found in protected spring waters, rather being an indicator of contamination occurring from colonized equipment in the bottling plant or from plant personnel. The organism is not regulated in bottled waters in the United States, although concern has been raised as to its presence in waters used for mixing baby formula (see *Pseudomonas*, this Encyclopedia).

Many other organisms are normally found in spring waters. These include species of *Acinetobacter*, *Achromobacter*, *Flavobacterium*, *Alcaligenes*, and other usually gram-negative species (12–14). Typically, springs tend to have their own characteristic autochthonous flora. These organisms are present in typically minimal numbers at the source and do not present a problem to healthy individuals. The presence of allochthonous, or nonindigenous organisms, often indicates some type of problem, either during the manufacturing process or from a contaminated source. An unusual increase in the HPC count of source water also indicates grounds for concern. Schindler (15) reported the presence of noncoliform enterobacteriaceae in 41 of 54 manufacturing facilities that had hygienic problems and recommended the use of these organisms as a quality criterion for bottled mineral, spring, and table waters. Enterobacteriaceae are typically found in the intestinal tract of humans and other animals, although some are soil microorganisms.

TREATMENT OF WATER

Source water in the European Community may not be treated in any manner in order to remove microorganisms (8). For this reason, the purity of the source is of primary concern. In the United States, where bottled water may come from a variety of different sources, the water is typically treated in some manner to remove or decrease the number of organisms present. In the case of waters taken from municipal sources, that is, identical to tap water, chlorination has usually preceded other treatment and will have removed a large portion of the microbial population present. Water from springs and wells is not usually chlorinated and this fact is often used in marketing bottled water. The water may be filtered to remove small particles and/or bacteria.

In general, disinfection is accomplished through the use of ultraviolet irradiation and/or ozonation. Ultraviolet irradiation at wavelengths between 220 and 300 nm is effective primarily during multiplication and acts by forming dimers, or covalent bonds, among thymine molecules in the DNA of the organism. Resistant forms, such as bacterial spores, are minimally affected by this type of disinfection. Since glass and plastic containers are impervious to ultraviolet irradiation, disinfection of bulk waters, before bottling, may result in incomplete killing of organisms present, with subsequent regrowth within the container. Ozonation makes use of the principle that O_3, an unstable form of oxygen, acts as a strong oxidizing agent. In this regard its action in water is similar to that of chlorine, except that, whereas chlorination usually leaves a residual in the finished product, ozone, because it is unstable, decomposes quickly, leaving no residue. It is expensive and, as with ultraviolet irradiation, does not result in sterility, but it has the advantage of leaving no chemical taste in the treated water. Reverse osmosis, or hyperfiltration, is used to purify water by removing bacteria, salts, and other constituents having a molecular weight larger than 150 to 250 daltons. The water is pushed through a semi-permeable membrane, usually with the aid of a pumping mechanism. Contaminants are retained by the membrane and do not pass across it. A cleaning cycle, or backwash, programmed into the operation of the process, prevents a buildup of contaminants, which would

require increased pressure to force the water across the membrane.

In the absence of proper maintenance of plant equipment, bacteria may colonize membranes, filtration units, distribution lines, and other equipment, or contamination may occur through human error.

NOMENCLATURE OF WATERS

Labeling of water as other than "bottled" may result from various treatment methodologies. "Demineralized water" or "Purified Water" may be produced through distillation, demineralization, or reverse osmosis. "Sparkling waters" contain carbon dioxide, either from the spring or added during treatment. "Deionized water" is defined as water from which both anions and cations have been removed by an ion exchange process. "Distilled Water" is defined as water that has been purified by passage through an evaporation-condensation cycle. It may contain small amounts of dissolved solids.

BACTERIA IN THE FINISHED PRODUCT

Once water is bottled, unless it is sterile, quantitative changes appear in the microbial population. (Sterile water, such as that used for injection, is totally free of microorganisms, the latter having been removed by heat treatment or filtration.) Depending on the type and amount of organic matter present in the water, those bacteria present will begin to use the nutrients available to them (see Assimilable Organic Carbon (AOC) in Treated Water: Determination and Significance, this Encyclopedia). As noted previously, the organic content of bottled waters is usually low, and those organisms best adapted to living under these conditions will be at an advantage. In 1940, Heukelekian and Heller (16) showed that bacteria tend to attach to the walls of containers. Bacteria may live suspended in an aqueous environment, but it is much more economical for the organisms to utilize the nutrients in the water as they "flow by" than to have to utilize energy in moving through the liquid to reach the food sources. The attachment of bacteria to surfaces is generally referred to as biofilm formation. In either case, as suspended organisms or being attached to the sides of the container, bacteria will proliferate shortly after the container has been filled (17,18). At room temperature, it will take only a few days for the suspended organisms to reach concentrations as high as 10^4 to 10^5/ml. As the organic matter is depleted, the organisms will slowly begin to die-off, remaining viable for a period of months, with the more hardy forms utilizing the breakdown products from those no longer viable (19). Under conditions of refrigeration, there is a lag in multiplication, but organisms remain in the water for longer periods. However, their numbers do not reach those found in room-temperature stored containers (20). In contrast, tap water does not remain in a static state for extended periods since bacteria are flushed through the pipes whenever the faucet is turned on.

Heilwasser, or water from "Heilquellen" is the name given to water from springs with allegedly health-giving or curative properties, and is a product commonly sold in Europe. These waters may come from "heilquellen" or springs, which are rich in certain minerals. Heilwasser is usually recommended for treatment of various ailments including urinary, heart, and kidney disorders. Thus, immunocompromised individuals may be exposed to greater numbers of organisms than are typically found in other mineral waters (12).

PLASTIC AND GLASS CONTAINERS

All types of materials have been found to serve as solid substrates for bacterial attachment and biofilm formation. Mackenzie (21) used an agar-overlay method to determine adherence of *Staphylococcus epidermidis*, a common organism found on human skin, to polystyrene, polyvinyl chloride, polyethylene, and polytetrafluoroethylene, compounds often used in the manufacture of plastic containers for bottled water. Hamilton and Rosenberg (22) used an agar-overlay dye method as well as scanning electron microscopy to characterize the attachment of bacteria found in polyethylene bottled water containers obtained from the shelves of grocery stores. After storage at room temperature, containers of water with low initial bacterial counts (100 or less per ml. of water) were found to develop increasing levels of biofilm. Only low levels of attached bacteria were observed on containers stored under refrigeration.

Bottled water in plastic containers has been shown to contain higher numbers of bacteria than water in glass bottles (12,14,23,24). This may be due to nutrient release from materials in the container, as well as diffusion of oxygen through the thin container walls. Glass bottles tend to be reusable and are well cleaned before being refilled. Plastic containers may be produced in the bottling plant using an extrusion process, but are more often purchased from vendors. The caps for containers may come from other sources and lack of sterility may introduce organisms into the water when the containers are shaken or during transport by the consumer (25).

SHELF STORAGE

Many bottlers place an expiration date on the bottled water containers. This is often two years after bottling. From a microbiological standpoint, this makes little sense since most users of bottled water drink the product shortly after purchase when the numbers of bacteria tend to be highest. Multiplication of bacteria during early storage, that is, within a few days following bottling, may rapidly increase the number of organisms to a point where they exceed the regulatory limitations placed on water at the source, or within 12 hours of bottling. Water may adhere to EPA standards, or the more stringent European Union standards, when taken from a source, or immediately after the bottling process. Storage on the grocery shelf (without refrigeration), or at home, may increase the heterotrophic plate-count to as high as 10^5 or 10^6 CFU/ml (26). The bottler may have fulfilled his obligation in adhering to standards and thus cannot be held responsible

for bacterial multiplication "downstream." Naturally occurring organisms present little risk to the healthy individual under these conditions (27), but opportunistic organisms present in minuscule amounts in the source water may nevertheless multiply to numbers capable of producing potential problems in immunocompromised individuals.

PSEUDOMONADS IN BOTTLED WATER

The group of bacteria known as pseudomonads, which are commonly found in source waters, and thus in the finished product include opportunistic species capable of initiating nosocomial infections. *Pseudomonas aeruginosa* is known as the most prevalent *Pseudomonas* species in human disease. It is rarely found in pure spring waters and is usually considered to be associated with contamination during the bottling process. It can be considered a reliable indicator of manufacturing problems, although it has not been accepted as such in the United States. Other countries such as the European Union and Canada have recognized its importance and adopted stringent regulations concerning its presence. Pseudomonads have been shown to survive and multiply in bottled water for extensive periods. The fact that they require such miniscule amounts of organic matter and their potential to use breakdown products from other organisms in the water contribute to their longevity (28–30). *Burkholderia cepacia* and *Stenotrophomonas maltophilia* are commonly found in source waters. These organisms have been considered of particular concern to immunocompromised individuals (31,32). Their ability to grow on minute traces of carbon sources, including adhesives found in bottle cap-liners, contributes to their ubiquitous presence.

ANTIBIOTIC RESISTANCE OF PSEUDOMONADS

Pseudomonads are also known to be resistant to many of the commonly used antimicrobials. In a study of German mineral waters, Rosenberg and Hernandez-Duquino confirmed the resistance of pseudomonads associated with nosocomial infections to a variety of commonly used antibiotics. Of 12 antibiotics studied, the highest resistance among 81 organisms of 9 different species isolated was to cephalothin, ampicillin, and carbenicillin, in that order. Only one organism was resistant to tobramycin, and four to kanamycin and trimethoprim-sulfamethoxazole (12). In results obtained from studies in Greece, multiple-linked resistance was found to chloramphenicol, tetracycline, erythromycin, and nalidixic acid. *Pseudomonas aeruginosa* and *Pseudomonas stutzeri* were susceptible to the newer antibiotics such as ceftazidime and ciprofloxacin. *Stenotrophomonas maltophilia* showed the highest resistance (69.2%) to these newer antibiotics (33). In an Italian study, greatest resistance was found to nalidixic acid (34).

CARBONATED AND NONCARBONATED WATER

In 1974, during a cholera outbreak in Portugal, a strain of the bacterium *Vibrio cholerae* was isolated from two springs supplying mineral water to a commercial bottling plant in the Lisbon area (5). Seepage into a limestone aquifer was apparently responsible for the contamination. An investigation showed that cases of the disease occurred in individuals who ingested noncarbonated mineral water from the spring, whereas no cholera cases occurred in those who drank carbonated mineral water. In the case of *V. cholerae*, the organism is able to survive for less than a day in carbonated water (35), and prefers and tolerates conditions of high alkalinity. Several studies have characterized the sequence of bacterial growth in bottled uncarbonated mineral water. Morais and daCosta (36) noted an increase from low numbers to 10^4 to 10^5 CFU/ml within a few days after bottling, with fairly constant numbers remaining for a period of a year when incubated at 22 C. Gonzalez and coworkers (37) showed an increase from an initial population of 10^1 to 10^2 CFU/ml to 10^5 to 10^6 CFU/ml within three days storage. Similar results were shown by Rosenberg and coworkers. In this study, bottled water at room temperature and under refrigeration was sampled weekly over a period of six weeks. The increase in numbers of organisms at room temperature was basically identical to that shown in the study by Gonzalez and coworkers, with numbers beginning to decrease after six weeks storage. Where water was refrigerated, bacterial counts eventually reached those of nonrefrigerated waters, though this did not occur for about three weeks, and the decrease in numbers was prolonged over a period of several months (20). In their studies on German mineral waters, Rosenberg and Hernandez Duquino (12) showed that water in plastic containers, which typically has no carbon dioxide added, generally showed considerably higher counts of bacteria than that in glass containers with indigenous or added carbon dioxide. Noncarbonated waters are usually bottled in plastic, whereas carbonated waters require bottling in glass as well as screw caps to maintain carbonation.

ARTIFICIAL INOCULATION OF WATERS WITH BACTERIA

Several studies have measured the survival of pathogens in bottled water by inoculation. Warburton and coworkers (38) reported on the viability of *E. coli* O157:H7, a strain causing hemolytic uremic syndrome. Low levels of the organism (about 100 CFU/ml) were inoculated into mineral water and were shown to survive for up to >300 days at room temperature. Kerr and coworkers (39) terminated their experiment after 42 days, at which time the organism was still viable in natural, noncarbonated mineral water.

The artificial addition of organisms to a bottled water cannot be compared to the microbial flora and characteristics of natural spring or bottled waters. The equilibrium existing in such waters is bound to be upset by the intentional addition of a relatively large numbers of potentially pathogenic allochthonous species. Nevertheless, such studies show that bottled water will sustain the presence of medically important organisms and that frequent analyses and stringent regulations are of prime importance in maintaining the health of the consumer.

AEROMONAS SP.

Aeromonas sp. may be found in environmental water sources and are capable of causing diarrhea. Brandi and coworkers (40) noted the ability of *Aeromonas* spp. to remain viable for longer than 100 days in mineral water. However, neither Hunter (41) nor Massa (42) isolated *Aeromonas* spp. from natural mineral water in England or Italy. The Scientific Committee on Food, in an opinion given to the European Commission on March 19, 1998, concluded that "*Aeromonas hydrophila* and *Aeromonas caviae* in natural mineral water do not present a potential risk to human health" and that limits for these organisms cannot be justified (43). The U.S.EPA, on the other hand, has listed *Aeromonas* as a potential candidate for further regulatory consideration in drinking water.

VIABILITY OF BACTERIA WITHOUT MULTIPLICATION

Bacteria are capable of surviving in aqueous environments under conditions where multiplication does not occur. These organisms are referred to as being "viable but nonculturable." The induction of protective mechanisms allows the organism to enter a latent stage (see VIABLE BUT NOT CULTURABLE (VBNC) MICROORGANISMS, this Encyclopedia). This may occur under conditions of low nutrient concentration such as are found in bottled water. Plating on nutrient-poor media, such as those used to quantify HPC organisms, or on selective media that may contain toxic dyes or other substances, may prevent growth and thus, identification of these organisms. Typically these organisms are allochthonous, or foreign to the water source.

ISOLATION OF AMOEBAE FROM MINERAL WATERS

Free-living amoebae were isolated from Brazilian mineral water by Salazar and coworkers (44). A study from Mexico (45) describes the isolation, from the three best-selling brands of mineral water in the country, of *Naegleria* and *Acanthamoeba*, amoeba including species that have been associated with fatalities in humans. *Mycobacterium* and *Legionella* species also have the ability to replicate within *Acanthamoeba*.

FLUORIDE IN BOTTLED WATER

When municipal waters are used for bottling purposes, the presence of fluoride is generally equivalent to that found in tap water supplies from the same source. However, in the case of springs and other aquifers, fluoride is not usually added to the final product. The question of whether bottled waters may not give the same protection from cavities as treated municipal waters has been raised by members of the dental profession (46). In an Ohio study, Lalumandier and Ayers determined the fluoride content of fifty- seven samples of bottled waters and determined that only 5% of these samples, as compared to 100% of Ohio tap waters, fell within the required fluoride range recommended by the state (47).

BOTTLED WATER DISPENSERS

Many grocery stores sell water through "water dispensers" where customers bring their own bottles and purchase water from a machine dispenser. Potential problems include the lack of thorough rinsing of reusable containers used by the consumer and the proliferation of bacteria in the dispenser apparatus itself.

Water dispensers in offices, theaters, and other locales have become extremely popular in the United States. Most of these units dispense cold water, although some dispense hot water for tea and coffee as well. The carboys, often made of polycarbonate, usually contain five liters of water, identical to that sold in bottles by the distributor. Thus, the bacterial flora and its growth within the carboy are similar to that found in bottled water. The carboy is placed within the dispenser and rests on the neck of the bottle within a reservoir (Fig. 1). As water is removed for use, the reservoir is replenished by additional water flowing from the carboy. Bacteria attach to the walls of the reservoir and utilize organic matter present in the water that flows by. It has been shown that the greater the number of individuals in offices using water from dispensers, the higher the number of organisms present. 10^5 to 10^6 organisms/ml were routinely found in several dispensers. This is apparently due to the replenishment of organic matter from new bottles and subsequent growth of organisms attached to the reservoir walls within the unit (48). Proper cleaning of the units with a bleach solution will remove the bacterial biofilm.

USE OF BOTTLED WATER FOR CLEANING CONTACT LENSES

The use of bottled water for use with contact lenses is not recommended due to the presence of potential ocular pathogens (49). Coliforms, amoeba, and fungi, *P. aeruginosa*, and a variety of other potential pathogens were isolated from spring, drinking, and glacier bottled waters tested.

The lack of sterility allows for contamination of contact lenses following only brief exposure.

ENDOTOXIN IN BOTTLED WATER

When gram-negative bacteria die off the lysis of their cell walls results in the formation of endotoxins. The most important clinical effects are fever and shock, which result from the presence of endotoxins within the bloodstream of the host. The presence of endotoxins in bottled waters is not uncommon, due to the numbers of bacteria present in the water itself and attached to the sides of the container. Endotoxin can easily be detected using an assay using material from the horseshoe crab, *Limulus polyphemus*. Caramello and coworkers detected endotoxin levels higher than 0.5 ng/ml in 40 of 44 mineral water samples (50). Borders and Rosenberg (51) showed that endotoxin readily attached to bottled water container surfaces, approximately ten times as much attaching to the bottom of containers as to the sides. Potentially, diarrhea can result from endotoxin in bottled waters.

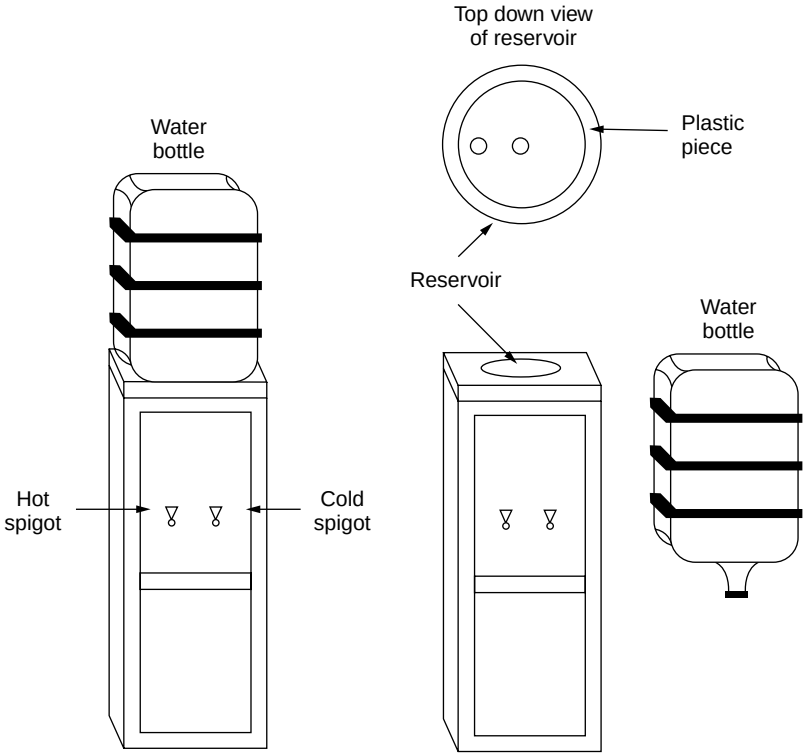

Figure 1. View of typical bottled water dispenser.

NEW TECHNIQUES IN BOTTLED WATER MICROBIOLOGY

A number of newer techniques have been adapted to determine the quantitative and qualitative characteristics of bacteria in bottled and mineral waters. Guillot and Leclerc (52), utilizing ribosomal RNA gene restriction patterns, showed a distinct specificity of bacteria isolated from four brands of French mineral water tested from the bottling lines of the companies, with few common patterns among springs. *Pseudomonas* sp. were shown to be the predominant culturable bacteria present.

The authors noted that only about ten percent of the bacteria present could be cultured on bacteriological media commonly used to grow mineral water isolates.

Using a LIVE/DEAD BAc Light™ VIABILITY kit, together with epifluorescence microscopy, Defives and coworkers (53) measured the variation in bacteria present in French mineral water taken directly from the spring. Viable but noncultivable bacteria were estimated by taking the difference between viable and viable culturable counts. Numbers of organisms increased from less than 10/ml., with only 20 to 30% of these being culturable on R2A medium, to approximately 3×10^5/ml after six days postbottling, and subsequently stabilized. Again, the majority of isolates belonged to the pseudomonads. Bottling stress and low amounts of organic material resulted in bacteria changing into the viable but nonculturable state.

The Food and Drug Administration has often considered the cost to the bottler of testing for *P. aeruginosa* as one of the reasons for not adapting this organism as an indicator of contamination, as is the case in Europe and Canada. A new methodology, using nucleic acid probes, has shown that a specificity of 100% for the identification of *P. aeruginosa* can be obtained by use of soybean peroxidase-labeled peptide nucleic acid probes, which are targeted to a species-specific sequence in the ribosomal RNA of the organism. The bacteria are identified directly on the membrane filter used to filter the sample (54).

Many viruses can be tested for in bottled water using the reverse transcription-polymerase chain reaction. An example is the Norwalk virus, a calicivirus (single-stranded RNA) that has been shown to cause diarrheal disease together with other systemic symptoms. It is the major cause of nonbacterial gastroenteritis in the United States and obtained its name during one of the first reported outbreaks, in Norwalk, Ohio, in 1969. Norwalk-like virus sequences were detected in 21 mineral waters imported into, or bottled, in Switzerland (55). The authors note that they are unaware of epidemics due to contaminated mineral water having been reported, but the possibility of nonreported individual cases cannot be disproved.

CAMPYLOBACTER JEJUNI AND OTHER ENTERIC *CAMPYLOBACTER*

SIMON F. PARK
University of Surrey
Guildford, United Kingdom

The members of the genus *Campylobacter* cause a wide spectrum of infections in both humans and animals, including gastroenteritis, systemic disease, and reproductive disorders in domestic animals. The organisms can be isolated from a wide variety of environments, including surface water, foods, and the intestinal tract of various animals and are accordingly considered to be among the most ubiquitous bacterial pathogens known to man. The remarkable prevalence of campylobacters makes them important from both clinical and economical perspectives. *Campylobacter jejuni*, in particular, is widely distributed in the intestinal tract of poultry, livestock, and warm-blooded domestic animals and is the leading cause of bacterial food-borne diarrheal disease throughout the world. In the United States alone this organism has a 4 to 35% isolation rate in patients with acute gastroenteritis (1). Given the high carriage rate of campylobacters in domestic and wild animals, large numbers of these organisms are continually excreted into the environment. As a consequence, the environment plays an important role in maintaining the contamination cycle of these pathogens. The following discussion focuses specifically on the major enteric pathogens of the *Campylobacter* genus, which are *C. jejuni* and *C. coli*. In addition, particular emphasis is given to the ability of these pathogens to persist in the environment and the role that the environment plays in promoting their contamination cycle.

GENERAL ASPECTS OF *CAMPYLOBACTER* AND *CAMPYLOBACTER JEJUNI*

Historical Perspective

The current impact of *Campylobacter* species on human health is indisputable, and currently they are considered to be among the most ubiquitous pathogens known to man. Compared with other bacterial pathogens, however, their association with human disease has been established only relatively recently. *Campylobacter*-like bacteria were first described in 1913 but were originally classified in the family *Vibrionaceae*. The genus designation *Campylobacter* (Campylo — curved, bacter — rod) was not introduced until 1963 (2).

The pathogenic campylobacters have specialized growth requirements, an optimum growth temperature of 42 °C, and a requirement for a microaerophilic atmosphere. Consequently, the first isolation of *Campylobacter* from humans suffering from acute gastroenteritis was not reported until 1972. For a time afterward, however, campylobacters remained obscure and merely generated medical curiosity as their fastidious nature hindered their isolation. The use of selective media for the detection of campylobacters in food and clinical samples in 1977 (3) marked a water shed in our understanding of these pathogens and provided for the first time a window that revealed the probable impact of these bacteria on human health. Having found these pathogens in more than 7% of diarrheal samples, Skirrow predicted that these microbes could pose a serious public health risk. Reports of enteritis caused by *Campylobacter* species have since then risen dramatically, and currently *C. jejuni*, in particular, is regarded as the leading cause of bacterial food-borne illness worldwide.

Taxonomy of the Genus *Campylobacter*

Today, the *Campylobacter* genus, which belongs to the epsilon subclass of proteobacteria, comprises 15 species (4), of which a particular number are of importance to human health (Table 1). The genus comprises slender, spirally curved, gram-negative rods with a characteristic corkscrew-like darting motility. In addition, campylobacters do not ferment or oxidize carbohydrates and generally are microaerophilic, although some species are able to grow aerobically and some grow under anaerobic conditions. A number of *Campylobacter* species are capable of causing disease in humans. However, *C. jejuni, C. coli*, and *C. lari* are considered to be the most important species causing human diarrheal disease, and whereas other species have been implicated as human pathogens in immunocompromised people, these species are isolated infrequently and generally represent only 1% of clinical *Campylobacter* isolations. However, the true impact of non-*jejuni*/*coli* species may not be fully appreciated as isolation techniques, routinely used for the detection of *C. jejuni* and *C. coli* in many diagnostic laboratories may not support the growth of these other species.

Campylobacter jejuni and *Campylobacter coli*

Campylobacter jejuni is considered to be closely related to *C. coli*, but whereas *C. jejuni* comprises 80 to 90% of all *Campylobacter* isolations in developing countries, *C. coli* infections represent only about 7%. The reason for this difference in incidence is not known. However, one study has suggested that the differential distribution of *C. jejuni* and *C. coli* in food does not account for this ratio of infection and thus has concluded that *C. jejuni* is more efficient in colonizing and causing enteritis in humans than *C. coli* and other *Campylobacter* species (5).

Table 1. Species of *Campylobacter* Associated with Human Disease That Can Be Isolated from the Environment

Organism	Reservoirs	Primary Vectors	Disease Association
C. jejuni	Man, mammals, birds, poultry	Food, poultry, raw milk, and water	Enteritis, systemic illness, GBS
C. coli	Mammals, pigs, birds	Food, poultry, and pigs	Enteritis
C. lari	Man, mammals, birds	Food and water	Enteritis
C. fetus	Cattle, sheep	Uncooked meat, beef, and pork	Systemic illness, bacteremia, meningitis
C. upsaliensis	Domestic pets	Dogs and cats	Rare, bacteremia, enteritis
C. hyointestinalis	Cattle, pigs, hamsters	Raw milk, hamsters	Rare, enteritis
C. mucosalis	Pigs	Meat, pork	Rare, enteritis
C. concisis	Man	Unknown	Periodontal disease, rare, enteritis
C. sputorum	Man, cattle	Unknown	Periodontal disease
C. curvus	Man	Unknown	Periodontal disease, enteritis
C. rectus	Man	Unknown	Periodontal disease

In terms of the incidence of human infection, *C. jejuni* is unquestionably the most important member of the *Campylobacter* genus, it being the most frequent cause of gastrointestinal illness in the developed world (1). Although the public at large is generally unaware of the impact of *C. jejuni* on human health, it causes infections more frequently than either *Salmonella* or *Shigella*, both of which command better public awareness. It is estimated in the United States that *Campylobacter* strains cause more than two million cases of diarrhea annually. In the United Kingdom, the incidence of *Campylobacter* enteritis has risen steadily during the last decade, and in 1998, more than 58,000 cases were laboratory confirmed. Remarkably, the true incidence of campylobacteriosis may be considerably higher because even for countries with sophisticated epidemiological surveillance systems, the true extent of *C. jejuni* infection may be underestimated. In the United Kingdom, for example, it has been established that for every case that is reported, approximately eight cases occur within the community but are not identified (6).

CLINICAL ASPECTS AND EPIDEMIOLOGY

Clinical Aspects

Campylobacteriosis is essentially a food-borne zoonosis, with *C. jejuni* commonly found in the gastrointestinal tract of a number of animals. The manifestation of the disease caused by this organism and other enteric campylobacters differs significantly between industrialized and developing nations. Although the incidence of *Campylobacter* infections in developing countries is much higher compared with that in industrialized nations, the actual rate of symptomatic illness generally is lower. In developing nations, the symptoms are mostly mild and characterized by a noninflammatory watery diarrhea. In contrast, in industrialized nations the usual manifestation of *Campylobacter* enteritis is acute inflammatory diarrhea that generally occurs one to seven days after infection. Symptoms include bloody diarrhea, fever, and abdominal pain persisting up to seven days, although the acute diarrhea lasts only two to three days. Although the acute symptoms may disappear in a matter of days, the pathogen can still be isolated at rates of between 10^6 and 10^8 organisms per gram of feces for up to two to three weeks after infection. The disease usually is self-limited, but on rare occasions the organism can cause appendicitis, bacteremia, meningitis, and other extraintestinal infections. Recurrence of symptoms can occur in 25% of cases.

Autoimmune Sequelae

A number of sequelae are associated with *Campylobacter* infection, and approximately 1 in 1,000 of the patients suffering from the acute form of gastroenteritis can subsequently develop acute inflammatory demyelinating polyneuropathy or Guillain-Barré syndrome (GBS). This is a serious neurologic complication that may result in severe and sometimes fatal paralysis. Although the risk of developing GBS following *C. jejuni* infection is low, in the United States as many as 1,300 cases of GBS may be attributable to prior infection with this pathogen (7). The pathogenesis of GBS and the role of *C. jejuni* in the disease process are not clear, but molecular mimicry between the bacterial LPS structures of certain serotypes and the ganglioside components of motor neurons may play an important role in the development of the disease (8).

Pathogenicity Mechanisms

Even today, the mechanisms that enable *C. jejuni* to cause disease remain largely unknown. Several reviews serve to condense the information concerning the pathophysiology of *C. jejuni* infection, in general terms (9–11), in terms of the interaction of the organism with eukaryotic cells (12), and focusing on the role of toxins in the disease process (13).

Animal Reservoirs for *Campylobacter* Species

Many domestic and wild animals such as poultry, swine, sheep, cattle, dogs, and cats carry campylobacters in their gastrointestinal tract without displaying overt symptoms, although the disease symptoms may arise in young animals (14). Consequently, the gastrointestinal tract of certain warm-blooded animals is considered to be the natural habitat of *Campylobacter* species. In particular, birds, and especially poultry, are regarded as the primary

reservoir for *C. jejuni*. For chicken and turkey, the organism is a commensal, it being able to permanently colonize the cecum in an asymptomatic manner. The intimate relationship between poultry and *C. jejuni* is further emphasized by a consideration of its temperature requirements for growth. In this respect, the optimum growth temperature of the organism (42 °C) mirrors that of the avian gut, which differs considerably from that encountered in the mammalian gut (37 °C). The high cecal carriage rates of commercially raised chickens of between 30 and 100% (15,16) are a further reflection of the intimate nature of the interaction between *C. jejuni* and poultry. Nevertheless, with the implementation of strict hygiene measures, including thorough cleaning and disinfecting procedures, disinfection of drinking water, change of footwear at the entrance to each broiler house, and the control of vermin, *Campylobacter* colonization of broiler flocks can be significantly reduced (17).

While poultry may be the primary vehicle for *C. jejuni*, other farm animals are also susceptible to colonization by campylobacters. For example, pigs from the day of birth are highly susceptible to enteric colonization, with the prevalence of campylobacters in commercial pig farms ranging from 76 to 100%, depending on the age or sex of the pig (18). Typically, *C. coli* is more often associated with swine that *C. jejuni*.

Transmission and Epidemiology

The epidemiology of *Campylobacter* infection demonstrates a number of interesting and notable features. First, while *C. jejuni* and *C. coli* are the leading causes of bacterial food-borne illness in developing countries, unusually for food-borne pathogens, the pattern of infection tends to be sporadic, with large outbreaks of infection caused by these organisms occurring rarely. Furthermore, the epidemiology of clinical cases of *Campylobacter* enteritis in temperature climates shows a striking seasonality. In the United Kingdom and the United States, for example, the rate of infection shows a marked and consistent increase in May that peaks in July. This variation in incidence may reflect warmer temperatures and concomitant changes in eating habits.

The infective dose for *C. jejuni* is generally considered to be low, and one report, which utilized human volunteers, demonstrated that oral ingestion of as few as 500 viable bacteria can result in clinical symptoms (19). In reality, the infective dose required for infection is likely to vary significantly from this figure for a number reasons. First, since not all persons exposed to the organism develop symptoms, the susceptibility to *Campylobacter* infection may vary from individual to individual. A further complication to consider is the fact that individual isolates of *C. jejuni* may differ significantly in their ability to establish infection and cause disease (20).

Given the high contamination rate of commercially raised chickens and the relatively low infectious dose, it perhaps is not surprising that the main infection route of *C. jejuni* to humans in most industrialized nations is through the consumption of undercooked poultry or food tainted by cross-contamination. The isolation rate for *Campylobacter* from poultry sold in many major outlets varies but generally is high. For example, in the United States, 69% of chickens bought from a local supermarket were found to be contaminated with *C. jejuni* (21). Once poultry harboring *C. jejuni* is introduced into the kitchen, it inevitably serves as a focal point for contamination. This aspect of *Campylobacter* epidemiology has been emphasized by a recent study that demonstrated that the preparation of chicken resulted in the contamination of multiple sites within domestic kitchens with campylobacters. Disturbingly, routine cleaning with detergent and hot water had no effect on the frequency of contamination (22).

Unpasteurized milk is also regularly implicated as a vehicle for infection. In addition, contaminated drinking water, in which *C. jejuni* can survive for extended periods, has been the cause of several large outbreaks of *Campylobacter* infection. In the United States, for example, between 1978 and 1986, 11 of 57 outbreaks of *Campylobacter* infection were waterborne and were associated with the consumption of unboiled surface water, contamination of groundwater with surface water, inadequate disinfection, or contamination of water by avian feces (23).

Other foods, including saladgreens, fruit, and fish, have also been implicated as vehicles for *Campylobacter* infection, but the risk associated with these is generally low (6). More unusual vehicles for food-borne campylobacteriosis include garlic butter (24) and milk that has been contaminated following the action of birds pecking through the aluminum bottle tops (25). Finally, domestic animals are also considered to be a possible source of infection. In particular, contact with puppies that have diarrhea has been shown to cause gastroenteritis in children (14), while a study centered on a health cooperative in the United States estimated that 6.3% of *Campylobacter* enteritis cases could be attributed to exposure to diarrhetic animals (26).

The Detection and Differentiation of *Campylobacter* Species

The development of selective media for the detection of *Campylobacter* in food and environmental samples in 1977 (3) marked a turning point in our understanding of these organisms. Today, however, traditional cultural methods, which involve preenrichment, selective culture (27,28), and final identification by biochemical or serological tests (29), are considered to be labor-intensive and take a minimum of four to five days for confirmation. In addition, given the limited metabolic capacity of campylobacters, the biochemical tests available for *Campylobacter* identification are generally regarded as unsatisfactory. Differentiation of *C. jejuni* strains has traditionally been achieved using serotyping, either based on heat-stable antigens (30) or using a rapid-slide agglutination technique (31). However, the serotyping of campylobacters is problematic because of its complexity, because of the labor investment required for antisera production, and because significant numbers of strains are nontypable. Consequently, the requirement for simple high-resolution identification systems for the epidemiological typing of strains has led to the development of a number of DNA-based methods (29,32).

ENVIRONMENTAL SURVIVAL OF CAMPYLOBACTERS

Factors Limiting Growth in Food and the Environment

The lower temperature limit for the growth of *C. jejuni* reported in the literature varies between 30 and 36 °C. This factor and the microaerophilic nature of the organism are generally considered to prevent its growth in food and the environment. Consequently, although *C. jejuni* is environmentally ubiquitous, having been isolated from river water, wastewaters (33), and sand on bathing beaches (34), it is not considered to be free-living, and therefore is capable only of survival, not of growth, in these environments.

Environmental Sensitivity of Campylobacters

Campylobacters' sensitivity to oxygen and inability to grow at temperatures below 30 °C are probably the major factors limiting the growth and survival of the organism outside of the host. However, *C. jejuni* is also susceptible to a number of other environmental conditions and is generally less able to tolerate environmental stress compared with other food-borne pathogens (Table 2). For example, the organism is very sensitive to desiccation and accordingly does not survive well on dry surfaces (35). In addition, campylobacters are also susceptible to raised levels of sodium chloride (36) and are killed readily at low pH (37). Despite being termed *thermophilic*, *C. jejuni* is also sensitive to exposure to high temperatures (Table 2), and consequently, the organism should not survive in food that has been adequately cooked.

In conclusion, campylobacters appear to be particularly susceptible to environmental stress, at least under laboratory conditions, and based on these observations, the organisms would not be expected to survive for long periods outside the host. Outside the laboratory, however, it is clear from the measured incidence of infection and from reports of the ubiquity of campylobacters in the environment that the organisms are able to persist to a greater extent than can be anticipated from laboratory-based studies.

General Aspects of Survival

The ubiquitous presence of campylobacters in the environment suggests that there are multiple and permanent sources for contamination and that large numbers of the organisms are excreted into the environment in a continuous fashion. In this respect, high rates of fecal shedding of *C. jejuni* have been detected in dairy cattle (38), sheep (39), and wild birds (40). In addition, campylobacters can also be introduced into the environment, following the discharge of sewage effluents into surface waters. In this situation, the campylobacters are thought to originate mainly from abattoirs and animal processing plants, because seasonal peaks in the frequency of *Campylobacter* isolation from sewage effluents parallel the incidence of zoonotic infections (41). As a consequence of these processes, surface waters are frequently contaminated with campylobacters. Again, because the minimal growth temperature for *C. jejuni* is between 32 and 36 °C, it can be assumed that *C. jejuni* survives rather than grows in aquatic environments.

Compared with other enteric bacterial pathogens, *C. jejuni* appears to be uniquely limited in its ability to grow at relatively low temperatures (Table 2). Because this deficiency places limitations on the ability of this organism to replicate in food and water, which are the primary vehicles for its transmission, the response of *C. jejuni* to low temperatures has been studied in some detail. The lower limit of bacterial growth is usually determined by the fluidity of lipids and membrane components, but whether these parameters are related to the temperature growth limitations of *C. jejuni* is not known at present. A feature that may give some insight into the limited temperature growth range for this pathogen, is the fact that, unlike other microorganisms, which show a gradual reduction in growth rate near the minimal growth temperature, *C. jejuni* shows a dramatic and sudden growth rate decline near the lower temperature limit (42).

Despite its failure to replicate at environmental temperatures, *C. jejuni* is metabolically active at temperatures far below its lower growth limit. For example, *C. jejuni* is able to perform respiration and generate ATP at 4 °C, which implies that the electron chain and substrate transport systems are active, despite the fact that this temperature is well below the minimum required for growth. Furthermore, *C. jejuni* is motile at 4 °C, indicating that, although replication at this temperature is not possible, the organism still retains the capacity to move toward favorable environments (42).

At even lower temperatures, viability is rapidly lost, and although campylobacters can still be isolated from frozen meats and poultry products, freezing significantly

Table 2. The Limits of Growth and Temperature Sensitivity of *C. jejuni* Compared with Other Food-Borne Bacterial Pathogens

Organism	Temperature °C			Typical D-Value at 55 °C	Minimum a_w	Minimum pH	Oxygen Requirement
	Minimum	Optimum	Maximum				
C. jejuni	30	42–43	45	1.0	0.987	4.9	5–10%
Salmonella typhimurium	5.2	35–43	46	4.7	0.93	3.8	Facultative
Escherichia coli	7–10	35–40	44–46	5.5	0.95	4.4	Facultative

Source: Data taken from reference 74.

reduces their survival. Although several factors including ice nucleation and dehydration have been implicated in the freeze-induced injury of bacterial cells, more recently oxidative stress has been shown to contribute to the freeze-thaw-induced killing of campylobacters (43).

Survival in Surface Waters

Although growth is not possible in the environment, surface waters play a vital role in maintaining the contamination cycle of *C. jejuni*. Data on the occurrence of campylobacters in surface waters vary widely, and this probably reflects the degree to which slaughterhouses, the presence of waterfowl, or waste treatment plants impact the quality of water within the cachement area. Isolation rates for river water, for example, vary from 53% in southern England to 37% in central Washington and 82% in Germany (44). Nevertheless, it is clear that campylobacters can persist for extended periods in surface waters. For example, at low temperatures and in nutrient-poor conditions survival can be as long as one to four months (33).

Generally, the survival of *C. jejuni* in surface waters is dependent on a number of environmental parameters such as temperature, the presence of oxygen, and the availability of nutrients. The rate of loss of viability in river water, a *microcosm* containing nutrients, is markedly less than that observed in deionized water (42,45). Temperature, however, appears to have the greatest influence on *Campylobacter* survival. Thus, although survival is poor at higher temperatures (37 °C), it is optimal at lower temperatures (5–15 °C), which do not promote growth and correlate to some environmental temperatures (45). The issue of environmental survival of campylobacters is further complicated by the fact that, certain strains of *Campylobacter* appear to be better equipped for environmental survival. In other words, not all strains of *Campylobacter* survive at equivalents rates in the environment. In general, strains of *C. coli* appear to be more sensitive to adverse environmental conditions (46) than *C. jejuni*. In addition, *C. jejuni* appears to be the more resilient strain in terms of survival in water, and for this reason *C. jejuni* is regarded as the main protagonist of water-mediated campylobacteriosis (45).

Survival of *Campylobacter* in Sewage and During Sewage Treatment

Wastewater is inevitably contaminated with fecal material and, as a consequence, is invariably contaminated with fecal pathogens. Thus, it is not surprising that wastewaters regularly contain campylobacters. The levels of these pathogens detected in wastewaters vary widely. This may reflect the presence of slaughterhouses or other sources of campylobacters in the collection area for the treatment plant (33).

The survival of campylobacters during the sewage treatment purification process, has been investigated by a number of different groups. The most significant reduction in *Campylobacter* numbers is most often associated with primary sedimentation, with reported reduction rates during this process varying between 56 and 99% (33). This reduction in numbers has been attributed to the attachment of *Campylobacter* to sedimentary particles (47) and to ingestion by protozoa (48). The survival and prevalence of campylobacters during wastewater treatment, however, was not correlated with water temperature, sunlight, or the intensity of rainfall (49). Surprisingly, given the microaerophilic nature of *C. jejuni*, there also appeared to be no correlation between the concentration of oxygen and the reduction in numbers of this pathogen. In conclusion, in the absence of a dedicated disinfecting process, it is clear that although aerobic biological purification of wastewater generates a substantial lowering of numbers, it does not result in the complete elimination of campylobacters (33). Consequently, these effluents may serve to contaminate surface waters.

In wastewater treatment, primary sedimentation brings about the settling of mainly fecal solids, and accordingly, a large proportion of the fecal bacteria including pathogens is carried into the primary sludge. In particular, campylobacters can be isolated from untreated sludge derived from primary sedimentation and the levels can be correlated with the incidence of infection within the community (50). In contrast, the organisms in activated sludge generally are those of aquatic origin rather than those of fecal derivation because the activated sludge process provides a hostile environment to the latter.

The treatment of sludge has a marked effect on the survival of campylobacters and thus significant implications for the safety of the treated biosolids if they are to be disposed of on arable lands. Although aerobic digestion has been shown to eliminate campylobacters completely (51), some studies have demonstrated that anaerobic digestion has little effect on reducing the numbers of viable campylobacters (52). The differential survival of campylobacters during these processes may reflect the microaerophilic nature of the pathogen and, in particular, its sensitivity to oxygen. In conclusion, although the disposal of aerobically digested sludge on terrestrial sites is not likely to contribute significantly to the environmental prevalence of campylobacters, the application of raw or anaerobically treated sludge to arable land may present possible hazards in terms of the presence of campylobacters.

The Role of Viable Nonculturable Stages in the Contamination Cycle

In aquatic and food environments, pathogenic bacteria, which most often grow optimally at temperatures that are equivalent to that of their host and which generally have fastidious requirements for nutrients, often encounter stress in the form of starvation, osmotic, and temperature stresses. As a consequence of these stresses, certain bacteria may enter a viable nonculturable (VNC) state. This novel concept of a bacterium that remains infectious but can no longer be cultured by conventional means was first proposed by Colwell following a study on the survival of *Salmonella* in aquatic systems (53). Such bacteria may retain metabolic activity, yet are unable under the prevailing environmental conditions, to undergo the cellular division required for growth. Furthermore, conversion from the VNC form has been shown to be

reversible with the advent of improved environmental conditions (54). Clearly, the presence of a VNC form of *Campylobacter* would have significant ramifications for the detection and epidemiology of this pathogen. In this context, a VNC form of *C. jejuni* was first reported by Rollins and Colwell (55), and since then there has been continuous debate as to whether a VNC form for *Campylobacter* actually exists.

Given the fastidious nature of *Campylobacter*, the loss of culturabilty in this organism is relatively easy to induce. For example, cultures rapidly lose viability, as assessed by plate counting, following exposure to oxygen, changes in temperature, and starvation. In particular, exposure to oxygen brings about a rapid decline in recoverable organisms (55), and generally, the higher the temperature and the more nutritious the media, the greater the loss of viability (56). The reduced metabolism of the cell at low temperatures and in conditions of limited nutrient availability may lessen the buildup of toxic metabolic products and thereby promote survival (56).

The viability of the VNC stage has been attributed largely to the ability of this form to modify chemical indicators of viability. For example, tetrazolium salts, which are colorless and water-soluble electron acceptors in the oxidized state, can be reduced by metabolically active cells to water-insoluble colored formazans. A number of studies have shown that VNC forms reduce certain tetrazolium salts, and this has subsequently been interpreted as an indicator of viability (57,58). In addition, the longevity of certain macromolecules within the VNC form has been correlated with the viability of this stage. For example, the chromosomal DNA of nonculturable cells has been shown to remain intact after 116 days storage at 4 °C (59).

Recovery or reversion of the VNC form has been reported by a number of groups, but these studies have often generated controversy. Accordingly, the recovery of VNC forms, which are not detectable by conventional culture techniques, has been reported in a number of different animal models (60,61) and more recently in embryonated eggs (62). In addition, VNC forms that were induced by oxygen starvation were reported to have been recovered following the provision of a microaerobic atmosphere. The authors of this study, however, could not exclude the possibility that at least some of the recovery could be attributed to the multiplication of residual viable cells (63). Further evidence for the existence of VNCs has been derived from the direct observation of nonculturable forms in untreated water supplies from a broiler farm by immunofluorescence microscopy and the subsequent colonization of *Campylobacter*-free chickens by these cells (64).

In contrast, a number of studies have failed to induce the recovery of VNC cells of *C. jejuni* in animal models (65,66), and these results have cast doubt on the existence of a VNC form and the role that it plays in the environmental transmission of campylobacters. Consequently, controversy concerning the existence of a VNC form for campylobacters still abounds. A recent study, however, may explain the basis for the disparate results concerning the VNC form. In this respect, Tholozan and coworkers (58) have demonstrated that only a limited number of isolates are able to form the VNC stage. In light of this study, it is possible that the contrasting results that concern the VNC form may simply be due to strain differences. Further emphasis for this contention can be derived from the fact that, of a total of 36 strains of *C. jejuni* of human origin examined, only three were able to enter the VNC state (58).

The Role of Coccoid Cells in *Campylobacter* Survival

The decline in viability and loss of culturability in campylobacters that occurs following exposure to certain unfavorable environments is often associated with a change in cell morphology from a spiral rod–like form into a coccoid form (55). This phenomenon has also been shown to occur with other bacteria including *Helicobacter pylori* (67). Because the rate of appearance of the coccoid form often parallels the loss in culturability, much research has focused on the possibility that the coccoid form is in fact the dormant VNC stage of *C. jejuni*.

A number of studies have suggested that the coccoid stage is merely a degenerative form that contains decreased levels of nucleic acids and peptides and also lacks cellular integrity (68,69). However, these conclusions that all coccoid forms are degenerate may be too simplistic because different types of coccoid forms, containing different fatty acid compositions, may be generated following exposure to different temperatures (56). Because the formation of cocci is not prevented by the inhibition of protein synthesis brought about by the addition of chloramphenicol or by irradiation, whatever the role of the cocci, the process must be a passive one rather than an active one, requiring de novo protein synthesis (56). More recently, it has been suggested that conversion to the VNC form and the transition to the coccoid form are two different but related phenomenon, with the real VNC stage to be found among the spiral rod–like population (59).

Oxidative Stress and Environmental Survival

The microaerophilic nature of *C. jejuni* and *C. coli* species implies an inherent sensitivity toward oxygen and its reduction products, particularly the superoxide anion. The reason for the lack of resistance to oxygen in atmospheric concentration is not known at present. However, it does not appear to stem from an absence of detoxification mechanisms. In this context, three pathways for the removal of oxidative radicals have been characterized in campylobacters (70). For example, the deleterious effects of exposure to superoxide radicals are counteracted by the activity of superoxide dismutase (SOD). *Campylobacter* mutants lacking this enzyme are hypersensitive to exposure to atmospheric oxygen during survival in a number of different environments. Consequently, the ability of *Campylobacter* cells to counter the effects of superoxide radicals is fundamental to their survival in the environment (71).

Analysis of the genome sequence indicates that the key regulators of oxidative stress defense enzymes found in *E. coli* and *Salmonella typhimurium*, namely, SoxRS and OxyR are not present in *C. jejuni*. Additional factors must

therefore be involved in the regulation of the oxidative stress response. In this context, a negative regulator termed *PerR*, which has considerable homology to the ferric uptake regulator *Fur*, mediates the response to oxidative stress (72).

Genetic Factors Influencing Survival in the Environment

The primary habitat of campylobacters is considered to be the gastrointestinal tract of warm-blooded animals. Consequently, when these microorganisms are released into the environment, they generally encounter conditions that are detrimental to their survival. Many bacteria, including enteric pathogens, are capable of surviving diverse environmental conditions. This ability is often essential for the survival of the bacterium and necessitates that the organism can sense its surroundings and modify its physiology to counter the effects of the stress imposed by the prevailing environmental conditions.

Until relatively recently, scientists knew little of the mechanisms governing the survival of campylobacters outside its host. However, some recent studies and the publication of the genome sequence for *C. jejuni* NCTC 11168 (72) have given them important insights into the mechanisms controlling the survival of this pathogen in the environment and how it recognizes environmental cues and is able to respond to them (Table 3; 70). Despite the ability of *C. jejuni* to survive in a diverse range of environments including the gastrointestinal tract of animals and humans, food, and oligotrophic environments such as surface waters, its capacity for regulating gene expression in response to changes in environmental parameters is very limited in comparison to other bacteria. A number of key global regulatory proteins that are important in the stress responses of other bacterial pathogens are absent (Table 3).

Initiation of transcription in eubacteria by the DNA-dependent RNA polymerase is regulated by a family of small proteins called *sigma-factors* (σ-*factors*). These associate in a reversible way with the core enzyme and provide bacteria with a mechanism for modulating gene expression in response to specific environmental stimuli. However, the capacity of *C. jejuni* to modulate gene expression in response to stress through the use of alternative sigma factors is very limited, as only two alternative σ-factors, σ^{54} and σ^{28} are present. Compared with *E. coli* and *Bacillus subtilis*, which possess six and 17 alternative σ-factors, respectively, this number is minimal. Notably, the alternative sigma factor *RpoS* is absent from *C. jejuni*. Generally, it is assumed that bacteria isolated from the stationary phase are more resistant to environmental stresses and toxic agents than cells in the exponential phase of growth and that this is a programmed adaptation mediated by RpoS in gram-negative bacteria. However, it has recently been shown that stationary phase cultures of *C. jejuni* do not enter an RpoS-mediated resistant state, as has been observed for a number of other gram-negative bacteria and that the tolerance of this bacterium to certain stresses is greatest in exponential phase and actually declines during early stationary phase (73).

Table 3. A Comparison of Key Proteins Involved in the Resistance to Environmental Stress in Other Bacteria with Those Present *C. jejuni*

Protein	Occurrence	Function	Presence in *C. jejuni*
Fur	*E. coli*, *S. typhimurium*, other bacterial species	Repressor of iron uptake, regulates iron uptake	+
SoxRS	*E. coli*, *S. typhimurium*, other bacterial species	Positive regulators of the response to superoxide stress	−
OxyR	*E. coli*, *S. typhimurium*, other bacterial species	Positive regulator of the response to peroxide stress	−
PerR	*B. subtilis*	Negative regulator of the response to peroxide stress	+
RpoS	*E. coli*, *S. typhimurium*, other bacterial species	Alternative sigma factor, regulates the response to stress, starvation, and stationary phase	−
RpoN	Numerous bacterial species	Alternative sigma factor, regulates nitrogen assimilation and other unrelated functions	+
RpoH	*E. coli*, *S. typhimurium*	Alternative sigma factor regulating the heat shock response	−
HspR	*Streptomyces albus*	Negative regulator of the heat shock response	+
HrcA	*Bacillus subtilis*	Negative regulator of the heat shock response	+
CspA	*E. coli*, *S. typhimurium*, *B. subtilis*	Major cold-shock protein	−
CsrA	*E. coli*, *S. typhimurium*,	Carbon storage regulator,	+
Lrp	*E. coli*, *S. typhimurium*	Global regulator of metabolism,	−
Crp	*E. coli*, *S. typhimurium*, other bacterial species	cAMP receptor protein, allows use of alternative carbon sources	?

Source: Data taken from reference 72.

The presence of a number of two-component regulatory systems suggests that these are a major regulatory family in this organism, and it is likely, therefore, that these play a central role in the physiological response of campylobacters to the environment (72). The lack of established regulatory mechanisms in *C. jejuni* is intriguing and suggests that alternative mechanisms for coping with environmental stress may operate in campylobacters.

CONCLUSION

Campylobacter jejuni is the leading cause of bacterial food-borne diarrheal disease throughout the world and is regarded as among the most ubiquitous bacterial pathogens known to man. Despite its incidence, in the laboratory at least, *C. jejuni* behaves as a relatively fragile organism compared with other food-borne pathogens and accordingly is sensitive to many environmental stresses. However, outside the laboratory it apparently is able to survive in aquatic environments and in food for extended periods and its ability to persist under these conditions is cardinal to its contamination–infection cycle.

Even today, more than 20 years since its role as a leading cause of enteritis was first brought to prominence, very little is known of the mechanisms that enable *C. jejuni* to survive in food and the environment. For example, we still await definitive answers concerning the existence of VNCs and the role of coccoid forms in its survival and transmission. However, the mechanisms that enable the organism to counter the effects of oxidative stress have recently been shown to be important for the survival of the pathogen in a number of environments. The development of strategies for the effective control of *C. jejuni* in the food chain are also hindered by a poor understanding of the physiology of this organism. However, the recent publication of the genome sequence of *C. jejuni* greatly increases our understanding of this pathogen, and during the next decade the application of postgenomic technology should greatly enhance our understanding of this important pathogen.

CAPILLARY ELECTROPHORESIS IN GENETIC ANALYSIS AND RIBOTYPING OF MICROBIOTA IN THE ENVIRONMENT

KEITH R. MITCHELSON
University of Queensland
Brisbane, Australia

Among the main obstacles frequently encountered by microbiologists are the identification and taxonomic classification of new microbial entities or the identification and differentiation of microorganisms known for a long time but whose subspecific entities are difficult to determine. At sub-specific taxonomic levels, differences may be so reduced that traditional techniques are in some cases absolutely ineffective. In all these cases, the use of molecular markers, which exploit the natural variation present inside DNA to identify and differentiate pathogens, may help overcoming current limitations. Remarkable progress has been made in recent years in the development of new methods for elucidating relationships among groups of more or less related microorganisms. The advent of molecular biology techniques, mainly a consequence of developments obtained in the medical field, has allowed new and unexpected approaches to environmental microbiology, giving a great boost to systematic and diagnostic studies of communities in the environment.

GENETIC CLASSIFICATION BY DNA POLYMORPHISM

One more general approach used widely in both general and environmental microbiology involves the identification of DNA polymorphism located at specific sites. These analyzes are used to generate "genetic fingerprints" of the genome of individuals or families of related individuals or even unrelated or closely related members of a species for the purpose of identification of genetic markers as tools for the selection of organisms for environmental use, for diagnostic, commercial, or ecological purposes. These techniques have been applied to other fields of biology and were extremely successful in the rapid identification and differentiation of several genetically distinct groups of closely related organisms (1,2). The transfer of such methodologies to the study of microbiological communities has been rapid and has confirmed the high-resolution power of these techniques, as outlined in several recent reviews of the application of molecular technologies in molecular ecology and pathology (1–4). Although this review is intended to examine developments in microbiology, new developments in technologies employed for the study of microorganisms affecting human health and food have wide relevance to molecular microbiology and are included.

The great advance in the diagnostic microbiology is driven by the need to speed identification and differentiation techniques at the level of subspecies, variety (or pathovar), *formae speciales* and race beyond traditional morphological and physiological difference–based techniques. The identification of species based on culturability and on morphological or

biochemical differences (5–7) is slow and may underrepresent microorganisms requiring fastididous growth conditions. Surveys of many terrestrial and aquatic ecosystems indicate that 99% of microorganisms resist cultivation in the laboratory. Therefore, to study such unculturable organisms we have to rely on DNA-based technologies. Similar constraints affect both environmental microbiology and medical microbiology where the scoring of symptoms for infectious disease evaluation, especially of early symptoms, is difficult and still retains a subjective element (5,8–10). The infection process is strongly influenced by a range of environmental factors including temperature, moisture, light intensity, etc. For these reasons, it is quite variable in its initial symptomatic expression even in the same combination strain/clone or race/cultivar. The phenomena of symptom convergence, that is, when different pathogens cause the same type of alteration, and of symptom divergence, when the same pathogen causes different types of alterations, further complicates the problem (11–13). All these difficulties pose serious problems for the diagnosis of the causal agents of diseases as well as to the differentiation and taxonomic classification of many groups of microorganisms and frequently several independent methods such as ribotyping, repeat element polymorphism, random amplified polymorphis DNA (RAPD), and pulsed-field gel electrophoresis (PFGE) analysis of chromosomal fragments and plasmids are used (14–16). Recently, fluorescent in situ hybridization (FISH) analysis and image-analyzed microscopy have been applied for the rapid identification and quantification of particular microorganisms within environmental communities (17,18) and in health and clinical environments (5–19). Typically, the FISH probes are specific to characteristic ribosomal gene elements of particular microorganisms.

RIBOTYPING

Analysis of polymorphism of regions of the ribosomal gene complex is one of the most commonly used methods of differentiation of microorganisms (20). This is because of the ease in amplifying the ribosomal gene regions in many different bacteria and fungi by application of "universal" PCR primers to the highly conserved ribosomal gene repeats, and following DNA sequence analysis, the relative ease of defining highly specific PCR-primers to ribosomal gene loci for particular microbial and fungal species of interest, or by the definition of characteristic restriction fragment length polymorphism (RFLP) for particular microbial strains or species. Ribotyping is a general term applied to RFLP analysis of the internal transcribed spacer (ITS) regions located between the small and large subunits and encompassing the 5.8S rRNA gene (21–23) or to the nontranscribed intergenic spacer between the large subunit and the following small subunit, frequently encompassing the 5S rRNA genes (24,25). It is also applied to RFLP of the most part or all of the ribosomal gene repeat (26–29), or specifically to microbial 16S-18S small subunit rRNA (SSU rRNA) (4,5,8,30) and 23S large subunit (LSU) rDNA genes (7–19). Less frequently the tandemly repeated transfer RNA (tRNA) gene loci are used for microbial identification (31), reflecting the absence of suitable PCR primers for tRNA genes to most species and the lack of known characteristic polymorphism.

RIBOTYPING AND PHYLOGENY

One particular advantage of gene-specific "fingerprinting" methods such as ribotyping is that the results are absolutely reproducible and thereby suitable for compilation into databases for a comprehensive account of ribotyping. (see RIBOTYPING METHODS FOR ASSESSMENT OF IN SITU MICROBIAL COMMUNITY STRUCTURE, this Encyclopedia). Using ribotyping, the phylogeny of the fungi examined may be computed from the discrete character matrix for presence or absence of fragments by sequence parsimony programs such as the PHYLIP package and results in complete accordance to the phylogeny derived from ribosomal RNA sequence analysis (1–20). Thus, if sufficient different polymorphic loci are examined across the ribosomal genes in "long-range ribotyping," the accuracy of method may be equal to DNA sequence analysis of the same locus. However, a gene locus-specific method such as ribotyping may fail to distinguish between different bacterial or fungal strains, even when a large region of the ribosomal intergenic spacer or a number of different spacer regions between the various rRNA genes is examined (32,33). Therefore, parallel or complementary application of random genome-scanning methods such as polymorphic repeat element fingerprinting is advised for identification of strains and to detect a more complete picture of genetic diversity (34).

CAPILLARY ELECTROPHORESIS FOR HIGH-THROUGHPUT DNA POLYMORPHISM ASSAYS

Capillary electrophoresis (CE) is an analytical electrophoresis technique that offers high throughput and high resolution, automatic operation and on-line detection with automatic data acquisition (35) (Fig. 1). These features have particular stimulated application to the analysis of DNA polymorphism for genetic analysis, and medical diagnosis (35–37). The advantages provided by

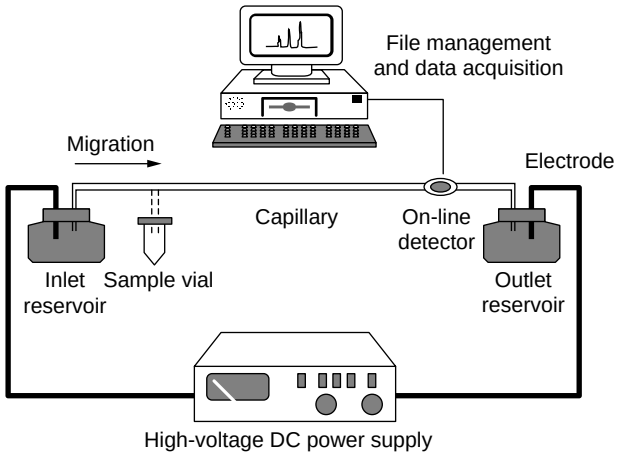

Figure 1. Schematic diagram of capillary electrophoresis (CE) apparatus. [K. R. Mitchelson, J. Cheng, and L. J. Kricka, *Trends Biotechnol.* **15**, 448–458 (1997).]

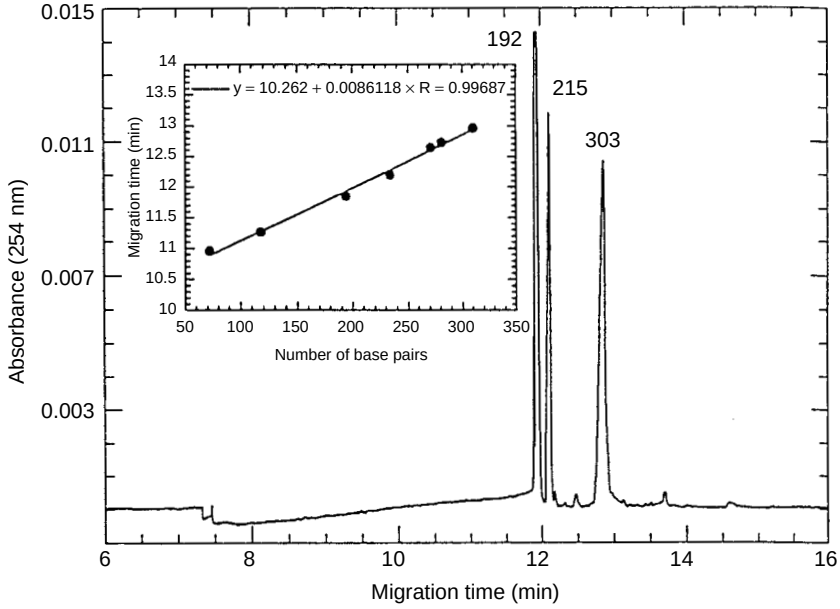

Figure 2. CE separation of *Rsa*I restriction fragments of the ribosomal IGS of the fungus *Laccaria bicolor*. Inset shows a calibration plot of migration time versus size of fragments of a ϕX174 *Hae*III digest. [F. Martin, D. Vairelles, and B. Henrion, *Anal. Biochem.* **214**, 182–189 (1993).]

the ability to automate CE operations have also given impetus to the miniaturization of capillary electrophoresis equipment to silicon-chip-based devices (38), which provide all of the earlier-mentioned facilities and a significant improvement in the speed of analysis and to the degree of automation. Particular development of other miniaturized electro-separation devices including molecular dielectric trapping using microelectrodes (39), may be integrated with CE to create microanalytical or micropreparative devices.

TOOLS FOR RIBOTYPING

Attempts to transfer capillary electrophoresis methods to microbiology have not been extensive, but several examples confirmed their high-resolution power and the potential of automation of these techniques. These techniques include capillary electrophoresis in conjunction with RFLP analysis of PCR-amplified ribosomal gene loci (40–43) (Fig. 2), direct linear DNA sequencing, and dideoxy fingerprinting (44). Characteristic repeated DNA polymorphisms that discriminate species and strains may be PCR-amplified using specific primers and assayed using CE. DNA polymorphisms include ribosomal gene regions (40) and bacterial repeat sequences (45) (Fig. 3). CE is also particularly useful for analysis of short tandem repeat (STR) loci (46).

SCANNING METHODS EMPLOYING CAPILLARY ELECTROPHORESIS

Capillary electrophoresis techniques have also been developed for DNA polymorphism scanning methodologies that detect polymorphism through alteration in the electrophoretic mobility of DNA fragments. These methods include single-strand DNA conformational polymorphism (SSCP) (47–49) and heteroduplex DNA analysis (HPA) (50) (Fig. 4). Although these methods can identify single base differences between short (typically

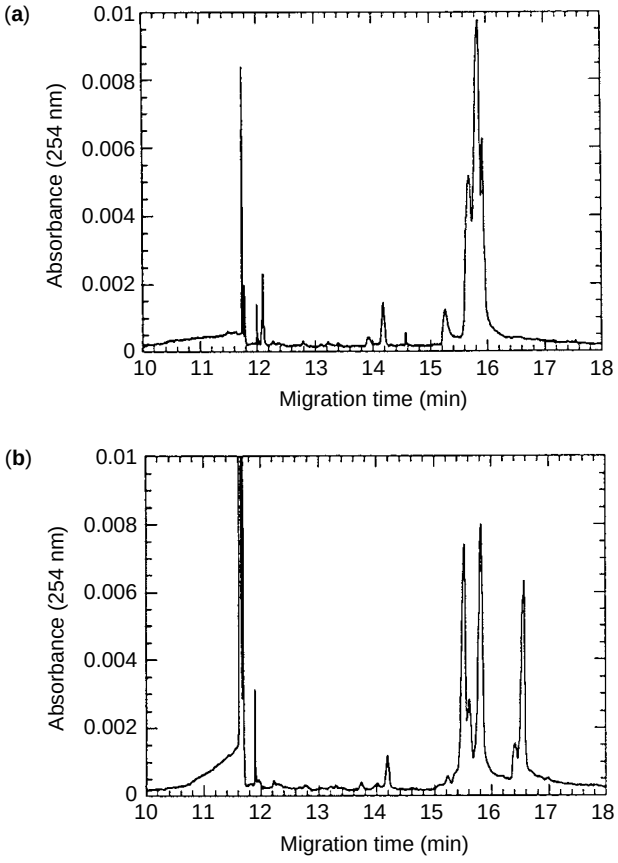

Figure 3. CE separation of heterogeneous undigested PCR products amplified from the ribosomal IGS from different strains of the fungus *Laccaria bicolor*; (**a**) strain 81306; (**b**) strain 83222. The heterogeneous IGS amplification products migrate past the detector from 15 to 17 minutes [F. Martin, D. Vairelles, and B. Henrion, *Anal. Biochem.* **214**, 182–189 (1993).]

<200 bp) fragments, the resolution between haplotypes requires optimization of the electrophoresis conditions

(**a**) *P. aeruginosa* ATCC10145; (**b**) *B. cepacia* CIP80.24; (**c**) *C. acidovorans* ATCC15668; (**d**) *B. vescularis* ATCC11426; (**e**) *S. maltophilia* CIP60.77; (**f**) *A. xylosoxidans* CIP61.20. Samples were analyzed in the same run and aligned using GeneScan500 size standards. [R. Ghozzi et al., *J. Clin. Microbiol.* **37**, 3374–3379 (1999).]

(Fig. 5). Related sensitive methods that amplify the heteroduplex polymorphism effect include constant denaturant capillary electrophoresis (CDCE) (51), which is a modified version of denaturant gradient gel electrophoresis (52), and thermal-programmed capillary electrophoresis (TPCE) (53) in which a variable temperature is increased during a run using computer-controlled thermal ramping. These have typically been applied for detection of defined polymorphism in genes such as in "ribotyping" of ribosomal gene fragments. A comparable technology for the detection of single-base polymorphism is denaturing high-performance liquid chromatography (DHPLC), and separated single-strand DNAs (54). These techniques are both fast, about 5-minute analysis for DHPLC and about 15 minutes for CDCE, and can be used to identify low frequency mutations and to genetic screening of pooled samples for detection of rare DNA variants. Further, chemical mismatch cleavage which identifies heteroduplex molecules and cleaves the heteroduplex to size resolvable fragments can also be rapidly analyzed using CE (55). The high sensitivity and speed of CE analysis has been used in medical and diagnostic circumstances to detect post-PCR amplification virus-specific DNA fragments (56) using on-column dye-labeling (57) (Fig. 6). Dideoxy fingerprinting is a further application on CE in which both structural (SSCP) and sequence information from single dideoxynucleotide-extension tracking analysis is used to identify the location of gene polymorphism (58).

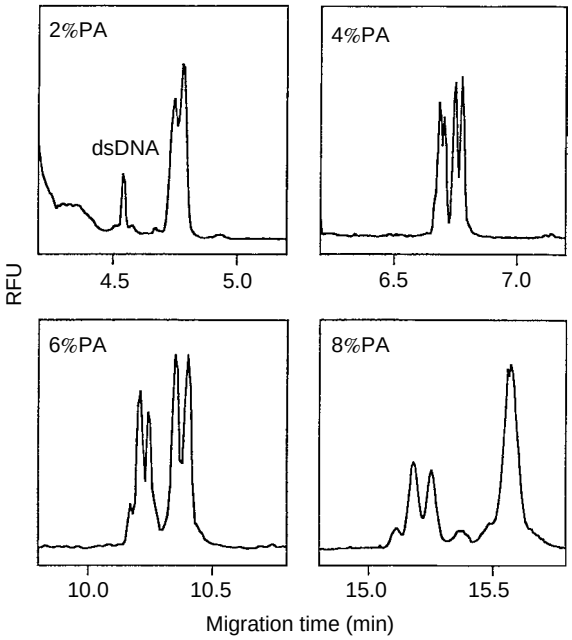

Figure 5. CE-SSCP assay is influenced by the choice of sieving matrix and by electrophoresis conditions. The "% PA" refers to the concentration of polyacrylamide sieving buffer. [J. Ren, A. Ulvik, P. M. Ueland, and H. Refsum, *Anal. Biochem.* **245**, 79–84 (1997).]

Ribotyping Using Capillary Electrophoresis

Species-specific ITS2 regions that are variable in amplicon length, may be amplified using primers for conserved sequences of the 5.8S and 28S ribosomal DNA (rDNA). The sequence variability of the internal transcribed spacer 2 (ITS2) region of fungi is potentially useful in rapid and accurate diagnosis of invasive fungal disease of immunocompromised patients (10). Terminal-restriction fragment length polymorphism (T-RFLP) of the 16S rDNA has been analyzed by capillary electrophoresis and used to characterize marine bacterioplankton communities for the detection of operational taxonomic units (OTUs) (52) (Fig. 7). Capillary electrophoresis-single-strand conformation polymorphism (CE-SSCP) analysis of PCR-amplified 16S rRNA gene fragments was used for rapid identification of *Pseudomonas aeruginosa* in patients with cystic fibrosis (49). Mycobacterium species have been identified based PCR amplification of polymorphic genetic regions with fluorescent primers followed by restriction analysis (PCR-RFLP) and by fluorescence capillary electrophoresis analysis of a 439-bp segment of the 65-kDa heat shock protein gene using *Hae*III and *Bst*EII digestion, and of a 475-bp hypervariable region of the 16S rRNA gene at the 5′ end using *Hae*III and *Cfo*I (43). The ability of CE to resolve DNA fragments efficiently has been employed for the analysis of bacterial growth rates in physiological situations by monitoring plasmid copy number — effectively a multicopy fragment analysis (59,60). Linearized plasmids were monitored off-line by CE, permitting both a rapid estimation of bacterial numbers and an assay of bacterial variants through the size of fragments (Fig. 8).

PULSED-FIELD CAPILLARY ELECTROPHORESIS

Pulsed-field gel electrophoresis formats have found wide application in the improved separation of large (20–100 kb) (61) and very large (several Mb) DNA

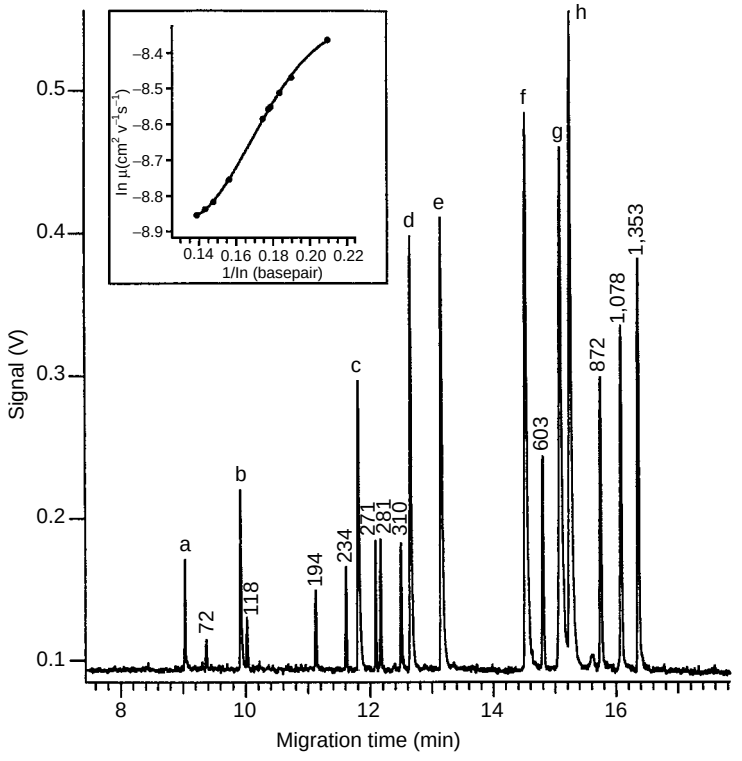

Figure 6. Detection of eight *Hpa*II digest fragments (a–h) of duck hepatitis viral DNA by capillary electrophoresis with internal size standards (base pair) and on-column dye labeling. Inset shows a calibration plot of migration time versus size of fragments of a ϕX174 *Hae*III digest. [W. G. Tan, D. L. Tyrell, and N. J. Dovichi, *J. Chromatogr. A* **853**, 309–319 (1999).]

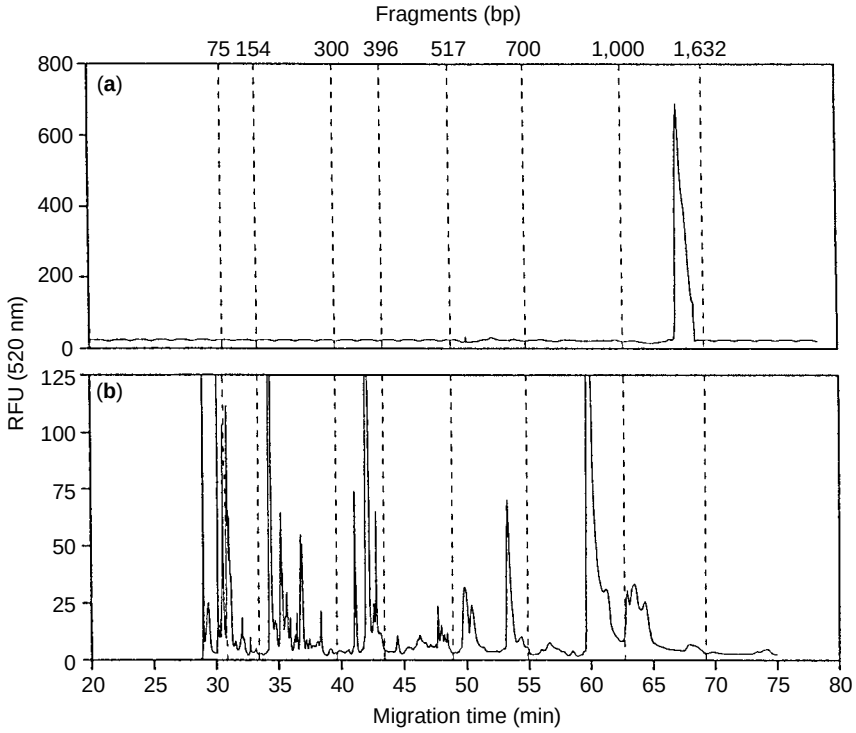

Figure 7. (**a**) Whole 16S rRNA PCR products and (**b**) T-RFLP fingerprinting by *CfoI* digestion of complex marine bacterial communities by CE. [M. M. Moeseneder et al., *Appl. Environ. Microbiol.* **65**, 3518–3525 (1999).]

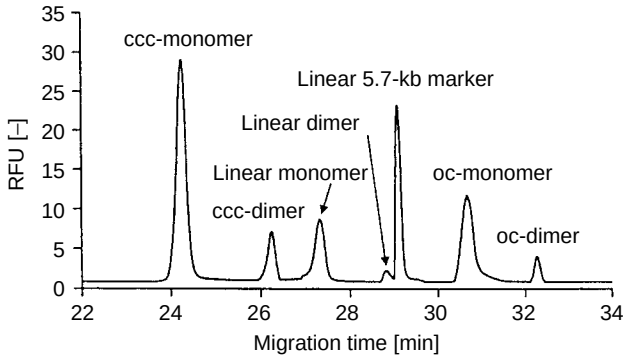

Figure 8. Quantitative analysis of a mixture of untreated, UV-treated (oc, open circle; ccc, closed concatameric circle), and linearized plasmid forms by CE. [T. Schmidt et al., *Anal. Biochem.* **274**, 235–240 (1999).]

molecules. However separations are slow because of the low field strength and low mobility of large molecules in solid gels. Pulsed-field electrophoresis with entangled solution-sieving media in a capillary format (61,62) and field-inversion capillary electrophoresis (FICE) (63) have been applied for separation of both large and very large DNA molecules with an improvement in speed by one to two orders of magnitude (64). Pulsed-field CE methods would be suited to a microdevice format, where very substantial gains in speed of separation would also be realized. Genetic diversity among bacteria may be characterized by PFGE pattern analysis. This analysis is applied to genomic fragments, plasmids and to ribosomal gene repeat fragments and is often performed in conjunction with ribotype analysis (65). Although some comparative studies of fingerprinting methods have found low information content from pulsed-field electrophoretic–RFLP studies compared to other PCR-based fingerprinting methods (RAPD's, REPs, PCR-RFLP) (16), other studies have found PGFE-RFLP to be complementary to ribotyping and for PFGE pattern analysis to subdivide the ribotypes into several PFGE genotypes, and further within a PFGE genotype, into subtypes following restriction with different enzymes (14,65–67). These PFGE studies would benefit from the large increase in speed by transfer to a capillary format (Fig. 9).

CAPILLARY ARRAY ELECTROPHORESIS

The recent development of capillary array electrophoresis (CAE) that offers all the advantages of conventional CE, but additionally provides very high throughput with up to 100 samples were simultaneously analyzed in parallel capillaries (68) with processing of multiple DNA fragments in under 70 minutes. Capillary array electrophoresis could conceivably be used for any other analytical procedure applicable to capillary electrophoresis (36,37) such as SSCP and HPA analysis. The advantage of high throughput could benefit direct sequence determination of sets of known characteristic polymorphic genes as capillary array electrophoresis apparatus is capable of running and analyzing 48 DNA sequencing samples simultaneously with runs of approximately 1 hour for about 500 bases as a throughput is on the order of 720 templates per day (44,69) (Fig. 10). As the cost and scarcity of such equipment falls, such rapid analysis increases the scope for epidemiological and taxonomic studies in fungi. In addition, small capillary array electrophoresis (CAE) chips have the capacity to rapidly analyze (2–3 minutes) differences in the mobility of DNA

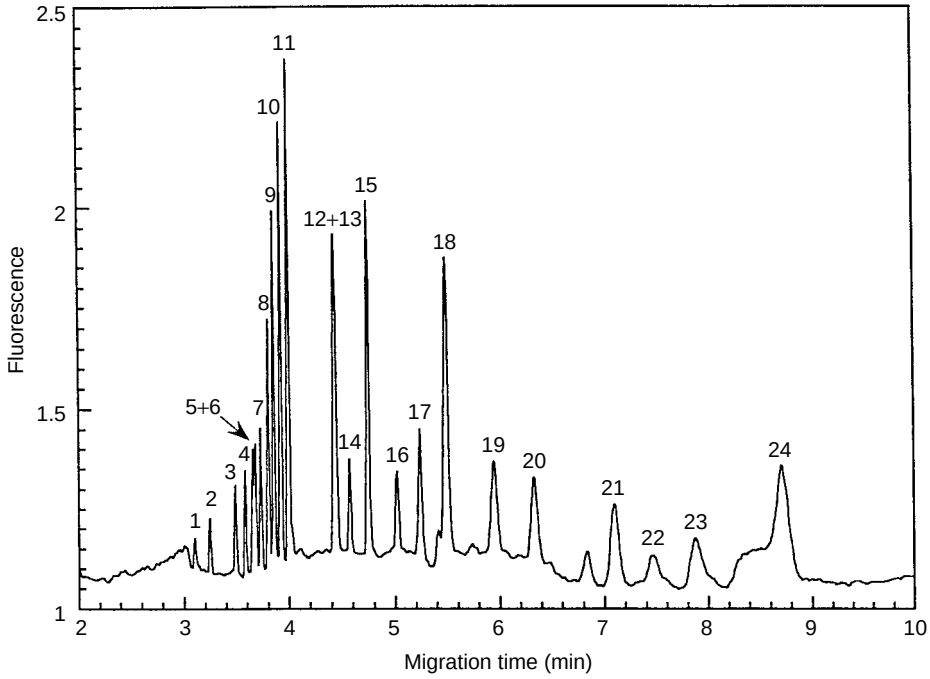

Figure 9. Separation of a mixture of ϕX174/*Hae*III fragments (72–1,656 bp), high molecular weight marker (8,271–38,416 bp) and Lambda-phage DNA (48,502 bp) by FICE in a 0.4% hydroxypropylcellulose sieving. Alternating peak sizes are in base-pair: (1) 72 bp; (3) 194 bp; (5) 271 bp; (7) 310 bp; (9) 872 bp; (11) 1,656 bp; (13) 8,612 bp; (15) 12,220 bp; (17) 17,057 bp; (19) 22,621 bp; (21) 29,942; (23) 38,416 bp and (24) 48,502 bp. [S. Magnúsdóttir, H. Isambert, C. H. Heller, J.-L. Viovy, *Biopolymers* **49**, 385–401 (1999).]

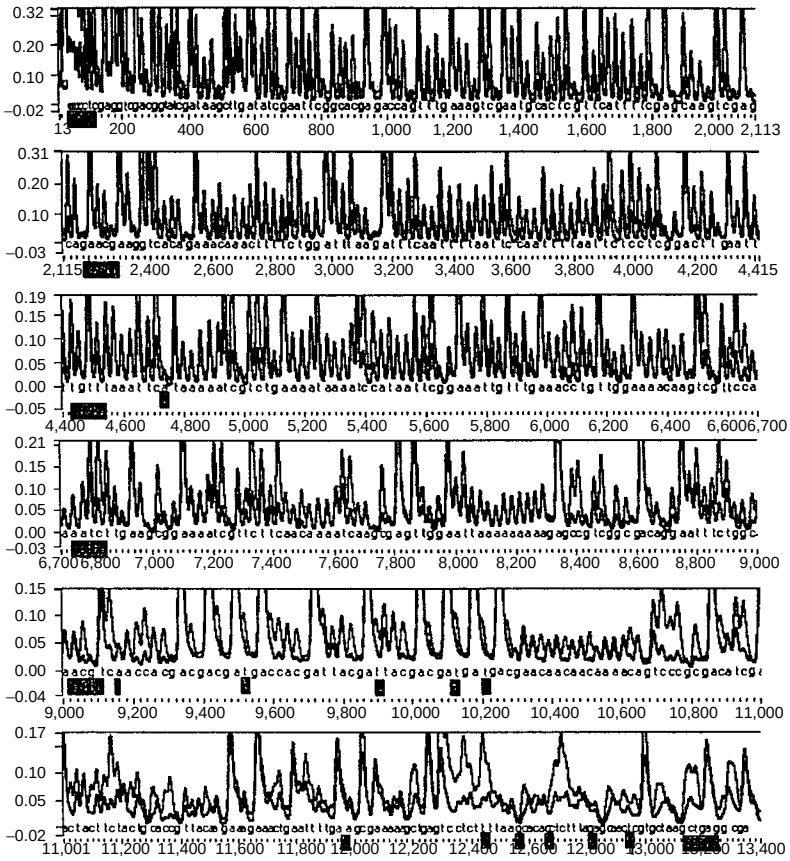

Figure 10. Multiplexed automated DNA sequencing directly from lysed single bacterial colonies by CE. [Y. Zhang, H. Tan, and E. S. Yeung, *Anal. Chem.* **71**, 5018–5025 (1999).]

fragments in parallel in multiple different samples and offer the potential for ultra-high speed, high-throughput genotyping by RFLP analysis (38,70) (Fig. 11). Microchip-based electrophoretic method for rapid detection of herpes simplex virus PCR products employed direct introduction into the microchip without a desalting step using a novel fluidic interface (71). The analysis achieves 100% sensitivity and specificity compared to the established gel methods with a detection of HSV DNA in less than 110 sec/sample (Fig. 12).

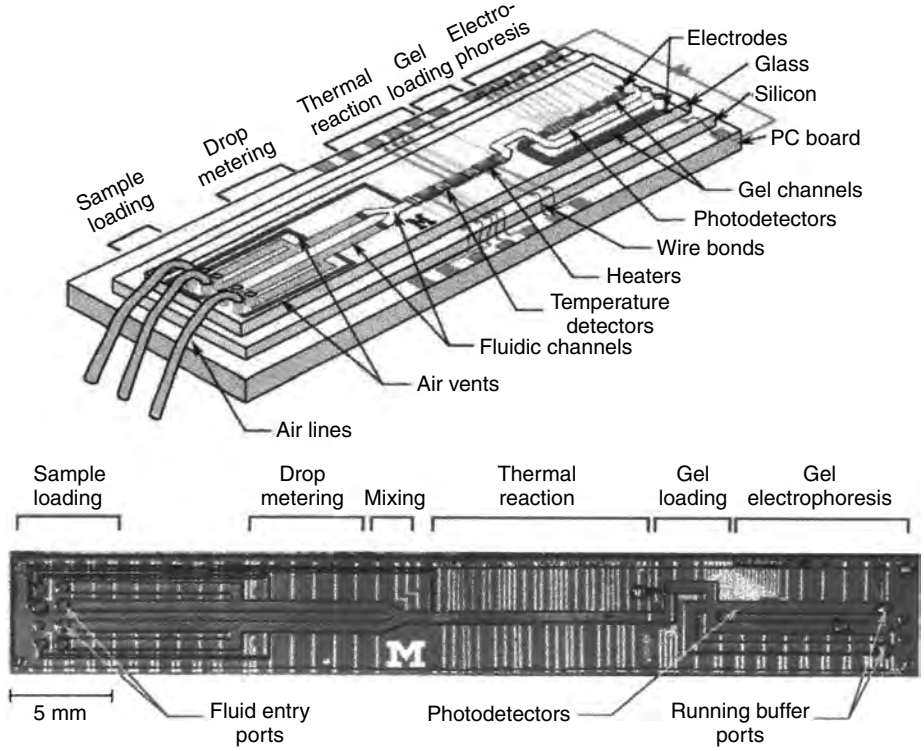

Figure 11. Schematic of integrated silicon device with two liquid samples and electrophoresis gel present (**a**) and an optical micrograph of the device from above (**b**). The microfabricated silicon chip has an integrated metering capability, a thermal pump, an isothermal reactor, a CE structure and an integrated photodetector. DNA amplification is achieved through an exponential isothermal "strand-displacement" amplification technique. The total analysis on the device from the metering of the reactants to the CE-based separation and detection took about 20 minutes [M. A. Burns et al., *Science* **282**, 484–487 (1998).] See color insert.

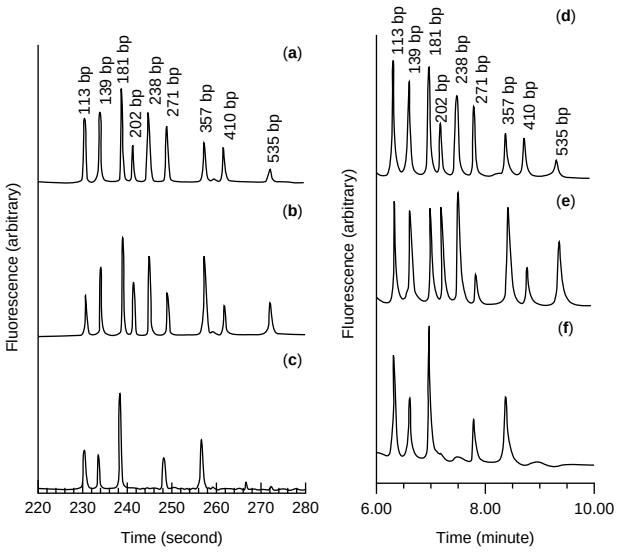

Figure 12. Comparison of chip CE electropherograms with conventional CE electropherograms. (**a**) control, PCR in a GeneAmp test; (**b**) PCR amplicons generated in a silicon-glass; (**c**) PCR amplicons from an affected patient generated in a silicon-glass chip; (**d–f**) conventional CE electropherograms. [J. Cheng et al., *Anal. Biochem.* **257**, 101–105 (1998).]

PARAMAGNETIC BEADS AND RIBOTYPING

Biotin-labeled DNA primers specific for gene regions can be used to amplify particular cDNA fragments from cellular mRNA using reverse transcriptase combined with PCR (RT-PCR), and these cDNA are collected specifically by binding to immobilized avidin (72). Both the quantitative level of gene expression and putative sequence variation within such cDNA fragments could be examined by SSCP analysis following release of a single DNA strands from the amplified dsDNA (73). One application is for the genotyping of bacteria (42) and fungi (74) in which length and sequence polymorphism analysis of rRNA-intracistronic and rRNA-intergenic regions are examined. The use of SSCP-CE analysis in combination with magnetic bead separation of the DNA strands allowed detailed CE migration profiles and creation of conformation isoforms for each isolate (74). An alternative approach might be a capture and detection system using biotin-labeled probes (75) to capture the DNA segments that contain specific regions of the genes by DNA-DNA hybridization, following PCR amplification or RT-PCR. Future use of DNA chips for genome-wide analysis of gene expression may stimulate the development of diagnostic applications of new technologies such as dynamic DNA hybridization using paramagnetic beads for expression analysis (76) (Fig. 13).

FUTURE DEVELOPMENTS

Nubel and his associates, (8) used temperature gradient gel electrophoresis (TGGE) to detect small sequence heterogeneities in PCR fragments of 16S rRNA genes from individual strains of *Paenibacillus polymyxa* (Fig. 14). The different strains of *P. polymyxa* showed heterogeneity in 10 variant nucleotide positions in a 347-bp fragment of the V6 and V8 regions in the RNA molecules.

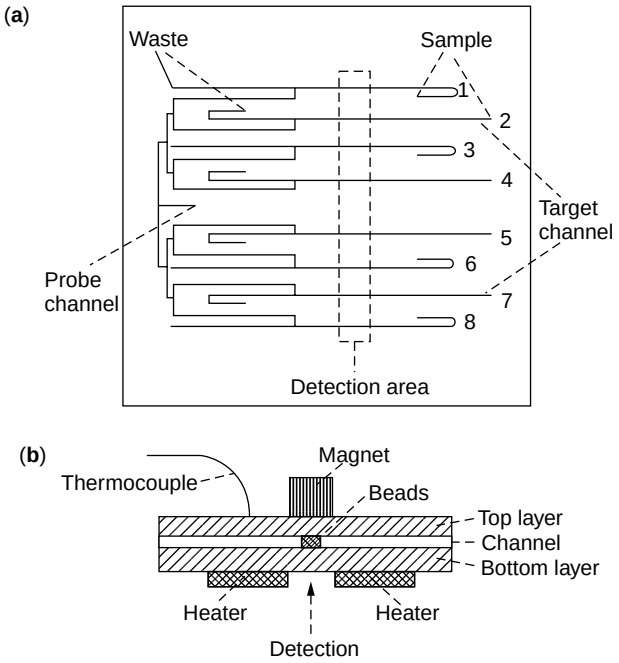

Figure 13. Dynamic hybridization of DNA on a microfabricated device using paramagnetic beads. (**a**) layout of the chip showing eight parallel channels for introduction of DNA and beads. (**b**) a cross-sectional view of the device. A magnet localizes beads at the detection area. Target DNA attached to the beads is assayed by successive hybridization against complementary probes which can be replaced by flushing. Selective hybridization is controlled by the thermocouple/ heater elements. [Z. H. Fan et al., *Anal. Chem.* **71**, 4,851–4,859 (1999).]

This analysis regime is well suited to capillary electrophoresis as the precise temperature control of capillary environments is superior to the conventional gel format (53). The ability to generate precise thermal gradients into the separating capillary columns is well established and TGGE is strongly established in the CE format (51,53). Amplifications of reverse-transcribed rRNA from ribosome preparations revealed a predominant representation of particular sequences in ribosomes of exponentially growing laboratory cultures (8). TGGE may be used for the structural analysis of heterogeneous rRNA genes and for their expression during stress conditions. Modern structure-specific cleavage of ribosomal genes (77) can also be directly assayed using capillary electrophoresis.

Remote Assay and Microanalytical Assay Systems

With the recent development of transportable and potentially "in the field" microsensors and microanalytical systems (71,78–80), the future holds promise for adaptation of these devices for the assay for the presence of specific target organisms and biological activities or processes under physiological conditions (80,81) or in situ conditions (18). These technical developments have parallels with field forensic systems (35,80) that amplify specific DNA fragments from target organisms, and may enable microbiologists to study the abundance, localization, and activity of microorganisms in situ. These systems may involve a

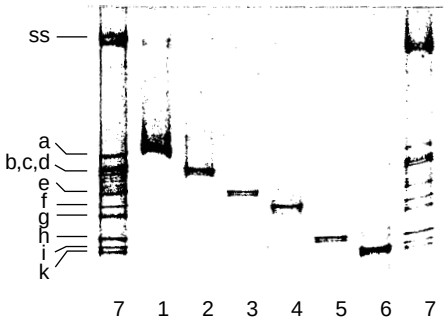

Figure 14. Temperature gradient gel electrophoresis (TGGE) separation of different 16S rDNA fragments from *P. polymyxa* strain DSM36, showing sequence polymorphism in gene copies. Lane 7 shows the mixed PCR products of the 16S rDNA gene, and lanes 1 to 6 show PCR products amplified from individual plasmid clones of the fragments. [U. Nubel et al., *J. Bacteriol.* **178**, 5,636–5,643 (1996).]

specific PCR or amplification reaction stage to increase the abundance of a specific target molecule, and an analysis stage to characterize the identifying amplicon. Typically, analysis can involve the determination of molecular size or DNA sequence that can be elegantly performed using capillary electrophoresis (60,82). The development of low-power microcapillary electrophoresis systems that provide analytical performance and plate efficiency comparable or better than conventional CE systems, with a separation efficiency on the order of 10^4 theoretical plates over a short effective separation distance of, say, 1.5 to 2.0 cm, in which analysis is completed within 5 minutes (83–85), will be of great benefit in future microbiological studies (Fig. 15).

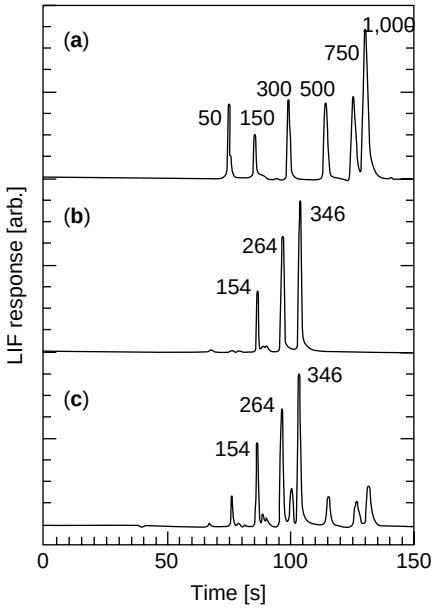

Figure 15. Chip CE electropherogram of: (**a**) a sizing ladder, (**b**) PCR products amplified from *E. coli* genomic DNA, and (**c**) PCR product mixed equally with the sizing ladder. [L. C. Waters et al., *Anal. Chem.* **70**, 5,172–5,176 (1998).]

WHOLE MICROBIAL ANALYSIS

A further advance in the application of capillary electrophoresis is in the fractionation of whole microbes in the manner of molecules, by microbial size and shape using polymer-based modulation of capillary electroosmotic flow, and separating by surface charge of the microbes by capillary isoelectric focusing (86,87). Potentially, pure microbia pools could be collected from the capillaries, allowing additional genetic analysis of each fractionated species peak by ribotyping techniques. Rapid, on-line identification of microbia could also then be made by direct physical measurements of microbial surface molecules, for example, a subset of microbial proteins, using Fourier transform-infrared (FT-IR) spectrography, or by mass spectrography (MS) (88). Small specific DNA fragments PCR-amplified from the microbial genome can also be readily analyzed directly, by electrospray ionization mass spectrometry (ESI-MS) or by time of flight mass spectrography (TOF-MS) (54). Both HPLC or CE instruments can be coupled directly to ESI-MS instruments; however, the outlets must be coupled with a sheath flow system to transport the molecular species into the MS (89). Sample stacking of CE peaks is also necessary before delivery into the MS device.

Another microfabricated device that allows the selective separation and purification of bacteria from other cells uses physical electrical forces such as dielectrophoresis and EEO (90). This exciting technology is an initial step toward the development of an integrated system that would combine elements for cell separation, DNA processing and signal detection. Other microfabricated devices that provide both DNA processing and signal detection elements have also been described (78,91). These separation and analysis microdevices could be applied together for the development of such an integrated total microanalysis system.

Microbial ecology has undergone a renaissance in recent years. The diversity of life on the surface of this planet has been probed more deeply than ever using new approaches. In contrast, the earth's subsurface remains comparatively unexplored. The spatial extent, collective biomass, phylogenetic diversity, and geochemical role of the subsurface biosphere remains conjectural (1,2). However, this milieu has received steadily increased attention in recent years (2–5). (see also Caves and Other Low-Light Environments: Aerophitic Photoautotrophic Microorganisms, this Encyclopedia). Yet, despite the emerging prominence of the field, the acquisition of meaningful samples remains a persistent obstacle to research (6,7). As an alternative to remote extractions (e.g., coring from surface), microbiologists have increasingly sought preexisting voids within the earth for direct sampling opportunities.

In the case of natural caves, biospeleological environments constitute an important and globally distributed biome in their own right (8). Underground mines permit directed passage into otherwise solid continental rock masses. In this article, we describe approaches to the microbiological sampling of these habitats. Natural caves may contain a variety of subsurface mineral habitats, including carbonates, quartzites, arkoses, sandstones, some varieties of volcanic substrata, and others (9). Many caves are influenced by surface microbial communities via streams, periodic flooding, groundwater, animals transporting materials in and out (trogloxenes), and air. Others are ancient in nature (10) and may house microbial communities isolated from direct outside influence for thousands to perhaps millions of years (10–14). Even here, the intricacies of karst hydrology can make prediction of recharge times tricky. Surface water input

into seemingly sealed caves may exhibit either slow or rapid movement along faults and fissures (15). Some caves may exhibit ongoing chemical excavation mediated by subsurface microbial communities, including acid-generating, autolithotrophic, sulfide-oxidizing bacteria (3,13,14,16–23). The very walls of the subterranean spaces that allow human access may thus represent exactly the right places to seek certain classes of subsurface microbes and to witness globally relevant biogeochemical processes in action (24,25).

Mines, by comparison, are artificial excavations. As such, they penetrate rock types not normally accessible to natural caves and often extend to greater depths. Mines may also represent conduits of potential surface-derived contamination into the subsurface biosphere. In any mine, all surfaces of potential microbiological interest will have undergone extensive alteration by the mining process. Material representative of the native subsurface may exist only centimeters beyond a given excavation face, but with each round of mining, a new contamination front is established between the microbiologist and the potentially pristine material. For this reason, great care must be taken in interpreting the significance of observed microbes and microbial activity in mines.

Microbially interesting cave systems and mining operations are often located in remote locations. Working underground in a cave or mine can be physically demanding and potentially dangerous. Equipment and samples may have to be carried over difficult terrain. The vertical relief typical of many wild caves necessitates specialized rock-climbing skill and equipment. Some cave atmospheres differ significantly from surface air and contain dangerous or lethal concentrations of various gases, including H_2S, CO_2, CO, NH_3, and others (8,22 and unpublished data). In underwater cave microbiology, the aquatic matrix itself imposes logistic and safety challenges. Only certified cave divers can conduct the sampling, and time limits are inflexibly constrained by air supply of the diver and blood gas physiology (26). Although in this case, underground mine research is also time-constrained mostly by blasting and cage schedules. In spite of these difficulties, underground samples must be collected with care to minimize contamination and postsampling changes.

SAMPLING AIR-FILLED CAVES

Cave Habitat Types

Air-filled caves present an array of potential microbial habitats, most of which parallel corresponding habitats of surface systems (Fig. 1). Habitats include running stream water, still pools varying from fresh to brine, and to alkaline, wet rock surfaces, flowstones and speleothems, dry rock surfaces, muds and cave soils, unconsolidated mineral deposits and pastes of various compositions, and highly organic microbial mats, streamers, and strings clinging to all surfaces of both the cave and the exoskeletons of

Figure 1. Terrestrial caves come in a large variety of types. As can be seen from the partial list of potential environmental variables earlier mentioned, the conditions under which sample taking is conducted will also vary tremendously. Every situation from walking-accessible caves where working is pleasant and easy to caves with poisonous atmospheres that make sampling potentially life-threatening can be encountered. cave invertebrates (8). Even stromatolitic microbial sediment structures are found in cave environments (27). Cave sites of potential interest can occur in the near-entrance twilight zone under skylights where varying degrees of attenuated light is present, or deeper into the cave where no light but the occasional caver's headlamp will ever reach. Many caves have invertebrates and vertebrates that access them occasionally (trogloxenes), frequently (troglophiles), or who live their entire lives in the confines of the cave (troglobites). Many of the invertebrates and some fish graze directly on microbial films. Some caves are sufficiently deep and isolated, such that they are primarily or exclusively microbial preserves (28). This can provide an ideal situation for microbiological study without the interfering effects of higher organisms.

Cave Conditions

Whatever the cave type, physical conditions (e.g., temperature and humidity) remain relatively invariant over time. Some caves experience greater fluctuations than others because of their specific three-dimensional structure, degree of closure, and hydrology, but they are more constant than most surface environments. Some caves allow entrance and pooling of cold air resulting in permanent ice deposits, even where summer surface temperatures are very hot. Caves in tropical environments reflect the higher annual average surface temperatures in their temperature.

Caves are highly mineralized and have mineralizing environments because they are essentially a subcomponent of the lithosphere. Additionally, the water-free portions of caves are good environments for preservation of organism remains and organic matter. Although humidity-saturated, caves under arid and desert surfaces can preserve organisms, their remains, and traces of organic matter for very long periods of time in the absence of episodic flooding. Cave air may contain significant concentrations of carbon dioxide (e.g., 7% carbon dioxide in a northern Arizona cave). Episodic levels of hydrogen sulfide and carbon monoxide in a Mexican sulfur cave have reached as high as 204 ppm hydrogen sulfide and 140 pm carbon monoxide (P. Boston, unpublished data).

Most caves are also oligotrophic environments with low levels of organic input derived primarily from the surface. In some cases, utilizable carbon sources may be contained within the parent rock housing the cavern or possibly enter as low molecular weight carbon compounds from deeper geological layers housing petroleum basins. In a few cases, large fluxes of hydrogen sulfide coming into caves via springs provide the basis for a greatly enriched food chain relying on primary productivity of sulfur-oxidizing chemolithotrophs. This additional nutrient base is reflected in noticeably greater biomass than is found in other caves (12,22,29,30).

Cave Microorganism Properties and Methodological Consequences

In general, the relatively constant environmental conditions in most caves endow their microbial inhabitants with a sensitivity to rapid change in parameters such as temperature and humidity. Unlike their surface relatives, cave organisms do not experience weather phenomena, diurnal temperature change, photic oscillations, or seasonal or periodic desiccation. They do not have to cope with ultraviolet radiation, but some caves do have to cope with periodic flooding. Caves with streams running through them from the surface have more organic input than drier caves. In the latter, inhabitants are highly adapted to low-nutrient conditions and highly susceptible to disturbance by the introduction of organic materials. Various minerals in caves, including iron oxidizers, manganese oxidizers, sulfur oxidizers, and others, can provide habitat for a variety of chemolithoautotrophic organisms (8,22,28).

These principles must be kept in mind when designing culturing techniques or other sample-collection methodologies. In general, we recommend performing as much analysis in situ as is practical. For example, metabolic tracer and uptake studies, exoenzyme and biomass assays, and staining with biological dyes can be performed at the site with sufficient redesign of well-known techniques (8). For culturing studies, greater success in recovery of diverse organisms can be achieved by in situ incubation of newly inoculated cultures for as long as possible. We regularly employ extended incubations from weeks to months before removing cultures, particularly in the case of slow-growing chemotrophs.

Dirt is a problem. Most caving involves becoming moderately to extremely filthy and caked with a variety of substances. This is not conducive to good aseptic techniques. We employ sterile nonlatex surgical gloves for most manipulations (Fig. 2). In the humid cave environment, glove-wrestling events can be avoided by using a size larger than normal. Use unpowdered gloves to avoid introducing an unintended contaminant. In addition to dirt, human contamination is a major problem in oligotrophic cave environments. The shedding of hair and skin cells produces a virtual blizzard of organics on a

Figure 2. Long-term in situ incubations of glass or parent rock slides in cave or mine habitats is a handy means of collecting biomass without making much of a sampling impact on the environment. Sterile gloved hand is shown placing a glass slide in Cueva de las Barrancas, New Mexico, a pristine unexplored science-only cave. Slides will be left in place from months to years before collection. Image courtesy of V. Hildreth-Werker.

scale that can be significant for obligate oligophiles. In addition, human-associated microorganisms can persist in the cave environment by using this nonnative nutrient source (A. Hunter and P. Boston, unpublished data). In cases where caver proximity may compromise asepsis, sterile tyvek clean room garments are useful (Fig. 2).

In tiny deposits or puddle-sized cave pools, only minute quantities of sample can be taken to avoid negative impact on the miniscule environment. Miniaturization of procedures facilitates both the conservation of unique microbial habitats and also helps investigators to maneuver their scientific equipment through difficult passages and descents! An excellent way to minimize the quantity of collected material is through the use of microbial "traps." These can be conventional glass slides (Fig. 3) or slides machined from parent materials preferably collected from the surface outcrops of the country rock (Fig. 4). Slides can be hung on sterile monofilament lines to study airborne transport and colonization of organisms or at thin waterfilm-transported organism colonization.

Another useful technique to avoid decimating small bodies of water can be termed the *blood plasma* model of sampling. In this case, volumes of water can be withdrawn from a pool using large (100 cc) sterile syringes with large needles. This fluid can then be injected into a sterile microfiltration assembly. The filter traps organisms and particles of interest, whereas the water can be captured into a sterile collecting vessel and returned aseptically back to the pool. Filter-trapped organisms can be frozen for later DNA analyses, scraped, inoculated into growth media, subjected to a variety of staining procedures performed in situ, or chemically fixed for later examination with SEM or TEM.

Ideally, no-impact techniques are perfect for applications in caves. Many techniques are being developed that greatly minimize the impact on sample sites. Culture-free molecular measures of biodiversity (31,32) are being applied successfully to cave microflora (28,33). Indicator substances like exoenzymes are detected in situ (e.g., 34 modified in 8), biomass inferred in insoluble materials (35); both visualization of microbes (36) and biomineralization (37) have cave applications. A variety of techniques are reviewed in Hirsch and coworkers (38) and modified for cavers in Boston and coworkers (8).

As with many environments, perhaps a majority of species present in cave samples are not presently culturable even with highly specific, selective, and enrichment media that we create for them (32). The use of molecular techniques, specifically 16S rRNA analysis,

Figure 3. The hydrogen sulfide and carbon monoxide saturated atmosphere of Cueva de Villa Luz, Tabasco, Mexico, necessitates serious breathing protection and an emergency oxygen tank worn on the belt at all times to compensate for episodic dips of oxygen to levels as low as 9.6% (20.9% oxygen is standard at sea level). Sterile gloves and tyvek suit, and wiping helmet surfaces with an antimicrobial are precautions against contaminating the samples and provide some measure of protection for the skin against sulfuric acid dropping from the ceiling. Figure 4. Long-term aerial colonization study is set in place by caver D. Hamer. Country rock machined into slides, polished, sterilized, and hung on a sterile apparatus will be left in place in an off-limits area of Lechuguilla Cave, New Mexico. This experiment is testing whether there is aerial transport of organisms through the cave air circulation cells and colonization on new rock surfaces. Experiments of this nature can run for many years before showing results. Image courtesy of V. Hildreth-Werker.

provides both a measure of biodiversity and a variety of closest taxonomic affiliations, thereby providing potential insight into the composition and potential metabolic characteristics of cave communities. Although the specifics of these analyses are beyond the scope of this discussion (see 8,22,28,33), requirements of the techniques impact the sampling procedures. Because we are trying to achieve the analysis of an unaltered sample, staging of the material on dry ice is the preferred method of field preservation. It should be remembered that cave organisms are adapted to an extremely uniform thermal environment and are more likely to be perturbed or destroyed by even small temperature fluctuations than their surface relatives. Dry ice can be taken into the cave-sampling area in a conventional dewar, provided the cave is not difficult to negotiate. For demanding sites requiring vertical-ascent techniques or extensive crawling, a more robust version fabricated from unbreakable materials can be obtained. Dry ice must be handled with care and sublimating gaseous carbon dioxide must not be allowed to build up if the samples are collected in small, closed areas.

Small-scale coring can be done into parent rock, degradation products, and deposits like elemental sulfur. For soft materials, a simple sterilizable soil corer is required. For rocky materials, battery-powered drills fitted with sterilizable core bits of various configurations are suitable. Any cooling gas used to reduce drill bit temperature must be sterilized. Typically, nitrogen is a good choice for small tanks fitted with in-line microfiltration devices. Significant problems may be encountered when drilling because of the strict power limitations imposed by the necessity to carry the heavy batteries to remote sites.

SAMPLING WATER-FILLED CAVES

The microflora of phreatic conduits are not accessible by ordinary environmental microbiology sampling techniques. A combination of sterile technique and technical cave diving is required to sample these habitats. Challenges such as sample container buoyancy, confined space, darkness, remoteness of sampling sites, and an aquatic environment can, however, be met by cave divers sampling bacterial colonies while hovering in the water column in underwater caves.

Cave divers have observed bacterial colonies large enough to be visible to the naked eye in springs and underwater limestone caves within the Floridan aquifer in Florida (3,39), in underwater caves and meromictic sinkholes on the Yucatan Peninsula in Mexico (40,41), and the phreatic, brackish water caves in the Nullarbor Karst Plain in Australia (42). Divers' observations of these colonies include thin white or gray mats or tufts on cave floors, filamentous masses in the water column, drooping threads or sheets of slime, and gelatinous masses attached to the cave floor (Fig. 5a). Underwater cave fungi have been observed in a Yucatan cenote (Brigmon and coworkers, unpublished data). Underwater cave bacteria from Florida have been identified with monoclonal antibodies and examined with electron microscopy (3,43,44). Bacteria that are found in underwater caves (such as sulfide-oxidizing *Thiothrix* spp.) can form aquatic biofilms that, in other settings, contribute to biofouling of municipal water storage tanks, sewage treatment facilities, private wells, and drip irrigation systems (45). The bacteria of underwater caves may constitute a valuable genetic resource (39).

Approaches for sampling aquatic bacteria in underwater caves have been described previously by Martin and coworkers (26) and are presented in the following text. These methods were developed for research on *Thiothrix* spp. (3,39,43,44). They are based on a combination of standard environmental methods originally developed for sediment (46) and macroinvertebrate sampling in underwater caves (47–50). Microbiologists cannot sample in underwater caves unless they have amassed several years of extensive training and experience in scuba diving, cavern diving, and cave diving. Thus, it is most likely that the microbiologist will remain outside the cave while a professional cave diver collects the samples.

Diving Techniques and Equipment

A helmet-mounted light (commonly used by European and Australian cave divers, but rarely in the United States) can greatly facilitate the sampling work of divers in caves. Kayaking and bicycling helmets are preferred to caving helmets because of the bulkiness and straps of the latter. Helmets should fit over the diver's head with or without a neoprene hood. Light-mounting brackets can be purchased or made from schedule 40 PVC pipes. Lights for helmet mounting should be as bright and lightweight as possible and designed for one-hand operation. Because bacterial sampling requires the use of both hands, handheld lights, cameras, and diver propulsion vehicles must be set aside or passed to a safety or assisting diver before sampling.

Note troglobitic crayfish in upper center. (**b**) Martin collecting sample for sediment characterization from a sulfur bacteria biofilm at a groundwater discharge area in an underwater cave in North Florida. Sampling container nonsterile. Photos courtesy of Tom Morris.

This should be done carefully so as not to stir up bottom sediment. To accomplish this, the sampling diver needs to hover in the water column (low-flow areas) or crouch gently on the bottom downstream of the sampling site (practical only in high-flow areas) (Fig. 5b).

Sampling divers and assisting divers should carry at least one extra-underwater writing slate each. These slates should be formatted before the sampling dive with spaces for information that will be required to fill out a sample log sheet or field data notebook.

Sampling Containers and their Underwater Handling. Whirl-pacs (Nasco International, Fort Atkinson, Wisconsin) and many other commonly used sterile, environmental sampling containers cannot be used underwater because of their physical characteristics. The standard 50-mL polypropylene screw cap centrifuge tube is the only sterile sample container that has successfully been used in underwater caves.

During earlier underwater cave microbial sampling efforts, sampling containers were stowed in strapped-on pouch-pockets of a wet suit, or buoyancy-control vest pockets, or in water-filled "dry" boxes with handles that were clipped to a "D" ring. An improved method is the "Gomez tube," developed by the late cave diving microbiologist Peter Gomez. The Gomez tube is a thin-walled PVC pipe with the inside diameter of the sterile sampling tube wider than the outside diameter and of sufficient length to hold up to six sterile sampling tubes. Tire inner tube rubber is placed over each end of the PVC pipe and secured with a hose clamp. A slit is made in each piece of the rubber, allowing prelabeled sterile sampling tubes to be removed from the PVC pipe in a predetermined order. To remove the first prelabeled sterile sampling tube from the PVC pipe, an extrasterile sampling tube is inserted at one end of the PVC pipe, displacing the first. With the exception of the inner tube material, all of the materials required for constructing a Gomez tube can be obtained at a hardware store. If the entire Gomez tube is to be placed on ice after the sampling diver leaves the water, it should be short enough to fit in an ice chest.

Polypropylene tubes and sample bottles and their caps are positively buoyant, so the sampling diver must not let go of either underwater. To prevent cap loss, Velcro can be glued onto each cap and onto some area of the container (Dr. Jill Yager, Antioch College, personal communication). The ideal bacteria sample container for use in underwater caves is one that is slightly negatively buoyant underwater, water-filled, sterile, and easy to manipulate with gloved or cold hands.

Each diver can easily manage three or four air-filled tubes, or up to six when using a Gomez tube. Our experience in Florida caves has shown that divers have time to collect at the most four samples and still accommodate required decompression. In shallow caves such as those found in the Yucatan in Mexico, more than four samples per diver can be taken (Dr. Jill Yager, Antioch College, personal communication). The number of divers needed is a function of the size of the cave, the sampling tasks required, and requirements to minimize environmental disturbance. A two-diver team is desirable. In larger caves, a three-diver team may be necessary for safety and to handle the workload. We have observed no implosion of sterile 50-mL polypropylene centrifuge tubes at depths of 30 m or less, but some have imploded at greater depths. However, we have observed that at depths approaching 30 m, it was difficult to remove the lids from the sterile air-filled tubes because of the elevated pressure. For deep sampling (>30 m), sterile tubes can be filled with autoclaved water in a sterile laminar flow hood in the laboratory. Gas headspace must be close to zero, however, or caps will be difficult to remove at depth.

Sampling Technique

General Considerations. The collection of microbiological samples is a slow process for even the most efficient methods, so shallow sampling sites are most convenient. However, sites of interest may be deep. If samples are to be collected at sites of a depth greater than 30 m, be sure to factor adequate time into the dive plan. If possible,

water and bacteriological sampling should be done on the way into or down to the most distant/deepest sampling point during the dive (51). Careful region-by-region sampling, temperature measurements, and other operations should be done during the inbound part of the journey. In some caves, this is necessary to maintain the integrity of the water column stratigraphy and chemistry, which may otherwise be disrupted and/or contaminated by divers' movements and the upwelling of deeper, sometimes colder water by divers' air exhaust bubbles (51). Inbound sampling is particularly important in sinkholes. Whether it is best to sample bacteria in a siphon cave (caves where the entrance is upstream and divers must enter swimming downstream) on the way in or out depends on the penetration distance and the rate of cave water flow.

For some bacterial colonies, it is useful to collect one sample with and one without adjacent sediment. If the bacteria are growing on limestone, collection of a piece of substrate or adjacent limestone may be valuable. Rock samples are stored in labeled sterile bags. Some underwater cave bacteria are difficult to culture in the laboratory without springwater or other groundwater from the same or similar sites as an addition to growth media (3,43,44,52). Water for culturing should be collected from the aquifer where the bacterial colony is located. We have found that it is not necessary to use diving to collect these water samples if a surface spring or flooded sinkhole is present. Slurp guns are plastic suction devices designed for the live collection of fish and invertebrates in aquatic and marine settings. Assuming a slurp gun could be autoclaved or gas-sterilized, such a device may be used for the underwater collection of bacterial colonies.

We have found sterile 50-cc tubes to be the best container for sampling bacteria in underwater caves. The following procedures have proven successful (26). Uncap the tube while in direct proximity to the bacterial formation or sample surface. Try to get as much material as possible into the sample tube. Sample different morphologies in separate containers. In our experience, the best way to collect bacteria occurring as films on surfaces such as rock, clay, or iron oxide deposits is to scrape them off with the mouth of the tube, orienting the tube so that the bacteria (with a specific gravity slightly greater than water) sink into the tube. Flocculent bacteria, usually found in cave areas of low flow, can be collected by gently pushing the tube through the colony and, if necessary, prodding the sample into the tube with the cap. If it is necessary to obtain bulk in situ water for media preparation, collect as close as possible to the location of the original sample. Purge outside water from the sample container (prefilled with sterile water to minimize buoyancy and implosion pitfalls) with a compressed air nozzle while holding the jug upside down. Refill with cave water, purge, and fill again to ensure sample integrity (51). Where water flow is substantial, this can be done without stirring up cave-floor or ceiling sediment or contaminating in situ water samples with water of a different chemistry. Where cave water flow is limited, care should be taken to minimize the disturbance of ceiling sediment or mixed waters. Other methods for water sampling by scuba divers described by Miller (53) are not generally practical in the underwater cave setting.

On-Site Observations. Record pertinent measurements including water current on an underwater slate by the method of Wilson (54). If diving a Ghyben-Herzberg lens cave (an island or coastal aquifer cave with a lens of fresh water overlying seawater), such as those in the Yucatan, Bahamas, and elsewhere, indicate whether samples were taken in the fresh- or saltwater layer and the vertical distance from the halocline, if present. Note morphological and positional information of the sampled material.

Postcollection Activities. From the sampling site, the diver must swim the entire distance out of the cave, possibly picking up staged breathing tanks (stage bottles) and negotiating low or narrow restrictions where gear can be knocked about. The careful stowing of samples is critical. Before leaving the cave, the diver must often decompress for as long as an hour or more. During this time, samples will equilibrate to the local groundwater temperature. If the samples must be transported to the surface quickly, support divers can enter the cave and retrieve the samples from the decompressing divers and deliver them to the surface staff. Finally, the sampling or retrieving diver climbs out of the water, exposing gear and samples to more jostling. Carefully passing samples to surface staff before the divers exit the water can minimize disturbance. Some samples may require the addition of fixatives or concentrated acid if sampling for protozoans, sulfide, or soluble minerals. Treatment and processing of microbiological samples cannot be conducted until the sample containers have been removed from the water. This is a limitation not shared by microbiological sampling in air-filled caves or mines.

Sampling for Anaerobes. We have not sampled subaqueous cave anaerobes but Martin and coworkers (26) proposed the following modifications for sampling anaerobic bacteria in underwater caves: (*1*) Sterile sampling tubes should be configured for the sampling of anaerobes. The gas in sterile tubes should be nitrogen, and not air. Sterilized in-line microfiltration units are readily available in many connection styles for the sterilization of gas. If tubes are filled with sterile water, this must also be oxygen-free. (*2*) Do not use air from the scuba tank to purge the water sampling container. Rather, fill a "pony bottle" (tank with 25 or less cubic feet capacity) with pure nitrogen gas. If the tank is not a scuba cylinder, the valve must be modified with a fitting that allows attachment of scuba fittings. These fittings are available at some dive shops, particularly those catering to cave divers. Do not install a second stage regulator on this tank because breathing this gas could be fatal. To the first stage regulator on this tank, attach only a low-pressure hose with an air jet nozzle and a pressure gauge. Attach the nitrogen bottle to the double scuba tanks or wherever convenient to the diver and secure the nitrogen hose and nozzle where the diver can reach it and will not confuse it with an air nozzle secured elsewhere on the diver. (*3*) When collecting the sample, open and close the sample container only in

the anaerobic zone. (*4*) After the dive and after putting anaerobe samples in the cooler, purge the air from the cooler with nitrogen gas from the nitrogen tank. A separate cooler for anaerobic samples may be useful. Conduct all sample transfers "under" nitrogen gas to the extent possible under field conditions.

SAMPLING UNDERGROUND MINES

Mines may be thought of as portals into the subsurface, but to be useful for studies of the subsurface biosphere, a number of issues must first be addressed. Although the true extent of this habitat remains unclear, some minimal prerequisite conditions (moisture, pore volume, energy, and nutrient availability) within the mined country rock must be met for microbes to persist. These factors should be considered in the selection of study sites. Subsurface microbial communities are likely to be composed of nutrition with low collective biomass. Native biosignatures within freshly opened rock panels and groundwater intersections may be ethereal and competitively overwhelmed by those of mining contaminants. Thus, to detect indigenous microbial communities, process-induced contaminants must first be recognized or negated.

Choice of Mines

Mine excavations tend to be composed of multiple levels, one over another. Service or drain water and their associated microbes may move by cross connections only to be rediscovered at other locations and interpreted as indigenous. For this reason, newer workings penetrating virgin rock and lacking overlying mining activity are the most desirable for microbiological investigations (55,56). In some cases, however, the goal may be to investigate mine microbiota itself, and thus older workings can also be of interest (57,58). Mine microbial communities can have a direct relevance to excavations created for the deep burial of radioactive waste (58) where the corrosive effects of microbes, irrespective of origin, may represent a hazard.

Contamination Issues and Quality Assurance

Potential vehicles for the direct spread of microbial contamination in a mine include service and drain water, ventilation air, equipment, and miners and their wastes. Additionally, biostimulative changes that favor surface-derived organisms (e.g., aerobes) in the local environment surrounding mine workings may alter microbial ecology and further complicate interpretations. Mines most typically intersect quiescent, anaerobic strata rich in reduced or partially reduced minerals and infused with reducing gases such as methane, hydrogen, and hydrogen sulfide. Mines functionally serve as conduits for the injection of oxidizing equivalents (ventilation air and service water) into these zones. The oxidative nature of service water reflects not only saturating levels of dissolved oxygen but also accumulations of blasting and disinfection residuals (e.g., nitrate and chlorine). In the presence of water, the resulting geochemical gradients, often supplemented with fuel and lubricants from equipment, represent a novel energetic resource that can lead to luxuriant microbial blooms of mixed origin.

Every sample taken from a mine must be assumed potentially contaminated, at least on its outer surfaces. Although the mining process may alter the outer surfaces of rock samples, internal pore spaces often remain pristine. To track potential process-induced contamination, many workers intentionally dose drilling or service water with easily traced materials and monitor the movement of these as surrogates for contaminating microbes. Alternatively, the unique chemical and biological components of known sources of contamination can be tracked. The U.S. Department of Energy (DOE) Subsurface Science Program has used tracers for the evaluation of sample contamination (59, and references therein). Although not limited to mine research, many of these techniques are directly applicable to mine sampling. Natural caves, by contrast, generally represent biologically protected zones and thus disallow this potentially intrusive technique.

Tracers may be particulate or soluble. The most often used particulate tracers are fluorescent carboxylated latex beads (Polysciences Inc., Bay Shore, New York). Typically, 0.4- to 1.2-μm diameter beads are used to approximately estimate the size of a bacterium (60). The beads are tracked using a fluorescence microscope on 10 X objective (100 X final magnification) and can be detected at approximately $10^4\ g^{-1}$ in crushed rock samples (59) or $10\ mL^{-1}$ in liquid extracts (61). There are several caveats in the use of microsphere tracers that must be considered before this technique is elected. Many microbes are motile and may penetrate more deeply into a porous substrate than passively transported particles. Microbes possess varied surface charges and envelope characteristics that are difficult to mimic. Also, even trace levels of contamination by nonindigenous microbes may still lead to significant bioburdens after postsampling growth. These concerns aside, microspheres remain one of the best methods available and have received generally good acceptance as a measure of quality control.

Water-soluble fluorescent dyes such as Rhodamine WT (Crompton and Knowles, Green Hills, Pennsylvania, excitation/emission wavelengths 546/590 nm, respectively), can be detected in extracts from samples by fluorimetry at approximately $2\ \mu g\ L^{-1}$ final concentration (62). Inert perfluorocarbon tracers have been used in a variety of applications, including subsurface studies, and can be detected by pyrolysis gas chromatography at picogram per gram final concentrations (59). Dissolved ions can function as tracers as well. These may be intentionally added (e.g., lithium bromide, 63) or intrinsic to process fluids (ammonium, sulfate; 61,64). In mine service water, nitrate ion may be present in millimolar concentrations and thus the submicromolar detection limits possible from ion chromatography and flow injection techniques permit better than three orders of magnitude protection. Dissolved oxygen is another easily detected service water component. One caution for dissolved constituent tracking, however, is that not all are conservative. Oxygen, nitrate, and sulfate, for example, can be quickly consumed by microbial action under permissive conditions.

Field kits for the detection of dissolved oxygen, nitrate, and others can be obtained from various suppliers (e.g., Chemet kits, Chemetrics Inc., Calverton, Virginia). Assuming deep groundwater to be generally anaerobic and nitrate-free, positive field tests for nitrate and oxygen (and/or free chlorine) can be taken as evidence that a given sample is process-contaminated. Temperature, easily measured in situ, may serve as a physical tracer of water origins. In deep, hot mines, service water is chilled before being piped to depth. Water emanating from fractures at a temperature below the ambient temperature for a given depth is cause for suspicion. In the same way, anomalously warm drainage may indicate the upwelling of pristine water from deeper levels.

Bacterial membranes contain phospholipid fatty acids (PLFAs). PLFA profiles have been employed to differentiate microbial communities from drilling fluids and sediments, to provide information concerning overall physiological status, and to estimate total biomass of subsurface microbial communities (65,66). One PLFA class (the epoxides) can serve as a biomarker for oxidative stress in bacterial population. Chlorinated mine service water reliably contain epoxide biosignatures in their particulate fraction. The absence of detectable epoxide may be taken as an indication that a given sample contains little or no service water (67). Cultivable microbes may serve as either added or fortuitous tracers in their own right. Several authors, for example, have used coliform bacteria as tracers in drilling fluids (68,69). Aerobic bacteria and fungi can be cultivated from swabbings of mine surfaces and used to monitor the transfer of mine contaminants into samples (70). Dilution plate counts followed by comparison of colony morphology patterns have been used to compare samples and known sources of contamination (71). Community-level physiological fingerprinting (e.g., the Biolog system, Hayward, California) have been used to characterize drilling fluid microbial communities (65).

Molecular methods employing universally conserved ribosomal RNA genes (e.g., 16S rDNA in prokaryotes) are insensitive to culture bias because they detect environmental DNA directly (32). These approaches can be used for rDNA fingerprinting of the whole community [e.g., terminal restriction fragment length polymorphism (TRFLP) (72)] or rDNA clone libraries following amplification of target sequences from environmental DNA by the polymerase chain reaction (PCR). In our work in South African ultradeep gold mines, molecular biosignatures for service water and mine air proved diagnostic over time and distinct from putative deep groundwater intersections (73). Such prior knowledge of expected contaminant rDNA sequences can be employed to judge the quality of samples. Conversely, the presence of unusual rDNA signatures in samples can be indicative of sample quality as well. Samples dominated by rDNAs derived from known obligate anaerobes or hyperthermophiles, for example, would be inconsistent with service water origins.

Rock Sampling

Various types of rocks can be sampled in mines. For the purposes of the microbiologist, it is useful to divide mines into "hard rock" and "soft rock" because the methods for both mining and sampling differ. Hard rock mining (e.g., granite and quartzite) generally entails excavation by blasting, whereas softer materials (halite, coal, tuffs, etc.) can be mechanically worked. Hard rock mining uses water-cooled percussion drills to perforate advancing panels and allow the setting of charges. Approximately the outer half-meter is typically fractured following each blast cycle. Beyond this, a so-called *kick plate* boundary defines the outermost extent of unfractured, minimally contaminated pristine rock. Percussion drilling infuses the newly created fractured zone with service water before each blasting cycle. Subsequently, the act of blasting can drive water- and airborne contamination deep into microfractures.

For these reasons, precautions must be taken when sampling hard rock in mines. In this environment, samples will take the form of either blocks or cores. Core samples can be obtained by sidewall probings from well beyond the panel face assumed to be contaminated, but with a correspondingly high probability of acquiring surface contamination from pressurized drilling fluids. Even small diameter cores, however, will often contain pristine material inside and, with rigorous tracer testing, can yield provably uncontaminated subsamples (60). Freshly blasted mine panel grab samples afford some advantages of their own. First, they can be collected with minimal logistic commitment as soon as it is safe to reenter after blasting. Loosened wall blocks and even floor rubble present a potentially wide array of sample choices. A large block sample with a large diameter core will better insulate pristine inner material from contamination than could any other sample.

Although tracer addition before the blast cycle would be ideal, logistics generally mandate that tracers be applied afterward. The chosen rock sample is typically dosed with a concentrated solution of microspheres and/or fluorescent dye tracers, using a spray bottle, and then aggressively washed with a high-pressure mining hose. This treatment is intended to mimic the service water exposure that would be expected from panel drilling and dust suppression. After tracer addition, the sample is transported to the surface in a sterile autoclave bag (on ice if possible). The rock is coated with bright spray paint (e.g., blaze orange) to permanently mark all outer surfaces. Next, the sample is placed in an anaerobic chamber and the outer surfaces pared away using a hydraulic rock splitter and sterile hand tools (59,74; Fig. 6). We have found that wrapping the sample in clear plastic wrap (effectively sterile inside the roll) greatly enhances control and traps rock shrapnel. Outer parings are saved for comparative tracer studies and the inner subsample is stored or finely ground with an autoclaved Platner rock mill for cultivation studies.

In contrast, soft rocks can be excavated using an alpine miner or other boring machine. These devices employ rotary carbide bits to grind into the rock without the need of cooling water and thus minimize contamination from this source. Endolithic microbes were sampled by alpine miner at the Nevada Test Site (70), for example. The best alpine miner strategy is to enter the newly opened rock face as soon as possible after mining and collect with gloved hands and sterile hand tools. A number of researchers working in soft rock have reported that

simply chiseling away the contaminated outer surfaces of tunnels with hand tools (55,58) is sufficient to obtain endolithic samples for microbial studies.

Water and Biofilm Sampling

Mine-wall seeps associated with water-bearing fractures and dykes are often extensively colonized with biofilms. Generally, sterile spatulas or even the lip of a sterile plastic tube is effective for scraping material into a waiting sample tube. At times, zonation can be seen within a biofilm and a sterile syringe, without the needle, and can be used as a mini "slurp gun" to collect subsamples with precision. A number of workers have obtained samples for microbiology by collecting water dripping from the ceiling (55), although, as with surface biofilm sampling, the potential for mine contamination is high.

Exploratory boreholes can be exceptional opportunities for microbial studies in mines. Often situated at the periphery of mining development, water derived from such boreholes probably represents the least impacted deep subsurface material currently available. After initial water contact, mines generally valve a borehole and then allow it to drain in a controlled manner. The high flow rates of such holes ensure correspondingly high dilution factors and thus reduce the possibility of detecting mining contaminants. Even so, in the case of extremely low biomass fissure water, borehole wall colonists derived from the service water and inoculated during drilling may ultimately bloom to become detectable by molecular methods (73). Drained boreholes often gradually reach equilibrium and drip at slow rates for years.

Mine boreholes are typically lined at the wall face with steel casings (Fig. 7c), which facilitates sampling. Anaerobic samples can be obtained from flowing borehole outlets after sealing them with an inflatable packer or expansion plug (Fig. 7b). Sampling systems can take a variety of forms but must incorporate a pressure-relief valve for safety (Figs. 7a, 7c) because mine waters can reach dangerous pressures. We attempt to make our sampling designs suitable for an autoclave. Although the prototype model (Fig. 7) contained some metal parts, subsequent versions have been entirely made out of plastic to negate the possibility of compromising geochemical analyses by metal leaching or artifactual hydrogen production from groundwater-steel interactions. Plastics such as delrin, polysulfone, and even nylon mill are easily available and tolerate autoclaving. Plastic fittings, tube stock, valves, and information about their thermal stability and gas solubility properties are available from scientific and speciality suppliers (e.g., Cole Parmer, United States, Vernon Hills, Iillinois, and U.S. Plastics Corp, Lima, Ohio).

Once sealed, all or part of a borehole's flow can be diverted by a sterile hose into a collection container. Small-scale samples can be taken directly into sterile serum vials preloaded with filtered argon or nitrogen using sterile syringe needles with the Luer end threaded into a sampling hose of the correct inside diameter. A small-bore vent needle must be inserted into the bottle septum to bleed the headspace off as the bottle fills. For larger samples, stainless steel soft drink canisters of the

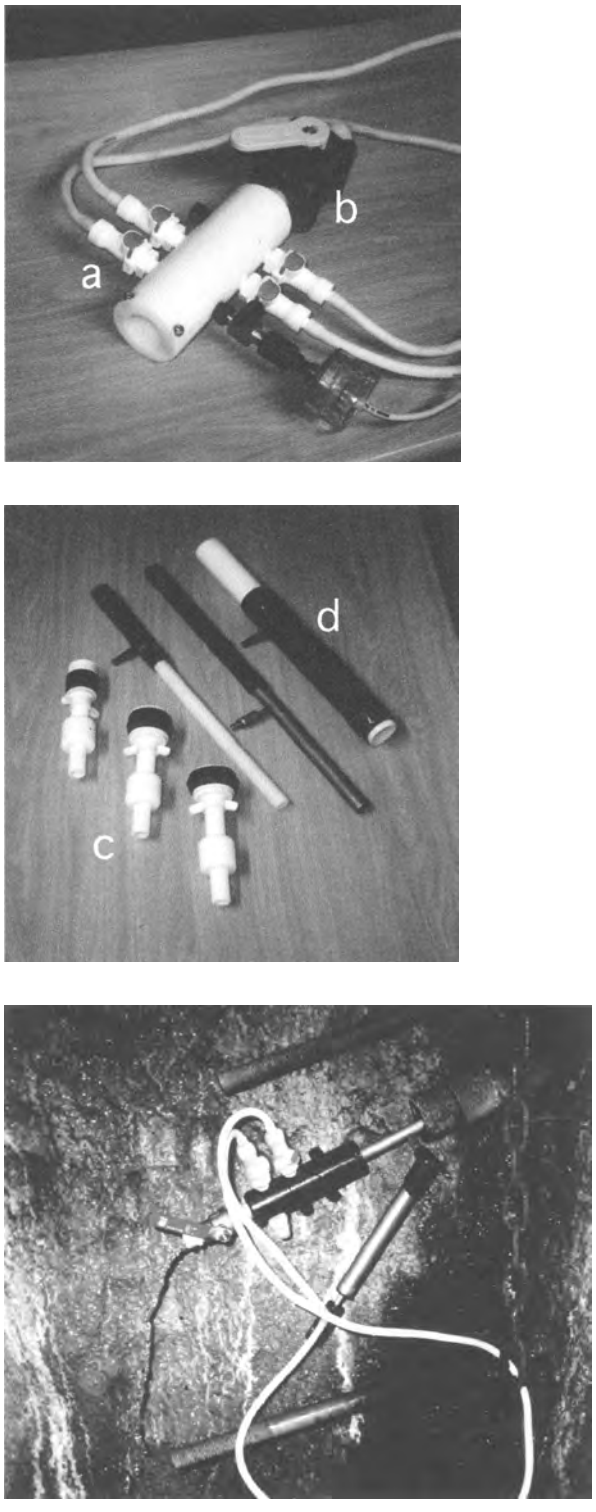

Figure 7. Sampling of flowing boreholes. (**a**) Sampling head, (**b**) quick connect fittings. Note pressure relief valve. Sampling head is securely affixed to standard diameter packer outlet by screw operated clamp and leaks prevented using grove-mounted O-rings inside delrin plastic manifold housing. (**b**) Borehole packers; (**a**) expansion drain plug design, (**b**) inflatable bladder design. (**c**) Borehole sampling in progress. Inflatable packer (note bicycle pump) is largely out of view inside the pipe casing. Water flow is controlled by throttling of pressure relief valve. Photos taken at Driefontein Mine, South Africa.

three gallon size (e.g., Vineland, syrup Inc., Vineland, New Jersey), with modifications (Fig. 8) have proven excellent for this purpose and are suitable for an autoclave. These canisters can be prefilled with argon for anaerobic sampling, and the anaerobic headspace vented during filling. Once filled, the canister is transported to the surface and, following the reestablishment of headspace pressure with inert gas, the sample filtered. Out of a variety of available membrane and housing assemblies, any one (0.1 or 0.2 μm) can be used to collect microbes for subsequent DNA extraction or cultivation (Fig. 8). Multiple subsamples can be obtained at once by splitting the flow using a manifold filtration. The major limitation of sampling with tanks is that only finite volumes of water can be collected and transported. In the case of low biomass samples, direct filtration would allow for the processing of much larger volumes.

An alternative method for microbiological sampling of boreholes is to collect cells on artificial substrates (glass, stainless steel, ceramic, polypropylene, etc.; 56,73). The flow from dripping boreholes can be directed through upflow cartridges filled with various physical substrates such as sand or rock chips (60, Fig. 9). This method allows the collection of considerable biomass under anaerobic conditions. After a suitable incubation period (typically months), the cartridge is sealed off, transported to the surface, and the entire assembly processed in an anaerobic chamber.

Mines cycle enormous volumes of ventilation air. This must be regarded as a major source of potential contamination. It is a good practice when sampling mines to obtain an air sample for comparative purposes along with each sample of interest. Battery-powered personal air-filtration units, generally used for lead and asbestos monitoring, are now widely available (Spectrex Inc, Redwood City, California, and F&J Specialty Products, Ocala, Florida). These can be fitted with membrane or glass fiber filters to capture particulates including airborne microbes and fungal spores. After sampling, filters can be either vortexed in buffer to release captured cells and spores for subsequent cultivation or extracted for DNA analysis. As an alternative approach, a number of air samplers (e.g., the Andersen N6 impactor type, Thermo Andersen Instruments, Smyrna, Georgia) disperse airborne microbes directly onto the surface of an agar plate for viable count analysis.

Transport and Storage of Samples

As with any environmental sampling, mine materials should be processed or fixed as soon as possible. Several studies have documented shifts in microbial populations in samples postsampling even with refrigeration (63,74). Haldeman (75) has recommended that sample analysis be initiated less than eight hours before collection. Biofilm samples can be fixed with preservatives such as glutaraldehyde solutions underground. More often, however, samples require surface processing. When feasible, samples should be transported on blue ice in a cooler. As an alternative to chilling, high-temperature samples (50 °C and greater) may be better protected by maintenance at ambient temperature. This approach

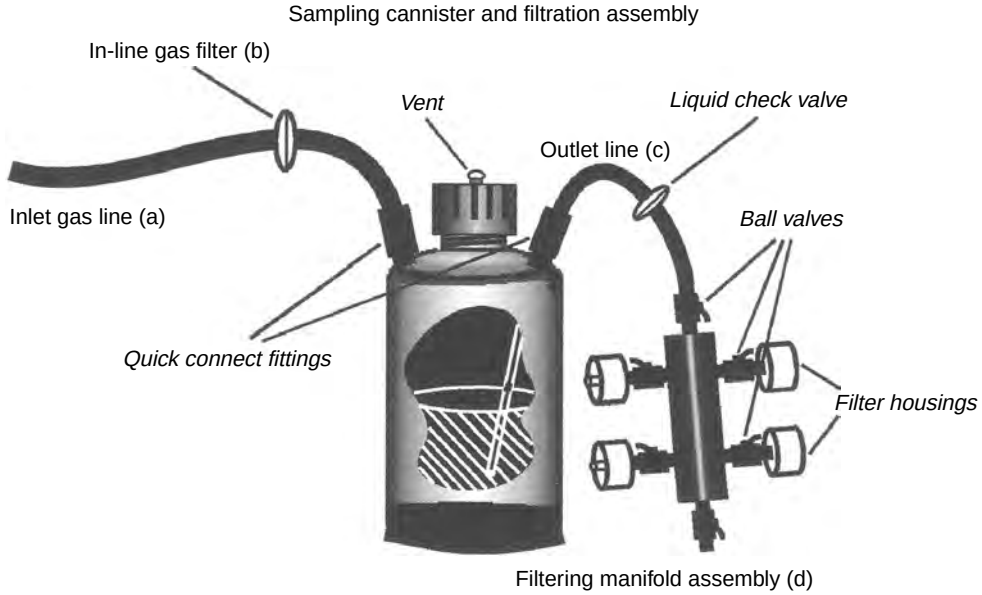

Figure 8. Stainless steel water sampling canister and laboratory setup of anaerobic filtration. A slight headspace overpressure is developed by (**a**) a compressed gas line charged with nitrogen and fitted with an (**b**) in-line filter. Sample is displaced because of gas pressure and extruded by straw and (**c**) outlet water line to (**d**) manifold filtering assembly. Filtrate is collected to measure the flow and can be used as a basal medium for cultivation.

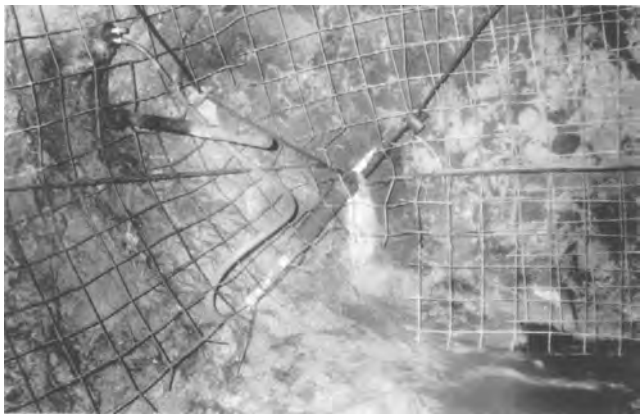

Figure 9. Up-flow substrate cartridge installed for the accumulation of biomass from a 3.2 km depth draining borehole in Driefontein Mine, South Africa. The cartridge was filled with crushed, sterile quartzite collected from the same mine. In-line chamber at the bottom of the cartridge contains a collection of mineral substrates for subsequent studies of microbe/mineral interactions. Cartridge was incubated in situ for two months before retrieval.

is especially applicable on large samples, which cool slowly, in effect drifting through the optimum growth temperature of every potential mesophilic contaminant as they do so. For filtered nucleic acid and polar lipid samples, ultracryopreservation ($-70\,^{\circ}C$ or colder) is best. This can be achieved for short periods in the field and during transport with dry ice or liquid nitrogen. Temporary storage at $-20\,^{\circ}C$ appears to be adequate for up to several weeks. Additional protection for nucleic acid samples can be secured at any temperature by the use of chemical preservatives such as 5-M guanidineisothiocyante buffer, (76).

CONCLUSION

Underground microbial habitats can be sampled successfully for microbiota, whether these be natural cave systems or anthropogenic excavations. Many of the technical aspects of working in these disparate habitats are similar, but there are concerns unique to each as well. Mines generally provide easier access than caves and have the benefit of the potential availability of power and heavy equipment underground. By virtue of their continual expansion into new zones, mines present additional and alternative sampling opportunities. However, contamination is always of concern. Natural cave systems offer the opportunity to study intact natural ecosystems.

Protection, Permitting, Legal, and Ethical Considerations

In the United States, all caves (including those privately owned) are legally protected (Federal Cave Resources Protection Act of 1988). In addition, caves that occur on land managed by federal agencies come under additional layers of permitting and management. The Bureau of Land Management, the USDA Forest Service, and the National Park Service are involved with cave and karst management on their lands. In other countries, similar protections are in place. Cave conservation policies have been adopted by the (U.S.) National Speleological Society, the Cave Research Foundation, the National Association for Cave Diving, and the (British) Cave Diving Group. Cave researchers should be aware of these organizations and their policies as well.

In countries lacking specific protections for their caves, ethical considerations still dictate extreme caution in undertaking any microbial sampling. Sampling programs should be designed to minimize disturbance to cave features and cave life. Caves not only house microbial communities of great value, but also contain unique higher fauna (sometimes indigenous to only one cave system) and often irreplaceable paleontological, archaeological, and historical materials. In natural caves, any excavation must be done purposefully by drilling or the chipping or breaking of material. The biogeochemical ecosystems created by cave bacteria are unusual, delicate, and easily disrupted by careless movement, thoughtless exploration (77), or overcollection (78,79). Many caves have long since ceased their active speleothem-forming period, and those geological and mineralogical specimens are truly irreplaceable. Ideally, microbiological techniques and those of auxiliary sciences will evolve toward low-impact or no-impact methods that are not consumptive for a sample.

Because mines, by definition, are extensively impacted by human activity, these sites represent very different circumstances in terms of conservation and legal issues. Permissions to sample are required as in caves, but because mines are typically private holdings, government regulations (other than safety) may not be applicable. In government operations (e.g., underground waste depositories), there are additional layers of security and regulation, which must be navigated. In either case, professional courtesy, openness, and data sharing have value in enhancing relationships with host organizations. In private mines, science is usually a secondary consideration to the economics. Mine researchers are thus well advised to minimize their impacts on the mining process. Mines often require training and heat-tolerance certification for underground workers, and guest researchers are expected to meet all legal requirements for mine workers and contractors.

Safety

All underground work has its intrinsic hazards. Safety should be the first order of business for mine or cave microbiologists. Safe terrestrial caving techniques are best learned from experienced, safety-minded, and conservation-aware cavers. The best practice for noncaving microbiologists who wish to sample caves is to work with cavers who have experience working on scientific caving expeditions (National Speleological Society website *http://www.caves.org/*). Although some caves offer walk-in access, others require extensive training and endurance. Additional insights into vertical caving that requires rope skills can be gained by consulting (80). Certain specific cave environments may present hazards out of the ordinary, for example, lethal concentrations of gases. Breathing gear ranging from simple acid gas–filtration units to carbon dioxide–removing rebreathers or complete oxygen–breathing systems may be necessary. In dry caves, the entire weight of such units must be borne without buoyant assistance from water.

Cave diving can be particularly unforgiving. Safety practices must be adhered to scrupulously at all times. Safety of divers takes precedence over all scientific objectives (81). Only experienced, "full cave" certified divers should engage in research cave diving. Research cave divers should maintain diver's accident insurance including air-ambulance coverage (26). For technical and safety details of cave diving practices, see Prosser and Grey (82), Saltsman (83), and Balcombe and coworkers (77), and older works by Exley and Young (84), Lavaur (85), Mount (86), and Lascu and Sarbu (87). For general information on research diving, consult Flemming and Max (81) and Miller (53). For specific recommendations on research cave diving, consult Balcombe and coworkers (77), Horne (51), Flemming and Max (81), Lascu and Sarbu (87), Murphey (88), Skiles (89), and Wood (90). None of these works, however, addresses methods for microbiological sampling with scuba in underwater caves or other underwater settings.

Conditions encountered in modern mines range from modern industrial settings (although deep underground) to some of the most extreme working environments. The most compelling mine sites for microbiological study tend to be deep and thus geothermal heating may be an issue. In some South African mines, virgin rock temperatures of 50 °C are not unusual and water ingressions can exceed 60 °C. Although, by law, working areas must be cooled down to industry standards, humidity and heat may challenge nonacclimatized researchers laden with samples and equipment. Heavy machinery such as locomotives and cable conveyances operating in tight quarters must be monitored. Lighting is generally provided by headlamp. Hearing protection in noisy areas is required. Accumulation of explosive gases can occur. For this reason, flame sterilization of tools can never be recommended and flash photography is generally not permitted in mines. The swabbing of tools with ethanol must suffice. As with cave sampling (or life for that matter), most dangers, however, can be minimized by adherence to common sense.

Acknowledgments

P. Boston extends gratitude to the many knowledgeable and good-humored cavers who have given their time, thought, and energy to expanding our understanding of the microbial world of caves. Funding of cave microbial research has come in part from NSF Life in Extreme Environments Program (LExEn, #DEB 9809096), NASA Institute for Advanced Concepts (CP 99–03 #07600–045), The National Geographic Society, and The National Speleological Foundation. She also thanks National Park Service cave personnel, especially Dale Pate, Stan Allison, Jason Richards, and Paul Burger, for their help and enthusiastic support, the U.S. Forest Service for permission to sample in caves under their jurisdiction, and to the gracious people of Tapijulapa, Tabasco, MX, who allowed us to work and live in their midst.

H. Martin thanks Dr. Robin Brigmon and Mr. Tom Morris for their collaboration on sampling microbes in underwater caves. He also thanks Mr. Peter Horne of the South Australia Underwater Speleological Society, Dr. Jill Yager of Antioch College, Dr. Gabriel Bitton, the late Peter Gomez, and the late Dr. Stephen G. Zam of the University of Florida, Mr. Bill Wilson of Subsurface Evaluations, Inc., and the staff at Ginnie Springs Resort for their assistance and advice. Funding for underwater cave microbiological research has come from

grants to the National Speleological Society and the PADI Foundation.

D.P. Moser acknowledges Dr. T.C. Onstott for initiating the South African ultradeep microbiology project. Also acknowledged are current and past members of the project's interdisciplinary research team and the pioneering work of the DOE Subsurface Microbiology Program. Moser gratefully acknowledges the professionals and management of Gold Fields Ltd. and Harmony Ltd. of South Africa for their support and hospitality. The staff and students of the University of Witwatersrand and the University of Orange Free State in South Africa and Turgis Technology LTD are gratefully acknowledged for technical, logistic, and academic support. George Rose of Princeton University deserves special commendation for assistance in the design and construction of the sampling equipment described here. This research was supported by grants awarded to T.C.O. from the National Science Foundation LExEn program (EAR-9714214) and the National Geographic Society (6,339–98).

CAVES AND OTHER LOW-LIGHT ENVIRONMENTS: AEROPHITIC PHOTOAUTOTROPHIC MICROORGANISMS

LUCIEN HOFFMANN
University of Liège
Liège, Belgium

Caves are generally considered to be aphotic habitats in which food must be imported from the surface or manufactured in situ by chemosynthetic bacteria. The

presence of photosynthetic microorganisms is, however, also frequently revealed in these environments as blue-green, brown, or gray biological patinas in areas in which sufficient irradiance is provided by natural light. Show caves equipped with lighting systems represent a particular case of cave habitats. Depending on the intensity, quality, and duration of the illumination, conditions conducive for photoautotrophic growth are created in these caves, allowing photosynthetic organisms to spread to areas in which they did not previously grow. This leads to an often luxuriant development of photoautotrophs around the sources of light; the flora that establishes under these conditions is referred to as *Lampenflora* (i.e., flora of the lamps) (1–3). Although microbial photoautotrophs are the major component of this flora, mosses and ferns (and in some cases even seed plants) are also frequently observed as soon as some soil is formed. Besides natural caves, there exist also artificial low-light environments, such as catacombs, tombs, etc., in which the illumination of frescoes, stuccoes, and marbles of historic and artistic value may lead to the development of photosynthetic organisms (4–7), often having a biodeteriorative effect on this cultural heritage.

The photoautotrophic microorganisms that thrive on the stony surfaces in low-light environments do not develop as single colonies but as components of complex biofilms. The possible role that these microbial photoautotrophs may play in the food web of these low-light habitats is still completely unknown.

In this article, the data available on the biodiversity, distribution, and biology of the aerophytic photosynthetic microorganisms living in low-light environments are presented, also focusing on the negative effects of the development of these biofilms in show caves or man-made hypogean environments of archeological interest.

HISTORICAL DEVELOPMENT

Although cave microorganisms have been studied since the eighteenth century (8), photosynthetic microorganisms were generally ignored. It is only since the second half of the Twentieth century that works devoted only to photosynthetic microorganisms have appeared. However, investigations on the taxonomy and ecology of low-light microbial photoautotrophs remain rather scarce and investigations of these microorganisms have only been conducted in about 20 different countries worldwide: Belgium, Bulgaria, France, Germany, Great Britain, Greece, Hungary, Israel, Italy, New Zealand, Romania, Russia, South Africa, Spain, Thailand, Ukraine, United States, former Yugoslavia, and Vietnam (9–14). Most data are available for limestone caves, studies from other types of substrata are scarce or absent.

THE LOW-LIGHT ENVIRONMENT

Caves can be considered as being nearly closed environments in terms of energy and mass flows. Three principal cave energy levels can be distinguished (15). High-energy caves are those that experience high-energy events such as regular winds and frequent flooding by allogenic rivers. Caves of moderate energy are influenced by events some orders of magnitude less than the previous. In low-energy caves, energy flow is minimal, consisting primarily of heat exchange between the cave atmosphere and the rock surfaces; low-energy caves are essentially closed to any impact from the outside environment. This is exacerbated in many show caves, which are completely shut off from the outside environment during the nontourist season by doors, which prevent light penetration at the entrance and atmosphere exchange with the outside (Fig. 1b).

Caves and other low-light habitats are generally hypogean environments with stable microclimates characterized by uniform temperatures throughout the year, constant and often high relative humidity, and low illumination, especially toward the deepest zones. The most important environmental factors, which govern the growth of photosynthetic microorganisms in these environments, are light, temperature, and humidity. Intensity of light is of course the governing factor for the distribution of the photoautotrophs. Fluctuations in temperature and water supply are extreme in the cave mouth (Fig. 1a), whereas light is the main controlling factor in the deepest zones. Availability of dripping water is also an important factor governing the distribution of these microorganisms in cave systems.

LOW-LIGHT MICROBIAL PHOTOAUTOTROPHS

The microbial photoautotrophs found in caves use oxygenic photosynthesis and are characterized by the presence of chlorophyll-*a*. They are phylogenetically very diverse and comprise two very distinct groups (*1*) prokaryotic cyanobacteria and (*2*) eukaryotic algae; the latter can be defined as photosynthetic eukaryotes/protists excluding land plants.

Members of the cyanobacteria have been treated both as bacteria and plants. They are also commonly referred to as *blue-green algae*, *blue-green bacteria*, *cyanophytes*, or *myxophytes*. Cyanobacteria possess some internal membranes, but lack membrane-bound nuclei, plastids, and mitochondria, and are in these respects bacteria-like. Other bacterial characteristics include their cell wall structure and chemistry and the presence of 70S ribosomes. Plant-like features include pigmentation (presence of chlorophyll-*a*) and the biochemistry of photosynthesis. Besides the liposoluble pigments chlorophyll and carotenoids, cyanobacteria also possess the hydrosoluble phycobiliproteins, which are organized as supramolecular structures, the phycobilisomes, located on the surface of the thylakoids. Several groups of cyanobacteria are capable of nitrogen fixation, often through the presence of specialized cells, called *heterocysts* (16). The classification of cyanobacteria into taxonomic categories below the level of the class has not been agreed upon. The traditional classification based on the cellular organization and the morphology of the organisms (17) is being challenged by bacteriologists (18), who point out that these criteria are, to a large extent, dependent on environmental conditions and do not reflect phylogenetic relationships upon which modern taxonomic schemes are, ideally, based.

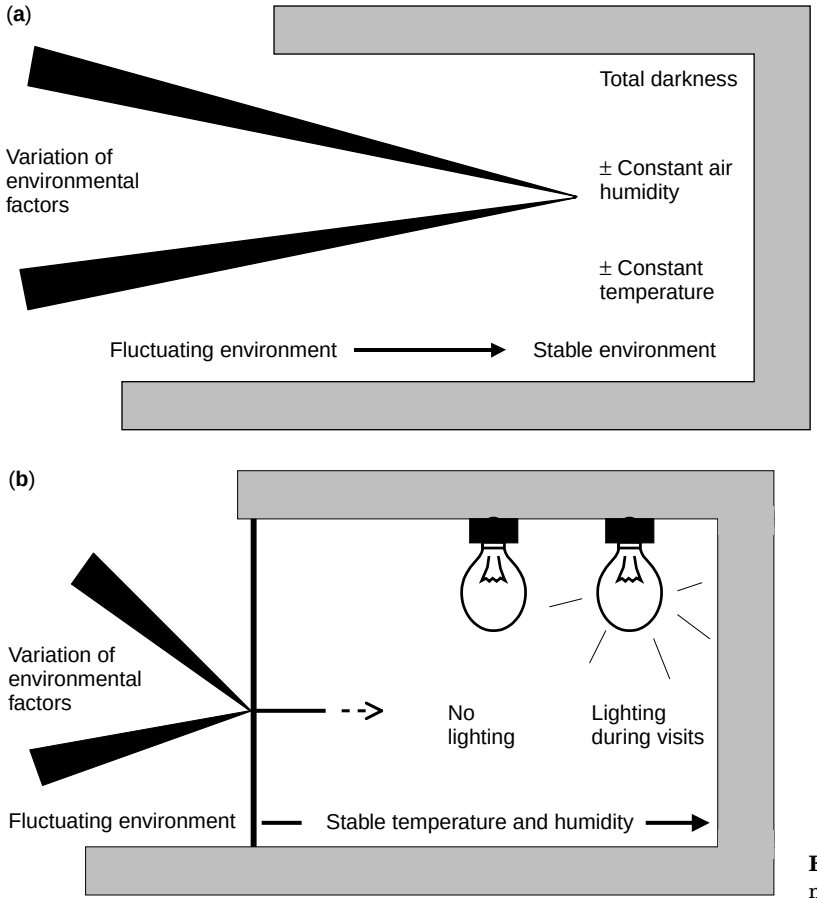

Figure 1. Variation of environmental factors in a natural cave (**a**) and a show cave closed by a door (**b**).

Eukaryotic algae are a phylogenetically heterogeneous group. The major lineages are the Chlorophyta (green algae), Rhodophyta (red algae), Glaucocystophyta, Euglenophyta (euglenoids), Chlorarachniophyta, Heterokontophyta (with the classes Phaeophyceae, Bacillariophyceae, Chrysophyceae, Xanthophyceae, etc.), Haptophyta, Cryptophyta, and the Dinophyta (19). These lineages mainly differ by their photosynthetic pigment composition, the nature and localization of their storage products, the ultrastructure of their plastids, and flagellar apparatus (Table 1).

The photoautrophic microflora of low-light environments mainly includes members of the following major groups: Cyanobacteria, Chlorophyta, Rhodophyta, and Heterokonta. Extensive growths are most frequently the result of cyanobacteria and green algae, which can also occur as lichen phycobionts but sometimes of Bacillariophyceae (diatoms), and less commonly of Xanthophyceae and Rhodophytes. Phaeophyceae, Haptophytes, Glaucocystophytes, Chlorarachniophytes, and Cryptophytes seem to be absent from terrestrial low-light environments. Under peculiar environmental conditions monospecific populations can occur, but more often different microbial photoautotrophs are associated with bacteria, fungi, mosses, and also higher plants.

The compilation of floristic lists is accomplished either by direct microscopic examination of samples scraped from the substrate in the least destructive way or by a number of indirect methods in which the presence of an alga in a sample is inferred following growth in an enriched medium. The establishment of unicyanobacterial/unialgal cultures is essential for the proper taxonomic treatment of many of the photosynthetic microorganisms. More commonly light microscopy, but also epifluorescence, scanning and transmission electron microscopy help in the identification of the taxa, as well as in the definition of the relationships among microorganisms and substrate.

About 350 taxa, of which about 58% belong to the cyanobacteria, 18% to Chlorophytes, and 18% to Heterokonts (especially diatoms) have been recorded from low-light environments, other groups are of marginal importance (10). In regard of these numbers, one might think that the photoautotrophic microflora of low-light habitats is abundant and diverse. The real diversity of the flora of low-light environments is, however, probably largely overestimated. Indeed, in many cases the floristic lists are based on the results from enrichment cultures; this often leads to the growth of organisms that only were accidentally present in the environment or as resting spores, thus falsifying the picture. The taxa recorded in the literature can be catalogued into one of the following three categories (10):

- *Troglobitic species:* these species are obligate cavernicoles and cannot survive outside of caves or other low-light environments.

Table 1. Diversity of Photoautotrophic Cave Microorganisms

Division (Common Name)	Distinguishing Features	Major Groups Present in Caves
Cyanobacteria/Cyanophyta (cyanobacteria, blue-green algae)	Prokaryotic; gram-negative cell walls; phycobilins; chlorophyll-*a*, (and -*b*); glycogen; free thylakoids with phycobilisomes	Chroococcales, Oscillatoriales, Nostocales, Stigonematales
Rhodophyta (red algae)	Chlorophyll-*a*, phycobilins; floridean starch; single thylakoids with phycobilisomes in chloroplast enveloped by two membranes, no flagella	
Chlorophyta (green algae)	Chlorophylls *a* and *b*; starch inside chloroplast; stacked thylakoids in chloroplast enveloped by two membranes	Chlorophyceae, Trebouxiophyceae, Ulvophyceae
Heterokontophyta	Chlorophylls *a* and generally *c*; chrysolaminarin; thylakoids grouped by three inside chloroplast enveloped by four membranes; heterokont	Bacillariophyceae (diatoms), Xanthophyceae (yellow-green algae), Chrysophyceae (golden algae), Eustigmatophyceae
Euglenophyta (euglenoids)	Chlorophylls *a* and *b*; paramylon; thylakoids grouped by three inside chloroplast enveloped by three membranes	Euglenophyceae
Dinophyta	Chlorophylls *a* and *c*; thylakoids grouped by three inside chloroplast enveloped by four membranes	Dinophyceae

- *Troglophilic species:* these species can grow and reproduce in low-light environments, but have their optimal development in other aerophytic habitats.
- *Trogloxenic species:* these species accidentally reach the low-light environment by air, seeping water, or other organisms; they are unable to develop in these environments and only survive as resting stages.

The last group is by far the largest group so that many of the species recorded from low-light environments are typically subaerial and ubiquitous. All Euglenophytes, Chrysophyceae, Dinoflagellates, and a large number of the recorded species of the other groups can be considered as trogloxenes (10).

Some species, such as the cyanobacteria *Loriella osteophila* Borzi, *Scytonema julianum* (Meneghini ex Frank) Richter, the red algae *Phragmonema sordidum* Zopf and *Cyanidium* cf. *caldarium* (Tilden) Geitler, and some widespread aerophytic diatom species can be considered as troglophiles.

Obligate cavernicolous species are very rare. At present only a few cyanobacteria, such as *Geitleria calcarea* Friedmann, *G. floridana* Friedmann, and *Herpyzonema pulverulentum* Hernandez-Mariné et Canals, are considered to be true troglobites. Other cyanobacteria may belong to this group, but their identification is doubtful because they are incompletely described, because they were probably misidentified (like *Atractella clavata* Serbanescu et Decu or *Ialomitzia cavernicola* Gruia initially described as cyanobacteria, but probably representing various stages of fungi) or because they were only found once (like *Symhyonema cavernicolum* Asencio, Aboal et Hoffmann, *Spelaeopogon cavarae* Borzi, *Oscillatoria rupicola* Hansgirg var. *cavernarum* Skuja, *Synechococcus sciophilus* Skuja, *Pleurochloris cavernicola* Skuja, *Chloromonas antrorum* Kostikov, *Caloneis borealis* Carter, *Cymbella diavola* Carter, *Navicula variolinea* Carter, *Navicula vula* Carter, and *Nitzschia disputata* Carter) so that it is difficult to assess their real ecological requirements.

The cave algae reach the environment as vegetative cells or spores by air (as shown by agar plate controls) and animals (insects, bats, etc.) (20). In show caves, transport by humans is of great importance, both for bringing in new spores or for the spreading of species already present. Many of the photosynthetic microorganisms recorded from caves are typical soil algae; they may be washed into the cave from the surface soil during heavy rain events. The introduced microorganisms are then subject to environmental selection, which is a product of the surrounding biological environment (species composition), climatological characters, and the geophysical nature of the substrate; only troglobitic or troglophilic taxa develop in this environment, the trogloxenes die or persist as resting stages.

SOME TROGLOPHILIC AND TROGLOBITIC PHOTOSYNTHETIC MICROORGANISMS

Cyanobacteria

***Geitleria calcarea* Friedmann.** *Geitleria calcarea* is a member of the Stigonematales lacking heterocysts. It is characterized by the presence of laterally and dichotomously branched filaments and by a characteristic calcite sheath (21–24). It is only known from limestone caves or other low-light habitats from tropical or warm temperate regions (Fig. 2) (25) in which it colonizes the deepest and least illuminated areas of the photic zone. It appears on the walls as a light gray, mold-like coat. A second species of the genus, *G. floridana* Friedmann (22), was described from caves in Florida in which it grows intermixed with filaments of *G. calcarea* and thus seems to have similar ecological requirements. The most obvious difference between the two species is size.

***Loriella* spp.** Like *Geitleria*, the genus *Loriella* Borzi (Stigonematales) is characterized by the presence of dichotomous branchings and by the presence of a calcified sheath; the two genera mainly differ by the presence (*Loriella*) or absence (*Geitleria*) of heterocysts. The genus was first recorded on various limestone substrates in low-light environments in Papua New Guinea (25) and recently rediscovered in Spanish caves (26) in which it forms almost monospecific populations or grows together with other cyanobacteria, especially *G. calcarea*.

Some other true-branching cyanobacteria were described from cave environments; these include *S. cavarae* Borzi, *H. pulverulentum* Hernandez-Mariné et Canals (27), and *Symphyonema cavernicolum* Asencio, Aboal et Hoffmann (28).

***Chroococcidiopsis kashaii* Friedmann.** *C. kashaii* (Chroococcales) forms a blue-green layer on the rock substratum, composed of microscopic clusters of cells that multiply by endospore formation. In soft substratum, it can penetrate a few hundred micrometers. Mature undivided cells are spherical, subspherical, or ellipsoid (29). It seems to tolerate substrata with high nitrate concentrations (30).

***S. julianum* (Menegini ex Frank) Richter.** *S. julianum* (Nostocales) is a heterocystous, false-branching cyanobacterium that is often observed on limestone substrates in low-light environments. It never colonizes areas of stone that are completely wetted, but high relative humidity is important for its growth. It is a calcifying cyanobacterium characterized by triradiate crystals (31–33); in dry parts the calcified sheath is often thin or even absent (7).

***Leptolyngbya* spp.** Narrow (<2 μm width) filamentous, nonheterocystous cyanobacteria of the genus *Leptolyngbya* Anagnostidis et Komárek (Oscillatoriales) often form the most abundant components of biofilms in some low-light environments. Many of these forms are very rich in phycoerythrin and are red (5,34,35).

Rhodophyta

***Cyanidium* sp.** The red alga *C. caldarium* (Tilden) Geitler is a typical representative of hot, acidic ecosystems. A morphologically similar alga has been reported, although rarely, from nonthermal, nonacidic habitats,

Figure 2. Geographic distribution of *Loriella* (dots) and *Geitleria* (squares).

especially from limestone caves (36). The cave *Cyanidium* is a bluish eukaryotic microalga, characterized by the presence of chlorophyll-*a*, phycocyanin, and allophycocyanin. It reproduces by autospores. The taxonomic relationship between the two organisms remains to be established.

***P. sordidum* Zopf.** The highly polymorphic bangioid red alga *P. sordidum* Zopf was first recorded in greenhouses (37). Its natural habitat may, however, be low-light habitats (38–40).

Bacillariophyceae (Diatoms)

Diatoms while perfectly adapted to aerophytic conditions seem to prefer humid conditions; low proportions of diatoms generally occur indeed in low-light environments of arid zones. Moisture is also the most important factor determining the distribution of diatoms in cavern systems (41,42). Although no troglobitic diatom species seems to be described so far, several diatom species are frequently observed in low-light environments; they are rarely dominant but grow generally mixed with other species in the biofilms. Among these species, *Diadesmis gallica* W. Smith, *Diadesmis contenta* (Grunow) D. G. Mann, *Orthoseira roeseana* (Rabenhorst) O'Meara, and *Hantzschia amphioxys* (Ehrenberg) Grunow can be considered as troglophilic (4,11).

Chlorophyta

Although quite a number of green algae were recorded from low-light environments, most of the recorded taxa can be considered as trogloxenes and are characteristic of other terrestrial environments. One of the exceptions is the troglophilic genus *Stichococcus* Nägeli that often forms almost monospecific thin and dry green biofilms in low-light environments.

Flora of the Lamps

A remarkable ruderal vegetation is formed by algae living in the vicinity of artificial light sources in caves (Fig. 3b). Microbial photoautotrophs generally are the pioneering organisms around lamps; with time they are followed by mosses and ferns (Fig. 4). Common atmophytic and freshwater microbial photoautotrophs often form a luxuriant vegetation here (1–3). Recorded cyanobacteria in this "flora of the lamps" are *Gloeocapsa alpina* Nägeli, *G. dermochroa* Nägeli, *G. sanguinea* (Agardh) Kützing, *Tolypothrix rupestris* Wolle, *Nostoc microscopicum* Carmichael, *Chroococcus varius* A. Braun, *Chlorogloea microcystoides* Geitler, *Aphanocapsa fuscolutea* Hansgirg, *A. castagnei* (Brébisson) Rabenhorst, and *A. saxicola* Nägeli. Common green algae are *Desmococcus olivaceus* (Pers. ex Ach.) Laundon, *Stichococcus bacillaris* Nägeli, *Gloeocystis rupestris* (Lyngbye) Rabenhorst, *G. vesiculosa* Nägeli, *Chlorella vulgaris* Beyerinck, and *Scotiella nivalis* (Shuttleworth) Fritsch. In this particular niche, cyanobacteria sometimes occur in spherical aggregates, up to 1 cm in diameter, almost exclusively composed of *G. alpina* Nägeli and *C. varius* A. Braun and in another of *A. fuscolutea* Hansgirg and *C. microcystoides* Geitler.

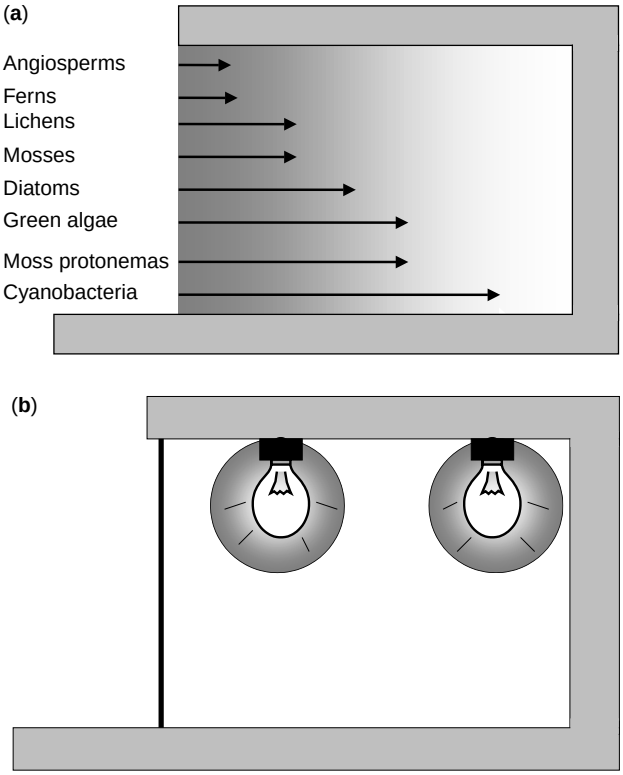

Figure 3. Distribution of phototrophs in a natural cave (**a**) and a show cave closed by a door (**b**). (The gray zone indicates photoautotrophic growth.)

DISTRIBUTION OF PHOTOAUTOTROPHS IN CAVES

Photosynthetic microorganisms living in the neighboring outside areas generally colonize the better illuminated wall surfaces near the entrance of the caves; towards the depth of the caves the microbial photoautotrophic vegetation becomes less dense and less diverse (43,44). Evidently, the depletion of species composition and of taxonomic spectrum is mainly caused by the reduction of intensity of illumination. Very few species are able to grow along the whole gradient of conditions. With decreasing light intensity, mosses and lichens generally disappear first (Fig. 3a). Extremely low-light irradiance can support the growth of photosynthetic communities mainly formed of cyanobacteria and chlorophytes (and moss protonema that can thrive at lower light intensities than the leaved gametophytes) (44,45). In most cases, the microbial photosynthetic communities at the dim end of the lighted zone are exclusively built by phycobiliprotein-rich cyanobacteria, many of which are able to regulate pigment composition.

PHYSIOLOGICAL ECOLOGY

Few species of photoautotrophs are able to withstand the low irradiance available in these environments, but data

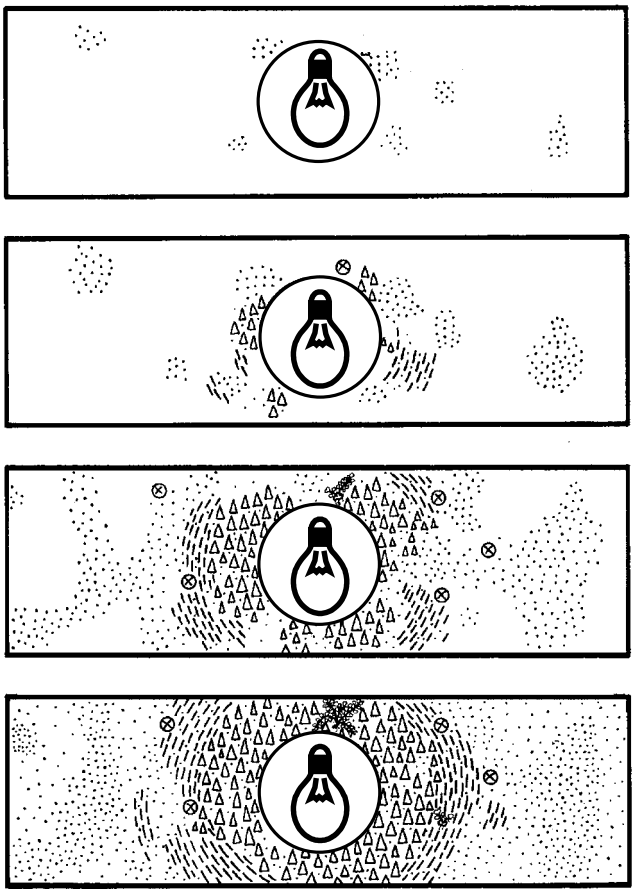

Figure 4. Ontogenesis of a "lamp vegetation" (adapted from Ref. 3). The dots indicate microbial photoautotrophs, the other symbols representing mosses and ferns.

on the biology and the ecophysiological adaptations of the microbial photoautotrophs to this particular extreme terrestrial environment are scarce. Some reports in the literature deal with photosynthetic microorganisms isolated in culture from samples taken from totally dark parts of caves. A large variety of mostly common aquatic and terrestrial cyanobacteria and eukaryotic microalgae was identified in these isolates, but no visible growth of these species was recorded in situ. Although the methodology of these studies may be beyond criticism, the presence of viable cells is not a sufficient indication of a cave vegetation. The cyanobacterium *G. calcarea*, one of the microbial cave photoautotrophs occurring in the deepest parts of the caves, lives at an irradiance that is generally below 5 $\mu mol\, m^{-2}\, s^{-1}$ (7). The photoautotrophs of low-light environments keep their color in contrast to animals, which are often discolored in cave habitats. Hypothetical adaptive characters that allow them to thrive under the extreme low photon flux densities are: (*1*) the possibility of ultrastructural changes (increase in photosynthetic membranes) as a consequence of low-light intensities (5,34,46) (this has been shown for cyanobacteria, but not for green algae); (*2*) the presence of large antenna owing to the presence of phycobilisomes in cyanobacteria, which may allow these organisms to capture the few photons available. The fact that at the lowest light intensities, eukaryotic microalgae cannot compete with cyanobacteria is generally explained by the lower maintenance requirements of the latter and their ability to adapt to low light (47–49).

The adhesion of the photoautotrophic microorganisms to stone surfaces is based on the production and secretion at the cell surface of mucilaginous substances providing the cells with a high degree of hydrophobicity. The exopolymeric substances secreted by these microorganisms vary by their consistency and thickness. They are commonly called *glycocalyx*, *capsule*, *sheath*, or *envelope*. The formation of these extracellular investments represents one of the most relevant steps in the early stage of the microbial colonization by helping to stick the cells to the substratum. Moreover, the polysaccharides secreted by the photosynthetic microorganisms contribute to the formation of firm microbial biofilms (44) supporting and stimulating the growth of other microorganisms, especially of heterotrophic bacteria and fungi (50), always present in the same microhabitats colonized by cyanobacteria and microalgae. Microbial cells attached to a surface can develop into a highly differentiated community in which photo- and heterotrophic organisms are enmeshed in a polysaccharide matrix that mediates intercellular communication as well as the interactions with the substratum. The often anionic nature of the exopolymers strongly absorbs cations and dissolves organic molecules from the underlying minerals. In these peculiar habitats, as in almost all terrestrial environments, and in contrast to aquatic systems, gram-positive bacteria appear to predominate as epiphytes (50). The release of inorganic and organic metabolites by microalgae determines interactions either with the substrate, which can be corroded, or with bacterial and fungal populations that can utilize these compounds. The production of these exocellular, highly hygroscopic, polymeric substances also ensures the survival of the colonizing organisms in adverse climatic conditions.

ECONOMIC IMPORTANCE: "GREEN SICKNESS" OF CAVES

Caves and other low-light environments are not only of interest to speleologists and scientists in general, but in many cases, they are also positively involved in the tourism and are thus of economic relevance. This is especially the case for show caves, which present interesting rock formations or are of archeological interest, as well as for many man-made low-light environments presenting various works of art. The photoautotrophic microorganisms are extremely successful in colonizing illuminated areas in these low-light environments. The reasons (52) are that these often hypogean environments are characterized by:

- A usually moist and wet atmosphere, with a relative humidity close to 100%;
- An often relatively constant illumination provided from the artificial lighting;
- Water filtering through the formations that are saturated with CO_3^{2-} and often also contains high concentrations of nutrients;

- High levels of carbon dioxide present in the atmosphere that dissolves readily into the water; and
- Uniform temperatures prevailing all over the year.

Besides the physical and chemical weathering caused by environmental pollutants, the presence of micro- and macroorganisms is a major factor for the deterioration of this cultural heritage. Indeed, once these low-light environments start to be illuminated by any natural or artificial light source, eukaryotic algae and cyanobacteria, lichens, mosses, and ferns proliferate, causing aesthetic, physical, and chemical changes. The development of photoautotrophs discolors the stalactites and stalagmites of karst formations, giving them a dirty and unsightly appearance (52). Besides stimulating the growth of the photoautotrophs, the illumination in show caves also allows the photoautotrophs to spread to areas in which they previously could not grow. Furthermore, the movement of the visitors through the caves causes a rapid spreading of the microorganisms. The concomitant increase in temperature also favors a rapid growth. An important secondary problem is carbon dioxide solution, dissolution and the impact thereof on the carbonate deposits. Microbial growth can cause the erosion of formations leading to irreversible damage. This is mainly because of their uptake of carbon dioxide and the dissolving of calcium carbonate. With increasing numbers of visitors, a degradation of the cave environs thus often becomes evident. Moderate and low-energy caves are especially vulnerable to the threats posed by tourism. Since the famous studies on the "maladie verte" (green sickness) (51) that affected the prehistoric mural paintings in the caves of Lascaux in France, the presence of photosynthetic microorganisms has been reported by a number of different authors, on walls and paintings in caves, churches, or more generally in confined low-light environments characterized by high humidity. Their conservation constitutes a problem that has nowadays assumed a worldwide interest.

Changes in the composition and luxury of the subterranean biofilms may also result from changes in the land use above the hypogean environment; this may lead for example to an increase in the nutrient concentrations in the water (owing to increased use of mineral fertilizers) or to an impact on the water cycle, decreasing or increasing the amount of dripping water.

The damaging effects on stones are produced by epi-, endo- and chasmoendolithic species. Aesthetic damage by photosynthetic microorganisms is caused by the development of colored biological patinas. Besides the production of aesthetic damage, the established microbial biofilm communities can be associated with different biodeteriorative effects.

The presence of microbial biofilms, which adhere firmly to stone surfaces, indeed increases the surface biosusceptibility to deterioration. A synergic biodeteriorative effect on stone surfaces is possibly achieved by concomitant growth of photoautotrophic and heterotrophic populations (50). Bacteria and fungi, in fact, are able to use the organic matter produced by the photoautotrophs. The metabolic activities (for example the release of acidic compounds) of the microbial consortia, and the polysaccharide matter of the biofilms contribute to chemical stone deterioration by solubilization, leaching, and chelating processes. A marked softening of the substratum and the progressive deepening of the biological growth in the layers beneath the surface is owing to the mobilization of elements and can thus cause stone surface weathering, increasing the loss of stone particles from the crystalline structure (50). The extracellular mucilages are also prone to increase the disruption damage by physical contraction and expansion of the polysaccharides.

As shown by pH microelectrode measurements in biofilms (47), both acidification owing to respiration during the dark period and alcalinization as a consequence of photosynthetic activity during lighting may occur to a sufficient extent to induce dissolution and reprecipitation of mineral compounds, especially in calcareous substrates. Intensive photosynthesis leads to a sharp increase of pH owing to the consumption of carbon dioxide and HCO_3^- and the consequent increase of CO_3^{2-}. This fact is relevant in changing the solubility of elements in the mineral substrate and thus influencing the interrelationship among resident microorganisms and lithic substrata with a subsequent increase of stone damage.

Mineral precipitation in the form of crystals has been observed in some cyanobacterial species, for example, *S. julianum* (7,31–33). The precipitation of calcium carbonate on the surface of the polysaccharide sheath of cyanobacteria in the form of calcite crystals seems to be promoted by live bacteria. Carbonate precipitation and/or solubilization are major factors in the biotransformation of calcareous substrata. After the death of calcifying microorganisms, the calcified filaments may remain on the substratum in which they can accumulate, forming a calcite layer. Deposition of successive layers, together with the processes of dissolution and precipitation of calcite, can result in the formation of whitish mineral crusts with a typical layering for stromatolithes (7).

In these low-light environments some dangerous species such as *Prototheca* sp. can sometimes occur in high concentrations among other populations of microorganisms. This genus seems to cause conjunctivitis and skin disease like protothecose for archeologists who permanently work in such environments. Furthermore, data exist that in low-light conditions, the destruction of abundant photoautotrophic biomasses can produce carcinogenic nitrosamines, compounds, which are immediately destroyed by light but which remain stable and can accumulate in low-light environments.

The eradication of the photosynthetic microorganisms living on stony substrates in low-light environments and the control of their development, necessitate a multilevel approach, involving preventative measures and the treatment of existing colonized areas (52). Nondestructive methods are especially needed in the case of valuable archeological and artistic surfaces. Preventative measures mainly concern the lighting used to illuminate the caves and how it is operated. Every effort should be taken to limit illumination of any area as much as possible.

The duration of illumination should be limited as far as possible by having alternate lamps illuminating the walkways over time, by using motion detectors and varying display illumination. Where areas need to be illuminated for longer periods of time colored lighting should be used and especially photosynthetically inactive wavelengths such as green light (white, reds, and blues should be avoided) (52). For treating colonized areas, spraying with algicides, antibiotics, hydrogen peroxide with subsequent washing with low pressure, application of gases and irradiation by UV germicide lamps have been applied (52–54).

To preserve these unique environments, it is thus necessary to determine a balance between recreational and commercial expectations versus the conservation and preservation of the cave environments. As a rule, the illumination should be reduced to a minimum and the number of visitors allowed should be such that, once the visitors leave these confined environments, parameters such as temperature and atmospheric carbon dioxide return to the same level prior to the visitors' entry (54).

Chemical Biological Center
Aberdeen Proving Ground,
Maryland

The U.S. Army has custody of chemical weapons (CW) containing nerve and blister (vesicant) agents located in eight different sites in the continental United States and at Johnston Island, a small island in the Pacific Ocean. The stockpile, which totals approximately 32,000 tons, consists primarily of three agents, the nerve agents GB (sarin) and VX, and the blister agent HD (sulfur mustard). The structures of these agents are shown in Figure 1. These agents are stored in one-ton bulk steel containers and in munitions such as bombs, rockets, artillery shells, and mines (Fig. 2). All the munitions and agents are between 25 and 50 years old. In addition, U.S. Army officials have identified 215 sites in 33 states that are likely to contain buried chemical weapons or to be contaminated with chemical agents (1). Besides the United States, several other nations such as the independent republics of the former Soviet Union also face cleanup tasks similar to that of the United States. The list of CW agents include organophosphorus (OP) nerve gases such as VX, GA (tabun), GB, and GD (soman); blistering agents such as HD and HT (a mixture of HD and agent T); and the organoarsenical agents Lewisite (L) and Adamsite (DA) (Fig. 1).

The Chemical Stockpile Disposal Program in the United States was initiated in 1985, when the Department of Defense (DOD) targeted to destroy at least 90% of the CW stockpile by September 30, 1994. As the program proceeded, the pace was slower than anticipated, and the target date for completion was revised several times. In 1988, Congress extended the completion date to 1997, and in 1990 to July 1999.

International events soon had an impact on this program. In 1990, the United States and the former Soviet

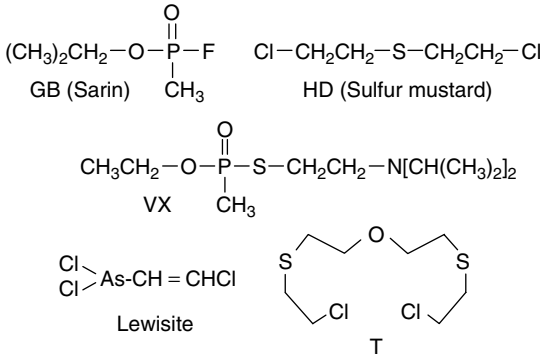

Figure 1. Primary agents in U.S. and Russian chemical weapons stockpiles.

Figure 2. Stockpile of sulfur mustard at the Aberdeen Proving Ground, Maryland.

Union signed a memorandum of agreement to cease chemical weapons production, dispose of inventories, share disposal technology, and develop inspection procedures. In addition, on September 3, 1992, the Conference on Disarmament approved the Chemical Weapons Convention (CWC), signed between January 13 and 15, 1993, by the United States and several other nations, forbidding the development, production, stockpiling, or use of chemical weapons. Upon ratification, the deadline (which supersedes previous deadlines) for stockpile destruction will be December 31, 2004, or later. In the case of the United States, the ratification of the CWC, which was on April 30, 1997, made the deadline April 30, 2007.

In the United States, the army has had an ongoing program for disposal of surplus and obsolete weapons. Before 1969, CW munitions were disposed of by open-pit burning, evaporative "atmospheric dilution," burial, and deep ocean dumping (2). The Marine Protection, Research & Sanctuaries Act of 1972, prohibited the ocean disposal of agents. In the 1970s, the principal methods employed for agent destruction were neutralization via alkaline hydrolysis for GB and incineration for HD. Because of problems with GB alkaline hydrolysis, incineration was selected as the preferred technology for destruction of obsolete components of the CW stockpile in 1982. Currently, two full-scale CW incinerator facilities are available in the Marshall Islands and in Utah.

The initial plan to use incineration for the destruction of the CW stockpiles has stalled due to considerable local and national opposition by citizens, environmental groups, and politicians. As a result, the army was directed by Congress to report on alternative technologies for CW stockpile destruction. The army requested the National Research Council (NRC) Committee on Review and Evaluation of the Army Chemical Stockpile Disposal Program to reevaluate the status of incineration. An additional NRC committee on Alternative Chemical Demilitarization Technologies was formed to examine alternatives for CW disposal. On the basis of the two NRC studies (3,4), alternative technologies were proposed. With the rapid progress in biotechnology during the last decade, one possible solution is to develop biological strategies for the large-scale decontamination of CW agents. The focus

of this article is to provide a summary of the recent developments in the area of biodegradation of chemical weapons. Direct biodegradation and the use of chemical neutralization followed by biodegradation are among the technologies under investigation.

MUSTARD GAS

Sulfur mustard, often referred to as "mustard gas," is 2,2′-dichlorodiethylsulfide (Chemical Abstract Services number 505-60-2, military designation, H or HD). Mustard is an oily liquid with a freezing point of approximately 14 °C and a boiling point of 217 °C. Because mustard is nearly insoluble in water, it is very persistent in the environment and can contaminate soils and surfaces for long periods. Mustard affects the eyes and lungs and blisters the skin. It causes severe chemical burns and painful blisters, and is lethal at high dosages, especially if inhaled. Symptoms are generally delayed for several hours after exposure (5–7). It was developed in Germany and used extensively during World War I during which it caused 80% of the gas casualties. It was also used by Italy in Ethiopia in 1936, by Japan against China in World War II, by Egypt in Yemen in the early 1960s, and by Iraq against Iran during the 1980s.

Because the blistering agent HD reacts with microbial proteins and is highly toxic to microbial cells, it is not amenable to direct biodegradation. Therefore, most studies have been focusing on combined chemical and biological degradation. The advantages of using hydrolysis as a neutralization reaction preceding biodegradation of HD include an aqueous medium, complete dechlorination, and products (primarily alcohols) that are amenable to biodegradation. Also, the hydrolysis reaction does not add any additional carbon that would require subsequent biological removal. Alkaline hydrolysis has been previously utilized for the destruction of Canadian HD stockpiles (8). Biodegradation has a widespread application in municipal and industrial wastewater treatment plants, is conducted at ambient temperatures, and offers a favorable mass balance for the process.

The mechanism of HD hydrolysis has been the subject of considerable study beginning just after World War I (9–15). It has been demonstrated that HD reacts through a series of sulfonium ion intermediates to produce thiodiglycol as shown in Figure 3. However, additional ether or thioether products can also form depending on the actual conditions of the reaction. Because HD is insoluble in water, the reaction involves hydrolysis at the water–organic interface with the products then dissolving in the water (14). Therefore, agitation during hydrolysis is a critical factor in carrying out this reaction. Both the rate of mass-transfer and the rate of hydrolysis can be accelerated at elevated temperatures.

The efficiency of conversion of HD to thiodiglycol (TDG) has been shown to be dependent on temperature and whether the base used for neutralizing the acid is added before or after the reaction (16). Elevating the temperature of alkaline hydrolysis reaction from 30 to 90 °C increased the TDG concentration from 62 to 84%. Running the hydrolysis in hot water alone (with base neutralization

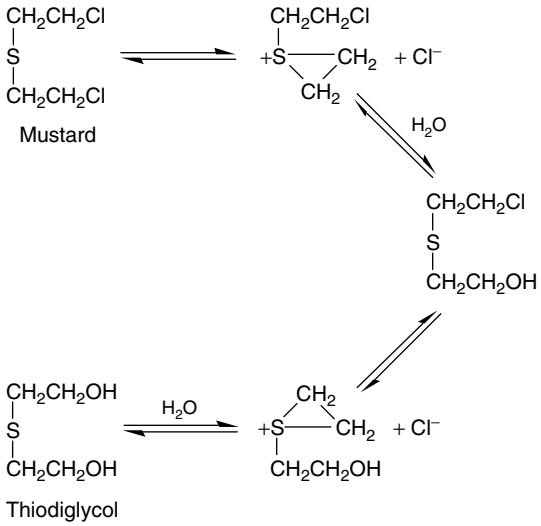

Figure 3. Hydrolysis mechanism for HD.

after cooling) further increased the TDG level to more than 95%. The hydrolysis reaction in either caustic or water was completed, with HD not being observed within a detection limit of 160 ppb.

Biodegradation of TDG

TDG, the primary hydrolysis product of HD, is a water miscible, nontoxic liquid. However, it is listed as a Schedule Two compound (chemical weapon precursor) in the CWC and therefore must be destroyed as part of any demilitarization processes. Earlier studies with *Alcaligenes* ssp. *A. xylosoxydans* demonstrated that TDG could serve as sole carbon and energy source for microbial growth (17).

The actual pathways by which TDG is metabolized have not been the subject of extensive investigation. Preliminary studies (18) with *A. xylosoxydans* indicated that this organism oxidized TDG by means of sequential NAD-dependent butanol dehydrogenase reactions to give thiodiglycolic acid (TDGA) as shown in Figure 4. NMR analysis of the cell-free dehydrogenase reactions yielded two oxidation products from TDG: hydroxyethylthioacetic acid (HETA) and TDGA. The identity of these products was confirmed by mass spectrometry analysis. Therefore, it appeared that in this organism, the biodegradation of TDG proceeds via an oxidative pathway that first yields a monoacid product and then the diacid product. Recent studies have confirmed that HETA and TDGA are intermediates in the TDG pathway (19). The fate of the TDGA has not been determined.

In previous studies with microbial consortia and in earlier work with *Pseudomonas picketii*, the transient appearance of thiodiglycol sulfoxide was occasionally observed (20). Whether the sulfoxide is an actual metabolic intermediate in the degradation of TDG or the product of a side reaction is not known. However, by whatever means the sulfoxide is produced, it is the subject of further degradation as it is not found in the final effluent.

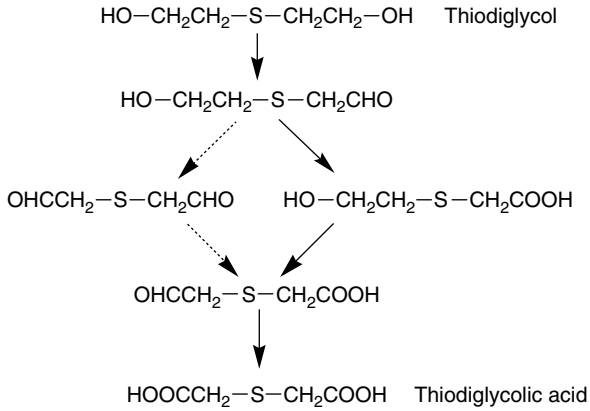

Figure 4. Thiodiglycol metabolism in *Alcaligenes* (18).

Large-Scale Biodegradation of TGD

For the biodegradation of hydrolyzed HD (21–22), the use of sequencing batch reactors (SBRs) was selected (Fig. 5). SBRs offer several important operational advantages for the treatment of chemical wastes (23). They are very efficient. The SBR is composed of a continuous flow stirred tank reactor (CFSTR) followed by a plug flow reactor, offering the ideal volumetric reactor configuration for unsteady state activated sludge systems. They operate in the batch mode that not only offers a kinetic advantage over conventional CFSTRs (therefore smaller in size) but also permit batch analysis and toxicity testing for hazardous waste treatment before discharge. They use a single tank for both treatment and settling; therefore, no secondary clarifier is required. Finally, they are robust and flexible. SBRs are intentionally operated over a rang of substrate concentrations, pH conditions, and oxygen concentrations, thereby allowing selection of a very diverse and robust population of microorganisms. Operational strategies can also be varied to accomplish carbon, nitrogen, and/or phosphorus removal.

The reactor cycle (24-hour) used in these studies normally consists of a four-hour aerated fill, an 18-hour aerated react, a 1.5-hour settle, and a 0.5 hour draw. The total organic carbon (TOC) loading in the feed was 3,400 to 3,800 mg/L. The hydraulic residence time (HRT) was 16 days and the original biomass for the SBRs was activated sludge from the Back River Waste Water Treatment Plant (Baltimore, MD). Trace metals were provided in a modified Wolin Salts Solution (24) in addition to NH_4Cl and KH_2PO_4 as nitrogen, potassium, and phosphorus sources. The hydrolyzed HD was the sole source of carbon and sulfur. The SBR was operated at a pH of between 6.5 and 8.5. Buffering was primarily accomplished through the addition of $NaHCO_3$ to the feed, although a NaOH solution was occasionally used on demand when the pH dropped below 6.5.

In SBR with caustic-hydrolyzed HD, the TDG was typically removed to greater than 99%; however, the effluent TOC showed a gradual increase until it reached approximately 1,000 mg/L. At this point, the feed was changed to the water-hydrolyzed HD. After 146 days of operation, the reactor had significantly lower levels of effluent TOC and suspended solids. MICROTOX analysis of the effluent showed it to be nontoxic (100% effluent produced no changes in the luminescence levels of the test bacteria). In addition, toxicity characteristic leachate protocol (TCLP) analysis of the effluent found none of the restricted organics and metals at levels of concern. A mass balance calculated per ton of HD is shown in Table 1

On the basis of results at the laboratory and bench scale, the neutralization-biodegradation method was selected by the army for the destruction of the HD stockpile at Aberdeen Proving Ground. A U.S. $86 million demonstration unit was approved and is in the permitting process. Site clearing for the demonstration unit and full-size facility has been initiated. The official groundbreaking ceremony for the facility was held on June 26, 1999. A U.S. $306 million contract has been awarded for the construction, operation, and dismantling of the full-size facility. The goal of the program is to meet the April 30, 2007 deadline for destruction as mandated by the CWC.

With the success obtained in the biodegradation of HD, a related material called HT was examined (25). HT is a mixture of 60 weight percentage of HD and 40 weight percentage of an analog bis-(2-(2-chloroethylthio)ethyl)ether or T. As with HD, treatment of HT with hot water hydrolyzes it into a mixture of TDG and bis-(2-(2-hydroxyethylthio)ethyl)ether (T-OH). Because the potential biodegradation of T-OH was not known, a number of studies were undertaken to determine if it could be

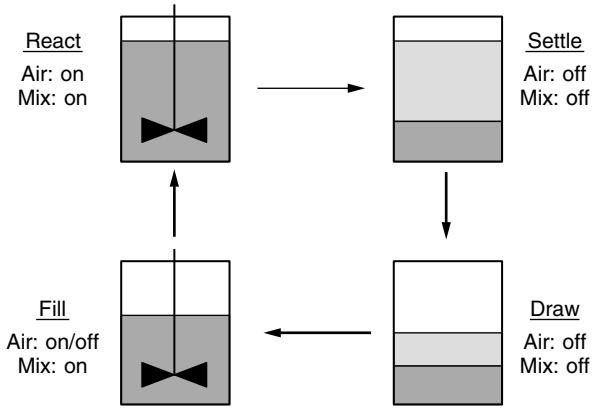

Figure 5. SBR operational cycle.

Table 1. Summary of Process SBR Mass Balance (16)

Input (tons)		Output (tons)	
HD	1.00	CO_2	0.55
NaOH	1.11	H_2O*	0.60
O_2 (air)	0.93	Biomass**	0.30
NH_4Cl	0.16	Na_2SO_4	0.88
KH_2PO_4	0.04	NaCl	0.90
		KCl	0.01
Total Input:	3.24	Total Output:	3.24

**Dry weight of biomass.

further hydrolyzed to TDG (approx. 20% is hydrolyzed to TDG by the hot water system). It was found that a considerable portion of the remaining T-OH is converted to TDG by conducting the hydrolysis in the presence of HBr or HI. However, it was later determined that this additional hydrolysis was not necessary to achieve biodegradation. SBR studies demonstrated that the water-hydrolyzed HT (after neutralization) could be efficiently biodegraded (comparable to hydrolyzed HD) and that the effluent from the systems has little (if any) toxicity.

Immobilized Cell Bioreactors

All the studies described earlier involved the use of SBRs for the biodegradation of the hydrolyzed agents. An alternative approach is the use of biofilm systems in which the microorganisms grow attached to a solid support. AlliedSignal Environmental Systems (part of AlliedSignal, Inc.) owns and operates mobile bioreactor units for on-site neutralization of various contaminated waste streams. These reactors, commonly called immobilized cell bioreactors (ICBs), use a stationary support of polyurethane foam blocks to grow the biomass on. Cylindrical polypropylene spacers are also used to allow for more efficient aeration and liquid circulation. AlliedSignal provided laboratory-scale ICBs for evaluation with hydrolyzed HD and VX. These units had a total volume of approximately 1 liter and a working volume of 600 to 800 mL. Studies were undertaken with the ICBs and both HD and VX hydrolysates (25).

An ICB was seeded with biomass from a HD SBR and allowed to acclimate in a batch feed mode. The feed for the HD-ICB consisted of (per liter): HD hydrolysate (3.8%), 333 ml; NH_4Cl, 1.2 g; KH_2PO_4, 0.35 g; Wolin salt solution (24), 10 ml; and $NaHCO_3$, 5.0 g (for pH control). The feed was adjusted to a final pH of 7.5 with HCl prior to use. In the initial batch operations, a recirculating loop and the addition of NaOH provided additional pH control. Once sufficient biomass had been produced and continuous operations were begun, the pH was controlled entirely by adjusting the level of sodium bicarbonate in the feed. Pumping air through a frittered glass disk at the base of the ICB provided continuous aeration.

The initial working volume of the HD-ICB was 750 mL. As the biomass developed, the working volume decreased to the point that when the studies were concluded, it was down to an estimated 287 mL. The feed rate to the ICB ranged from 100 to 300 mL per day, giving a hydraulic residence time (HRT) of 1.5 to 7.5 days. Very efficient mineralization of the TDG was achieved as long as the HRT was kept at greater than three days. In the laboratory unit, higher feed rates (and lower HRT) resulted in the biomass, which nearly plugged up the reactor. This resulted in anoxic or anaerobic zones where biodegradation of the TDG ceased. In full-scale units (using larger foam blocks, spacers, higher velocity liquid flow, and aeration) this plugging would not occur. Under all conditions in this study, the biomass stayed firmly attached to the support. The total suspended solids (TSS) in the reactor effluent were generally at or below standard detection limits. Overall, once established, the HD-ICB system was very efficient and required little daily maintenance. It would therefore lend itself to pump and treat operations or continuous-flow waste streams. Further studies will be necessary to determine whether biomass buildup would reach a point where it would hinder performance, and if the same level of TDG mineralization could be maintained over long periods.

Cryoimmobilized cultures of *A. xylosoxidans* have also been investigated for the hydrolysis of TDG. More than 150 mM TDG was metabolized within 24 hours and 100% of the initial activity can be maintained after four months of continuous use (26).

OP NERVE AGENTS

German scientists first developed OP nerve agents over half a century ago while conducting research on organophosphate insecticides (27). During World War II and warfare competition afterwards, the world saw a rapid proliferation of such agents (Table 2). The use of these agents has resulted in large numbers of casualties. During the past 15 years, Iraqi troops employed nerve gas against Iranian soldiers and Iraqi Kurdish civilians and nerve gases were considered a major threat to allied personnel during the Persian Gulf War. Normally, only combat personnel would be exposed to nerve agents, although other people living close to the battle fields may get intoxicated by the soil and groundwater or drinking water. However, the use of sarin against Japanese civilians during a terrorist attack on the Tokyo subway system in 1995, resulting in more than 5,500 casualties (28), alerts us about a new and much more dangerous type of exposure (29–30).

These OP nerve agents are highly toxic and inhibit acetylcholinesterase (AchE) in the central nervous system synapses of most animals including humans (31). Exposure to organophosphates results in acetylcholine (ACh) accumulation, which interferes with muscular responses and the function of vital organs. High dosages of organophosphates can prove fatal. Chronic or prolonged exposure to sublethal doses of organophosphates may result in delayed cholinergic toxicity and neurotoxicity (32). The classic symptoms of nerve agent poisoning

DE: Germany.

include salivation, lacrimination, urination, and defecation. Miosis and bradycardia are also common (27). In the disaster of Tokyo subway incidence, patients with severe poisoning showed greatly reduced consciousness levels, miosis, marked fasciculation, flushing, tachycardia, raised blood pressure, respiratory distress, and flaccid paralysis; whereas those with mild poisoning complained of headaches, dizziness, nausea, chest discomfort, abdominal cramps, and showed marked miosis. All are typical symptoms caused by sarin gas intoxication (29).

The progression of nerve agent toxicity, in character and speed, is not only dose-dependent but also dependent on the route of entry into the body. In the vapor phase, they are absorbed rapidly across the respiratory epithelium. They are also absorbed across the cornea where by a local effect they produce miosis. As liquids, they pass relatively rapidly across the skin and mucous membranes without damaging them. They may also be absorbed from the gut and, when carried into wounds, are rapidly distributed throughout the body. The absorption of nerve agents from air taken into the respiratory tract is almost 90% (27).

Currently, fielded decontamination solutions, such as DS2 and bleach, are quite effective in degrading OP-based CW agents (33). However, they are corrosive in nature and result in hazardous waste. Microbial- or enzyme-based decontamination systems not only provide rapid removal of CW agents but are also environmentally safe and noncorrosive in nature. The use of enzymes has considerable potential for decontamination of equipment, vehicles, large fixed sites, and cleanup operations that might result from a terrorist attack.

Enzymatic Degradation of OP CW Agents

Mazur was the first to describe the enzyme hydrolysis of the phosphorous-fluorine bond of diisopropyl fluorophosphates (DFP) by a crude preparation of rabbit tissue (34). Subsequently, several different enzymes such as paraoxonases, DFPase, and somanases from sources as diverse as hog kidney, rabbit, human, and squid have been shown to detoxify DFP or other related OP nerve agents (35–37). However, in most cases, only crude enzyme extracts were used to demonstrate the hydrolysis of these OP CW agents.

In the early 1980s, several studies were initiated to search for microorganisms that could degrade OP CW agents. The initial focus was on the microorganisms that are capable of hydrolyzing related OP insecticides. Among a range of enzymes that hydrolyze OP insecticides, only organophosphorus hydrolase (OPH) isolated from *Pseudomonas diminuta* (38) and *Flavobacterium* sp. (39) is active in degrading nerve agents, if at all (40–41). Cleavage of the P–F, P–S or P–CN bonds render the OP agents relatively nontoxic as the bond broken is that involved in the irreversible inhibition of acetylcholinesterase (42). OPH is also the only well-characterized OP-degrading enzyme, which has been shown to hydrolyze the P–S bond of OP agents (43–44).

The gene encoding OPH, *opd*, was isolated from both *P. diminuta* and *Flavobacterium* sp. (45). Because the economics of culturing the native soil bacteria is not very attractive as a result of the slow specific growth rate, the *opd* gene has been cloned into *Escherichia coli* (46), insect cell (fall armyworm) (47), *Streptomyces* (48), and soil fungus (49) to explore the possibility of expression in alternative hosts. To date, *E. coli* has been used most extensively for expression. The kinetic properties of the recombinant OPH are virtually the same as the native form (46,50).

Recombinant OPH is a homodimer with equal active sites at the C-terminus of each monomer (51–52). Each active site has a binuclear metal center, and different metal-associated forms of OPH with Zn^{2+} or Co^{2+} demonstrated significantly different hydrolytic capabilities (53); the activity of the Co-form is consistently five- to tenfolds greater (54). OPH has a broad substrate range and has the ability to hydrolyze several insecticides (55), CW analogs (41) and the actual CW agents (40,43). Catalytic specificities (k_{cat}/K_m) vary from diffusion limited for paraoxon to more than eight orders of magnitude lower for acephate (55). The rate of hydrolysis for members of OP CW agents, including VX and sarin, are slow compared to hydrolysis of insecticides such as parathion and coumaphos (56). A comparison of specificities for different substrates is shown in Table 3 (57). Practical applications of OPH-based technologies for the biodegradation of CW agents would necessitate an improvement not only in the catalytic rate but also OPH availability, shelf life, and stability.

Another interesting enzyme that is receiving more attention in recent years for the biodegradation of CW agents belongs to a class of enzymes known as organophosphorus acid anhydrolases (OPAA) (58). As shown in Table 4, the OPAA enzymes are capable of catalytically hydrolyzing a wide variety of substrates, the fluoride-containing CW agents such as soman, sarin, and GF, and also the cyanide containing agent tabun. A number of *Alteromonas* sp., containing high levels of OPAA activity, has been isolated (58–60). The genes coding for OPAA have been cloned from *Alteromonas* sp. strain JD6.5 (61) and *A. haloplanktis* (62) and functionally expressed in

Table 3. Comparison of Substrate Specificity of OPH (63)

Substrate	k_{cat}/K_m (s^{-1})

recombinant *E. coli*. Sequence and biochemical analyses of the cloned enzymes suggested that OPAA is in fact a prolidase (61–62), a type of dipeptidase cleaving dipeptide bond with a prolyl residue at the carboxyl terminus (X-Pro). OPAA is highly active in hydrolyzing two dipeptide substrates of prolidase, namely Leu-Pro and Ala-Pro, but is not active against tripeptides. Computer modeling has suggested that the hydrolytic activity of OPAA against OP CW agents may be due to the fortuitous similarity of these compounds in size, shape, and surface charges to the X-Pro dipeptides (33).

Degradation of OP Agents by OPH

On the basis of the X-ray crystal structure of OPH, several mutant OPHs with enhanced activity against CW agents or analogs were generated (57a,b,63). These mutants were rationally designed based on amino acid substitutions in the enzyme active site. In particular, because the functional catalytic role and the coordination of metal centers have been studied, the initial approach was to generate mutants with substitutions in the residues responsible for binding the divalent metal cations. Site-directed mutagenesis was used to replace the original histidine residues at positions 254 and 257 (63). Of these enzymes, three variants (H254R, H254S, and H257L) retained only one metal at the active site. However, these enzymes retained activity against paraoxon with only a small reduction in k_{cat}/K_m. More importantly, mutants H254R and H257L showed a four- to fivefold improvement in activity and specificity against both VX and its analog demeton S (57a,b,63). OPH mutant H257L catalyzed the hydrolysis of soman and its analog NPPMP about fivefold better. The activity of the double mutant H254R/257L was even better with more than 20-fold improvement against demeton S compared to the wild-type OPH.

Another rational approach to design improved OPH mutants for enhanced DFP (an analog of sarin) degradation was demonstrated by Watkins and coworkers (64). This strategy was based on engineering the hydrophobic residues (Trp131, Phe 132, Leu271, Phe 306, and Tyr 309) involved in the putative leaving group of the active site. Because DFP has a fluoride-leaving group, replacement of one side chain with a residue capable of hydrogen bond formation and proton denation (His, Tyr, or Lys) was predicted to enhance catalysis. Eleven mutants were created by site-directed mutagenesis. The double mutants, F132H/F306H and F132H/F306Y, hydrolyzed DFP up to an order of magnitude faster than the wild-type OPH. However, because the K_m values were generally higher for these mutants, the overall specificity for DFP improved only by twofold.

Because the kinetic characteristics of OPH can be altered with relatively few amino acid substitutions, there is a realistic possibility of creating OPH variants with improved activity toward other OP agents based on rational design. Unfortunately, identifying all the amino acids responsible for substrate specificity and those that might give rise to extended specificity remains an overwhelming challenge. To this end, in vitro directed evolution is perhaps the more useful way to sample this sequence flexibility in a simple and rapid fashion (65). Not only is this method considerably easier to perform, it can also test the effects of amino acid changes, insertions, and deletions in regions of the protein that do not have predictable roles in activity (66–67). Moreover, the database generated on the protein sequence space can be merged with structural information for future rational design of OPH. We have recently demonstrated the directed evolution of OPH for enhanced degradation of methyl parathion, a substrate that is degraded 50 times slower than paraoxon by the wild-type OPH (unpublished results). Mutants generated more than 30-fold faster after two rounds of screening degraded methyl parathion. More interestingly, mutations outside of the active sites were shown to be important for the improved activity. It is difficult to comment on how these mutations contribute to the improved activity against methyl parathion; however, it is clear that these positive mutations cannot be predicted "a priori" simply based on structural information. Directed evolution is powerful precisely for this ability to identify distal mutations that involve subtle, long-range interactions.

Practical applications of OPH for rapid detoxification of OP compounds have been investigated. Both native and recombinant OPHs have been immobilized onto nylon (membrane, powder, and tubing), porous glass, and silica beads to develop a reusable or recoverable biocatalyst system for the detoxification of OP compounds (68–70). In addition, OPH has been immobilized in polyurethane foams that can potentially be applied as sponges or wipes for the cleanup of spills (71–72). Dry foams stored at room temperature retained significant activity over 50 days (73). Unfortunately, the immobilization of OPH by physical adsorption or covalent binding often results in a significant reduction in operational activity and/or stability because of sensitivity to changes in pH or temperature. In addition, the enzyme kinetics parameters for these modified OPH's are often less desirable because of the inaccessibility of the enzyme's active site.

More importantly, practical applications of large-scale enzymatic degradation have so far been limited by the tedious protocol and the high cost associated with purifying OPH. Although secreted OPH from *Streptomyces lividans* can be purified from the culture medium without cell disruption (48), the level of production is relatively low and ion-exchange chromatography and gel filtration are still required. We have recently developed an economical alternative by using whole cells with OPH anchored on the surface (74). This strategy is attractive for bioreactor applications but may be difficult to implement for any in situ applications because of the use of recombinant strains. It is clear that any commercial application of OPH for a wide range of degradation necessitates the development of a reliable and economic means of purifying and immobilizing OPH.

Enzyme immobilization using an affinity tag offers the advantages of (*1*) reversible but strong immobilization under mild conditions, (*2*) proper enzyme orientation on the support material so all active sites are fully accessible to the substrate. We have recently demonstrated this possibility by generating fusion enzymes between OPH and a family III cellulose-binding domain (CBD_{clos})

from *Clostridium cellulovorans* (75), enabling purification and immobilization onto different cellulose materials in essentially a single step (76). The kinetics values of the immobilized fusion enzymes were similar to OPH with a modest increase in K_m. The pH profile of the cellulose-immobilized enzymes was also only minimally affected. The CBD-OPH fusion enzymes could be immobilized onto a variety of cellulose matrices, and retained up to 85% of their original activity for 30 days. Repeated hydrolysis of paraoxon was achieved in an immobilized enzyme reactor with 100% degradation efficiency over 45 days. These fusion proteins should prove to be invaluable tools for the development of low-cost OPH-based cellulose materials for the simultaneous absorption and degradation of stored or spilled organophosphate wastes.

Another interesting application of OPH for decontamination was recently reported by incorporating OPH into fire-fighting foam (77). This approach was motivated by the problems encountered in decontaminating surfaces because the OP agents are difficult to extract and are quite volatile. When OPH is integrated into the foam, however, volatilization is minimized and agents can be extracted.

Degradation of OP Agents by OPAA

A simple procedure for the production and purification of OPAA in recombinant *E. coli* was developed (60–61). The recombinant OPAA produced was of the same molecular weight as the native OPAA. Production in small-scale batch fermentations reached up to 1 g/L of culture. Fractionation of crude extracts with $(NH_4)_2SO_4$ resulted in OPAA enzyme that is 75% pure.

A simple and safe enzyme-based decontamination system was developed based on the use of freeze-dried enzyme (78). This approach provides long-term stability and it greatly reduced logistical burden. The lyophilized enzyme could be reconstituted with any solvent and sprayed onto the contaminated surfaces using fire-fighting equipment. Because OPAA can be fully maintained in $(NH_4)_2CO_3$-buffered water, such an innocuous and inexpensive solvent is ideal for the proposed system. Lyophilization with the disaccharide trehalose not only enhanced activity but also stabilized OPAA during prolonged storage at 37 °C with no loss in activity for 12 months (33).

A number of water-based foams and wetting agents were also investigated as potential matrices of delivery. Two such agents, "Cold Fire" and "Odor Seal" were found to enhance OPAA activity. Because both these are biosurfactants in nature, their presence in the decontamination formulation provides encapsulation of CW agents and enhance their solubility in the enzyme solution. Interestingly, OPAA also retained full catalytic activity in the commercial laundry detergent "Tide Free" and "Protectall" lotion, whose ingredients also included biosurfactants. These results again point to the stabilizing effects of biosurfactants on OPAA. Various formulations based on OPAA have already been demonstrated to be effective in degrading sarin and soman in actual testing at the Army Research Center (33).

Strategies for Degrading Bulk Agents

Destruction of CW agents must be irreversible such that even by-products must be destroyed, rendering them unusable for further military purposes. Steps are required to generate an acceptable waste stream following hydrolysis of OP agents. For example, the by-products generated by chemical hydrolysis of sarin with sodium hydroxide, sodium isopropyl methylphosphonate (IMPA), and sodium fluoride must be processed before discharge. Although no microorganism grows on IMPA as a carbon source, they can be used as the sole source of phosphorus and sulfur (79). In SBR systems in which sarin hydrolysate was supplied, IMPA concentrations decreased from 85 mg/L to less than 1 mg/L within 75 hours (1). The only drawback is the long acclimation period (six weeks) required for the consortia. Soman and VX can be similarly degraded as sarin by first treating with chemical hydrolysis followed by biodegradation. Again, the by-products of hydrolysis (PMPA and EMPA) can be used as a sole phosphorus source by microbial consortia (80). In SBR experiments, PMPA levels decreased from 164 mg/L to less than 1 mg/L within 60 hours (1).

VX-ICB Operations

The VX-ICB was also seeded from an existing SBR system. The feed for the ICB was the same as for the SBR with VX/caustic as the sole phosphorus and sulfur source. The feed rate was maintained at 50 milliliter per day for the entire study. At that time, the extra carbon source for the SBR was isopropanol. From the SBR studies, it was known that while isopropanol was readily metabolized, it did not generate much biomass. Therefore, the adaptation period for the VX-ICB was considerably longer than for the HD-ICB. At several points during this adaptation period, the feed was augmented with the addition of glycerol, glycerol and molasses, and molasses and inorganic phosphate, in an effort to increase the biomass.

Although the level of biomass production in the VX-ICB was always much lower than in the HD-ICB, the TSS was always higher. It appears that the biomass that was generated did not adhere to the support as readily. The performance of the VX-ICB for OP degradation was comparable or somewhat worse than the SBR system, the highest levels being in the 30 to 40% range. As with the SBR systems, it is presumed that increasing the auxiliary carbon source (increasing the C : P ratio) and switching to one that would give a much higher cell yield could improve this. Alternatively, a secondary stirred tank reactor could be added (with the additional carbon) to complete the OP mineralization.

On the other hand, unlike the SBR, the level of OS mineralization was surprisingly good. In general, the OS compounds were nearly always 95 to 100% degraded. There are two mysteries with regard to this performance that remain to be solved. The first is the actual metabolic pathways for the degradation of these materials. Possible metabolic intermediates were not observed in the ICB effluent. The second is the fate of the sulfur. Although the initial level of inorganic sulfate in the ICB effluent corresponded to the amount of sulfur in the feed, this

dropped considerably thereafter. This is despite the fact that the OS degradation remained at approximately 100%. Because the system was well aerated, it does not appear to be likely that it could have been converted to hydrogen sulfide or other gaseous form. Alternatively, it was thought that the activated carbon on the surface of the polyurethane foam might have preferentially adsorbed the VX-thiol (disulfide). However, if it was only adsorption without degradation, the carbon should have become saturated very early in the operation of the ICBs (which initially ran for 190 days).

More recent studies coupled the ICBs with a secondary stirred tank reactor (STR). The OS compounds continued to be totally removed in the ICB. By the addition of dextrose to the STR as a primary carbon source, the OP compounds are also fully degraded (25).

Other CW Agents

Other than mustard gas and OP agents, arsenic-containing CW agents belong to the largest group of CW agents produced (81). Arsenic is highly toxic to microorganisms; as a result, biodegradation of these mixtures is problematic. However, several Russian scientists have successfully developed laboratory-scale processes for destroying these agents (1). Following the treatment of Lewisite by chemical hydrolysis, the remaining arsenic intermediates were treated with electrolysis and electrocoagulation, yielding formate, acetate, and arsenous and arsenic acids. After precipitation of arsenic from the solution, the remaining organic acids are mineralized in a fluidized bed reactor using a natural consortium.

Large-Scale ICB Operations

The successor to The Alternative Technologies program is the Assembled Chemical Weapons Assessment (ACWA) program. Unlike the former, which only dealt with bulk agents (HD and VX), the ACWA program deals with weaponized agents and all the materials that may be involved in their destruction (explosives, propellants, etc.). As with the bulk agent program, the agent would first be chemically neutralized and the hydrolysate processed further. A number of different technologies are being evaluated, one of which is the use of ICBs followed by an oxidative polishing step. A 1,000-gallon ICB unit was set up by AlliedSignal to process hydrolyzed HD (primary carbon source) and hydrolyzed Tetrytol (a mixture of the explosives Tetryl and TNT) as primary nitrogen source. After an acclimation phase, the ICB was run at 200 gallons per day for a 40-day operational trial. The final report from this trial has not been completed. Although the biological system worked well for TDG degradation, the extent of Tetrytol degradation has not been determined. Whether this technology will be further evaluated for use in stockpile destruction is not known at this time.

CONCLUSION

Significant progress has been made on the biodegradation of CW agents during the past decade. Both microbial consortia and enzymes are now available for the destruction of various CW agents. In some cases, chemical neutralization combined with biodegradative processes can play a substantial role in destroying stockpiles of CW agents. This approach appears to be most readily adaptable to dealing with sulfur mustard (HD). Just such a method has been successfully demonstrated and is being put into operation at Aberdeen Proving Ground to destroy the 1,600 tons of the agent located there.

For dealing with the nerve agents GB and VX, the potential use of biodegradation is dependent on finding a more efficient means of dealing with the C–P bond in these organophosphonates. This would eliminate the need to add the extra carbon that greatly increases the cost and scale of the current systems. Although the use of biological systems for the destruction of the nerve agent stockpiles is still undecided, these studies have lead to the discovery of a number of very interesting enzymes. These may play an important role in agent decontamination on the battlefield, after terrorist attacks, or in dealing with spills or leaks that may occur at demilitarization facilities.

CHOLERA

ANWAR HUQ
ERIN LIPP
RITA COLWELL

Biotechnology Institute
Baltimore, Maryland

Cholera is perhaps one of the few ancient diseases that so far has managed to prevail in the modern world, carrying a devastating power that different regions have experienced from time to time. Cholera is a diarrheal disease that has long plagued populations in tropical areas of the world and traditionally near the Ganges Delta. Cholera has also been historically a global disease. The seventh pandemic is currently in progress. In this respect, cholera is a unique and insidious waterborne disease, capable of causing massive, worldwide epidemics. Currently, more than 75 countries in the world are listed as having cases of the disease. This disease generally occurred in epidemic form only in certain countries, until recently.

A bacterium, *Vibrio cholerae*, commonly found in all aquatic environments, such as marine, estuarine, river, and pond water, is now known to cause cholera. Only in recent years has *V. cholerae* been recognized as an autochthonous member of the aquatic microbial community and an opportunistic human pathogen. Powerful and sensitive tools and techniques for detection, identification, and characterization are rapidly evolving, with revived interest within both the scientific and lay communities. This increased awareness and interest, coupled with improved methods for detection, cholera disease, and the causative agent, *V. cholerae*, are now increasingly being reported from more locales throughout the world.

HISTORY OF CHOLERA

The Disease, Cholera

Cholera is a devastating disease involving production of cholera toxin by the bacterium, causing severe diarrhea of such prodigious volume that hypotensive shock can cause death within 12 hours of the first symptom (1). It is an enteric disease and is dose dependent. Usually, the infection is caused when the pathogen, *V. cholerae*, is ingested via food or water. The minimum effective dose may vary from 10^4 to 10^6 cells, depending on the susceptibility of the individual (2). *Vibrio cholerae* is highly sensitive to acid, therefore, hypochlorohydric people, that is, individuals with low acidity in their stomach are susceptible to a lower infectious dose and are at a higher risk of contracting the disease (2–4).

There is no conclusive agreement about the origin and use of the word "cholera." In Greek, the word means "gutter" or can be derived from the Greek words "chole" (bile) and "rein" (to flow), thus meaning the flow of bile (5–7). However, there is no disagreement among cholera historians about the occurrence of cholera-like disease in Asia and Europe during ancient times. The Sanskrit word, "visuchika," believed to denote cholera, was recorded around 500 to 400 B.C. (8). Given the lack of earlier recorded evidence, cholera in India was not discovered before the sixteenth century (9).

Cholera as an Emergent and Reemergent Disease

The modern history of cholera begins after 1817, when cholera was reported in the Middle East, Asia, Europe, and the shores of America (5–7). The question remains whether the pathogen was already on the American continent as part of the natural microbial flora or, as it was widely believed until recently, physically crossed the Atlantic. Historical records show human infection and clinical descriptions that match the descriptions obtained from different parts of the world, notably India. Until 1960, the disease was rampant across the world and took tens of thousands of lives. The disease was often considered as a curse from God. One artistic rendition that has appeared in many publications depicted the disease as a "ghost." In the United States, the last recognized indigenous cases of cholera occurred in Massachusetts and New York in 1911, until an individual case appeared in Port Lavaca, Texas, in 1973 (10). Thereafter, sporadic cases of cholera in the United States have been reported, most, however, being related to foreign travel, consumption of imported food, or consumption of "bootlegged" seafood from polluted waters in the U.S. Gulf Coast.

Although in 1854 John Snow first showed the possibility of environmental water contamination as a cause of cholera, not much was done to pursue this idea because scientists were primarily interested in the clinical aspects of the disease. The first report of toxigenic *Vibrio cholerae* from an environmental water source in the United States was made in 1978 (11). Interestingly, all the toxigenic strains of *V. cholerae* isolated from environmental sources in the United States between 1973 and 1990 are identical, except for one strain, as observed by Wachsmuth and coworkers (12). These Gulf Coast strains are unique in ribotype (assessed by restriction fragment length polymorphisms (RFLP) of rRNA genes (13).

A major event in the recent history of cholera was the 1991 outbreak in South America, after a century of freedom from the disease. Since then, small outbreaks continue to be recorded in and around Central and South America (14–16). The reemergence of cholera in the Americas drew the attention of both clinicians and microbial ecologists. The next key event came in 1992, when a massive epidemic caused by a new epidemic serotype, O139, originated in the southeastern part of India, gradually moved to the north of the Bay of Bengal and proceeded to Bangladesh (17,18). Before that time, *V. cholerae* O1 was the only serotype known to cause epidemics of cholera. The question of whether serotype O139 was a "novel" serotype or merely newly recognized remains unanswered at this time. If it is due to recent origin, researchers hypothesize that it may

have been converted from other existing serotypes in the environment. One point in support of this notion is the close resemblance of *V. cholerae* O139 to the El Tor biotype of *V. cholerae* O1 (19,20).

THE PATHOGEN, *V. CHOLERAE*

Taxonomy and Classification

In 1854, Pacini first described the causative agent of cholera in Italy as *V. cholera*; it was later termed *Kommabazillen* by Koch in 1883. The name was then subsequently changed to *V. comma*, based on the shape of the bacterium as determined using the technology of the time. This name persisted in the literature for several decades, before the microorganism was finally renamed as *V. cholerae*, following Pacini's original designation.

Vibrio cholerae is a γ-proteobacterium classified under the family *Vibrionaceae*. According to *Bergey's Manual of Determinative Bacteriology*, 9th edition (21), this family encompasses the genera *Aeromonas, Enhydrobacter*, *Photobacterium*, *Plesiomonas*, and *Vibrio*. However, an earlier study based on molecular evidence suggests that *Aeromonas* and *Plesiomonas* should be placed in a new family designated *Aeromonadaceae* (22). Within the family *Vibrionaceae*, *Vibrio* is considered to be the type genus and *V. cholerae* the type species within the genus. In Bergey's Manual the genus *Vibrio* is described as, "gram-negative, straight, or curved rods, 0.5 to 0.8 μm in width and 1.4 to 2.6 μm in length. Motile by one or more polar flagella, which are enclosed in a sheath continuous with the outer membrane of the cell wall, facultatively anaerobic and chemoorganotrophic, having both a respiratory and fermentative type of metabolism." Most of the species in the genus have an absolute requirement for Na^+ and at minimum the ion stimulates growth in all species (21). Therefore, it is not surprising that these microorganisms inhabit a wide range of estuarine and marine environments.

Vibrio cholerae is conventionally distinguished from other *Vibrio* spp. by a series of biochemical tests because there is no individual phenotypic trait that can confirm the species' identity (23). As a first-order test, presumptive isolates are screened on a *Vibrio*-specific medium (e.g., thiosulfate citrate bile-salt sucrose (TCBS)). *Vibrio cholerae* is sucrose-positive and, therefore, produces yellow colonies on TCBS agar. *Vibrio cholerae* is also positive for starch hydrolysis, oxidase, catalase, nitrate reductase, tryptophanase, lecithinase, gelatinase, and lysine and ornithine decarboxylase [a complete list of biochemical reactions can be found in the *Manual of Clinical Microbiology* (24)]. Conditions for the growth of *V. cholerae* include temperatures between 15 and 42 °C, salinity up to 50‰ (NaCl concentration of 5%), and pH between 5 and 10. Although, Na^+ stimulates growth, *V. cholerae* is among the few species in this genus that can tolerate low NaCl if grown in a complex medium where sufficient Na^+ is available (23,25). *Vibrio cholerae* is also negative for arginine decarboxylase and esculin hydrolysis, and when combined with results from TCBS agar, this series of three biochemical tests plus growth at 0% NaCl in a complex medium is a fairly reliable and quick method to identify presumptive *V. cholerae* isolates (26). Inhibition of *V. cholerae* by the vibriostatic agent O/129 (2,4-diamino-6,7-diisopropylpteridine) was once considered to be a key test for identification; however, owing to increasing resistance among clinical and environmental strains, this test no longer serves the purpose (27,28).

Approximately 200 serogroups of *V. cholerae* are known to date, determined by surface antigen variations in the lipopolysaccharide (29). However, so far only two serotypes are acknowledged for their potential to cause epidemics of the disease. Serotype O1 was implicated in all large epidemics of cholera until 1992 when O139 epidemics emerged, first in India and then Bangladesh. Characterization of serotypes is traditionally accomplished by serum agglutination tests for O1 and O139; however, specific monoclonal antibodies are now available and O1 and O139 cells can be detected directly by immunofluorescent microscopy (30,31). Within the O1 serotype, isolates can be further classified into two biotypes. The classical biotype was associated with all pandemics except for the latest (seventh), pandemic, which started in 1961 and was replaced with the El Tor biotype. Differentiation of biotype is based on the presence of hemolysin in El Tor strains and susceptibility to Mukerjee's cholera type IV bacteriophage (32). In the early literature, the El Tor biotype was assigned to a species separate from *V. cholerae* O1 Classical, designated *Vibrio eltor* (6). Furthermore, any *Vibrio* spp. that did not agglutinate with O1 antiserum was designated as nonagglutinating (NAG), which is a misnomer because these strains would, in fact, agglutinate with the appropriate non-O1 antiserum (33). Additionally, clinical and environmental isolates from both endemic and nonendemic cholera regions show little variability (34–37).

Ecological Perspectives

Vibrio cholerae is a bacterium that occurs naturally in the aquatic environment. Studies over the last 20 years have clearly defined *V. cholerae* to be a part of the autochthonous bacterioplankton, found almost everywhere in the aquatic environment, if attempts are made using appropriate tools. We were able to demonstrate the seasonal fluctuations in abundance of *V. cholerae* in Chesapeake Bay throughout the year, with large numbers of the cholera bacterium present during the summer months (38–40). In addition, because cholera is now considered a re-emerging disease, the level of awareness is at an all time high among microbial ecologists, oceanographers, biologists, and the medical community at large, especially after the 1991 outbreak in Latin America, which spread to 21 countries in 24 months (41).

Several major multinational and multiinstitutional studies have been undertaken in the past five to seven years investigating the mechanisms of survival, multiplication, and persistence of *V. cholerae* in the environment, as well as its characterization and detection, using immunodiagnostic and molecular tools for monitoring the

environment. Clearly, a new era in the environmental microbiology of *V. cholerae* began during the past decade, which we believe opens avenues for multidirectional and multidisciplinary investigation.

Survival and Growth

Drinking water was first implicated in the spread of cholera almost 150 years ago by John Snow in London, England, and, subsequently confirmed by Robert Koch's isolation and description of *V. cholerae* in 1884, following the work of Pacini in 1854. Despite numerous investigations during the 1960s demonstrating the survival of *V. cholerae* in different kinds of natural water over an extended period of time (42–44), the perception remained unchanged until the late 1970s that the source of the causative agent of cholera was the patient ingesting contaminated water and/or food. Unfortunately, in studies before the early 1970s all of the diagnostic methods available for isolation and characterization of *V. cholerae* were primarily developed for clinical use (45). Most diagnostic tests have a threshold for sensitivity, which becomes critical when clinical and environmental samples are compared, solely because of concentration differences. Without other choices, researchers relied on conventional culture methods as the best-available technology. Assays for detection of viable but nonculturable cells were not available. As a result, accurate monitoring for the presence and survival of these pathogens was impaired until appropriate and sensitive methods were developed in the 1980s and 1990s (46). In addition, cells of *V. cholerae* present in natural water adapt to a variety of environmental conditions, such as low pH, variable salinity, temperature, and solar radiation, and conditions that are not optimal for growth and multiplication (47). Therefore, *V. cholerae* O1 from environmental conditions may not necessarily grow on conventional laboratory media.

Viable but Nonculturable (VBNC) State

The viable but nonculturable phenomenon has been described as a survival strategy of microorganisms, notably human pathogens in the aquatic environment (48). In the 1930s, it was noted that there were significant differences between the numbers of autotrophic and organotrophic bacterial counts of water samples (49). A few years later, another group of investigators concluded that a significant portion of a given bacterial population that did not appear on culture plates must be present in a resting stage (50). Around the same time, further investigation led to the demonstration of metabolically active bacteria, which could be detected by microscopy, but did not form colonies on microbiological media (51,52). Half a century ago, Zobel reconfirmed earlier findings that only a small percentage of bacterial cells present in a given sample of seawater will grow on agar plates (53). The evidence for viability has been crucial. Coliform bacteria not growing in culture media in the laboratory (once considered dead) were subjected to measurement of their ATP level, the results of which suggested that these *Escherichia coli* cells were alive (54). Some of the pioneering work in this area was conducted at the University at Maryland in the 1980s. The investigators examined the viable but nonculturable phenomenon in *E. coli* and *V. cholerae*. Using nalidixic acid to prevent cell division, and yeast extract to promote growth, the researchers demonstrated that cultures, which did not produce colonies on bacteriological media, were indeed metabolically active, as observed by the presence of elongating cells under microscopic examination (55,56). In these studies, for the first time, investigators were able to demonstrate induction of culturable *V. cholerae* O1 cells to a nonculturable state in laboratory microcosm experiments. These metabolically active cells do not form colonies on bacteriological culture plates, making it impossible to isolate them.

Bangladesh has been one of the major endemic areas for cholera. Without exception, there are epidemics almost every year (57). Nevertheless, it has been difficult (and in some cases impossible) to isolate *V. cholerae* from surface water in Bangladesh between cholera seasons, even with intensive monitoring and epidemiological surveillance, or from water not directly contaminated by the patient's stool (58). Yet the discovery of the viable but nonculturable phenomenon in *V. cholerae* facilitated much higher rates of direct detection in bodies of water serving as drinking water sources in Bangladeshi villages. Huq and coworkers (59) showed that these VBNC *V. cholerae* could be detected by direct immunofluorescent microscopy throughout the year in these water sources, even when the organisms could not be cultured using conventional media.

It is evident that the main obstacle in the study of *V. cholerae* in the environment is the detection of target cells when the concentration of bacteria is very low, as is often the case in environmental waters during winter months. Although water has been suspected to be the source of the cholera bacterium, as far back in time as 150 years ago, there is, even at present, no effective technique available to isolate the VBNC cells from water supplies directly. However, methods are available that allow direct detection of the pathogen in the VBNC state from environmental sources, using both immunological and molecular methods (59).

Methods for Detection

Among the problems associated with studying microbial communities in the environment, is the lack of cost-effective, reliable methods for detection. In addition to viable but nonculturable *V. cholerae* and related gram-negative bacterial pathogens, most bacteria present in seawater have never been cultured. Therefore, advances in field research rely on effective means to detect nonculturable organisms.

Traditionally, detection and identification of bacteria in environmental samples was based on conventional culture methodology. Water samples were plated onto selective or nonselective media and a battery of biochemical tests was run. While this approach has not been given up entirely, because it still can provide valuable information about those isolates that are culturable, increasingly researchers

are using molecular tools for detection and to determine viability and potential community function.

Tools for direct detection, generally speaking, can be divided into two categories, immunobased or nucleic acid–based. Immunodetection is where labeled antibodies specific to the target are added to a sample and have been used extensively for microscopic assays. Using this approach, and targeting the toxigenic serotypes O1 and O139, *V. cholerae* has been detected in a variety of source materials by both direct and indirect immunofluorescent assays (30,31). Because this approach allows detection of both culturable and viable but nonculturable cells, it has substantially improved assessment of the occurrence of *V. cholerae* in the environment. Using this approach, Ruiz and coworkers found significant numbers of *V. cholerae* in the ballast water of ships arriving in Chesapeake Bay (60).

With the advent of the polymerase chain reaction in the 1980s (61), nucleic acid–based detection gained in popularity and is now used extensively in studies of *V. cholerae* in the environment. PCR-based methods offer specificity at several levels, can target any nucleic acid sequence, and are relatively quick and easy to perform. Primers are now available for the specific detection of *V. cholerae* in environmental samples and do not cross-react with the closely related *V. mimicus* (62,63). One disadvantage of the nucleic acid–based approach is that they do not differentiate between viable and nonviable cells. Therefore, research is now beginning to focus on combining microscopic detection with nucleic acid hybridization. With fluorescent in situ hybridization (FISH) assays, fluorescent-labeled probes are added to whole fixed samples. The probe then hybridizes to the complementary sequence within the target cell and is detected by a fluorescent signal viewed under epifluorescent microscopy (64). This approach can be combined with 4′6-diamidino-2-phenylindole (DAPI) staining to determine cell viability (65).

Role of Plankton in the Ecology, *V. cholerae* and Incidence of Cholera

Most of the major outbreaks of cholera epidemics during the past 25 years originated in coastal areas (66), including the outbreak caused by the newly recognized O139 serotype of *V. cholerae* (67). As cited earlier, until recently, the prevailing view of the ecology of cholera was that *V. cholerae* was associated only with humans. In the early 1980s, Colwell and coworkers (68) showed that *V. cholerae* is an indigenous, autochthonous member of brackish and estuarine environments. Several subsequent studies provided evidence to support this hypothesis (69–71). The autochthonous nature of this organism has since proven to be an important factor in understanding the epidemiology of cholera, promoting insight leading to new knowledge and further investigation into the prevention of cholera (72).

The association of *V. cholerae* with plankton and changing environmental conditions in water, particularly changes in pH, was first addressed in the 1960s. Cockburn and Cassanos (73) demonstrated a positive correlation between the incidence of cholera and the presence of chlorophyll-bearing organisms in water. Interestingly, *V. cholerae* produces an enzyme, mucinase, which actively degrades mucin and mucinlike substances present in plant cells and in the gut of humans (74). Earlier, it was demonstrated that, with the disintegration of a large number of algae after a peak bloom, the gram-negative heterotrophic bacterial population, including *V. cholerae*, begins to rise (75). Different organic compounds and other nutrients released by the disintegrating plankton in the water served as a major source of energy for those heterotrophic bacteria. The authors further noted that the gelatinous cover of filamentous blue-green algae filaments contained high concentrations of gram-negative rod-shaped bacteria. The mucilaginous sheath of the cyanobacteria, *Anabaena variabilis*, was found to serve as a site of attachment for *V. cholerae* cells (76,77). Using direct detection methods, Islam and coworkers (78,79) demonstrated that *V. cholerae* persisted for approximately 15 months in the mucilaginous sheath of *A. variabilis*. These are convincing results to assume that the bacteria may become associated with algae as a method for prolonged survival in the environment and added evidence for the long-term survival of *V. cholerae* under varying environmental conditions. There is, however, no evidence that *V. cholerae* actually multiplies or proliferates in association with blue-green bacteria.

In addition to mucin, most vibrios, including *V. cholerae* produce a chitinase enzyme that degrades chitin and, thereby, supply nutrients needed for survival (80). The digestion of chitin appears to provide the chitinase active cells with protection from harsh acidic environments (4,81). The association of *Vibrio parahaemolyticus* with microscopic crustaceans, a major component of zooplankton, was reported by Colwell and colleagues in 1975 (81) and is considered a significant finding because of the chitin composition of the carapace of copepods. In subsequent studies, Huq and coworkers demonstrated the ecological relationship of copepods and the survival and multiplication of *V. cholerae* in the aquatic environment (81a, 81b). According to a recent study, surface proteins of *V. cholerae* play an important role in attachment by vibrios to chitin particles (82). In addition to providing a nutrient source, attachment of *V. cholerae* to chitin particles protects these organisms from the lethal actions of gastric acid (83). Such protection is perhaps an important factor for *V. cholerae* in the natural environment. *Vibrio cholerae* cells attached to live copepods are also more resistant to chlorine and, therefore, can resist water treatment (84). Chitin is also able to protect *V. cholerae* O1 against the effects of low temperature, suggesting a contribution to extended survival of cholera vibrios in the environment, especially at freezing temperatures (85).

Billions of gallons of water are transported from one part of the world to another via ballast (a device introduced in the early 1900s in ocean-going ships for balancing) and has been implicated in the rapid transmission and distribution of marine vertebrates and invertebrates globally (86). Researchers have observed several species of copepods of Asian origin in the Pacific Coast of North America within a 15-year period. Copepods are usually found in large numbers in water (86) as they are the most abundant group of zooplankton (87,88). According

to the Continuous Plankton Recorder survey in the northeast Atlantic established by Sir Alister Hardy in the 1930s and carried out each month from 1948 to the present, phytoplankton and zooplankton populations demonstrated a decline between 1948 and 1980 (89). However, since 1980 the trend has reversed (89). Gelpspan (1991) reported that algal blooms surpassing the usual spring bloom were observed at various points worldwide, such as North Carolina, California, Finland, Iceland, Tasmania, Japan, and Thailand. As phytoplankton are the "primary producers" of organic compounds (90), the size of zooplankton populations, which feed on phytoplankton, has also increased significantly. This observation coincides with the preceding period's two major modern cholera events, the reappearance of cholera in South America in 1991 and the emergence of serotype O139 in India in 1992.

Cholera is dose-dependent. Once the number of *V. cholerae* O1 cells is large enough to constitute an infectious dose (10^4 to 10^6 cell ml^{-1}), depending on the physiological state of the victim (91), the cells are ingested by humans while bathing, swimming, or drinking untreated water from ponds, rivers, and lakes of cholera-endemic countries, an epidemic can be initiated (92). The high numbers of *V. cholerae* cells attached to copepods offers a concentrated source of infection, should these organisms be present in drinking water. Furthermore, the reversion of viable but nonculturable cells to a culturable state and the association with copepods and environmental factors may have important epidemiological implications (93). These will be critical factors in predicting outbreaks.

GENETIC TRANSFER IN THE ENVIRONMENT AND EMERGENCE OF TOXIGENIC STRAINS

In general, bacteria are known for their considerable diversity, both in phenotype and genotype. Unlike other taxonomic domains, there is also a high degree of genetic variance even within a particular taxonomic group. While point mutations are a common source of variability among all forms of life, these alone cannot explain the diversity seen among the bacteria. Evidence suggests that lateral or horizontal gene transfer, whereby, pieces of genetic material are transferred from a donor to a recipient cell, is an important component of both bacterial evolution and diversification (94,95). Once a genetic element has been transferred to a new recipient species, the trait can then be passed onto progeny, along with point mutations, by vertical transfer. This type of genetic acquisition is believed to be an important mechanism by which toxigenic strains of *V. cholerae* arise from nontoxigenic progenitors, as may have been the case for the emergence of toxigenic *V. cholerae* O139.

DNA acquisition by integrons or temperate phages is a significant contributor to the genetic variability and transfer of virulence genes in *V. cholerae* (20,96,97). Evidence of significant gene reassortment in this species was also demonstrated in the recent analysis of the fully sequenced genome (95). The smaller of the two chromosomes present in *V. cholerae* contains a high percentage of genes of hypothetical function and many of these do not appear to be γ-proteobacterial in origin, which is also supported by the presence of a large integron island for gene capture (95).

In 1996, Waldor and Mekalanos first demonstrated that the *V. cholerae* CTX element was coded for by a filamentous, single-stranded DNA, temperate phage, CTXΦ, and was responsible for the production of the cholera toxin (CT) in toxigenic strains (20). This phage could be induced to form infectious particles and shared many properties of the M13 coliphage (20,96). In *V. cholerae* the main virulence genes tend to exist in clusters, or cassettes, as in the CTX element, responsible for production of the secretory enterotoxin CT (cholera toxin) and the *V. cholerae* pathogenicity island (VPI), which carries the genes for the toxin coregulated pilus (TCP) (96). The CTXΦ may be present in a host cell as a replicative form (RF, plasmid) or as a prophage integrated into the chromosome at specific attachment sites (att_{RS}). More recently, Karaolis and coworkers (97) provided evidence that the *V. cholerae* pathogenicity island, including TCP, may be encoded by a second temperate filamentous phage, VPIΦ The TCP gene in the prophage has dual role as the viral capsid protein and the receptor pilin for CTXΦ infection.

Because of the widespread clinical importance of these mobile genetic elements, research is increasingly focused on determining environmental conditions that stimulate genetic exchange via induction and subsequent infection. It has been demonstrated that CTX prophage could be induced from *V. cholerae* on exposure to sunlight (98). Interestingly, there is little evidence for prophage induction in the intestine (99), highlighting the importance of environmental factors in the propagation of viral particles. Environmental conditions may also be important in the subsequent infection and integration of *V. cholerae* phages (100).

Vibrio cholerae also show genetic rearrangements and phenotypic differentiation in other properties (101,102). Researchers have observed phage mediated biotype conversion between Inaba and Ogawa (103), and later seroconversion of non-O1 to O1 was demonstrated in laboratory microcosms (104). This evidence is especially interesting in cholera-endemic areas where O1 and O139 serotypes are far less prevalent than non-O1 in the environment. The rate of seroconversion is enhanced in seawater and by key environmental parameters, particularly warm temperatures (104).

Vibrio cholerae offers an interesting clinically and environmentally relevant model for the study of gene rearrangement and transfer. Increasingly, evidence is mounting that gene transfer among *V. cholerae* is occurring at a high rate in the environment (37,99,105–107). Research in this area is only now beginning to elucidate the patterns and mechanisms by which nontoxigenic environmental *V. cholerae* strains may give rise to new epidemic varieties.

ENVIRONMENTAL AND CLIMATE MODELING–BASED APPROACHES TO PREDICTING OUTBREAKS

During the past few years there have been studies on global climate change and its impact on ecosystems (108).

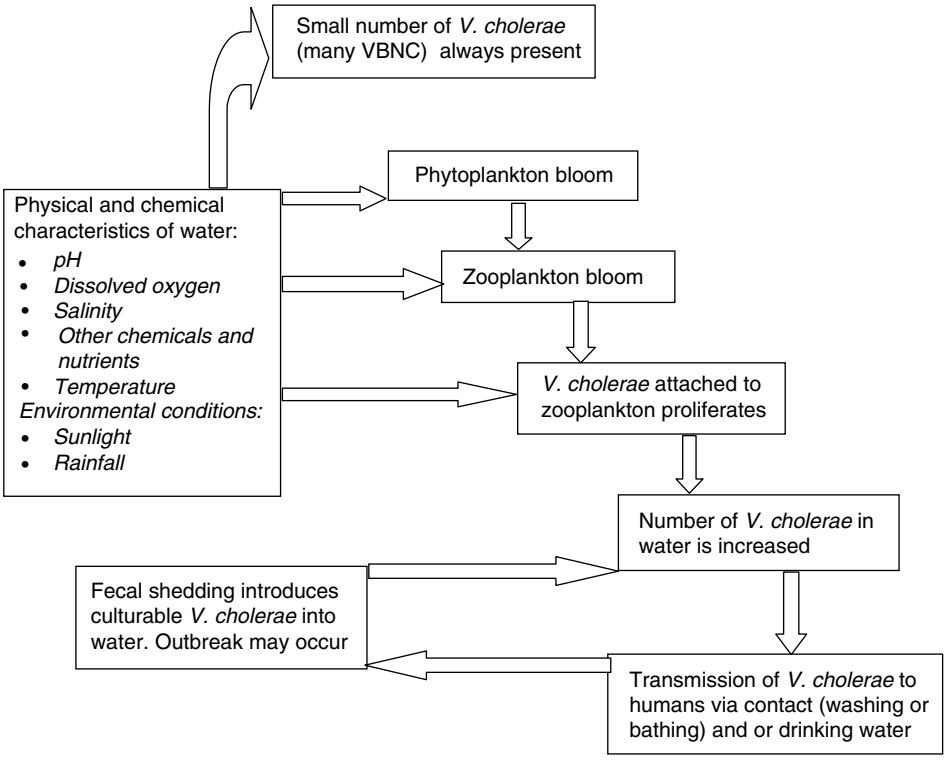

Figure 1. A model for possible survival and transmission of *V. cholerae* in the natural environment. (Modified from the original model published earlier. Permission obtained from the original: A. Huq et al., M. Yasuno and B. A. Whitton, ed., *Biological Monitoring of Environmental Pollution*, Tokai University Press, Tokyo, Japan, 1988, p. 262).

Changes in climate may directly and indirectly affect the ecology of all living creatures. Fluctuations in weather conditions have minor to major effects on the environment that may bring ecological changes to various regions, such as soil erosion, deforestation, drought, and human migrations from rural to urban areas. The direct influence of sunlight and dissolved chemical nutrients on aquatic plants and phytoplankton, resulting in increased pH and concentration of dissolved oxygen (109), provide a favorable environment for *V. cholerae*. A hypothetical model was proposed by Huq and coworkers (110) and subsequently modified by Colwell and Huq (46), suggesting a role for the various physicochemical and biological factors of the aquatic environment in the transmission of *V. cholerae*. This model is further modified by proposing the possible direct and/or indirect role of phytoplankton blooms and subsequent zooplankton blooms influenced by the physicochemical parameters that play a role in the survival, multiplication, and transmission of *V. cholerae* in the natural environment (Fig. 1). Islam and coworkers described the relationship of different environmental parameters on the formation of phytoplankton blooms and the multiplication of *V. cholerae* (79). Conditions triggering an increase in the number of *V. cholerae* in water may include increased numbers of zooplankton following blooms of phytoplankton. When untreated natural water is the only source for domestic use, copepods in the water are likely to be ingested by humans and the associated *V. cholerae*, thereby, may cause disease.

Because of the seasonality of cholera, climate is strongly considered an influencing factor in the ecology of the organisms and the epidemiology of cholera. The El Niño-Southern Oscillation (ENSO) is a major component of climate variability that appears to drive the interannual variation of the disease where temperature plays a significant role (111). Interestingly, the reappearance of cholera in South America coincides with the 1991–1992 El Niño event. Furthermore, warmer temperatures and the 1997–1998 El Niño have been implicated with increased numbers of diarrhea cases in Perú (112). Recent studies have suggested that the temporal variability of cholera in Bangladesh has an interannual component also strongly correlated with El Niño events (111). Preliminary investigations showed that cholera cases in Bangladesh closely follow sea surface temperatures (SST), which were obtained by satellite for the Bay of Bengal (113,114). Furthermore, sea surface height (SSH) can be measured remotely with the Advanced Very High Resolution Radiometer (AVHRR) satellite and such data provides insight as to the incursion of water with plankton, to more inland areas. It was interesting to note the correlation of SST and SSH to cases of cholera in Bangladesh (Fig. 2) (114). However, in 1993, the association was not observed. Although the SST were within the normal range for that year, SSH in the spring was the lowest observed during the entire study period. Therefore, less intrusion of water took place and perhaps fewer interactions between people and water suggesting SSH may also have significant implications, in addition to SST, for predicting outbreaks and epidemic of cholera.

CURRENT STATUS AND FUTURE DIRECTIONS

It has become evident during the past two decades that there is a tremendous need for further information concerning the ecology of *V. cholerae*. Specifically, we still

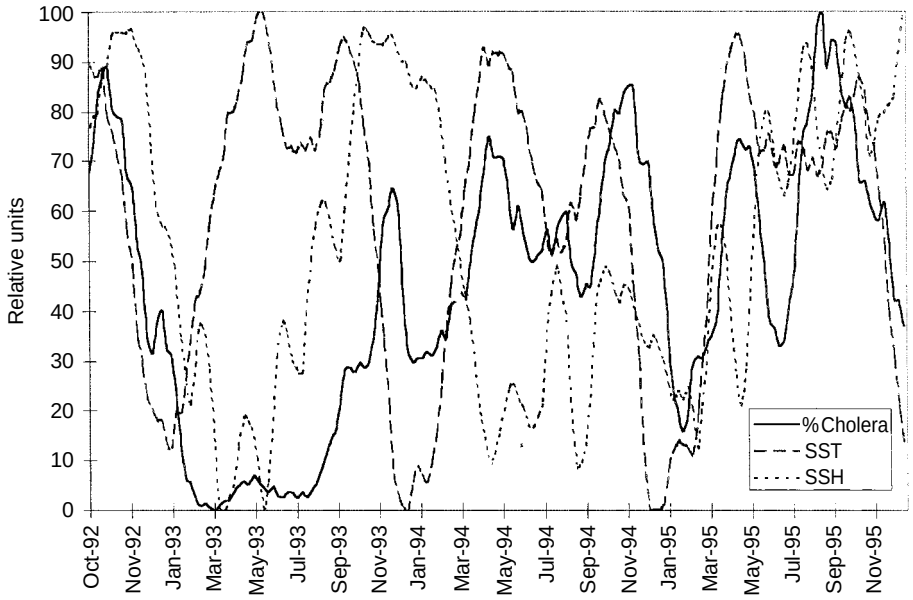

Figure 2. Cholera cases (solid line), SST (dashed line) and SST (dotted line) data from October 1992 to December 1995, cholera cases followed by the SST cycle; however in spring 1993, SST was the lowest for this period (B. Lobitz et al., *Proc. Nat. Acad. Sc.*, vol. 97, pp. 1,438–1,443, reproduced with permission).

do not understand why epidemics of cholera tend to occur only in certain parts of the world, and the causative organism can be found almost anywhere. Obviously, the level and quality of public health awareness and safety are significant factors. Accessibility to safe drinking water and reliable and effective methods for sewage treatment are critical.

Due, in part, to the lack of a successful cholera vaccine, efforts to control the disease is now relying on understanding the ecology of the causative agent and its genetic variability. Based on environmental and ecological studies on cholera, carried out during the past 25 years, one of the most interesting adaptations in the fight against cholera is the simple filtration of water using sari cloth, a domestic material available in every Bangladeshi village household, where cholera is a problem. Using four layers of sari material to filter surface water, less than or equal to 99% of the *V. cholerae* attached to copepods or other particles can be removed, significantly reducing the dose (115). A recent field trial demonstrated a reduction in cases, in the village population, using drinking water prefiltered with a sari, as compared to the population using water without such filtration (116).

The entire genome of *V. cholerae* has now been sequenced (95). This will push the field forward in understanding the ecology and pathogenicity of this important and historical pathogen. Because of the nature of this organism as an autochthonous member of the aquatic microbial community and an opportunistic human pathogen we may not be able to eradicate the disease, but certainly continued research should help reduce the numbers of cases and/or the amount of suffering.

GENERAL CONCEPTS

Bacteria from the genus *Clostridium* are gram-positive, anaerobic, generally motile, spore-forming rods. These generally obligate anaerobes are ubiquitous saprophytes common in nature and are also part of our normal flora. Many clostridia are transient or permanent members of the normal flora of the human skin and the gastrointestinal tracts of humans and animals. Unlike typical members of the human bacterial flora, most

clostridia can also be found worldwide in the soil. They induce diseases that can be acquired through contaminated foods or wounds.

The clostridia are classically anaerobic rods, but some species can become aerotolerant on subculture; a few species can grow under aerobic conditions. Most species are gram-positive, but a few species stain very weakly or are gram-negative. Also, many gram-positive species easily lose the gram reaction in culture, resulting in gram-negative cultures. Clostridia employ butyric fermentation pathways to generate energy and, as a result, often produce a foul odor.

The clostridia can vary considerably in their biochemical and physiological properties (1). Clostridia are able to ferment a wide variety of organic compounds. They produce end products such as butyric acid, acetic acid, butanol, and acetone, and large amounts of gas (CO_2 and H_2) during fermentation of sugars. A variety of foul-smelling compounds are formed during the fermentation of amino acids and fatty acids. The clostridia also produce a wide variety of extracellular enzymes to degrade large biological molecules in the environment into fermentable components. Hence, the clostridia play an important role in nature in biodegradation and the carbon cycle. In anaerobic clostridial infections, these enzymes play a role in invasion and pathology.

The clostridia produce a spherical or oval spore that results in a characteristic bulge generally located at the terminal or subterminal end, giving the bacterium the appearance of a long drumstick. The body of the bacterium is stained, whereas the spore remains unstained during a gram stain providing a visual clue to the identification that is particularly helpful when differentiating weak gram-positive or gram-negative species from true gram-negative bacteria such as Bacteroides. The spores are produced when the environment becomes unfavorable and are extremely resistant and can survive in the environment for very long periods. Poorly canned foods create an anaerobic environment under which any surviving spores can germinate and produce toxin.

Of the anaerobes that infect humans, the clostridia are the most widely studied. They are involved in a variety of human diseases, the most important of which are gas gangrene, tetanus, botulism, pseudomembranous colitis, and food poisoning. In most cases, clostridia are opportunistic pathogens; that is, one or more species establishes a point of infection in a particular site in a compromised host. All pathogenic clostridial species produce protein exotoxins (such as *botulinum* and tetanus toxins) that play an important role in pathogenesis.

Clostridium perfringens produces large oval subterminal spores (rarely seen in standard culture) and is nonmotile. This species is most often associated with feces and wound infections. *Clostridium tetani* is motile and produces terminal spores with the appearance of a squash racket. *Clostridium botulinum* produces oval subterminal spores and is motile.

Clostridium difficile produces large oval subterminal spores. Ordinarily, this species cannot compete with normal intestinal flora, but when antibiotics eliminate the normal flora *C. difficile* can flourish, producing disease.

CLOSTRIDIA IN DISEASE

Clostridia are ubiquitous pathogens that produce many toxins and hydrolytic enzymes. Because the toxin-encoding genes can be located on extrachromosomal elements or in variable regions of the chromosome, several pathovars have arisen, each of which is involved in a specific disease. The various diseases caused by clostridia are diarrhea, botulism, tetanus, blackleg, malignant edema, infectious necrotic hepatitis, enterotoxemia, and gas gangrene. They affect all types of animals (2–6).

Food-borne infections are frequent because of poor hygienic practices or incorrect food-handling practices (7–10) and have resulted in numerous outbreaks (11). These infections are the source of significant economic costs worldwide (12,13). Todd (14) reported that acute food-borne disease infections and intoxications are much more of a concern to governments and the food industry today than a few decades ago. Meaningful monitoring of increases or decreases in food-borne disease requires an effective surveillance system at the local, national, and international levels. The apparent decrease of *Staphylococcus aureus* and *C. perfringens* outbreaks in industrialized countries may be related to improved temperature control in the kitchen.

Clostridium perfringens continues to be a common cause of food-borne disease (6,9). Characteristics of this organism that contribute to its ability to cause food-borne illness include the formation of heat-resistant spores that survive normal cooking and heating temperatures, a rapid growth rate in warm food, and the production of enterotoxin in the human gut. Time and temperature abuse associated with food preparation contributes to the majority of outbreaks of *C. perfringens* food-borne disease. CPE-induced diarrhea has been reported in the absence of a defined food vehicle. These cases have been typically associated with the elderly and those following a course of antibiotic therapy. The incidence of CPE-induced diarrhea may be expected to increase with the growing population of immunocompromised (disease-, treatment-, or age-induced) individuals.

The impact of *C. difficile* has been discussed by Settle (15) and by Groschel (16). Infection with this bacterium can give rise to a wide range of symptoms, from diarrhea to fulminating colitis and toxic megacolon. Changes in the composition of natural intestinal flora, mainly due to antibiotic therapy, permit its colonization and multiplication in the colon. The disease is caused by enterotoxin A and cytotoxin B, and infection ranges from asymptomatic carrier state and mild diarrhea to pseudomembranous colitis. The clinical diagnosis is made by observing inflammatory, sometimes bloody, diarrhea and by the colonoscopic detection of epithelial necrosis, ulceration, and, in the advanced state, pseudomembrane formation.

Clostridium tetani is the causative agent of tetanus (lockjaw). The organism is found in soil, especially heavily-manured soils, and in the intestinal tracts and feces of various animals. Carrier rates in humans vary from 0 to 25%, and the organism is thought to be a transient member of the flora whose presence depends on ingestion.

The organism produces terminal spores within a swollen sporangium, giving it a distinctive drumstick appearance. Although the bacterium has a typical gram-positive cell wall, it may stain gram-negative or gram-variable, especially in older cells. Tetanus is a serious disease of humans. Mortality rates that were reported vary from 40 to 78%. The disease stems not from invasive infection but from a potent neurotoxin (tetanus toxin or tetanospasmin) that is produced when spores germinate and vegetative cells grow after gaining access to wounds. The organism multiplies locally and symptoms appear remote from the infection site. Because of the widespread use of the tetanus toxoid for prophylactic immunization, fewer than 150 cases occur annually in the United States, but the disease is a significant problem worldwide where there are more than 300,000 cases annually. Most cases in the United States occur in individuals more than 60 years of age, which is taken to mean that waning immunity is a significant risk factor. Spores are highly resistant to adverse conditions and spores of some strains resist boiling in water for up to three hours. They may resist dry heat at 160 degrees for one hour and 5% phenol for two weeks or more. In water, iodine (1%) can kill the spores within a few hours.

Clostridium botulinum is a widely distributed saprophyte occurring in soil, vegetables, fruits, leaves, silage, manure, the mud of lakes, and sea mud. Its ability to produce a potent neurotoxin in food and resistance of its spores to inactivation combine to make it a formidable pathogen of humans and a range of animals and birds. Insufficient heating in the process of preserving foods is an important factor in the causation of botulism, and great care must be taken in canning factories to ensure that adequate heating is achieved in all parts of the can contents (Reed 1994a). Botulinum toxins are among the most poisonous natural substances known that are classified into seven types (A to G), with types A, B, and E most frequently associated with human disease. Botulism is a severe, often fatal, form of food poisoning characterized by pronounced neurotoxic effects. The disease can be caused by a wide range of foods, usually preserved hams, large sausages, home-preserved meats and vegetables, canned products such as fish, liver paste, and even hazelnut puree and honey. Foods responsible for botulism may not exhibit signs of spoilage. In recent years, it has been recognized that the organism is capable of causing a distinct syndrome of illness in infants. Infantile botulism arises when spores present in food (usually honey or corn syrup) germinate in the intestinal tract and produce toxin (17,18). Typically, cases occur in the second month of life and always in infants aged one or less. The case fatality rate is about 2% compared with 15% in adult food-borne botulism.

CULTURE

Methods for the detection and enumeration of clostridia can be found in official or standardized methods (19–22). Not surprisingly, attempts to develop a single isolation medium for all species that occur in foods have not been entirely successful, and the problem is compounded by the need to recover both vegetative cells and spores, some of the latter being unable to germinate without heat activation. Most available isolation media, except some of those used in the dairy industry, include sulfite and an appropriate iron salt, so that blackening caused by sulfite reduction can serve as a differential test for clostridia. An unresolved issue is whether special precautions are needed to exclude oxygen during sample preparation and dilution, preparation of media, and in conditions used for anaerobic incubation. Although such stringency may be required for maximum recovery of sublethally damaged cells or spores, practical constraints in laboratories necessitate use of relatively simple procedures for detecting clostridia routinely. Most species will grow sufficiently well with standard anaerobic atmosphere generating systems, but for some (e.g., *C. tetani*) it is essential to ensure complete removal of oxygen for good growth.

The detection of clostridia, primarily *C. perfringens*, in water is based on the most probable number (MPN) or membrane filtration (MF) methods. Media frequently used are tryptose-sulphite-cycloserine agar (TSC) with or without egg yolk (23,24), Shahidi-Ferguson *perfringens* agar (SFPA) or oleandomycin-polymixin-sulphadiazine *perfringens* agar (OPSPA) (19), m-CP medium (25), iron milk medium (22), lactose-sulfite (LS) broth (26). The respective value of each medium is related to its particular use, and differences in efficiency have been reported (24,27).

OCCURRENCE

Habitat

The main habitat of clostridia is the soil but many species are also found in dust, sewage, rivers, lakes, seawater, milk, vegetables, fresh meat, fish, insects, and the intestinal tract. Sulfite-reducing clostridia (SRC), and in particular *C. perfringens*, are present in the feces of man and other animals (pig, chicken, dog, cow, horse, sheep, calf), although not all species are exclusively fecal in origin (4,28–32).

Occurrence of clostridia is fairly common in human feces and may be affected by diet. Geldreich (28) reported the presence of *C. perfringens* in 13 to 35% of humans and *C. tetani* in 1 to 25% of people. Numbers of SRC in human feces are typically in the region of 10^3 per gram but can rise as high as 10^{10} per gram. Vela and coworkers (32) reported carriage rates of *C. perfringens* in feces of a northern Mexican population where the organism was found in 126 of the 200 fecal samples obtained from healthy individuals. The samples had an average of 7.4×10^3 spores per gram, with the elderly population showing the highest levels.

Clostridia are found in various concentration in wastewater (typically 10^4 to 10^5 per 100 ml in raw sewage and up to 10^3 to 10^4 per 100 ml in sewage effluents) and wastewater-contaminated waters (typically 10^2 to 10^3 per 100 ml) around the world (25,33–37). The similarity of counts obtained suggests that the majority of SRC in sewage are *Clostridium perfringens*. Further evidence for this comes from a study comparing the performance of MCP agar and TSC agar for the detection of *Clostridium perfringens* and sulfite-reducing clostridia in sewage and other wastewater (38).

Food and Animal Wastes

Clostridia are frequently found in a wide range of foods (7,14–45). Anderson and coworkers (46) reviewed the problems of the food industry with spore-forming bacteria including *Clostridium*. Spore-forming bacteria are a special problem for the food industry as it is not always possible to apply sufficient heat during food processing to kill spores. *Clostridium perfringens* mainly causes food poisoning through food served in restaurants, hospitals, or homes for elderly people. The practices that lead to food poisoning are always the same: meat-containing dishes stored after cooking with insufficient cooling and reheating. Even though it should be relatively easy to control, *C. perfringens* remains one of the most common causes of food-borne diseases. Proper disinfection is necessary to control this type of food poisoning, as it is now clear that only kitchen strains of *C. perfringens* are able to produce the large amounts of enterotoxin necessary to cause food poisoning.

Fransen and coworkers (47) reported that clostridia were present in raw sludge from pig and poultry slaughterhouses at a level of 3.1 to 5.8 (in log10 N/g) (raw sludge was collected at pig ($n = 8$) and poultry ($n = 5$) slaughterhouses).

Surface Waters

In many surface waters, particularly streams and rivers, it has been shown that the principal source of SRC is municipal wastewater (30,34,35,48,49). Low counts of *C. perfringens* are generally observed in lakes and streams, draining land used for housing and grazing livestock despite relatively high levels of other indicator bacteria. Streams receiving treated wastewater contain high numbers of SRC immediately downstream of the discharge. Watercourses not receiving inputs of wastewater contain low levels of *C. perfringens* compared with fecal coliforms, whereas stream samples collected downstream of wastewater discharges contain higher levels of *C. perfringens* that decrease progressively further downstream.

A number of studies investigating the removal of indicator organisms and pathogens during the production of drinking water from river sources provide information on the levels of clostridia in surface water. Despite geographic and analytical differences (Canada, North America, and Europe), the range of counts are remarkably similar for *C. perfringens* or sulfite-reducing clostridia, ranging from less than 1 to 2,000 per 100 ml (33,35,50–52).

Bezirtzoglou and coworkers (26) determined the numbers of *C. perfringens* in river and lake waters of rural northwestern Greece. The numbers of *C. perfringens* fluctuated depending on the sampling site, ranging up to 10^2 per 200 ml in rivers with lower occurrence in lakes. It was significantly more common in the vicinity of industrial or domestic activities. Sartory (48) reported similar results for fecal clostridia (sulfite-reducing clostridia capable of growth at 44.5 °C) for an eutrophic impoundment and its feeder rivers in South Africa. While fecal clostridia levels in the river inflows ranged from 20 to 3,100 cfu per 100 ml, those in the impoundment ranged from less than 1 to 150 cfu per 100 ml. *Clostridium perfringens* made up 78% of the identified isolates.

Griffin and coworkers (53) assessed the microbial water quality in canal waters throughout the Florida Keys (United States) and determined the concentration of microbial fecal indicators and the presence of human pathogenic microorganisms. Numbers of *Clostridium* spp. ranged from less than 1 to 520 cfu per 100 ml, indicating that the canals and nearshore waters throughout the Florida Keys are being affected by human fecal material carrying human enteric viruses through current wastewater treatment strategies such as septic tanks. In the same area, effluent and waters from onshore shallow monitoring wells revealed the presence of fecal indicators in two of five nearshore wells, whereas offshore wells showed little sign of contamination.

The levels of fecal coliforms (FC), indole-positive FC (presumptive *Escherichia coli)*, fecal streptococci (FS), *Streptococcus faecalis*, and *C. perfringens* in the natural water sources used by 29 rural settlements in Sierra Leone were investigated by Wright and coworkers (54). Levels of the same indicators in human feces were also investigated. The incidence of *Salmonella* spp. in both habitats and the temperature, pH, and conductivity of water sources were also recorded. All water sources were contaminated with the indicator bacteria, with mean numbers of FC greater than those of *E. coli*, FS, *C. perfringens*, which were at a similar level, but were all in greater number than *S. faecalis*.

Clostridium difficile has been recovered from four river waters in South Wales, United Kingdom, in numbers ranging from 1 to 5 cfu per 100 ml (14 of 16 samples being positive) (55). Similar numbers, but with a lower positive sample rate (7 of 15 samples) were recorded from lakes. The majority of the isolates produced toxin A.

Marine Waters

Marine waters affected by sewage outfalls have been widely studied and clostridia provided insight on the impact of fecal pollution on beaches as well as local habitats. Davies and coworkers (56) reported their results for Australian waters. The survival of culturable fecal coliforms, fecal streptococci, and *C. perfringens* spores in freshwater and marine sediments from sites near sewage outfalls was studied. Studies using in situ membrane diffusion chambers showed that, with the exception of *C. perfringens*, die-off of the test organisms to 10% of their initial numbers occurred in both marine and freshwater sediments within 85 days. Also in Australia, a pilot study was conducted on the occurrence of sewage-derived viruses and bacteria in the beach and nearshore waters off Bondi, Sydney (57). Enteroviruses were isolated from 41% of a total of 66 sewage, seawater, grease, and sediment samples. Poliovirus vaccine strains accounted for 78% of the isolates. The number of fecal coliforms, fecal streptococci, *Aeromonas hydrophila*, and *C. perfringens* in the sewage ranged from 10^4 to 10^7 cfu per 100 mL. An initial reduction of 10^2 to 10^3 in bacterial counts was observed in the plume (the effluent's initial dilution zone) and a further reduction of 10^2 to 10^4 in counts in samples that were collected away from the plume.

In the United States, Hill and coworkers (58,59) enumerated *C. perfringens* in sediment samples collected at the Deep Water Municipal Sewage Sludge Disposal Site (also called the 106-Mile Site), off the coast of New Jersey (United States). The counts of *C. perfringens* found in sediment samples collected within and to the southwest of the 106-Mile Site were significantly elevated compared with counts of samples from reference stations of similar depth (2,400 to 2,700 m), topography, and distance from the continental shelf, indicating that the benthic environment was contaminated by sewage dumping at this site. In areas heavily impacted by sludge dumping, *C. perfringens* counts were generally highest in the top 1 cm of sediment and exceeded 9,000 cfu/g (dry weight) of sediment.

Edwards and coworkers (37) investigated the spatial distribution, movement, and impact of the untreated wastewater outfall from McMurdo Station, Antarctica, under early austral summer conditions. The benthic environment was examined to determine the distribution of *C. perfringens* in sediment cores and the intestinal contents of native invertebrates and fish along a transect of stations. These stations extended about 411 m south of the outfall. The findings revealed that the concentration of *C. perfringens* decreased with depth in the sediment and distance from the outfall. High percentages of tunicates and sea urchins were colonized with this bacterium along the transect. Coprostanol (a fecal sterol bioindicator of pollution) concentrations were also measured in sediment samples taken from each of the transect stations, and a similar trend was observed. These results are in agreement with the findings of previous studies performed with the water column and collectively provide evidence that the disposal of domestic wastes deserves special consideration in polar marine environments.

In their study of *C. difficile* occurrence, Al Saif and Brazier (55) recovered the organism from 7 of 15 seawater samples from the Bristol Channel in the United Kingdom, with counts ranging from 3 to 6 cfu per 100 ml.

Aquaculture

Pullela and coworkers (60) reported the nature and number of indicator and pathogenic microbes in fish reared using recirculating and nonrecirculating water systems. *Clostridium botulinum* was isolated from all the aquacultured fish sampled except pacu and tilapia grown in a recirculating aquaculture system, however, the counts were very low, ranging from 0.0 to 2.3 MPN/g

Hielm and coworkers (61) reported the distribution of *C. botulinum* serotypes A, B, E, and F in Finnish trout farms. *Clostridium botulinum* type E was found in 68% of the farm sediment samples, in 15% of the fish intestinal samples, and in 5% of the fish skin samples. No other serotypes were found. The spore counts determined by the most probable number method were considerably higher for the sediments than for the fish intestines and skin; the average values were 2,020, 166, and 310, *C. botulinum* type E spores per kg, respectively. The contamination rates in traditional freshwater ponds and marine net cages were high, but in concrete ponds equipped with sediment suction devices, the contamination rates were significantly lower.

Groundwater

In many parts of the world, groundwater is an important source of drinking water (wells, boreholes, etc.), and because of this the microbiological quality of water abstracted from underground sources is often monitored. Information on the presence of SRC in groundwaters is available from the scientific literature and water utility monitoring programs and databases. Surveys from Cairo (Egypt) (62) and from Teheran (Iran) (63) showed that most wells were contaminated not only by *C. perfringens* but also by other indicators of fecal contamination (total coliforms, fecal coliforms, and fecal streptococci). The presence of *C. perfringens* was influenced by the depth of the well and the extent of urbanization. Depending on the local conditions, *C. perfringens* was detected in up to 70% of sample sites within geographic areas of the city and its surroundings.

Groundwater supplying United States drinking water systems considered to be vulnerable to viral contamination, yet which were not under the direct influence of surface water nor vulnerable due to inadequate construction have been investigated (64,65). *Clostridium perfringens* was detected at one-third of the sites and was the bacterial indicator encountered least often. There was no seasonal pattern to the finding of clostridia and the relative frequency of indicator presence was not affected by the depth of the well, although the overall percentage of positive samples was. Interestingly, *C. perfringens* was not detected in any of the shallow wells (<50 ft). All indicator organisms (as above plus coliphages, F-specific RNA bacteriophages, and *Bacteroides* bacteriophages) were poorly correlated with the presence of enteric virus.

Abbaszadegan and coworkers (66) evaluated the use of the molecular methods (PCR) for detection of enteric viruses in groundwater and included clostridia as one of the potential indicator. A total of 150 samples (1,500 liters or more) were analyzed by performing cell culture assays for enteroviruses and by performing reverse transcription PCR (RT-PCR) analyses for enteroviruses, hepatitis A virus, and rotavirus. Thirteen samples (8.7%) produced cellular cytopathic effects on cell culture. By molecular methods, enteroviruses were detected in 40 of 133 samples (30.1%), hepatitis A virus in 12 of 139 samples (8.6%), and rotaviruses in 18 of 130 samples (13.8%). *Clostridium perfringens* was rarely found in this type of water (personal communication).

Clostridia were also detected as part of the microbial flora of thermal mineral water springs that are used as spas in Spain (67). The authors postulated that in the absence of *E. coli*, the presence of fecal streptococci and SRC did not represent actual fecal contamination, but rather that the organisms entered the spring from soil and hence their presence was indicative of inadequate natural filtration or insufficient protection of the spring.

In the United Kingdom, the occurrence of SRC in groundwater was reported by a water utility to be 8% over a five-year period (1990–1995) when 575 samples

were analyzed (68). Another utility investigated the quality of water drawn from a series of boreholes located in an unconfined magnesian limestone aquifer operating at depths between 70 and 200 m. Over a 20-month period sulfite-reducing clostridia were present in the absence of fecal streptococci, and fecal streptococci were isolated in the absence of sulfite-reducing clostridia. *Escherichia coli* was never isolated from what is considered to be a high-quality groundwater, with no evidence of being under the influence of surface water or other sources of contamination. Sartory (69), reviewing monitoring data from 82 groundwater sources in central England for a 27-month period reported only 2 SRC positive samples of 859.

Before the introduction of the Dutch national standard, a survey of groundwater sources used for the production of drinking water was carried out to determine the incidence of sulfite-reducing clostridia (70). During 1980–81, 585 samples were analyzed for SRC consisting of untreated groundwater ($n = 290$) and the associated final (treated) drinking water sampled at the treatment works ($n = 295$). Only one sample was positive for SRC and total coliforms were also isolated from that sample. The sample was from a plant treating groundwater that had recently introduced a new well. Clostridia were not detected in a sample taken a few days later (Havelaar, personal communication, 1996).

Bottled Waters

There is very little information on the occurrence of clostridia in bottled waters. In Europe a standard for "natural mineral waters" of absence in 50 ml has been established (71). In a survey of bottled water sold in Canada, Warburton and coworkers (72) did not detect SRC in any of the 267 samples.

Drinking Water Supplies

In Europe, SRC have been used as indicators of water quality since the beginning of the twentieth century. They were formally an intrinsic part of regulations (71), with a maximum admissible concentration, based on a most probable number analysis, of (1 per 20 ml). Monitoring was at the discretion of member states and some introduced national standards for sulfite-reducing clostridia: Netherlands (<1 per 100 ml), France (<1 per 20 ml), and Belgium (<1 per 100 ml). In the revised regulations (73), SRC have been replaced by a monitoring standard for *C. perfringens* at <1 per 100 ml, to be applied to surface water sourced supplies. In North America, neither SRC nor *C. perfringens* have been used as legal indicators of drinking water supplies.

Drinking water samples collected from several community supplies in the United States were examined by Bisson and Cabelli (25) using a newly developed medium. The source of these supplies was described as wells, springs, brooks, and surface water; many systems were not chlorinated. *Clostridium perfringens* was detected in 3.8% of chlorinated samples and 24% of samples from unchlorinated supplies. Coliforms were not recovered from any of the chlorinated samples, although enterococci were, demonstrating the relative resistance to chlorine of coliforms (least), enterococci, and clostridia (most). Although not described in the paper, it is likely that treatment was rudimentary and as a consequence, the findings are not particularly relevant to larger (and more complex) treatment systems, the most complex systems being able to efficiently remove the highest levels of bacteria.

Several studies have been undertaken to investigate the removal of pathogens and indicator organisms, including clostridia, during water treatment. Removal of clostridia ranged from less than 1 to 7 more than log removal according to the type of treatment applied (19,33,50–52,74–78).

Payment and Franco (33) proposed the use of *C. perfringens* as surrogate for the removal of pathogens and described their removal through the water treatment train of three works. When large sample volumes (100 to 1,000 liters) were used, a correlation between *C. perfringens* and human enteric viruses was observed after filtration. However, because *C. perfringens* is not present in sufficient numbers in many surface waters, their value to estimate removal is limited to sites with high fecal contamination.

As part of a national review on the occurrence of (SRC) in drinking water data derived from monitoring carried out by a number of U.K. water utilities was collated (68). Analysis of these data was complicated by differences in analytical procedures or type of samples analyzed but it does indicate that low level occurrence of SRC can be expected in normal drinking water treatment and supply (Table 1).

Distribution Systems

Few publications give information on the presence of SRC in drinking water distribution systems. Willis (79)

Table 1. Occurrence of SRC in U.K. Water Supplies

	Sample Type	*n*	SRC per 100 ml (%)	*Clostridium Perfringens* (% of SRC)
Utility 1	Treated groundwater	4,474	78(1.74)	38.5
	Treated surface water	913	30(3.29)	83.3
Utility 2	Treated surface water	65	1(1.54)	—
	Ex-service reservoirs	345	3(0.87)	—
	Distribution	870	11(1.26)	
Pooled data (3 utilities)	Treated water (unspecified)	449	12(2.67)	—

investigated a municipal water supply in England. Treatment consisted of slow sand filtration followed by chlorination. Sulfite-reducing anaerobes were detected more often in samples collected from distal parts of the distribution system than adjacent to the outlet of the treatment plants. The frequency of occurrence varied seasonally and was highest during the winter when up to 88% of samples from consumer's taps contained *C. perfringens*. Interestingly, spores were present in only 6% of these positive samples, leading the author to conclude that sulfite-reducing anaerobes were growing in the distribution system. Other studies have shown that SRC are regularly present in mains flushings (80, Meheus, personal communication 1996). SRC present in mains sediments could be the result of spores accumulating and persisting in dead ends or areas of low flow (81).

Growth of SRC in water distribution systems would be restricted to areas where amounts of oxygen are very small. Although some species require strictly anaerobic conditions, others will grow (but not produce spores) in the presence of oxygen; growth is enhanced and spores are formed only in the absence of oxygen (82). These conditions are most likely to arise within mains sediments, biofilms, and particularly corrosion tubercles. Evidence that clostridia species grow in these microenvironments within treated water distribution mains is provided in a study carried out by Emde and colleagues (83). Corrosion tubercles collected from a section of pipe removed from the distribution system contained 460 clostridia per g. Clostridia were not detected in the water drained from the same section of pipe. Organisms capable of reducing sulfate and thiosulfate were present in the same samples, indicating that clostridia may play an active role in cycling sulfur within corrosion deposits, and possibly biofilms.

REMOVAL AND DISINFECTION DURING TREATMENT

Removal

Several groups (33,50–52), have reported the removal of clostridia during the production of drinking water or during wastewater treatment. Payment and coworkers (50) reported the absence of *C. perfringens* in treated water at two water filtration plants. They later studied the elimination of human enteric viruses, coliphages, and *C. perfringens* during a conventional complete drinking-water treatment process (76). The respective concentrations (geometric mean) per 100 liters in river water were viruses, 79 mpniu, coliphages 6,565 pfu and clostridia, 11,349 cfu. After predisinfection, flocculation with alum, and settling, human enteric viruses were not detected in any of the 100 L samples (less than 4 mpniu per 100 L), but coliphages were detected in 7 of 14 samples and clostridia in 15 of 16 samples. In filtered water samples, human enteric viruses were detected in 2 of 31 samples, coliphages in 10 of 33, and clostridia in 17 of 33. Finished water was free of human enteric viruses (0 per 162 samples), but coliphages were detected in one sample (1.5 pfu/100 L) and clostridia in three, at 1.0, 4.1, and 7.0 cfu/100 L. They suggested that coliphages and clostridia, which are present in larger numbers than viruses in river water and which may have similar resistance to drinking water treatments, may be useful for estimating the level of treatment attained when large volumes of water (1,000 L or greater) are sampled and when they are present in sufficient numbers in the source water. Further studies at three water treatment plants (Payment and Franco 1993) suggested the value of *C. perfringens* as an indicator of drinking water quality and treatment efficacy with respect to chlorine-resistant pathogens such as enteric viruses and protozoan parasites.

Oxidizing Disinfectants

Venczel and coworkers (84) reported the resistance of *Cryptosporidium parvum* oocysts and *C. perfringens* spores to chlorine and other drinking water disinfectants. *Clostridium perfringens* spores have been suggested as a surrogate indicator of disinfectant activity against *Cryptosporidium parvum* and other disinfectant-resistant pathogens in water. A mixed-oxidant solution was considerably more effective than free chlorine, inactivating both microorganisms. A 5 mg/L dose of mixed oxidants produced a greater than 99.9% inactivation of *Cryptosporidium parvum* oocysts and *C. perfringens* spores in 4 hours. Free chlorine produce no measurable inactivation of *Cryptosporidium parvum* oocysts by 4 or 24 hours, although *C. perfringens* spores were inactivated by 1.4 log10 units after 4 hours.

Payment (85) reported the inactivating power of residual chlorine in a distribution system using test microorganisms (*E. coli*, *C. perfringens*, bacteriophage phi-X 170, and poliovirus type 1), which were added to drinking water samples obtained from two water treatment plants and their distribution system. Except for *E. coli*, microorganisms remained relatively unaffected in water from the distribution systems tested. When sewage was added to the water samples, indigenous thermotolerant coliforms were inactivated only when water was obtained from sites very close to the treatment plant and containing a high residual chlorine concentration. *Clostridium perfringens* was barely inactivated, suggesting that the most resistant pathogens such as *Giardia lamblia*, *Cryptosporidium parvum*, and human enteric viruses would not be inactivated. The author suggested that the maintenance of a free residual concentration in a distribution system does not provide a significant inactivation of pathogens and that it could even mask events of contamination of the distribution thus providing only a false sense of safety, with little active protection of public health.

Fujioka and colleagues (86) investigated the effectiveness of chlorine dioxide to inactivate poliovirus type 1 and indicator bacteria in sewage. They measured the fraction of organisms surviving after 10 minutes contact with a range of chlorine dioxide doses. Indicator bacteria (*C. perfringens*, total and fecal coliforms) were naturally present in sewage at sufficiently high counts. The sewage was seeded with poliovirus. Although the other indicators were inactivated by 3.2 to 3.8 log10, *C. perfringens* was inactivated by only 0.5 log10 at a concentration of 3 mg/L.

Chlorine dioxide appears more effective than free chlorine in inactivating *C. perfringens* spores. Free chlorine (dose 5 mg/L, pH 7 demand-free buffer, 25 °C)

reduces the viability of a laboratory-grown suspension by 1 log10 after one hour, rising to 1.7 log10 after 24 hours (Sobsey, personal communication, 1996).

Times taken for a two Log10 (99%) reduction in counts of pure cultures following the addition of a solution of chlorine were measured by Hirata and coworkers (87). They exposed a concentration of approximately 10^5 cells/ml suspended in chlorine-demand free phosphate buffer to different concentrations of chlorine and counted surviving cells after intervals of time. Their results are expressed as the relationship between chlorine concentration and the contact time required for a 99% inactivation. From these data it is possible to calculate the resistance relative to *E. coli*, or any of the other species tested: indigenous *C. perfringens* were 90 times more resistant, whereas a laboratory strain was 30 times more resistant.

The effectiveness of chlorine and ozone in inactivating indicator bacteria and bacteriophages in effluents from four wastewater treatment plants was also investigated by Tyrrell and coworkers (88). The results demonstrate the sensitivity of fecal indicator bacteria to chlorine compared with two types of phage. *Clostridium perfringens* was found to be relatively insensitive to inactivation by chlorine and ozone, with Log10 reductions of 0.25 and 0.125, respectively.

Ultraviolet Radiation

Nieuwstad and colleagues (89) investigated five different designs of UV reactors for disinfecting treated (secondary) wastewater measuring decimal reduction values (DR) of reoviruses and a range of indicators (bacteria and bacteriophages), including spores of SRC. SRC were barely inactivated by the treatment (less than 0.5 log10). These experimental data are borne out by findings from operational UV wastewater treatment plants in Hawaii (90) and Canada (91).

Although there are few comparative data, it is apparent that clostridia are considerably more resistant to chlorine-based biocides (hypochlorite, chlorine dioxide), ozone and UV irradiation than indicator organisms (bacteria and bacteriophages). On the basis of the available data it may be assumed that under conventional conditions of drinking water disinfection, there will be a negligible reduction in the numbers of viable spores of SRC.

CORRELATION WITH OTHER MICROORGANISMS

Clostridia, and in particular *C. perfringens*, were proposed as indicators of fecal contamination as early as 1899 (92). The spores of SSRC are capable of surviving in water and sediments for considerable periods persisting long after coliforms and other fecal indicators have disappeared. Because of their persistence, they have traditionally been regarded as indicating intermittent or remote contamination (19). In this respect, they can be valuable, for example, in assessing whether groundwater is prone to fecal pollution, especially if the water is not disinfected before use. Bisson and Cabelli (25) suggested their use as indicators of fecal pollution. More recently it has been suggested that *C. perfringens* could be used as an indicator of drinking water quality and treatment efficacy with respect to chlorine-resistant pathogens such as enteric viruses and protozoan parasites (33).

Clostridium perfringens is routinely present in the intestinal tract of humans and other animals along with *E. coli* and fecal streptococci, albeit at lower levels. Therefore, clostridia may be expected to be present in wastewater and receiving waters in association with coliforms, *E. coli*, fecal streptococci, and other fecal organisms. The extent to which indicator bacteria persist in the environment depends, among other things, on the inherent robustness of the species involved. The ability of SRC to form environmentally hardy spores enables them to persist for long periods. This is illustrated by the use of clostridia to track the movement and dispersal of sewage solids around sea disposal sites (93). Survival studies using in situ membrane microcosm chambers have demonstrated that in freshwater sediments, fecal coliforms and fecal streptococci decrease by up to five and one order of magnitude, respectively. In comparison, spores of *C. perfringens* showed no decrease in viability after 85 days (94). In laboratory microcosms, *C. perfringens* isolated from sewage was found to be three to four times more persistent in natural river water than oocysts of *Cryptosporidium parvum* (95), although the indicator bacteria, fecal coliforms, and fecal streptococci died at a rate 50-fold greater than the oocysts.

A number of investigations examining the relationships in drinking water sources between the occurrence of protozoan parasites and clostridia have been carried out (33,49,69,96). Correlation coefficients between clostridia and protozoan parasites were determined in each of these studies. There is no consistent pattern to the relationships identified in each of these studies. Two demonstrated a correlation between the presence of clostridia spores and *Cryptosporidium* and *Giardia*, although one study revealed a negative correlation with *Giardia*. The remaining studies produced no correlation. In one of these (49), significant correlation with indicators (fecal streptococci and somatic coliphages) were only evident when data from different sampling sites were grouped. When the association was analyzed for each river separately, the correlation was not significant. The authors concluded that the relationship between the density of protozoan (oo)cysts and *C. perfringens*, or any other indicator, may vary from one aquatic system to another or possibly be site-specific for a given river. The data of Sartory (69) comprised 2,503 samples from 30 river sites in central England. There was no correlation between numbers of *Cryptosporidium* and SRC, but there was an increase in frequency of detection of *Cryptosporidium* with increasing counts of SRC.

More recent data from 45 water treatment plants along the Saint Lawrence River (Canada) over a period of three years suggested that their presence in raw water provided an estimate of the probability of occurrence of *Giardia*, *Cryptosporidium*, or human enteric viruses (35). The probability estimates were derived by logistic regression analysis and suggested relationships with fecal coliforms, total coliforms, and *C. perfringens*. The described correlation in this particular study suggest that

the use of logistic regression methods might provide a better tool for analysis.

A U.K. Water Industry Research Ltd study (68) also reported that there are insufficient data from which to estimate the incidence of clostridia in samples taken from customers' taps. Clostridia may be found in drinking water distribution systems. However, these could represent spores present in the source water and which have accumulated in mains sediments. Alternatively, they may have risen due to growth of SRC in corrosion nodules, biofilms, or sediments. It is important to establish whether SRC can grow in water distribution systems, and if so, the species that are involved and to understand their ecology. If it were shown that SRC grow in distribution systems, then these organisms have no public health significance. However, there are occasions when it is desirable to confirm (or otherwise) whether contamination is fecal in nature, for example, following detection of coliforms in the absence of *E. coli* in routine samples. In these circumstances *C. perfringens* is a more appropriate indicator than the less specific SRC.

Clostridia could be used as an index of fecal pollution and indicator of pathogens in seafood. Burkhardt and coworkers (97) studied the ability of hard-shelled clams (*Mercenaria mercenaria*) to accumulate fecal coliforms and other microorganisms (*E. coli*, *C. perfringens*, and male-specific bacteriophages) over a one year period. Bacteriophages and *C. perfringens* showed significantly higher rates of accumulation than either the fecal coliform group or *E. coli*, especially during the spring. The higher incidence of human viral gastroenteritis associated with the consumption of shellfish during this period may be a result of the extraordinary concentration of certain microorganisms, including enteric viral pathogens.

Nichols and coworkers (98) reported concurrent measurement of the sewage tracer coprostanol and fecal indicator bacteria for water and sediments from coastal waters off Sydney, Australia. Good correlations were observed for both water and sediment samples between coprostanol and the two fecal indicator organisms, fecal coliforms and *C. perfringens* spores, thereby validating the use of coprostanol as a sewage signature in this environment. In a study by Sartory (48), the ratios of median SRC : faecal coliforms (FC) and SRC : faecal streptococci increased as the sampling sites became more distant from the sewage discharge. The persistence of clostridia, particularly the spores, and their resistance to disinfection means that they are not suitable indicators of the presence of labile pathogens such as *Campylobacter*, *Shigella*, or salmonellae.

It has been suggested that *C. perfringens* could be used as an indicator of drinking water quality and treatment efficacy with respect to chlorine-resistant pathogens such as enteric viruses and protozoan parasites (33). It is argued that the resistance of clostridial spores to disinfection and their small size (1 μm), may make them useful indicators for the presence of oocysts of *Cryptosporidium* or the cysts of *Giardia*. It was suggested that the organism was most valuable as an indicator of treatment effectiveness as opposed to pathogen occurrence.

Gericke and colleagues (99) examined the occurrence of *Giardia* cysts and *Cryptosporidium* oocysts in raw and treated drinking water in South Africa. Samples were collected from ten different treatment plants over a year and examined for *Giardia*, *Cryptosporidium*, total and fecal coliforms, *Candida albicans*, and *C. perfringens*. There was no correlation between the presence of *C. perfringens* and *Giardia* or *Cryptosporidium*. *Candida albicans* and *C. perfringens* both survived treatment processes better than the parasites, and the authors concluded that their suitability as indicators for the presence of parasites is questionable. Finally, in a review of routine monitoring data from 82 boreholes and springs, Sartory (68,69) reported that the range of counts was 0 to 40 per 20 ml (859 samples). For these data, there is no relationship between SRC levels and the occurrence of *Cryptosporidium* oocysts.

CONCLUSION

Of the anaerobes that infect humans, the clostridia are the most widely studied. *Clostridium* bacteria are ubiquitous microorganisms. They are involved in a variety of human diseases, the most important of which are gas gangrene, tetanus, botulism, pseudomembranous colitis, and food poisoning. In most cases, clostridia are opportunistic pathogens; that is, one or more species establishes a point of infection in a particular site in a compromised host. Of interest in environmental microbiology, is the natural resistance of the spores of these bacteria as well their occurrence in the feces of many warm-blooded animals.

Clostridium perfringens can be used as index of fecal pollution and the spores of SRC can serve as indicator of treatment process efficiency. Their resistance to environmental conditions as well as to water treatment processes are key factors that can provide both researchers and regulators with a robust parameter of water quality. Their absence, in water that also does not contain other indicator or index microorganisms, gives further reassurance that such waters are free of the most resistant pathogens.

Cold-adapted, psychrophilic and psychrotrophic, microorganisms are distinguished from mesophiles by their ability to grow at temperatures around 0 °C. Because a large part of the Earth's biosphere is at temperatures below 5 °C, cold-adapted microorganisms are widely distributed in nature. To survive and grow successfully in cold environments, they have evolved a series of adaptations of all their cellular constituents, including membranes, protein synthesis, energy-generating system, enzymes, and the components responsible for nutrient uptake. These adaptation strategies and the resulting considerable biotechnological potential are described in this review after a brief consideration of the terminology and the habitats of cold-adapted microorganisms.

COLD-ADAPTED MICROORGANISMS — DEFINITION

Forster (1) was the first to call attention to the growth and reproduction of bacteria at low temperatures when

he reported that organisms isolated from fish could grow well at 0 °C. The term *psychrophilic* was first used in 1902 by Schmidt-Nielsen (2) to describe microorganisms that are able to grow and multiply at 0 °C. During the following decades, many publications have dealt with these microorganisms, and during the 1950s and 1960s, in particular, there was disagreement concerning the use and meaning of the term *psychrophilic* (3). Visible growth on laboratory media within one or two weeks at 0 °C was considered as a criterion of psychrophiles (4). Some authors noted that the optimum growth temperature of many of these microorganisms was close to that of mesophiles. Morita (3), who distinguished between psychrophilic and psychrotrophic microorganisms on the basis of their cardinal growth temperatures (optimum, maximum, and minimum), acknowledged this fact. It is his definitions that are most widely accepted: Psychrophiles (cold-loving) are characterized by a maximum growth temperature of 20 °C or below, an optimum growth temperature of 15 °C or below, and a minimum growth temperature of 0 °C or below. Psychrotrophic (cold-tolerant) microorganisms are distinguished from mesophiles by their ability to grow at 0 to 5 °C, and have optimum and maximum growth temperatures greater than 15 and 20 °C, respectively. Of course, as with all definitions, there are exceptions, and the cardinal growth temperatures of some cold-adapted microorganisms span those of psychrophiles and psychrotrophs.

ECOLOGY

It is not surprising that cold-adapted microorganisms are widely distributed in nature because cold temperatures are ecologically much more common than high temperatures. Nearly three quarters of the Earth is covered by oceans, and more than 90%, by volume, of the marine environment is characterized by a temperature of 5 °C or less. Very low temperatures are also typical of the polar regions that constitute about 14% of the Earth's surface.

The ecological niche, in which psychrophiles that grow only over a restricted temperature range, can persist and compete successfully with psychrotrophs is the permanently very cold natural environment such as deep ocean waters, some polar regions and some particular terrestrial habitats (e.g., sediments in cold caves and on glaciers). Environments that are subject to periodic, diurnal, or seasonal fluctuations in temperature are favorable to psychrotrophs, which are able to grow over a wide temperature range and to restart their metabolic activity rapidly after thawing (5,6). Possible biochemical differences between psychrophiles and psychrotrophs have been discussed (7). The lowest temperature at which microbial growth is possible is assumed to be −12 °C (8) because it is at this temperature that intracellular ice formation occurs, accompanied by increases in the intracellular solute concentrations (9).

A wide diversity of cold-adapted microorganisms can be found in all cold environments, including fresh and marine waters, polar and high alpine soils, glacier ice, cold deserts, permafrost sediments, cold caves in subarctic or mountain areas, but they are also associated with plants or cold-blooded animals (5,6,10,11). Detailed information on microorganisms living in polar sea ice, freshwater ice, snow, permafrost soils, or cold deserts can be obtained from other articles in this Encyclopedia.

Cold-adapted microorganisms contribute essentially to the processes of nutrient (C, N, P, and S) cycling and biomass production in all cold ecosystems. A wide range of metabolic activities has been detected in cold habitats (5,6,10,11), including nitrogen fixation, photosynthesis, methanogenesis, and degradation of natural or xenobiotic organic compounds (e.g., proteins, carbohydrates, lignin, hydrocarbons, and aromatics). Anaerobic respiration and *in situ* nitrification have rarely been described. Cold-adapted thiobacteria and chemoorganotrophic bacteria have also been isolated. Other challenging conditions in cold environments are low nutrient contents, low water activity and high pressure.

Some cold-tolerant bacteria, including *Xanthomonas campestris*, *Pseudomonas syringae*, and *Erwinia herbicola*, are often responsible for frost injuries in plants because they are able to induce ice nucleation in crop plants under field conditions (12). This ice nucleation activity is, on the other hand, advantageous for food processing and for the energy-saving production of artificial snow or ice (see section on Application in this article). Cold-adapted (psychrotrophic) microorganisms are responsible for food spoilage in frozen or chilled food (13). Some of them (e.g., *Clostridium botulinum*, *Bacillus cereus*, *Listeria monocytogenes*) produce toxins and are therefore pathogenic.

There are psychrophilic and psychrotrophic bacteria, yeasts, higher fungi, and microalgae (5,6,10,11,13). Independent of the origin, the ability to grow well at 0 °C is possessed by a rather limited group of bacteria, mainly gram-negative, aerobic, non−spore-forming rods. Even within this restricted group, most strains belong to the genus *Pseudomonas* and to a lesser extent to the genera *Flavobacterium*, *Alcaligenes*, *Aeromonas*, *Xanthomonas*, *Vibrio*, *Serratia*, *Escherichia*, *Proteus*, *Psychrobacter*, *Shewanella*, and others. Some strains belong to the yellow-pigmented *Flexibacter-Bacteroides-Cytophaga* phylum. *Arthrobacter*, *Bacillus*, and *Micrococcus* dominate among gram-positive cold-adapted bacteria. A great number of bacterial isolates from glaciers and cold water samples were found to be pigmented, which gives them increased protection from UV radiation and free radicals.

Cold-adapted yeasts have been reported among the genera *Candida* (the most common genus), *Torulopsis*, *Cryptococcus, Rhodotorula*, and *Saccharomyces*; they were isolated from polar ice, snow, soil, and other materials, but also from refrigerated food. The preponderant genera among cold-adapted higher fungi are *Penicillium* and *Cladosporium* (14).

Snow algae are among the best cold-adapted microorganisms with a very low optimum growth temperature (usually below 10 °C) and have sometimes a narrow growth-temperature range (3). They are distributed in snow-covered habitats where they inhabit the upper 1-cm layer of snow, giving it a red, green, yellow, or grey coloration (10). Because snow algae are fixed annually in the ice accumulation area of Himalayan glaciers, snow algal biomass and community structure recorded in glacier ice

cores could be a new information source for the study of past climate change (15).

To survive and grow successfully in cold habitats, cold-adapted microorganisms have evolved a complex range of adaptations of all their cellular constituents that will be outlined in the next section of this article.

MECHANISMS OF ADAPTATION TO COLD

Growth Characteristics

When the environmental temperature of a population of microorganisms is lowered, the growth rate decreases until a point is reached when one or more critical functions proceed so slowly as to be insufficient to support cellular requirements and cell (culture) growth ceases. The effect of temperature on overall growth rate of a microbial culture is described in basic terms by the Arrhenius law relating the exponential rise of the reaction rate to the temperature increase:

$$K = \mathrm{A}\, \mathrm{e}^{-Ea/RT}$$

where A is a constant (related to steric factors and molecular collision frequency), Ea is the activation energy, R is the gas constant, and T is the absolute temperature.

A number of other plots may be used to represent the thermal dependence of growth. These are based on alternative mathematical descriptions of microbial growth in liquid culture and include the so-called "square root equation" in which the square root of the specific growth rate (μ) is plotted against temperature in degrees Kelvin (T), as developed by Ratkowsky (16). It is from such graphic representations that the cardinal growth temperatures, discussed earlier, can be calculated. The plots for mesophiles and thermophiles are shifted to the left for Arrhenius plots and to the right for "square root" plots (i.e., to higher temperatures), of course, relative to that of psychrophiles. Otherwise, the general form of the plots is the same for organisms from different parts of the viable growth range spectrum.

Whether an Arrhenius or square root plot is used, it is usually found that the slope of the curve is greater at the high temperature compared with the low-temperature end of the scale. The reason lies in the different mechanisms that are responsible for setting the upper and lower limits of growth, particularly for cold-adapted microorganisms, as explained in the following paragraphs.

The upper limit results from the (heat) denaturation of cellular proteins. In theory, it could be a single type of protein that is denatured, if that protein was pivotal to the overall growth/survival of the microorganism. Evidence for such a proposal comes from studies of mutants of *P. uratovorans* (formerly *Micrococcus cryophilus*) that demonstrated that one or a few thermolabile aminoacyl-tRNA synthetases were the cause of the upper limit of 25 °C (17).

Thus, the reason psychrophiles have upper growth limits that are at lower temperatures than those of psychrotrophs, and why both are below those of mesophiles, is because of the particular thermolability of one or more of their proteins (enzymes) that are essential for growth. The molecular basis of that thermolability is discussed later. Here, it is pertinent to note that because heat denaturation of a protein generally occurs over a narrow range of temperature, the high-temperature slope of Arrhenius plots is steep.

Another distinction between psychrophiles and psychrotrophs is that the latter often display Arrhenius plots with an extensive plateau region of optimum growth rate, which may extend for 15 centigrade degrees or more. In contrast, the optimum growth rate of psychrophiles is not only at a lower temperature but is also over a narrower range. That does not mean necessarily that the cellular enzymes are working at optimum rates over a wider range in psychrotrophs. Indeed, it is possible that none of the enzymes may be operating at $V_{\max}$ or optimum catalytic efficiency ($V_{\max}/Km$; see following section). It does mean that there is a balance of enzyme activities in psychrotrophs, which gives more or less equivalent growth rates over a wide temperature range, reflecting the more thermally adaptive lifestyle of psychrotrophs compared with psychrophiles.

The lower growth-temperature limit of psychrophiles is usually below 0 °C and it may be very difficult to determine practically because of very slow growth rates and the need to include antifreeze in the culture medium that may further reduce the growth rate. The linear nature of the square root plot makes it possible to extrapolate the regression line so as to give a theoretical minimum, which is not possible from Arrhenius plots: the theoretical minimum for psychrophiles may be as low as −26.5 °C (18). However, it must be stressed that this estimation assumes that there has been no phase change in the system. In fact, this is a real possibility because when temperature is lowered, pure water will eventually begin to freeze leaving a more concentrated salt solution outside the microbial cells that will alter the phase behavior of the external medium. The microorganisms will accumulate intracellular compatible solutes to counteract the imposed osmotic stresses and to maintain cellular enzyme function, but a point will be reached when enzymes fail and, additionally, intracellular ice may also begin to form. Thus, there are a number of potential phase changes that will make such calculated lower temperature limits an overestimate of the true biological value.

Clearly, the basis of the upper growth-temperature limit (heat denaturation of proteins) is distinct from that of the lower limit (intracellular salt concentration and/or cell water freezing). Although the phenomenon of cold denaturation of proteins is well documented (19), it generally occurs at a temperature below −15 °C (20) and so it is not likely to be the cause of the practical lower growth-temperature limit of even cold-adapted microorganisms. However, recent evidence suggests that this may not be true in all cases (see following section).

Besides the properties of proteins, the stability and functions of membranes, as reflected by the physicochemical properties of the lipid component, will also influence the growth-temperature range. The contributions of membrane fluidity and phase changes to the upper and lower thermal limits of growth are discussed later.

Cellular Adaptation

The primary sequence of cellular proteins (and therefore the three-dimensional structure that gives them cold activity; see following section) is fixed in the genomic sequence of DNA bases, so a microorganism cannot respond to low temperatures by changing the basic structure of its proteins. It can alter the pattern of proteins made through the thermal regulation of gene expression. Changes in enzyme levels will lead to alterations in the overall cellular composition of cold-adapted microorganisms in response to changes in growth temperature. The amounts of different proteins and RNA will be altered, membrane lipid composition will change, and cell wall composition may be modified. Such phenotypic changes may be constitutive or inducible, and will modify growth rate and thus the ability of the microbe to compete with other (micro)organisms, but will have little effect on the upper or lower growth-temperature limits. That would require the selection of mutations, that is, genotypic change in, for instance, the thermal characteristics of a key enzyme that was involved in setting the upper limit of growth. Genotypic changes occur over an evolutionary timescale, in comparison with phenotypic changes that occur during the lifetime of a cell or (generally for microorganisms) a population (culture).

Sudden decreases in temperature will elicit a specific alteration in gene expression known as the cold-shock response (21,22), which is distinct from the general stress response (heat shock) in terms of both the nature of the proteins induced and regulatory aspects — for example, unlike heat shock, cold shock does not involve special "cold" sigma factors. The cold-shock response involves the induction and synthesis of cold-shock proteins. Class I cold-shock proteins are expressed at very low levels at moderate temperatures and are induced at least tenfold by cold shock, whereas Class II cold-shock proteins are synthesized at reasonable levels at moderate temperatures and are less strongly induced by cold shock. While the cold-shock response is not confined to cold-adapted microorganisms, it is relevant to consider its essential characteristics because the phenomenon has a bearing on the mechanism of cold adaptation. The cellular function that is most sensitive to inhibition by cold shock is protein synthesis, particularly the initiation of translation, and the main functions of cold-shock proteins are in protein synthesis and in mRNA folding; some may act in freeze protection, although that is less well defined.

The major cold-shock protein, CspA, belongs to a family (CspA, CspB, etc.) of two to nine small proteins (~7-kDa molecular size) and is a transcriptional regulator (23,24). They share a common structural motif comprising a β-barrel with five antiparallel strands that is found in eukaryotic Y-box proteins, which are also transcription factors and RNA-masking proteins. The CspA protein is able to bind to the characteristic Y-box base sequence of ATTGG and regulate gene expression; in *Escherichia coli*, this includes the cold-induced proteins GyrA (the α-subunit of the topoisomerase DNA gyrase) and HN-S, both of which are involved in DNA supercoiling. These proteins may also be RNA chaperones, because they have several solvent-exposed phenylalanine residues that can bind RNA and so could minimize the formation of secondary folding that is favored at low temperatures. By maintaining nascent mRNA in a linear form, these chaperones would help to protect the initiation of translation from thermal inhibition.

The regulation of cold-shock protein synthesis is multifactorial, being controlled at the levels of both transcription and translation, as well as mRNA and protein stabilities. The genes of several cold-shock proteins have AT-rich upstream regulatory elements, and CspA mRNA is more stable at low temperatures because of an unusually long 5′untranslated leader region that has a specific secondary structure. Within this 5′UTR there is a highly conserved 11-base sequence called the "cold box" that has been proposed as a repressor-binding site (25). Unlike those of housekeeping genes, the mRNAs of several cold-shock proteins are still translatable after cold shock because of the presence of a downstream box within the coding region that has a complementary sequence to one close to the ribosome-binding site-decoding region in 16S rRNA. When translational capacity decreases following a cold shock, the A-site on ribosomes becomes blocked by charged species of tRNA that leads to lower levels of the regulatory guanosine nucleotides, (p)ppGpp. The induction of cold-shock proteins such as CsdA and RbfA that are ribosomal factors, restores the ability of ribosomes to recognize and translate non-cold-shock mRNAs. An important function of CsdA is the unwinding of stable secondary structures that form in mRNA at low temperatures. In this sense the ribosome acts as a thermoregulator.

A major distinction between psychrophiles/psychrotrophs and mesophiles/thermophiles is that in the cold-adapted microorganisms, the synthesis of housekeeping gene products is not inhibited by cold shock, and the number of cold-shock proteins is usually higher and increases with the severity of the cold shock. The synthesis of one set of proteins is permanently induced by continuous growth at low temperature. These are known as cold-acclimation proteins, but little is known about their cellular functions (26). At least one cold-acclimation protein is analogous to CspA (27).

Lipids and Membranes

Lipid Composition. The membranes of microorganisms, like other organisms, contain a lipid bilayer that is essential for many of the major cellular functions, including passive and active permeability, nutrient uptake, electron transport, environmental sensing, photosynthesis, and recognition processes. All of these functions demand the maintenance of membrane stability that can be considered in terms of two properties of the lipid continuum, namely, the fluidity and the phase. Although all parts of the molecules contribute, lipid fluidity is most influenced by the fatty-acyl moieties, whereas lipid phase depends more on the nature of the head-group of the membrane lipids (28). The gel to liquid-crystalline transition as well as the bilayer (lamellar) to nonbilayer phase transition are both influenced by growth temperature. However, changes in microbial culture temperature usually lead to greater

modifications in the fatty-acyl composition than the headgroup composition of membrane lipids, and so the focus of attention has been on fluidity effects. There are very few reports of lipid phase behavior specifically in relation to cold adaptation of microorganisms. One of the best documented is a study of the behavior of lipids extracted from an endolithic lichen community living beneath rock surfaces in Antarctica (29). In comparison, there is a plethora of reports on the temperature-dependence of fatty acid composition in a wide range of microorganisms.

When growth temperature is lowered, the most frequently observed change in fatty acid composition is in the extent of unsaturation. In bacteria, it is usually the ratio of saturated to monounsaturated fatty acids, whereas in eukaryotic microorganisms, there are alterations in the proportions of saturated, monounsaturated, or polyunsaturated fatty acids (28,30). An important exception among cold-adapted bacteria to this general distinction is Antarctic marine bacteria (mainly species of *Shewanella* and *Colwellia*), which contain significant proportions of polyunsaturated fatty acids, the relative proportions of which are growth temperature–dependent (31). In gram-positive bacteria, methyl-branched fatty acids are particularly common as the acyl chains of membrane lipids (32). They are iso- and anteiso-branched, and in response to a decrease in temperature the proportion of total branched fatty acids may increase and/or the ratio of anteiso- to iso-branched fatty acids may increase (30). In all microorganisms, there is the potential for temperature-dependent changes in fatty acid acyl chain length: a decrease in temperature leads to a shortening of the average acyl chain length (30). Another feature of lipid structure that influences the gel to liquid-crystalline transition temperature is the distribution of the (usually two) fatty acids between the so-called *sn*-1 and *sn*-2 positions on the (usually) glycerol backbone of acyl membrane lipids (33).

Membrane Lipid Organisation. Thus, to summarize the preceding section, a decrease in growth temperature may increase unsaturation or branching (particularly anteiso branching) or decrease chain length. All of these changes influence the way in which the membrane lipids pack within the membrane by introducing steric constraints and modifying the degrees of freedom for molecular motion, that is, they affect both the order and viscosity of the lipid bilayer, which is summarized in the combined terminology "membrane fluidity" (28). The "homeoviscous adaptation theory" (34) proposes that following a decrease in growth temperature, the lipid composition changes so as to restore the original level of fluidity, that is, it assumes that throughout the growth-temperature range, the membrane fluidity is relatively constant.

A second theory, the "homeophasic theory," emphasizes the necessity for the maintenance of the bilayer phase (35). In response to growth temperature changes, the lipid composition changes so as to adjust for thermally-triggered changes in lipid packing that are governed by such factors as the size, charge, and water-binding capacity of the lipid molecules. These factors determine whether lipid molecules associate to form a lamellar (bilayer) phase or one of a number of nonbilayer phases, and changes in lipid composition serve to maintain the overall bilayer continuum of the membrane (28). An attempt to resolve the apparent contradictions of these two models is made in the "dynamic phase behavior model" (36), which emphasizes the need for a constant balance between the gel to liquid-crystalline (fluidity) transition and the bilayer to nonbilayer (phase) transition. A number of other theories seek to explain specific aspects of membrane function, such as the maintenance of proton permeability (which is crucial for cell bioenergetics) at low temperature (37).

Membrane Lipid Biosynthesis and Thermal Regulation. When the growth temperature of bacteria is altered, it has two effects with regard to their lipid composition. The first is a direct one on the physical properties of the lipid bilayer, to increase or decrease fluidity and alter the phase behavior. The second is an indirect effect in which temperature changes modulate the activity of the enzymes involved in fatty acid and lipid biosynthesis, which leads to alterations in either the acyl chains of existing membrane lipids (fast changes) or in the pattern of fatty acid synthetase and phospholipid products for subsequent incorporation into the membrane (slow changes). The basis of fast and slow changes lies in their metabolic origins, which to some extent depend on the bacterial type (30). In all microorganisms, fluidity and phase behavior can be modified by changes in polar lipid and fatty acid compositions. Additionally, in yeasts, fungi, and algae, there may be changes in the amount and type of sterols that regulate both aspects of membrane fluidity by modulating lipid packing and acyl chain motion (28).

Fatty acids are synthesized by a fatty acid synthetase (FAS) enzyme complex in the bacterial cytoplasm (32). The primary products of FAS are saturated fatty acids that are either straight-chain or branched-chain depending on the type of primer molecule that is used. Unsaturated fatty acids are made by two mechanisms: either as secondary products of an aerobic desaturation system within the membrane, for which the substrate is probably the preformed acyl chains of membrane lipids; or as products of a modified FAS system, which is anaerobic and produces a mixture of saturated and monounsaturated fatty acids (30,32). Generally, bacteria contain only one type of system for making fatty acids, but some that live at low temperatures in sea ice or other cold pelagic habitats, and that have polyunsaturated as well as saturated and monounsaturated fatty acids, possess both biosynthetic mechanisms. The monounsaturated fatty acids are synthesized using an anaerobic system but the polyunsaturated fatty acids are made by an aerobic desaturase mechanism (38).

Temperature influences these biosynthetic processes differently: some are regulated by (de)activation of the enzyme protein(s), others by enzyme induction (30). It is the nature of the thermosensor (or "molecular thermometer") and the biochemical mechanisms of the change that together determine whether the response is fast or slow. Temperature-triggered changes that are mediated via desaturases can occur quickly, whether activation or induction is involved, because the substrates are usually

existing membrane lipids. The product of a gene that is induced by cold shock in *Bacillus subtilis* has been identified as a membrane desaturase (39). This is consistent with the rapid response time of cold shock. In contrast, alterations in unsaturation by the anaerobic pathway or of methyl branching are slower because they must be mediated by *de novo* fatty acid (and acyl lipid) synthesis, followed by integration into the membrane. Whatever the mechanism, there is tight control of membrane lipid composition by temperature, which underpins the capability of bacteria to be thermally adaptable.

Cold-Active Enzymes

Basic Aspects. Low temperatures strongly inhibit the activity of most enzymes. As described earlier, this is described by the Arrhenius equation. Accordingly, for an enzyme, drop in temperature from 37 °C to 0 °C induces a 20 to 80 times lower activity, and sometimes more, for a mesophilic enzyme. This is one of the main factors preventing the growth of mesophilic bacteria at low temperatures because the most temperature-sensitive enzyme (catalyst) in a pathway will restrict metabolic fluxes to levels incompatible with growth requirements. In order to compensate for this thermal inhibition, psychrophiles synthesize enzymes having an up to tenfold higher specific activity at low temperatures (Fig. 1). This is in fact the main physiological adaptation to cold at the enzyme level (40). Looking at the effect of temperature on the activity of psychrophilic and mesophilic enzymes in Figure 1, one can also note three other basic features of cold-active enzymes. First, the effect of temperature on psychrophilic enzymes is less pronounced. For instance, increasing the temperature by 10 centigrade degrees produces a 1.6-times higher activity for the cold-active amylase (this is the so-called Q_{10} value) compared with a 2.3 times higher reaction rate for the mesophilic enzyme. This is the consequence of smaller values of the activation energy Ea for cold-adapted enzymes, which render chemical reactions relatively less temperature-dependent (41). Secondly, the temperature for apparent maximal activity for cold-active enzymes is shifted toward low temperatures, reflecting the weak stability of these proteins and the distortion of the active site, followed by unfolding, at moderate temperatures. Finally, the adaptation to cold is not perfect. It can be seen in Figure 1 that the specific activity of the psychrophilic enzymes at low temperatures, although very high, remains generally lower than that of the mesophilic enzymes at 37 °C. These aspects will be detailed in the following sections. It is worth mentioning that these typical features of psychrophilic enzymes also apply to cold-adapted animals and, in fact, pioneering works in the field were carried out on invertebrates and fish (40–42).

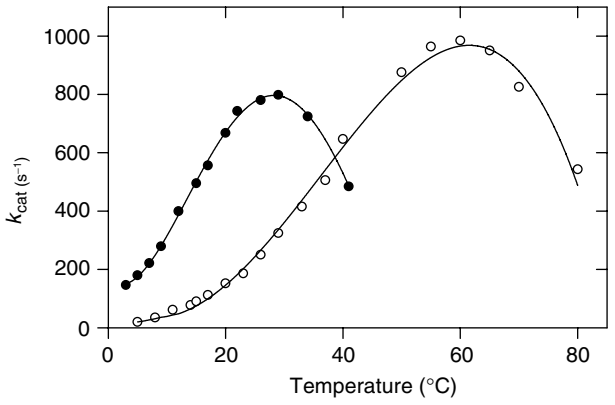

Figure 1. Effect of temperature on the activity of psychrophilic (●) and mesophilic (○) enzymes. This classical experiment, here on α-amylases from the psychrophile *Pseudoalteromonas haloplanktis* and the mesophile *Bacillus amyloliquefaciens*, illustrates the four main adaptive traits of psychrophilic enzymes. (*1*) The rate constant k_{cat} (the specific activity) is higher at low temperatures. (*2*) The Q_{10} values are lower (this is visually biased by the superior activity of the cold-active enzyme; see text for values). (*3*) The temperature for maximal activity is reduced as a result of a weaker stability. (*4*) The rate constant at the temperature of the environment nevertheless remains lower (compare k_{cat} at 3 °C for the psychrophilic enzyme and at 37 °C for the *Bacillus* enzyme). Adapted from G. Feller et al., *J. Biol. Chem.* **267**, 5,217–5,221 (1992).

Intracellular Versus Extracellular Enzymes. Extracellular enzymes secreted by bacteria and adsorbed on organic debris are thought to catalyze reactions at saturating substrate concentrations and therefore can simply increase the reaction rate constant k_{cat}. By contrast, the k_{cat}/Km ratio is the operational parameter for intracellular enzymes working at low substrate concentrations. Inspection of kinetic parameters indicates that cold-active enzymes have either increased k_{cat} or decreased Km or both, compared with mesophilic enzymes (44). It should be kept in mind that substrate binding is strongly temperature-dependent because interactions in the enzyme-substrate complex rely on weak interactions having sometimes opposite thermal dependencies: electrostatic interactions such as H-bonds, ion pairs, or Van der Waals Forces tend to be stabilized at low temperatures, whereas hydrophobic interactions are destabilized. It was noted for instance that two aromatic residues involved in substrate binding of mesophilic chitobiases are replaced by polar side chains in a cold-active enzyme, providing the possible structural basis for its 10 times lower Km value.

Structural Basis of Enzyme Adaptation to Cold. The numerous homology-based models and mainly the recently solved X-ray structures of α-amylase (45,46), citrate synthase (47), malate dehydrogenase (48), triose phosphate isomerase (49) and Ca^{2+}, Zn^{2+} protease (50) from psychrophilic bacteria have provided new insights into the molecular mechanisms of cold adaptation. The information gained from gene homology modeling has been compared with that obtained from direct structural determination from X-ray diffraction of crystals (51). The active site of psychrophilic enzymes has been subjected to careful examination, which has revealed that all amino acid residues involved in the reaction pathway, as well as all side chains pointing toward the catalytic cavity, are strictly conserved with respect to their mesophilic homologs. Therefore, point mutations are not responsible for the improved activity, contrary to Km, which should be achieved by changes

in the structure occurring distantly from the active site. The most widely accepted hypothesis accounting for the dominant adaptive traits of cold-active enzymes, that is, the high activity and the weak stability, suggests that there is a correlation among the activity, the flexibility, and the stability of the enzyme molecule (52,53). The flexible structure of psychrophilic enzymes can provide enhanced ability to undergo discrete and fast conformational changes at low temperatures imposed by the catalytic events. But the price to pay for such plasticity is, of course, the low stability of the native enzyme structure. Flexibility is a dynamic parameter, involving so-called "molecular breathing" or microunfolding, and consequently the static X-ray structures were mainly useful in revealing those structural factors responsible for the low protein stability. It was found that all structural factors currently known to stabilize the protein molecule could be attenuated in strength and number in the structure of cold-active enzymes. This involves the clustering of Gly residues (providing local mobility), the disappearance of Pro residues in loops (providing enhanced chain flexibility among secondary structures), a reduction in Arg residues that are capable of forming multiple salt bridges and H-bonds, as well as a lower number of ion pairs, aromatic interactions, or H-bonds, compared with mesophilic enzymes. The size and relative hydrophobicity of nonpolar residue clusters forming the protein core are frequently smaller, lowering the compactness of the protein interior. The N and C-caps of α-helices are also altered (weakening the charge–dipole interaction) and loose or relaxed protein extremities appear to be preferential sites for unzipping. The binding of stabilizing ions, such as calcium, can be extremely weak, with binding constants differing from mesophiles by several orders of magnitude. Finally, insertions and deletions are sometimes responsible for specific properties such as the acquisition of extra-surface charges (insertion) or the weakening of subunit interactions (deletion). Of course, all these factors are not found in every cold-active enzyme: each enzyme adopts its own strategy by using one or a combination of these altered structural factors in order to improve the local or global mobility of the protein edifice.

Recently, the surface of the molecule was also implicated in cold adaptation. Calculations of the electrostatic potential revealed an excess of negative charges at the surface of the molecule (47) and, indeed, the pI of cold-active enzymes is frequently more acidic than that of their mesophilic or thermophilic homologs. This has been related to improved interactions with the solvent, which could be of prime importance in the acquisition of flexibility near 0 °C (see below). Besides the balance of charges, the number of salt bridges covering the protein surface is also reduced. There is now a clear correlation between surface ion pairs and temperature adaptation, because these weak interactions significantly increase from psychrophiles to mesophiles, thermophiles, and hyperthermophiles, the latter showing Arg-mediated multiple ion pairs and interconnected salt bridge networks. Such an altered pattern of electrostatic interactions at the molecular surface is thought to improve the resilience or the "breathing" of the external shell of cold-active enzymes.

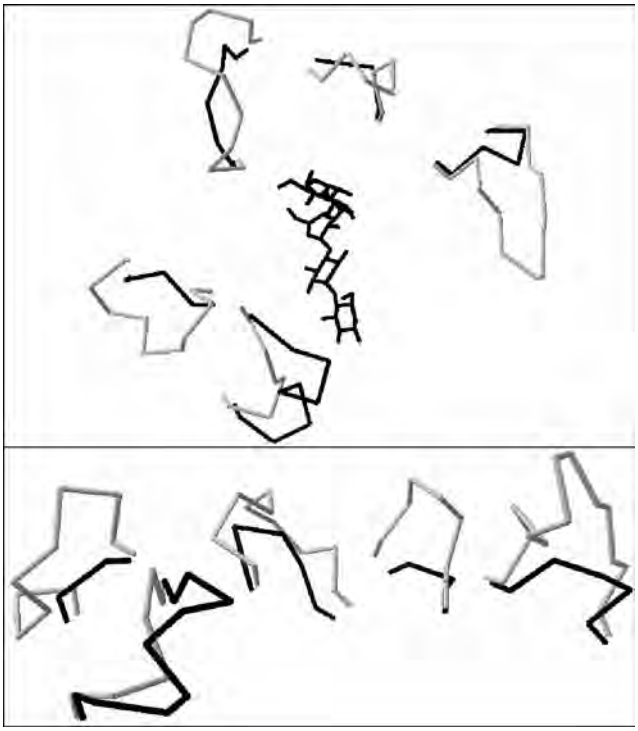

Figure 2. Active site accessibility. Upper panel: superimposition of the variable loops bordering the active site of the psychrophilic α-amylase from *Pseudoalteromonas haloplanktis* (backbone in black) and of pig pancreatic α-amylase (backbone in gray). The carbohydrate inhibitor acarbose bound to the active site is also shown (center of the figure, in black). These variable loops are markedly shorter in the cold-active enzyme. Lower panel: tangential view of the molecular surfaces facing the external medium (upper side). A carbose is removed for clarity. The loops around the catalytic cleft of the cold-active enzyme are less protruding and favor the active site accessibility. Picture generated by Swiss-PDB Viewer using data from N. Aghajari, G. Feller, C. Gerday, and R. Haser, Protein Sci. **7**, 564–572 (1998); M. Qian et al., *Biochemistry* 33, 6,284–6,294 (1994).

Another interesting feature enlightened by crystal structures arises from the calculation of the solvent-accessible area (46,47). It was noted that psychrophilic enzymes expose a higher proportion of nonpolar residues to the surrounding medium. This is an entropy-driven destabilizing factor caused by the reorganization of water molecules around exposed hydrophobic side chains (54).

The last important aspect revealed by crystallography refers to the active site that seems to be more accessible to ligands. An example of α-amylase is shown in Figure 2. This larger opening of the catalytic cleft is achieved by small deletions in loops bordering the active site or by distinct conformation of these loops, and by replacement of bulky side chains for smaller groups at the entrance. The reasons for such better accessibility are still not clearly understood but it is thought that cold-active enzymes can accommodate substrates at low-energy cost, as far as the conformational changes are concerned; it may also facilitate easier exit of products. Nevertheless, this typical feature of the active site has at least two consequences. First, nonspecific enzymes (accepting various substrates) should have a broader

specificity, because various substrates having slightly distinct conformations or sizes can fit and bind to the site. This property was in fact previously reported for a cold-active subtilisin, which is a nonspecific alkaline protease (55). As a second consequence, substrate(s) should bind less firmly in the binding site, if no point mutation(s) have occurred, giving rise to higher *Km* values. This is certainly one of the structural explanations to the observation that some cold-active enzymes, which are strongly homologous to mesophilic counterparts, have lower binding constants (44,47,52,55).

How to Reach Flexibility at Low Temperature. One can understand intuitively that low temperatures render a protein more compact or at least, less mobile. The structural factors listed earlier obviously contribute to the adaptive compensation aimed at regaining the flexibility required by catalysis at low temperatures. After a period of, say, visual inspection, the study of cold-active enzymes is now entering into a more analytical stage, which in fact converges on the general problem of protein folding. Evidently, psychrophilic proteins, as well as all extremophilic proteins, are useful models as a result of the extreme conditions imposed on the polypeptide structure and function.

A first step in this analytical approach was achieved recently by microcalorimetric studies (57). A definitive advantage of differential scanning calorimetry compared with other analytical methods is the fact that, in favorable conditions, three thermodynamic parameters related to protein unfolding are recorded directly (and not extrapolated or calculated from indirect data). The calorimetric records, or thermograms, of a psychrophilic α-amylase and of mesophilic α-amylases, including the heat-stable enzyme from *B. licheniformis* that can resist temperatures close to boiling, are illustrated in Figure 3. It can be seen that the low stability of the cold-active α-amylase is characterized by a low melting point at 44 °C (the top of the transition, corresponding to the equilibrium between the native and unfolded state) and by a low melting enthalpy (the surface below the curve, corresponding to the total amount of heat absorbed during unfolding). Deconvolution of the heat capacity function also indicates that the psychrophilic enzyme unfolds without any stable intermediate(s). This shows that all structural elements are unstable and unfold at the same time, contrary to mesophilic α-amylases that possess domains of distinct stability as illustrated for the *B. amyloliquefaciens* enzyme in Figure 3. However, in the case of phosphoglycerate kinase and chitobiase from Antarctic bacteria, it was found that the low structural stability could only affect one particular domain of the protein, giving rise to biphasic thermograms (Fig. 4). In addition, the reversibility of unfolding for these enzymes is improved because protein aggregation is not favored or does not occur at the low temperature of melting. The low hydrophobicity of the protein cores, which tend to aggregate upon solvent exposure, probably also, contributes to the reversibility of the unfolding process.

The parameters recorded by microcalorimetry were used to calculate the stability curve of the cold-active

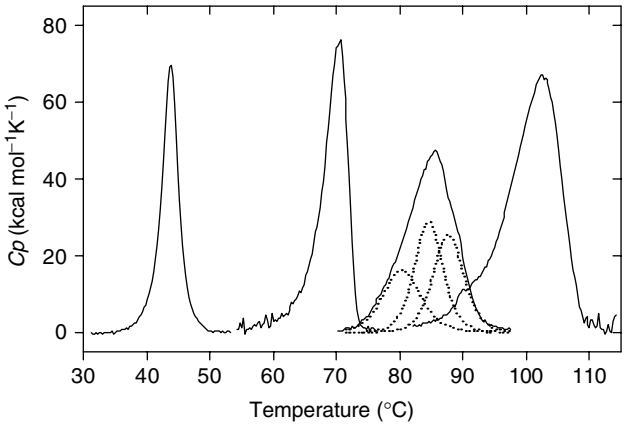

Figure 3. Thermograms of psychrophilic and mesophilic α-amylases recorded by differential scanning calorimetry. From left to right: heat-induced unfolding of α-amylases from the psychrophile *P. haloplanktis*, human salivary glands, *B. amyloliquefaciens* and *B. licheniformis*. The cold-active enzyme is characterized by a low melting point, *Tm* (temperature at the top of the transition peak) and also by a low enthalpy of unfolding, ΔH_{cal} (surface of the transition peak). Unlike the psychrophilic enzyme, all mesophilic α-amylases possess domains of distinct stability (the deconvolution into three cooperative transitions is shown as dashed lines for *B. amyloliquefaciens* α-amylase). Adapted from G. Feller, D. d'Amico, and C. Gerday, *Biochemistry* 38, 4613–4619 (1999).

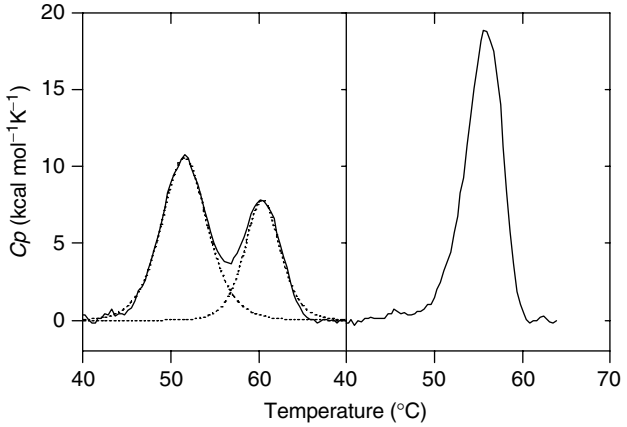

Figure 4. Thermograms of phosphoglycerate kinase. Differential scanning calorimetry thermograms of the enzymes isolated from the Antarctic psychrophile *Pseudomonas* sp. TACII18 (left) and from yeast (right). The psychrophilic enzyme is composed of two domains that unfold independently: a heat-labile domain and a heat-stable domain when compared with the yeast enzyme. Such an experiment reveals that the weak stability of psychrophilic enzymes can only affect one particular region of the protein, probably providing the required flexibility around the active site. Adapted from M. Bentahir et al., *J. Biol. Chem.* 275, 11147–11153 (2000).

α-amylase, that is, the Gibbs free energy of unfolding as a function of temperature (Fig. 5). This curve corresponds to the energy required to disrupt the protein structure at any given temperature and, by definition, is nil at the melting points. The weak stability of the cold-active

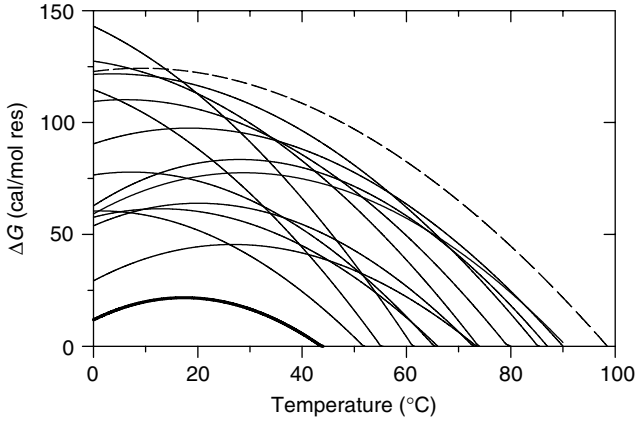

Figure 5. Stability curves of proteins from psychrophile (heavy line), mesophile (plain line) and thermophile (dashed line). Each curve displays the energy required to disrupt the protein structure (the Gibbs free energy of unfolding) as a function of the temperature. Extrapolation of the stability curve for the psychrophilic enzyme toward low temperatures indicates that cold unfolding should occur near −10 °C. Note also, that the physiological temperature for the organisms, from which the enzymes are isolated, lies on the left side of the bell-shaped curve for the psychrophilic bacteria and on the right side for both the mesophiles and the thermophiles. Adapted from G. Feller, D. d'Amico, and C. Gerday, *Biochemistry* 38, 4,613–4,619 (1999).

α-amylase is obvious in Figure 5, over the whole temperature range in which the native state prevails, that is, between both melting points. One should note that the temperature for maximal protein stability does not usually correspond to the environmental temperature of psychrophiles, mesophiles, or thermophiles. The temperature experienced by mesophiles and thermophiles lies on the right side of the bell-shaped stability curve, giving evidence that their enzymes reach the necessary balance between optimum stability (leading to a compact molecule) and flexibility (required for the catalytic function) by using the thermal dissipative force, responsible for unfolding at higher temperatures. By contrast, the environmental temperatures around 0 °C that are encountered by psychrophiles, are found far on the left side of the stability curve. We should mention at this point that the decrease in stability within this region of the curve shown in Figure 5, and ultimately leading to cold denaturation, arises from the hydration of protein groups that destabilize the protein at decreasing temperatures (54). It follows, that the origin of flexibility of psychrophilic enzymes at low temperatures involves group hydration mainly, and is therefore drastically different from mesophilic and thermophilic proteins, the latter taking advantage of the conformational entropy rise with temperature to gain in mobility. The improved interactions with the solvent of cold-active enzymes suggested by their crystal structures (see earlier section), reinforces the idea that group hydration plays an essential role in the acquisition of flexibility in the proteins of microorganisms living in permanently cold environments.

Limit of Protein Adaptation to Cold. A surprising consequence of the free energy function for the psychrophilic α-amylase shown in Figure 5 is its weak stability at low temperatures when compared with mesophilic and thermophilic proteins, whereas it was expected that cold-active proteins should also be cold-stable. This protein is in fact both heat labile and cold labile. Assuming constant properties of the solvent below 0 °C (i.e., no freezing) and the absence of protective effects from cellular components, this α-amylase should unfold at −10 °C. Incidentally, this temperature closely corresponds to the probable lower limit of bacterial growth (9) and therefore cold denaturation of some key enzymes in psychrophiles could be an additional, though unsuspected, factor contributing to the lower limit of life at low temperatures.

It was also shown that psychrophilic enzymes (or their heat-labile domains) have reached a state close to the lowest possible stability of the native state (57). Indeed, several experiments indicate that the cold-active α-amylase could not be any less stable than it is. If psychrophilic enzymes have indeed gained in flexibility at the expense of stability in the course of evolution, this implies that the actual native state precludes further adaptation toward a more mobile structure. This aspect accounts for the imperfect adaptation of the catalytic function in psychrophilic enzymes, mentioned at the beginning of this section and illustrated in Figure 1.

BIOTECHNOLOGICAL POTENTIAL

During the past decade, it has been recognized that cold-adapted microorganisms and their cellular constituents or products provide a large biotechnological potential, offering numerous economical and ecological advantages over the use of organisms and their enzymes that operate at higher temperatures (59–65).

The cultivation of microorganisms at low temperatures prevents or limits the risk of contamination with mesophilic bacteria or fungi (advantageous in continuous systems) and is energy-saving. The high activities and catalytic efficiencies of cold-adapted enzymes at low temperatures have a number of advantages: they may prevent undesired chemical transformations and the loss of volatile compounds; they can give high reaction yields from reactions involving thermosensitive components; they may shorten turn-round times for processes operated at low temperatures; they allow on-line monitoring at low temperatures; and they obviate the requirements of an increase in the enzyme concentration to compensate for the lower efficacy as is necessary when using mesophilic enzymes at low temperatures. In addition, the rapid inactivation of cold-active enzymes by mild heat treatment does not affect product quality, permits selective enzyme inactivation in a complex medium, and does not require expensive heating/cooling systems. On the other hand, low thermal stability and low reaction rates may restrict the application of cold-active enzymes.

Food Biotechnology

Food Processing. Low-temperature fermentation and ripening of food minimizes contamination by mesophilic microorganisms and provides better taste and quality of products when compared with products fermented at

higher temperatures (61,66). Psychrotrophic salt-tolerant bacteria, mainly micrococci, play an important role in flavor and taste development in the texture modification during ripening in the rind of soft cheese (67). Psychrotrophic lactic acid bacteria, mainly *Lactobacillus curvatus* and *L. sake*, have been suggested as useful starter cultures for dry sausage production (68). When ham was fermented with *Lactobacillus* sp. at 5 °C for three weeks, the desired color, cohesiveness, and consistency of the meat were obtained (66).

Cold-active enzymes are desirable for several processes in the food industry in order to improve taste, flavor, and texture, to maintain product quality and to improve preservation. Enzymatic hydrolysis of lactose, a major milk component, results in increased solubility, digestibility, and sweetness, and is conventionally carried out with ß-galactosidase enzymes obtained from mesophiles for a maximum of four hours at 30 to 40 °C or for 24 hours at 5 to 10 °C so as to limit contamination. A reduced incubation time and a minimized risk of contamination could be obtained by using cold-active ß-galactosidase (60). Such an enzyme has been isolated from psychrophilic *P. haloplanktis*; after 50 minutes at 4 °C, 33 and 12% of milk lactose was hydrolyzed by the cold-active and the commercial enzyme from *Klyveromyces lactis*, respectively (69). Commercially available thermolable microbial rennets (Marzyme II, Modilase) are useful alternatives to calf rennet in cheese manufacture, because they are rapidly heat-inactivated, and the processing of cheese does not result in residual coagulation activity when the whey is used in other dairy products (60). Transglutaminase from *Streptoverticillium* sp. that is used to improve protein texture, was shown to be useful in strengthening gels of minced fish flesh (surimi) at 10 and 25 °C (70). Biosensors (enzyme electrodes) that are functional at low temperatures could be useful for on-line monitoring and food quality control.

Ice-nucleation-active bacteria are advantageous for food processing. Nonphytopathogenic *X. campestris* has been used to freeze water at subzero temperatures above −5 °C for egg processing. High-pressure treatment at 300 Mpa and 5 °C for 5 minutes killed the cells without affecting their ice-nucleation activity. Thus, this treatment can be applied without any hygiene problems. The procedure reduced also the freezing and thawing time of egg white because of the formation of large ice crystals (71). Enhanced freeze concentration in the presence of ice-nucleation-active *X. campestris* has also been obtained for milk (72), fruit juice (73) and soy sauce (74) without loss of original flavor. Further, adding bacterial ice nucleators to food was reported to make its freeze-drying more efficient and to enhance a desirable powdering of the freeze-dried product. Antifreeze proteins (thermal hysteresis proteins) are used to improve the quality and texture of frozen food products that are eaten while in the frozen state, such as ice cream, or that are thawed before they are consumed (75).

An important aspect in food technology is preservation. According to the World Food and Agriculture Organization, hydrogen peroxide can be added to milk (0.05–0.25%) as a preservative if it is destroyed by catalase after processing (cold pasteurization). Thus, cold-active catalase is a potential enzyme for degrading the remaining hydrogen peroxide in milk at ambient temperature, which could be interesting for developing countries (76). Glucose oxidase from *Aspergillus niger* improved the preservation of shrimp at 0 to 2 °C by inhibiting psychrotrophic growth without affecting sensory factors (77).

Production of Alcoholic Beverages. A further field of application of cold-adapted microorganisms is the cost-effective production of alcoholic beverages with improved taste and aroma. Wine making at temperatures below 15 °C is not used on an industrial scale because the productivity is low. To decrease the fermentation temperature below 10 °C while retaining productivity, psychrotolerant *Saccharomyces cervisiae* strains were immobilized on solid supports, such as mineral kissiris, delignified cellulose, and gluten (78,79). The improved quality of wine produced at low temperatures can be attributed to the reduction in proportion of higher alcohols, whereas fruit esters are synthesized and retained to a greater degree, while the overall percentage of volatile compounds is increased. Further, low temperature helps the sedimentation of colloidal compounds and thus facilitates wine clarification. Beer brewed at low temperatures contains smaller amounts of higher alcohols, polyphenols, and diacetyl, with less bitterness and a lower pH than the traditional product (79).

Food Supplements. Functional mono-, di- and polysaccharides are attractive as sweeteners that cause less tooth decay. Enzymatic processes at low temperatures (5–25 °C) have been developed for the production of functional oligosaccharides, such as palatinose and cyclodextrin (80).

Long-chain polyunsaturated fatty acids (PUFA), such as docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA), arachidonic acid (AA) and gamma-linolenic acid (GLA), are attracting considerable attention as dietary supplements to counteract deficiency in essential fatty acids (60,63). Currently, many PUFAs are obtained from plant seeds or fish oil but this is associated with several problems such as the undesirable fish-odor and the difficulties of large-scale purification. Some cold-adapted microorganisms have a higher proportion of unsaturated fatty acids in their lipids than mesophiles. *Mortierella alpina* was reported to produce AA in large quantities (81) and to synthesize EPA (82) at 6 to 12 °C; lowering growth temperature resulted in the increased production of EPA. Marine psychrophilic bacteria, particularly *Shewanella* spp. also produce PUFA (31). The gene cluster involved in EPA biosynthesis by a marine *Shewanella* strain has been expressed in mesophilic *E. coli* (83) and in marine cyanobacteria that can be cultured at high densities (84).

PUFA-enriched substances are also produced by microbial lipases. A psychrotrophic *Pseudomonas fluorescens* lipase (with maximum activity at 40 °C) catalyzes the selective incorporation of PUFAs in lipids at low temperature; a *Pseudomonas* sp. lipase produced a high

concentration of monoglycerides containing 40% PUFA at 10 °C ((85) and refs. therein).

Detergent Industry

A major application field of cold-active enzymes (lipases, proteases, cellulases, and amylases) is the detergent industry where the use of such enzymes allows colder washing cycles and is thus energy saving. Promising candidates for detergent additives are enzymes from cold-adapted alkaliphilic microorganisms that are not only active at low temperatures but also active and stable at alkaline pH and in presence of surfactants and oxidants.

A commercially advantageous production of a cold-active detergent lipase (Lipolase™) from the filamentous fungus *Thermomyces lanuginosus* (formerly *Humicola lanuginosa*) was achieved by cloning the lipase gene into *Aspergillus oryzae*, a suitable host for large-scale production. This enzyme has optimum activity at 35 to 40 °C and pH > 10 and is resistant toward oxidation and proteases (86).

Alkaline cellulase K from *Bacillus* sp., active at 10 °C and more active toward amorphous than to crystalline cellulose, has been added to laundry detergents as an effective component. Several microbial cold-active proteases, produced from *Bacillus*, *Paecilomyces*, and *Nocardiopsis*, and active at 10 to 20 °C, have been used in detergent manufacturing [(85) and refs. therein]. Contact lens cleaning solutions, based on an alkaline protease from a marine bacterium, were capable of cleaning and sterilization at low temperatures, in both phosphate and nonphosphate-containing detergent formulations (87).

Organic Phase Biocatalysis — Production of Fine Chemicals

Cold-active enzymes are advantageous for the enzymatic synthesis of volatile and heat-sensitive compounds. Organic phase biocatalysis (OPB) refers to the performance of enzymatic reactions in media composed wholly or partly of organic solvents. The advantages of low temperature OPB with cold-adapted enzymes include: improved biocatalysis stability at low temperatures; increased solvent choice to include polar, water-miscible, organic solvents; increased product yield; improved compatibility with heat-sensitive reactants and products; improved oxygen solubility for oxidase-catalyzed reactions. Additional advantages arise from the characteristics of cold-adapted enzymes, such as increased enzyme flexibility and activity and increased interactions with the aqueous solvent (88). Two examples of the use of cold-adapted enzymes for low temperature OPB include a lipase from psychrotrophic *Pseudomonas* sp. for ester synthesis (89) and a neutral protease from *Vibrio* sp. for peptide condensation (90).

Acrylamide is used as paper strengthener, and for the production of intermediates of pharmaceutical agents. Immobilized cold-active nitrile hydratase from *Rhodocccus* sp. and an immobilized cell system of *Pseudomonas chloraphis* have been utilized for the industrial production of acrylamide at 0 to 5 °C ((85)) and refs. therein).

Agricultural Biotechnology

Improved Symbiotic Nitrogen Fixation. Legumes constitute an important protein source; they meet most of their nitrogen (N) requirement through biological nitrogen fixation in symbiosis with rhizobia, which overcomes the high costs of nitrogen fertilizers. Cold periods during the growing season can significantly limit the establishment of this symbiosis. To improve nitrogen fixation of temperate legumes at low temperatures, the selection of cold-adapted rhizobia is a valuable tool. With Arctic rhizobia from temperate legumes *Astragalus* and *Oxytropis* it was possible to improve legume growth by 30% under controlled and field conditions, and these strains showed also better competitivity and nitrogen fixation at low temperature (91). Survival of cold-adapted rhizobia to winter freezing is advantageous for early nodulation of perennial legumes in spring. Psychrotrophic rhizobia from legumes also constitute a good genetic reservoir to transfer cold adaptation to rhizobia that are specific to legumes of agricultural importance (92).

Plant Protection. Biocontrol of plant diseases and pests is a safe alternative to chemical pesticides. Cold-adapted biocontrol agents are relevant to areas of high latitude and altitude, and to pests and diseases of winter crops, as well as postharvest diseases in cold storage. Such agents (fungi) for use in temperate soils, in which temperatures of 0 to 5 °C are common, are already commercially available: for example, "Bio-Green" (*Metarhizium anisopliae*) is used for the control of a pasture pest in southern Australia, and "Plant-Helper" (*Trichoderma atroviride*) to combat many plant diseases. Development of a cold-tolerant isolate of *Phialophora* sp. (lobed hyphopodia) for the control of the take-all disease of cereals is close to commercialization. These biocontrol agents produce antibiotics, cell wall-digestive enzymes and toxins, or induce host resistance at low temperatures (0 to 5 °C). For the efficient control of snow molds, which can attack many economical plants under a cover of snow and cause extensive damage, cold-adapted biocontrol agents (saprophytic fungi such as *Typhula phacorrhiza*, *Acremonium boreale*, *Humicola grisea*) are in development ((93) and refs. therein).

Ice-nucleation-active (Ice+) bacteria are often responsible for plant frost injuries. The introduction of indigenous or constructed *P. syringae* strains that are incapable of inducing ice nucleation can reduce the amount of Ice+ strains on crop plants (94). On the other hand, insect pests have been shown to become more vulnerable to low temperatures after the application of Ice+ bacteria (95).

Biohydrometallurgy

Biohydrometallurgical processes involve the solubilization of minerals and metals by suitable microorganisms for recovering base and precious metals. Bioleaching of metal sulfides at temperatures below 15 °C is mediated by microorganisms belonging to the genus *Acidothiobacillus* (formerly *Thiobacillus*) and particularly by cold-adapted strains of *A. ferrooxidans*. No leaching of metal sulfides occurs when these strains are not present in the

leach liquors. Case histories of low temperature biohydrometallurgical operations carried out with satisfactory bioleaching performance include the Quebrada Blanca mine in Chile (where temperatures vary from −15 to 20 °C), the El Teniente copper sulfides and oxides mine in Chile (where temperatures are below 8 °C), the San Valentino di Predoi copper mine in North Italy (the temperature is constantly 8 °C all year around), Canadian mines (constantly at 10 °C), and commercial Russian plants (temperatures below 15 °C for several months of the year) (96).

Artificial Snow and Ice

The most widespread commercial use of ice nucleators is in the energy-saving production of artificial snow. A commercial preparation of ice-nucleation-active bacteria (SNOWMAX) are added to the water used in snow-making machines to raise the critical temperature for artificial snow making by several degrees (97), or to produce ice as a construction material for installations in Arctic and Antarctic areas (98).

Low-Energy Wastewater Treatment

The temperature of wastewater treatment is an important parameter because of its effect on chemical and biological reaction rates. An effective wastewater treatment strategy with minimal energy requirement in many cold areas is the use of lagoons, the most common and economical method for treating domestic and industrial sewage in cold regions of North America (99). The temperature of typical influent wastewater during the winter months is between 0.5 and 10 °C. Aerobic, anaerobic, or facultative aerobic lagoons (ponds) consist of natural or constructed cells, whereby a major portion of organic matter entering this system is decomposed by indigenous microorganisms. Periods of ice cover change the lagoon ecology such that psychrotolerant and psychrophilic organisms are favored. Lagoons can provide significant reductions in total suspended solids, nutrients, and indicator and pathogenic microorganisms; physicochemical treatment processes can be used to enhance the final quality. An unresolved problem is the persistance of some pathogens and indicator organisms, such as *Salmonella* and fecal coliforms, because their numbers appear to be enhanced by the cold temperatures (100).

Anaerobic treatment of cold wastewaters has so far been considered as unfeasible. Recently, a cold (8–12 °C) anaerobic wastewater treatment, using two module-expanded granular-sludge bed systems, has been developed for full-scale application to low strength non- or partially-acidified wastewaters, including various industrial wastewaters and settled domestic sewage. The system provided remarkable long-term (six months) stability at low temperature, despite large variations in organic loading rate and hydraulic retention time. The enhancement of the biodegradation process can be attributed to the development of a balanced microecosystem in the sludge. The COD (chemical oxygen demand) removal efficiencies were high and comparable to those found during mesophilic or thermophilic anaerobic treatment. Implementation of these systems, combined with physicochemical resource-recovery posttreatment methods, should lead to a significant decrease in the operational costs of wastewater treatment (101).

Anaerobic digestion of municipal wastewater and animal manures at low temperatures (5–25 °C) can be used successfully to produce methane from animal manure and other organic wastes (102,103). Anaerobic digestion at 20 °C in sequencing batch reactors reduced the pollution potential of swine manure slurry by removing 85 to 95% of the soluble COD, produced important quantities of biogas, and was successful in removing odors (104).

Bioremediation of Organic Pollutants

Bioremediation of contaminated soil and water, that is, the accelerated natural biodegradation through the modification of limiting environmental factors, is an economically and sometimes logistically favorable alternative to conventional physicochemical techniques. Temperature affects the rates of biodegradation via its effect on microbial metabolism, but also through the physical nature and chemical composition of the contaminants. Cold-adapted indigenous microorganisms play a significant role in the biological decontamination of cold environments *in situ*, in which ambient temperatures often coincide with the growth-temperature range of these microorganisms.

The biodegradation of many components of petroleum hydrocarbons by indigenous cold-adapted microorganisms has been reported in a variety of terrestrial and marine cold ecosystems, including Arctic, Alpine, and Antarctic soils, Alaskan groundwater and Antarctic seawater [(105) and refs. therein]. Several oil tanker accidents, such as those of the Bahia Paraiso in Antarctica and of the Exxon Valdez in Alaska during 1989, demonstrated that temperature was not the main limiting factor for oil biodegradation, but instead the effectiveness was limited by the availability of nitrogen and phosphorus.

Comparatively little is known about biodegradation of aromatic and polycyclic aromatic compounds under cold conditions. Psychrotrophic pseudomonads have been described with the ability to degrade phenol (106), toluene (107,108) naphthalene and phenanthrene (108) at low temperatures (5 to 10 °C). Aerobic degradation of polychlorinated biphenyls with up to three chlorine substituents has been shown to occur at 4 °C in contaminated river sediment (109) and at 7 °C in Arctic soil (110). High-rate chlorophenol (tri-, tetra-, and pentachlorophenol) biodegradation in groundwater was achieved in an aerobic fluidized bed system at 5 to 7 °C, and more than 99.9% mineralization was obtained at a loading rate of 740 $mg\,l^{-1}\,day^{-1}$. The effluent quality was close to drinking water standards. This system has the advantage that it can be operated and maintained at actual groundwater temperatures and avoids the heating costs (an increase of the process temperature from 7 to 25 °C increases annual operating costs by a factor of 2.5) (111).

Di-*n*-butyl-phthalate (DBP), one of the most widely used plasticizers, is at least partially biodegradable under

anaerobic conditions at 10 °C by a psychrotrophic *P. fluorescens* (112). Simulating a Canadian subsurface environment at ambient temperature (10 °C), biotransformation of DBP was observed under aerobic, nitrate-reducing, Fe (III)-reducing and sulfate-reducing conditions (113).

Molecular Biology

There are a number of uses of cold-active enzymes in molecular biology. Alkaline phosphatase catalyzes the dephosphorylation of nucleic acids, but enzyme inactivation after the reaction is required in order not to abolish the subsequent kinase or ligase reaction. Better product retention can be obtained with a heat-labile alkaline phosphatase isolated from an Antarctic bacterium; the enzyme has an optimum temperature of 25 °C and is irreversibly inactivated after 10 min at 55 °C (114).

Uracil-DNA glycosylase (uracil *N*-glycosylase, UNG) is used to prevent carry-over contamination in the polymerase chain reaction (PCR) and must be inactivated after treatment. UNG from *E. coli* is not completely inactivated by the heat denaturation step, so a sufficient amount survives to degrade the newly-synthesized PCR product. This can be avoided by using a new heat-labile uracil-DNA glycosylase from a psychrophilic marine bacterium that is rapidly inactivated in dilute buffers at 40 °C (45 °C), with a half-life of two minutes (0.5 min) (115).

Protein expression systems for the production of cold-active proteins have recently been reviewed (63). Transfer of genetic material between mesophilic donor bacteria and psychrotrophic recipients showed that plasmid-borne genes are successfully expressed at temperatures as low as 4 °C (116,117). Cold-adapted bacteria could be exploited as cell factories for the manufacture of adventitious proteins because lowering the temperature was shown to result in an increased recovery of soluble, correctly-folded protein (118). Remaut and coworkers (119) designed an efficient expression system and introduced *E. coli*-derived expression-controlling elements into psychrotrophic hosts, using broad-host-range plasmids as vector systems. They showed that the *E. coli lacI*^{q}*-Ptrc* repressor-promoter system is functional at temperatures as low as 4 °C in two different psychrotrophic species.

CONCLUSION

A wide diversity of cold-adapted microorganisms can be found in all cold environments. To preserve membrane function and to grow at low temperatures, psychrophilic and psychrotolerant bacteria adapt their membrane lipid composition, largely through changes in the fatty-acyl components of phospholipids and glycolipids. Decreases in temperature lead to increased fatty acid unsaturation and/or methyl branching, and a shortening of acyl chain length, all of which help to maintain a relatively constant level of membrane fluidity as described by the homeoviscous theory. The alternative homeophasic theory emphasizes the need also to maintain lipid bilayer integrity at low temperatures. The changes are regulated by thermal control of cytoplasmic fatty acid synthesis enzyme systems and by membrane-bound desaturase enzymes. The tight regulation of these systems contributes to the thermal adaptability of bacteria.

Cold-active enzymes produced by psychrophilic microorganisms display a high catalytic efficiency associated with low thermal stability. These properties are beginning to become understood, and the rules governing protein adaptation to cold appear to be relatively diverse. Psychrophilic enzymes are not only of extraordinary interest at the fundamental level to understand the structure-function relationships, but also to investigate the general problem of protein folding. Increasing our knowledge of these aspects will clearly require further multidisciplinary approaches. Nevertheless, cold-adapted microorganisms have much more to give to the field of biotechnology. Indeed, the application of these extremophiles and of their enzymes offers considerable potential in the detergent and food industries, for the production of fine chemicals and in bioremediation processes.

COLD SHOCK

Sangita Phadtare
Masayori Inouye
Robert Wood Johnson Medical School
Piscataway, New Jersey

When an exponentially growing culture is shifted from its optimum growth temperature to a lower temperature, the organism exhibits a response called as a cold shock response. The effect of cold shock is mainly twofold: (*1*) the membrane fluidity decreases, affecting the membrane-associated functions such as active transport and protein secretion; and (*2*) the secondary structures of RNA and DNA are stabilized, which may affect the efficiency of mRNA translation and transcription (1). In addition, protein folding is too slow or inefficient, and ribosomes need to be adapted to function properly at low temperatures (2,3).

The cold shock response has been studied in detail using *Escherichia coli* and *Bacillus subtilis* as model systems (1,4–13). Enterobacteria such as *E. coli* often encounter sudden drastic temperature changes as a result of excretion from animals. Cold shock response gives this bacterium a selective advantage of quickly adapting to the new environment. The knowledge accumulated through the study of the cold shock response in *E. coli* and *B. subtilis* can be applied to other organisms.

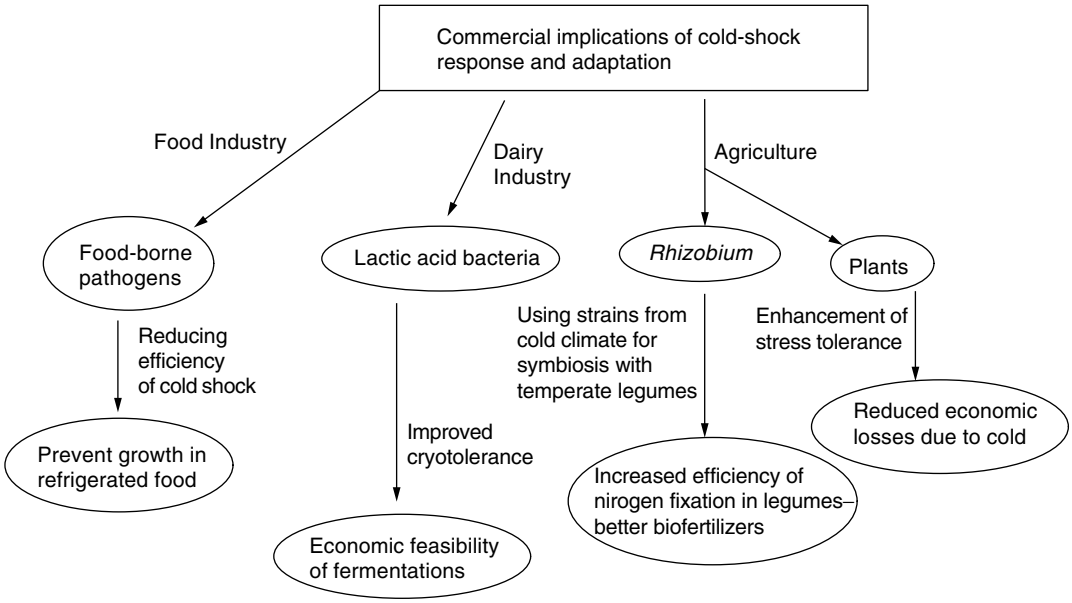

Figure 1. Commercial implications of cold shock response.

The study of cold shock response is now gaining importance because of its commercial and health implications. Figure 1 illustrates the importance of the study of cold shock response. One of the applications is in dairy industry wherein bacteria such as *Lactobacillus lactis* are used. The dairy fermentation processes involve harsh temperature changes, including lower temperatures. Therefore, it is important to use commercial lactic acid bacteria starter cultures that have been modified for better cold adaptation. This is essential to prevent losses in the activity and viability of the bacterial cultures. The economical feasibility of the fermentation process depends on this. Therefore, the study of cold shock response is important to manipulate *L. lactis* for better cold adaptation (14).

Refrigeration is a commonly used method for extending the shelf life of food. Thus, it is necessary to understand the cold shock response of food-borne pathogens. Examples of such bacteria include *Listeria* (15), *Clostridium* (16), *Pseudomonas* (17), *Enterococcus* (18), *Vibrio* (19), and *Yersinia* (20). *Listeria monocytogenes*, for example, is an opportunistic pathogen causing listeriosis, which primarily affects pregnant women, newborn babies, or immunocompromised patients, such as those suffering from AIDS (21). Thus, it is important to understand the cold shock response of these bacteria and to design means to reduce the efficiency of the cold shock response. This will prevent growth of these pathogens in the food stored at low temperatures. It is reported that if *B. subtilis* cells are cold shocked prior to freezing, the viability during the freezing is enhanced, suggesting that cold shock proteins (Csps) may directly or indirectly protect cells from the cold damage caused by freezing (22). On the basis of this report, the food-spoilage bacteria can be sensitized to damage through direct freezing. Also the viability and activity of frozen or freeze-dried commercial lactic acid bacteria starter cultures can be improved by cold shock–induced cryotolerance (14,23).

The study of cold shock response is also important in agricultural industry. *Rhizobium* is a nitrogen-fixing bacterium that lives in symbiosis with legume plants. Low temperature is one of the major limiting factors for this symbiosis in temperate climate. Thus, *Rhizobium* isolated from arctic (psychrotrophic) legumes is of considerable interest to the agricultural industry as it tries to improve the nitrogen fixation of legumes cultivated in temperate climate (24). In addition, a desaturase enzyme from a cyanobacterium, which plays an important role in maintaining the membrane fluidity after cold shock, has been shown to confer chilling resistance to tobacco plants (25). These instances imply that in the future the study of cold shock response is going to play a major role in biotechnology.

COLD SHOCK RESPONSE

The cytoplasmic membrane, ribosomes, and nucleic acids are implicated in sensing temperature changes (4). The cold shock response in *E. coli* is summarized in Figure 2 (4).

Cold Shock Response at the Level of Cytoplasmic Membrane

Bacteria exhibit a highly conserved cold shock response by adjusting the membrane lipid composition. The change in the fluidity of the membrane lipids is the first event that signals a change in temperature. The usual liquid crystalline nature of the membrane is changed to a gel-phase state upon cold shock. This affects the membrane-associated functions as the proportion of fluid (i.e., disordered lipid to ordered lipid) in the cell membrane plays an important role in membrane function. Different modes of adaptation are seen to compensate for this effect: (*1*) increasing the proportion of unsaturated fatty acids (UFAs) in the membrane lipids, (*2*) shortening of fatty

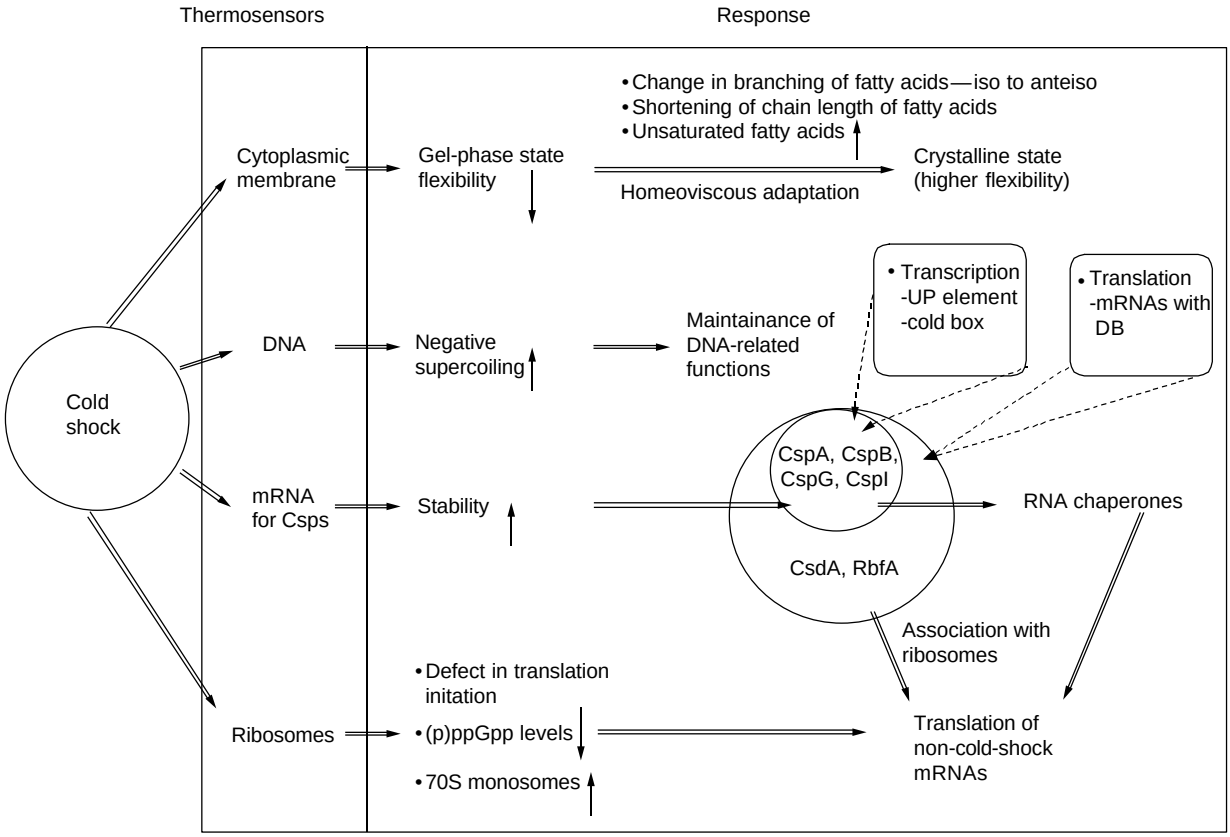

Figure 2. Model for cold shock response following the temperature downshift from 37 to 15 °C in *E. coli*. DB: downstream box and (p)ppGpp: guanosine 5′triphosphate-3′diphosphate (pppGpp) and guanosine 5′diphosphate-3′diphosphate (ppGpp) (collectively abbreviated as (p)ppGpp) (4).

acid chain length, and (*3*) alteration of fatty acid branching from *iso* to *anteiso*.

Phospholipids with UFAs have lower melting points and greater degree of flexibility than phospholipids containing saturated fatty acids. This change compensates for the negative effect of low temperature on the physical state of the lipid bilayer. This is known as *homeoviscous adaptation* (26). The increase in UFA is achieved by two mechanisms. In *E. coli*, the enzyme α-ketoacyl-acyl carrier protein synthase II converts palmitoleic acid to *cis*-vaccenic acid after the temperature downshift. Interestingly, the synthesis of this enzyme is not induced upon cold shock, but the enzyme is activated at low temperatures (27,28). On the other hand, the desaturation system in *B. subtilis* is cold-inducible. *Bacillus* (29–31) is the only nonphotosynthetic bacterium in which the presence and cold induction of desaturase is reported. The desaturase gene (*des*) transcript is barely detected at 37 °C, and following cold shock, the synthesis of a membrane *des* gene is transiently induced to 10- to 15-fold higher levels after four hours. The deletion of the *des* gene did not cause a detectable phenotype after cold shock in a rich medium (29). Recently, a two-component signal transduction system has been identified that consists of a sensor kinase DesK and a response regulator DesR responsible for the cold shock induction of the *des* gene. DesR binds to a DNA segment from the −28 to the −77 position relative to the start site of *des* gene. UFAs act as negative signaling molecules of *des* transcription. Thus, a regulatory loop composed of DesK-DesR controls the expression of the *des* gene at low temperatures (30). According to this model, DesK assumes different signaling states in response to a temperature-induced change in membrane fluidity. This is accomplished by regulating the ratio of kinase to phosphatase activity such that a phosphatase-dominant state is present at 37 °C, when membrane lipids are disordered. A kinase-dominant state predominates upon an increase in the proportion of ordered membrane lipids after a temperature downshift to 25 °C. DesK-mediated phosphorylation of DesR results in the transcriptional activation of *des*. Activation of *des* results in the synthesis of Des, which desaturates the acyl chains of membrane phospholipids. These newly synthesized UFAs inhibit *des* transcription either by favoring DesK dephosphorylation of DesR-P or by causing dissociation of DesR-P from its binding site (30).

In the case of cyanobacteria, deletion of the *des* gene caused cold sensitivity, as in these organisms, desaturation of lipids is correlated with acclimatization of photosynthetic activity at low temperatures. In these bacteria, the desaturases are bound to the thylakoid membrane. These are acyl-lipid desaturases that introduce double bonds into fatty acids that have been esterified to glycerolipids (32). They are efficient regulators of the extent of unsaturation of membrane lipids in response to temperature changes. In the case of *Synechococcus* sp., two of the desaturase genes,

desA and *desB*, are induced after temperature downshift from 38 to 22 °C. Their expression is tightly controlled by a combination of mRNA synthesis and stabilization at low temperatures (33). The introduction of the *desA* gene into the chilling-sensitive cyanobacterium *Anacystis nidulans* increased the cold resistance of this organism (34). These results suggest that desaturases are essential for the cold shock adaptation of cyanobacteria.

Using *Synechococcus* PCC 6803 strain, it was shown that the change in the fluidity of the membrane lipids is the first event that signals a change in temperature. In vivo, palladium-catalyzed hydrogenation of membrane lipids activated the transcription of *desA*, without the temperature downshift. As this catalytic technique affects only the plasma membrane, this result implies that the membrane acts as a sensor and that transcription of *desA* is enhanced in response to the altered lipid saturation (35). It was also shown that the energy produced by photosynthesis is necessary for the transcription of *desA*. Thus, the low temperature–induced desaturation of membrane lipids occurs only in the light but not in the dark. Gombos and coworkers (36,37) showed that polyunsaturated fatty acids are important for growth and for the ability to tolerate photoinhibition of photosynthesis at low temperatures. These results support the fact that the cytoplasmic membrane helps in sensing the temperature changes.

Recently, it has been shown that in *B. subtilis* the *anteiso*-branched fatty acids, and not the UFAs, are the major fraction after temperature. Using a defined minimal medium, it has been shown that cold shock adaptation of *B. subtilis* depends on the presence of isoleucine or precursors of *anteiso*-branched fatty acids. After shift to a lower temperature, the ratio of *anteiso*- to *iso*-branched fatty acids is dramatically changed. *Anteiso*-fatty acids have lower melting point than *iso* fatty acids (38). An Ile-dependent change in the fatty acid branching profile appears to be the main mechanism of cold shock adaptation of the membrane of *B. subtilis* (39). Similarly, in the case of *Listeria monocytogenes*, two modes of adaptation to lower temperature were found: (*1*) shortening of fatty acid chain length, and (*2*) alteration of braching fatty acid branching from *iso* to *anteiso*. The deficiency of *anteiso* fatty acids resulted in cold sensitivity (40).

A recent report by Weber and coworkers showed that deletion of *B. subtilis* fatty acid desaturase showed a severe cold-sensitive phenotype in the absence of isoleucine. The four UFA species of differing lengths, branching patterns, and positions of the double bond found in the wild-type strain are not synthesized in the *des* deletion mutant. Also, the mutant showed dramatically altered saturated fatty acid profile at the onset of the stationary phase in the presence of exogenous isoleucine sources. They reported that during cold shock adaptation, *des* expression could completely replace the isoleucine-dependent, long-term, fatty acid branching adaptation mechanism. They concluded that the crucial aspect in cold adaptation of the cytoplasmic membrane is not its specific molecular composition but rather its physical status in terms of its fluidity (41).

Cold Shock Response at the Level of Ribosomes

VanBogelen and Neidhardt (3) suggested that organisms sense the changes in temperature at the level of ribosomes. It was proposed that after an increase in temperature, the speed of translation is higher than that of the supply of charged tRNA; hence, the A-site of the ribosome is empty (11). On the other hand, following cold shock, translational efficiency reduced, so the A-site is blocked because of the high concentration of charged tRNA. This in turn lowers guanosine 5′triphosphate-3′diphosphate (pppGpp) and guanosine 5′diphosphate-3′diphosphate (ppGpp) (collectively abbreviated as (p)ppGpp) levels by inhibiting RelA-mediated synthesis of (p)ppGpp. Thus, the concentration of (p)ppGpp increases at high temperatures and decreases after a temperature downshift. Jones and coworkers (42) have shown that artificially induced high levels of (p)ppGpp diminish the expression of Csps, whereas low concentration increases their production. Thus, (p)ppGpp affects the magnitude of the cold shock response.

Cold Shock Response at the Level of Nucleic Acids

The extent of DNA supercoiling changes in response to various environmental factors, including exposure to chemicals and changes in osmolarity, and affects the expression of various genes (43,44). Wang and Syvanen (45) have suggested the supercoiling of DNA to be a thermosensor. To maintain DNA-related functions, such as replication, transcription, and recombination, it is important to regulate the DNA supercoiling in the cells exposed to thermal stress. DNA is usually negatively supercoiled, and in the case of *E. coli* and *B. subtilis*, negative supercoiling transiently increases after the temperature downshift (46,47). On the other hand, in *E. coli* it was seen that heat shock results in a decrease in the linking number (the number of base pairs per helical turn) (44). A change in the linking number is often due to a change in superhelical density. This change affects the normal arrangement between the −10 and −35 region of many promoters. Recognition of some σ^{70} promoters by RNA polymerase is dependent on the relative orientation of the −35 and −10 regions (45). The cold shock–inducible *E. coli recA* promoter is one such twist-sensitive promoter. It has also been shown that the change in supercoiling may be necessary to allow the DNA-dependent RNA polymerase of *B. subtilis* to start transcription from promoters of housekeeping genes after stress with unaltered efficiency (47). It has been proposed that DNA supercoiling may regulate UFA synthesis in *B. subtilis* (48).

Cold Shock Response and Csps

Microorganisms can be categorized on the basis of their temperature optima for growth. Thermophiles grow between 40 and 110 °C, whereas mesophiles grow between 10 and 50 °C. Psychrophiles and psychrotrophs can grow at or near 0 °C. The Csps are synthesized by all these three groups of organisms to counteract the deleterious effects of low temperature on RNA and DNA and consequently on transcription and translation. In the case of mesophilic

bacteria, such as *E. coli*, after the temperature downshift, there is a growth lag period during which Csps are dramatically induced, while the synthesis of most of the other proteins is arrested. The production of Csps is transient, and at the end of the growth lag period, their production is reduced to a new basal level. In the case of some mesophiles such as *B. subtilis* (22), there is no lag period after the temperature downshift and, in addition, the synthesis of non-Csps is not arrested but is reduced (49). Similarly, in the case of *L. lactis*, there is no lag period of growth after the temperature downshift (14).

As mentioned previously, *E. coli* has been extensively studied as a model system for bacterial cold shock response. In the case of this organism, proteins such as CspA (50), CspB (51), CspG (52), CspI (53), CsdA (54), RbfA (55), NusA (56), and PNP (57) are expressed at a low level at 37 °C and are dramatically induced after the temperature downshift. On the other hand, proteins such as the recombination factor RecA (58), the initiation factor IF-2 (59), the nucleoid-associated DNA-binding protein H-NS (60), the subunit of topoisomerase DNA gyrase GyrA (61), Hsc60, HscB (62), dihydrolipoamide transferase, and pyruvate dehydrogenase (63) are present at 37 °C, and their induction after cold shock is not dramatic (<10-fold). CspA, CspB, CspG, and CspI have been proposed to function as RNA and DNA chaperones; CsdA is a ribosomal associated protein with RNA unwinding activity; RbfA is a ribosomal binding factor; NusA is involved in termination and antitermination of transcription; and PNP is a ribonuclease. In addition, a trigger factor is induced after a lag of 2 to 3 hours upon cold shock, and it enhances viability at low temperatures (2). It probably helps protein synthesis and folding to continue at low temperatures. It may also help to maintain preexisting proteins in a functional form by promoting refolding of cold-damaged proteins.

Bacillus subtilis is another mesophilic bacterium, which has been studied in detail for its cold shock response. Similar to *E. coli*, *B. subtilis* also has a family of multiple CspA homologs. The three CspA homologs, CspB, CspC, and CspD, are essential for efficient growth at optimum temperature, efficient adaptation to low temperatures, and survival during stationary phase (64).

In addition to these CspA homologs, 37 other proteins were induced after temperature downshift from 37 to 15 °C in the case of *B. subtilis*. These proteins function at various levels of cellular physiology, such as chemotaxis (CheY), sugar uptake (Hpr), translation (ribosomal proteins S6 and L7/L12), protein folding (peptidyl propyl *cis*/*trans* isomerase), and general metabolism (cysteine synthase, ketol-acid reductoisomerase, glyceraldehyde dehydrogenase, and triosephosphate isomerase) (6,49). Table 1 summarizes Csps from *E. coli* and *B. subtilis*.

Table 1. Cold Shock Proteins of *E. coli* and *B. subtilis* and Their Functions

Proteins	Functions
E. coli (4)	
CspA, CspB, CspG, CspI	Proposed RNA chaperones
CsdA	RNA unwinding activity
RbfA	Ribosomal binding factor
NusA	Transcriptional termination and antitermination
PNP	Ribonuclease
RecA	Recombination factor
IF-2	Initiation factor
H-NS	Structuring chromosomal DNA
α-Subunit of DNA gyrase	DNA supercoiling
Hsc66, HscB	Cold shock molecular chaperones
Trigger factor (TF)	Maintenance and repair of proteins
Dihydrolipoamide transferase	Energy generation
Pyruvate dehydrogenase	Energy generation
B. subtilis (6,48)	
CspB, CspC, and CspD	Proposed RNA chaperones, initiation of translation
CheY	Chemotaxis
Hpr	Sugar uptake
Ribosomal proteins S6 and L7/L12	Translation
Peptidyl prolyl *cis*/*trans* isomerase	Protein folding
Cysteine synthase	Amino acid synthesis
Ketol-acid reductoisomerase	Amino acid synthesis
Glyceraldehyde dehydrogenase	Glycolysis
Triosephosphate isomerase	Glycolysis
Fructosebisphopshate aldolase	Glycolysis
Enterochelin synthase	Synthesis of enterochelin

CspA Family of Csps. The first Csp, CspA, was reported from *E. coli* (50,63) and since then its homologs, which constitute a subgroup of Csps, have been reported from a number of gram-positive and gram-negative bacteria, including psychrophilic, psychrotrophic, mesophilic, and thermophilic strains. CspA homologs have not been reported in archaea and cyanobacteria.

The CspA family of *E. coli* consists of nine homologous proteins, CspA to CspI, but among them only CspA, CspB, CspG, and CspI are cold shock–inducible. Transcription of *cspD* is dramatically induced upon stationary phase and upon glucose starvation, the induction being independent of the stationary phase sigma factor σ^s (65). CspC and CspE are produced at 37 °C and were identified originally as multicopy suppressors of a temperature-sensitive chromosomal partition mutant (66). Judging from the chromosomal location of the *csp* genes, it has been proposed that the large CspA family probably resulted from a number of gene duplications, and after subsequent adaptation, resulted in specific groups of genes that respond to different environmental stresses, for example, *cspA, cspB, cspG*, and *cspI* for cold shock, *cspD* for nutritional deprivation (1). Despite being the major Csp of *E. coli, CspA* is dispensable at both optimum and low temperatures. In a *cspA* deletion mutant, the production of CspB and CspG increased, suggesting that these proteins can compensate for CspA and probably have overlapping functions (67). Recently, it has been shown that deletion of *cspA, cspB, cspG*, and *cspE* resulted in cold sensitivity (68). CspA is differentially regulated from CspB, CspG, and CspI (53,69). The induction of CspA is observed after temperature shift from 37 to 30 °C, and high levels of CspA production are seen between 24 and 10 °C. CspB and CspG are produced only as temperature shifts below 20 °C, the maximum induction being at 15 °C. CspI is induced between 15 and 10 °C. Recently, it has been shown that CspA, CspB, and CspG are induced at low temperature under conditions that completely block protein synthesis (70). In the case of *B. subtilis*, a *cspB*/*cspC*/*cspD* triple deletion mutation was lethal, indicating that a minimum of one CspA homolog is essential for the viability of the organism, CspB being the most important of the three (64).

Regulation of CspA Family of Proteins. Expression of CspA is regulated at levels of transcription, translation, and mRNA stability. CspA is subject to transcription attenuation by virtue of the unusually long 5′ untranslated, highly conserved region (5′-UTR). It contains a unique 11-base sequence called the *cold box*, which is highly conserved in the cold shock genes. The cold box is a presumed transcriptional pausing site and is involved in the repression of cspA expression. It is proposed that CspA autoregulates its gene by attenuation of transcription (71). Immediately after the temperature downshift, RNA polymerase somehow bypasses the pausing site in the *cspA* mRNA. However, as cellular CspA concentration increases during the lag phase, CspA starts to bind its own mRNA to destabilize the elongation complex of RNA polymerase, leading to the attenuation of transcription. This is substantiated by the observation that overproduction of 5′-UTR at 15 °C resulted in the prolonged synthesis of not only CspA but also CspB and CspG (71,72). However, coproduction of CspA together with its 5′-UTR suppressed these effects.

It has also been shown that CspE negatively regulates the expression of CspA at the level of transcription (73). Using in vitro transcription assays, it was shown that CspE increases the efficiency of pausing by RNA polymerase. This is achieved by direct binding of CspE to the cold box region of *cspA*. This result is substantiated by the observation that *cspA* expression was derepressed at 37 °C in a *cspE* deletion mutant (73).

The dramatic stabilization of *cspA* mRNA (half-life more than 20 minutes) immediately following cold shock is another mechanism involved in the regulation of *cspA*. The *cspA* mRNA is extremely unstable at 37 °C (half-life less than 12 seconds). This stabilization is transient and is lost once cells are adapted to low temperatures. Deletion analysis of the *cspA* 5′-UTR showed that this region is responsible for its extreme instability at 37 °C and has positive effect on mRNA stabilization at low temperatures (74). Three base substitution mutations within the 159-base 5′-UTR caused 150-fold stabilization of *cspA* mRNA at 37 °C, which in turn resulted in the constitutive expression of *cspA* at 37 °C. This clearly indicates that the *cspA* promoter is active at 37 °C. This stabilization was found to be at least partially due to the resistance against RNase E degradation (75). It has also been suggested that *cspA* transcription is enhanced by an AT-rich sequence (upstream (UP) element) immediately upstream of the *cspA* promoter (74,76). Deletion of this region resulted in the diminished activity of the *cspA* promoter (74). In contrast to the induction of proteins by heat shock, the cold shock induction of *cspA* does not need any additional transcription factors.

Recently, significant production of CspA was detected in the early exponential phase at 37 °C. This high level of CspA expression was thought to be caused by (*1*) favorable gene dosage effect, as *cspA* maps near *oriC*; (*2*) the high concentration of its transcription activator Fis; and (*3*) higher stability of *cspA* mRNA due to lower RNase activity. With increasing cell density, the disappearance of Fis, accompanied by the accumulation of H-NS (transcriptional repressor) causes a reduction in the *cspA* transcript, and *cspA* mRNA disappears rapidly as a result of its increased rate of degradation (77). Later on, it was shown that this high level of CspA is due to the nutritional upshift and that the induction level is one-sixth of its cold shock induction level. It was also found that CspA induction can be achieved not only by the culture dilution but also by the simple addition of nutrients (78).

It has also been reported recently that polynucleotide phosphorylase selectively degrades *cspA* mRNA at 15 °C (79). It represses production of CspA homologs at the end of the lag phase. A similar phenomenon was also observed in the case of *Yersinia enterocolitica* (80). The exact mechanism of the selectivity is not known.

The *cspA* expression is also regulated at the level of translation. The *cspA* mRNA contains a sequence located 14 bases downstream of the initiation codon, designated as the downstream box (DB). The DB is also present

in CspB, CspG, CspI, CsdA, and RbfA (53,74,81,82). At 15 °C, there is a defect in the initiation of translation at low temperatures (83). It has been suggested that upon cold shock, ribosomes become nonfunctional for cellular mRNAs, except for mRNAs for Csps. DB may enhance the translation initiation by facilitating the formation of a translation preinitiation complex by binding to 16S rRNA. By having the DB, the *cspA* mRNA may be able to bypass the requirement of ribosomal factors such as RbfA and CsdA for translation initiation at low temperatures. Thus, DB increases translational efficiency for the mRNAs for Csps. After the lag period, however, cold-unadapted ribosomes are converted to cold-adapted ribosomes by acquiring cold shock ribosomal factors such as RbfA and CsdA, which are produced during the acclimation phase (84). Recently, Moll and coworkers proposed that there is no interaction between the DB and the 16S rRNA in translation initiation. However, they maintained that the DB might still enhance translation initiation in particular mRNAs. The exact mechanism of this event needs to be explored (85).

Bacillus subtilis csps, like *E. coli csps*, also have 5′-UTR regions, which are supposed to be implicated in the autoregulation of these genes. The artificial induction of CspB from *B. subtilis* in *E. coli* at 37 °C led to a marked decrease in cellular growth and a change in the pattern of protein synthesis. Hence, it was suggested that the change in the protein synthesis in response to cold shock is, at least in part, achieved by induction of Csps (86).

The CspA homologs are reported from a number of other mesophilic bacteria such as *Salmonella typhimurium* (87), *L. lactis* (14), *L. plantarum* (88), and *Enterococcus faecalis* (89). *Salmonella typhimurium* is similar to *E. coli* with respect to the regulation of the expression of CspA by mRNA stabilization and the presence of the UP element. *Lactobacillus lactis* differs from *E. coli* by lack of any lag period after the temperature downshift. Thermophilic bacteria, such as *B. caldolyticus* and *Thermotoga maritima*, also contain the CspA homologs. The CspA homologs from these bacteria are more stable than their mesophilic counterparts (90). A recent report shows that arginine3 and leucine66 confer thermostability to the CspA homolog from *B. caldolyticus* (91).

Structure and Function of CspA Homologs. CspA from *E. coli* binds RNA without apparent sequence specificity and with low binding affinity (92). It has been shown that CspA increases the translation of its own mRNA and renders the mRNA more susceptible to RNase degradation. At low temperature, secondary structures in the RNA are stabilized, and these are resistant to degradation by RNases. CspA destabilizes these structures. This is probably crucial for efficient translation at low temperature, as keeping mRNA in a linear form is an essential prerequisite for the efficient initiation of translation. Hence, CspA is proposed to act as an RNA chaperone (92). The nonspecific and weak binding of CspA to RNA and DNA is also important for the chaperone function, as this binding would not hamper ribosome movement on mRNA. CspB, CspG, and CspI are also speculated to function as RNA chaperones. *Bacillis subtilis* Csps were also proposed to act as RNA chaperones (8,64).

The three-dimensional structures of CspA from *E. coli* and CspB from *B. subtilis* have been resolved by X-ray crystallography and nuclear magnetic resonance analysis (93–97). These proteins fold in a two-state mechanism very rapidly without intermediates. They are marginally stable in solution. Two-state folding and a native-like activated state of folding seem to be inherent properties of these proteins (98,99). The protein consists of five antiparallel β-strands, β1 to β5, forming a β-barrel structure with two β-sheets. The protein has two RNA-binding motifs, RNP1 and RNP2, located on the β2 and β3 strands, respectively. The seven aromatic residues present on the surface of the protein are involved in the hydrophilic interactions between protein and nucleic acid. Mutations of three phenylalanine residues from the aromatic cluster adversely affected the DNA binding in the case of CspA from *E. coli* (100). Similarly, in the case of CspB from *B. subtilis*, the nucleic acid binding as well as the protein stability were abolished by the mutations in the two RNP sites (101,102). This surface patch has a functional role in single-stranded nucleic acid binding and it is also critical for maintaining the stability of the protein. This suggests that stability and function may have coevolved in these RNA- binding proteins. The protein has overall negative surface charge with a positively charged aromatic nucleic acid binding surface. After binding of the Csp protein to RNA, which may involve stacking of the aromatic side chains with RNA bases, the approach of other RNA for intramolecular or intermolecular base pairing will be prevented by charge repulsion. Hence, this structure is ideal for its proposed role as an RNA chaperone (8,64).

Hanna and Liu (103) demonstrated that CspE is implicated in transcription regulation. Interaction of CspE with nascent RNA during transcription elongation was detected by RNA-protein cross-linking. In addition, purified CspE was found to interfere with Q-mediated transcription antitermination. Recently, Bae and coworkers showed that CspA, CspE, and CspC decreased transcription termination at several intrinsic terminators and also decreased transcription pausing. They proposed that cold shock induction of *nusA, infB, rbfA*, and *pnp* might occur through transcription antitermination mediated by CspA and its homologs (104).

In the case of *B. subtilis*, if the levels of CspA homologs are experimentally reduced after temperature downshift, an decrease in overall protein synthesis is observed along with changes in the pattern of protein synthesis and significant reduction in the growth of the organism (64). Hence, increased levels of CspA homologs after cold shock appear to be important for compensating for higher stability of secondary structures in RNA at low temperatures.

It has been shown that CspB, CspC, and CspE can interact with RNA and single strand (ss) DNA sequence selectively. The preferred sequences for binding of these proteins are UUUUU, AGGGAGGGA residues, and AU-rich regions, respectively. This suggests that they may have additional functions than that of CspA (105). Recently, CspB from *B. subtilis* was shown to interact preferentially with polypyrimidine, especially T-based ssDNA templates (106,107). The in vivo significance of

these findings remains to be elucidated. Recently, CspC and CspE were shown to be involved in the regulation of UspA, RpoS, and subsequently RpoS-regulated stress proteins such as OsmY and Dps (108). It has also been shown that CspD forms a dimer, and with two independent β sheets interacting with ssDNA, functions as an inhibitor of DNA replication and may play a regulatory role in chromosomal replication in nutrient-depleted cells (109).

Proteins Analogous to CspA. Cyanobacteria, such as *Anabaena variabilis*, do not contain CspA homologs, but they have a family of cold-inducible RNA-binding proteins (Rbp) (110). These are similar to RNA-binding proteins from eukaryotes. These belong to the RBD (RNA-binding domain) family of proteins, which is structurally different from the CSD (cold shock domain) family of proteins. RBD and CSD seem to perform a similar function and have similar nucleic acid–binding surface, yet appear to evolve independently. This represents a very interesting case of convergent evolution in the sense that Rbp proteins could be the cyanobacterial counterparts of CspA from gram-positive and gram-negative bacteria (8,111).

In addition to Rbps, the other proteins that are induced in cyanobacteria after the temperature downshift are Clp proteins, the S21 protein in the small subunit of ribosome, and RNA helicases (112,113).

In the case of *A. variabilis*, four *rbp* genes (*rbpA1*, *rpbA2*, *rbpA3*, and *rbpC*) are regulated by cold. The level of the mRNAs for *rbp* genes increases transiently after the temperature downshift, whereas the level of corresponding proteins increases gradually and remains maximal for 24 hours after the downshift in temperature from 38 to 22 °C (112).

Transcription of the *rbpA3* gene is dependent on two different promoters, one of which is active at high temperature and whose activity is suppressed at low temperatures. The activity of the other promoter transiently increases after the temperature downshift. A putative cold-responsive *cis*-acting element in the 5′-UTR of the *rbpA1* gene has been identified. A 150-bp region between the initiation of transcription and a ribosome-binding site is absolutely necessary for its cold-induced transcription. Deletions within this region resulted in constitutive transcription at 38 and 22 °C. This suggested that transcription of the *rbpA1* gene at higher temperature might be repressed by a repressor protein. Two putative repressor proteins of about 75 and 32 kDa have been suggested to be candidates for controlling the activity of this gene. Whether these proteins are indeed the regulators of the cold shock response for this organism needs to be further explored (114).

Two genes for RNA helicases, *crhB* and *crhC*, have been identified in *Anabaena* sp. PCC 7120 (115). The *crhB* gene is expressed under a variety of stress conditions such as cold stress, salt stress, and nitrogen limitation, whereas the expression of CrhC occurs exclusively in response to cold stress. It has been suggested that CrhC has a role in the destabilization of the secondary structures of mRNAs, which allows the cells to overcome the cold-induced blockage of the initiation of translation that occurs at low temperatures (115). The cold shock induction of *crhC* is regulated at levels of transcription and translation. Similar to *cspA* of *E. coli*, *crhC* also contains an AT-rich UP element, a cold-box–like sequence, a long, highly structured 5′-UTR, and a DB.

The pattern of the cold-induced accumulation of S21 in cyanobacteria suggests that this protein may be involved in the cold acclimation of the translational apparatus, activity for which usually decreases upon exposure to cold shock (116).

Caseinolytic proteases (Clps) represent a new family of bacterial molecular chaperones that includes proteases that are expressed constitutively in some cases and induced by stress in others (117,118). ClpP1 is observed under cold stress and under UV light, and the amount of ClpP1 increases 15-fold within 24 hours of the temperature downshift (119). Deletion of its gene leads to severe impairment of growth at low temperatures.

ClpB in *Synechococcus* sp. PCC 7942 was identified initially as a heat-inducible molecular chaperone that is essential for the acquisition of thermotolerance. However, its synthesis is also strongly induced under cold stress. It has been suggested that ClpB may renature and solubilize aggregated proteins at low temperatures at which translation is repressed (120).

A low-temperature-inducible gene, *lti2*, in *A. variabilis* strain M3 was induced by temperature downshift from 38 to 22 °C, but its biological role remains to be elucidated (121).

COLD ACCLIMATION PROTEINS

Synthesis of Csps is an immediate response to cold shock, whereas cold shock acclimation proteins (Caps) are specifically synthesized during continuous growth at cold temperatures. Synthesis of Caps in mesophilic bacteria in response to continuous growth at low temperature has not been studied. *Enterococcus faecalis* is unique in the sense that despite being a mesophilic bacterium, along with 11 Csps, its cold shock response also includes 11 Caps (89).

The cold shock response of psychrophiles is well illustrated by studies on *Arthrobactor globiformis* (122,123) and *Pseudomonas fragi* (17). In the case of *A. globiformis*, four types of proteins are produced after the temperature downshift: Csps that are overexpressed only after large temperature downshift, Csps that are overexpressed after milder shocks, Caps, and late Caps. The presence of Caps is a general feature of cold-adapted microorganisms. These proteins may be involved in important metabolic function(s) at low temperature by maintaining membrane fluidity and/or by replacing cold-denatured peptides. A low-temperature-specific proteolytic system has been described for *A. globiformis* and some Caps may act as cold-specific proteases that eliminate denatured proteins whose accumulation can be detrimental to the cells. Also, unlike *E. coli*, the initiation of protein synthesis was much more resistant to a sudden decrease in temperature in the case of *P. fluorescens* (124). The CapA of *A. globiformis* is homologous to *E. coli* CspA. Posttranslational regulation has been suggested to account for the induction of the CapA mRNA. In the case of *P. fragi*, four homologs of CspA have been reported: CapA, CapB, TapA,

and TapB (temperature adaptation proteins). Persistent expression of CapA and CapB helps this organism to grow at low temperature (17).

In the case of psychrophilic and psychrotrophic bacteria, the synthesis of housekeeping proteins is never repressed following an abrupt temperature downshift, a large number of Csps are synthesized, relative level of Csps is moderate even after a severe cold shock, and synthesis of Caps is prolonged (122).

CONCLUSION

The organisms sense the temperature changes at the levels of cytoplasmic membrane, nucleic acid, and ribosomes. The content of UFAs in the membrane phospholipids increases to compensate for the reduced membrane functions at low temperatures. Shortening the fatty acid chain length and changing the branching of fatty acids from to *iso* to *anteiso* are also some of the important mechanisms for cold adaptation. Cold-inducible proteins are also important for cellular adaptation to low temperature. The cold shock response has been extensively studied in *E. coli* and *B. subtilis*. The expression of major *E. coli* Csp, CspA, is regulated at the levels of transcription, mRNA stability, and translation. Homologs of CspA are widely distributed in bacteria, and Rbps found in cyanobacteria are counterparts of CspA. Caps probably play an important role in cold acclimatization of psychrophilic bacteria.

One interesting question is why some bacteria, such as *E. coli*, have so many CspA homologs. Studies with multiple deletion strains of *cspA* homologs will help in answering this question. Csps are implicated in a number of functions, such as RNA chaperone, regulator of transcription and translation, but elaborate and extensive research is essential for thorough elucidation of their cellular roles. This is a limiting factor for the design of strategies for identifying the key regulatory elements responsible for the survival of the organism after cold shock. Understanding the expression of Csps and designing means of decreasing their accumulation can potentially reduce the efficacy of the cold shock response of food-poisoning bacteria and prevent their growth at low temperatures.

One of the major problems in expressing the recombinant proteins in *E. coli* to high levels is the formation of inclusion bodies, which are aggregates consisting mainly of the overproduced polypeptides. These proteins can refold in active conformation, but recovery yields are highly variable. Recombinant protein expression at reduced growth temperatures has the advantage of increasing the solubility of aggregation-prone recombinant proteins and limiting their degradation by heat shock proteases that are induced during the overexpression. However, efficiency of traditional promoters such as *tac* is strongly reduced at low temperatures. Hence, cold shock–inducible promoters are useful in directing the expression of recombinant proteins at low temperature. Using *cspA* promoter, β-galactosidase was efficiently expressed at low temperature (125,126).

The study of cold shock response in plants is essential for increasing stress tolerance and thus for reducing economic losses. In the case of mammals, it is gaining importance in areas such as storage of cells and organs, treatment of brain damage, and so forth. (127). These instances imply that in the future the study of the cold shock response is going to play a major role in biotechnology.

COLIFORM BACTERIA AS INDICATORS OF WATER QUALITY

EDWIN E. GELDREICH
Cincinnati, Ohio

The term *coliform bacteria* is perhaps the most common aquatic microbiological term used to define water quality in regard to fecal pollution. These bacteria are very common in the fecal tract of humans (10^7–10^9 per gram of feces), though their density is frequently exceeded by that of other fecal bacteria such as the strictly anaerobic *Bifidobacterium* (10^8–10^9 per gram) and *Bacteroides fragilis* bacteria (10^7–10^{10} per gram). Because detection of coliforms is less complex than a search for specific pathogens, these bacteria have traditionally been used as indicators of possible fecal contamination over the past century. During this time, a mass of microbiological data has been gathered from drinking water, recreational water, storm water, sewage, food-processing waste, landfill leachates, and ambient waters to demonstrate the usefulness of this indicator (1).

Coliform Bacteria: A Definition

"Coliform bacteria" by definition is an artificial grouping of convenience that encompasses a variety of common bacteria found in the intestinal tract and fecal discharges of humans and other warm-blooded animals. These organisms are gram-negative, non–spore-forming bacilli that ferment lactose (35 °C within 48 hours) with acid and gas production under facultative anaerobic conditions (2). Although this definition is useful for methodology use for multiple tube tests, the definition has been extended to the membrane filter testing approach to include detection of aldehydes. Similarly, the coliform definition was further expanded for the chemically defined test procedure to include metabolic activity for cleaving the enzyme β-D-galactosidase. Such differing characterization among coliform tests leads to a small but recognizable difference (about 5%) in the detected "coliforms" among the three different procedures.

Profile of Species. Profiling coliform species in feces reveals a number of factors that influence the makeup of the coliform population (2). The varied diet of humans and chickens appears to be a major reason there may be a large number of species and variants in strains found in the feces of these warm-blooded animals. Another factor is the exposure to antibiotics in food and medication. For example, as most humans have a predominance of *E. coli* in their intestinal tract, there may be a temporary predominance of *Klebsiella* in those individuals under medication. Coliform profiles in cows, pigs, and sheep reveal the species of coliforms to be almost exclusively *E. coli*. Fish and other cold-blooded animals have no permanent coliform flora; those present are transient in nature (lasting only a few weeks) and reflect the food and water supply in the animal's environment. Vegetation appears to have a predominance of *Klebsiella* and *Enterobacter* species that are environmental coliforms

Table 1. Enteric Bacterial Profiles in Raw Industrial Wastes

Enteric Bacteria	Occurrences (%)			
	Wood Pulp and Paper	Food Processing	Meat Processing	Municipal Sewage
Coliform species				
Escherichia coli	0.4	35.0	56.9	62.0
Klebsiella pneumoniae	92.3	55.0	21.5	18.0
Enterobacter species	6.7	3.3	13.8	14.3
Other bacterial genera				
Pectobacterium species	0.6	6.0	0.5	3.6
Salmonella species	0.008	0.7	7.3	2.1

of limited sanitary significance. This profile may change if the plants are exposed to fecal discharges of wildlife, storm water runoff, or poor-quality irrigation water. Coliforms in soil reflect contact with wildlife, agricultural use of land, or the influence of residential septic tanks and poor sewage collection systems. Thus, it is not surprising that soils gathered from remote regions of the Earth have very few fecal coliforms, whereas those in the pathway of sewage discharges may be overburdened by fecal contamination that is not reduced through natural self-purification processes in the environment. Other coliform species including *Klebsiella pneumoniae*, *Enterobacter aerogenes*, *Citrobacter freundii*, and various subspecies variants may also be detected in vegetation and soil. Furthermore, these coliforms often become the major part of the flora in a water biofilm occurrence, that is, water supply distribution systems, and in industrial processes impacted by biofouling, such as paper mill effluent and food-processing wastes, and their receiving waters downstream of discharge (1,3,4).

No single coliform species is permanently predominant in wastewaters from industrial activities, being subject to the individual processing conditions from which the organisms were introduced. However, there is a trend for certain coliform species to be found in the majority of these waters. For example, as shown in Table 1, waste in domestic sewage that does not include some industrial discharges most likely will have *E. coli* as the predominant coliform species. *Klebsiella pneumoniae* often predominates in paper mill wastes, whereas food processing discharges contain a fluctuating mix of environmental strains and some fecal contamination acquired during agricultural production.

Drinking water regulations limit the presence of coliforms in a safe water supply and when found are often the result of treatment problems or loss of distribution system integrity (Table 2). It is important to note that although a few coliforms may occasionally be tolerated in water supply (less than 5% occurrence during the month), none of these bacteria should be *E. coli*. If *E. coli* is detected, the water supply must be put on "boil water" advisory because of the concern for fecal contamination. Origin of the various non-*E. coli* strains shown in Table 2 reflects the intrusion of environmental strains from soil around a leaking or broken pipe segment or the development of a biofilm in the distribution system.

Table 2. Coliform Species Identified from 111 Public Water Distribution Systems in North America

Citrobacter	*Escherichia*
C. freundii	*E. coli*
C. diversus	*Klebsiella*
Enterobacter	*K. pneumoniae*
Enter. aerogenes	*K. rhinoscheromatis*
Enter. agglomerans	*K. oxytoca*
Enter. cloacae	*K. ozaenae*

COLIFORM SUBGROUPS AS INDICATORS

Although the majority of total coliform bacteria detected by lactose fermentation at 35 °C are found in the warm-blooded intestinal tract, the test is not specific to strains only of sanitary significance. Other coliform bacteria in the aquatic environment originate from soil and vegetation. This situation, therefore, requires careful consideration of the interpretation of total coliforms found in ambient waters and restricts their significance in treated water to that of a measure of process effectiveness.

Fecal Coliforms. In an effort to obtain a more precise measure of the coliforms associated with fecal pollution in the aquatic environment, Eijkman (6) proposed that public health authorities focus on the subgroup that produces gas from glucose at 46 °C, because coliforms that did not originate from the intestinal tract of warm-blooded animals would not survive this incubation temperature during cultivation. Unfortunately, this differential characteristic proved to be of low sensitivity. Various combinations of differential biochemical reactions (indole, methyl red, Voges-Proskauer, citrate utilization, hydrogen sulfite production, and so on) were then proposed in an effort to be more specific in this grouping of significant coliform bacteria. Again, classification was not clear-cut largely

because of the diversity of species included in the definition for all coliform bacteria (gram-negative bacilli that are non–spore-forming and facultative anaerobic, producing gas and leading to aldehyde formation from lactose fermentation within 48 hours at 35 °C).

Returning to the original concept of Eijkman, Perry and Hajna (7) redesigned the glucose medium base to include bile salts for selectivity and a buffer system as a barrier to low pH from metabolic activity in cultivation. They also reduced air temperature incubation to 45.5 °C (±0.5 °C) because even fecal coliforms die rapidly at temperatures above 46 °C. Any further reduction of temperature below 44 °C provided an opportunity for more of the environmental coliforms to survive and produce false-positive results.

Extensive studies of this concept by Geldreich and coworkers (3) on feces from a wide selection of animals, vegetation, soil, municipal waste effluents, industrial wastes, ambient freshwaters, coastal waters, and drinking water supplies led to the following conclusions:

- The most acceptable incubation temperature for differentiating the fecal group of coliforms is 44.5 °C (±0.2 °C), provided the temperature is precisely controlled in a water bath or a heat sink incubator.
- Elevated temperature incubation (44.5 °C) for positive lactose fermentation would exclude a variable small percentage of some stressed fecal coliform strains in the trade-off to eliminate those coliforms of no sanitary significance.
- Preliminary incubation for two hours at 35 °C, before selective growth at 44.5 °C, to improve recovery of any stressed fecal coliform strains may be counterproductive because some nonfecal coliforms may survive to give a false-positive result.
- Although *E. coli* is the predominant fecal coliform, there may be occasions when fecal *Klebsiella* are the organisms in dominance, such as in paper mill waste and sugar refining, but these often may be traced to combine sanitary waste introduced into plant operations.
- Provided these test conditions and environmental factors are understood, there is an excellent correlation between positive test results and those coliforms originating from the feces of warm-blooded animals.

After years of field testing and the development of specific fecal coliform procedures (A-1 medium for use in a multiple-tube procedure for testing shellfish waters and M-FC medium for the membrane filter procedure used for examining freshwater and wastewater), the fecal indicator concept has become established internationally and is used in a variety of water quality standards. The test has proven to be far superior to the total coliform concept as an indicator of sanitary significance for a variety of pollution monitoring situations.

***Escherichia coli*: A Fecal Indicator.** Efforts have been made to further narrow the detection of fecal coliforms to a specific indicator for *E. coli* (8). Rather then rely solely on fermentation in a lactose medium at 44.5 °C incubation temperature to screen out environmental strains of limited sanitary significance, detection is based on the recognition of special metabolic pathways in the test concept that is specific for most strains of *E. coli*. In this approach, *E. coli* is defined as coliform bacteria that possess the enzyme β-glucuronidase and are capable of cleaving the fluorogenic compound 4-methylumbelliferyl-β-D-glucuronide (MUG) with the corresponding release of the fluorogen when grown in EC-MUG medium at 44.5 °C within 24 hours. As is done in fecal coliform multiple-tube or membrane filter tests, this differential procedure is used as a confirmatory test, not being used directly on a water sample. Only the chromogenic chemically defined substrate medium, which incorporates the MUG reagent, can be used in a direct test of a water sample (9). In any of these procedures, fluorescence produced is observed by viewing the culture under a long wavelength ultraviolet (UV) light. The production of fluorescence by any of these methods, after appropriate culturing of the water sample, is an indication of a positive response to *E. coli* occurrence.

Unfortunately, these tests for *E. coli* and others for fecal coliforms may not detect the pathogenic *E. coli* 0157 : H7. This pathogenic *E. coli* serotype does not grow well at 44.5 °C, poorly ferments lactose, and does not produce a positive reaction in media that incorporate MUG as a reagent for differentiating *E. coli* (10). Screening for this pathogen generally is done on total coliform media incubated at 35 °C, with growth in the medium streaked onto sorbitol agar plates. Any colonial growth that produces white colonies indicates that the organism does not ferment sorbitol and may be *E. coli* 0157 : H7. These colonies are further tested for glutamate decarboxylase followed by serotyping. False-positives occasionally are encountered, one of which may be with Shigella, but because both these organisms are pathogenic, such occurrences are not considered to be a detriment to the test results.

Restricting the test to *E. coli* does result in some variable loss of recognition for other fecal coliform organisms. Approximately 30 to 40% of all warm-blooded animals, humans included, have *Klebsiella* in their intestinal flora, with individual densities ranging up to 10^8 *Klebsiella* per gram of feces (11,12). *Klebsiella* occasionally may predominate among coliforms profiled in the intestinal flora of a single individual for over a few weeks to several months. The cause often is the diet or the medical therapy. Approximately 60 to 80% of all *Klebsiella* from feces and clinical specimens are positive in the fecal coliform test. However, this trade-off in using a specific *E. coli* test also rejects the environmental strains of *Klebsiella pneumoniae* that occasionally appear when examining site-specific receiving waters downstream of nutrient waste discharges.

***Klebsiella*: A Biofilm Indicator.** The *Klebsiella* genus consists of *Klebsiella pneumoniae*, *K. oxytoca*, *K. planticola*, *K. terrigena*, *K. ozaenae*, and *K. rhinoscheromatis*. Most of these species are widely distributed in nature, occurring in soil, water, grain, fruit, vegetables, dairy products, hay, and cotton. Only those *Klebsiella* strains that are positive by the fecal coliform test (ferment lactose with gas production at 44.5 °C) are considered *K. pneumoniae* (13). This

characteristic is important because many of the commercially available differential test kits used for speciation of the coliform group do not take this parameter into account. Those coliform strains that yield biochemical profiles identical to that of *K. pneumoniae*, but negative in the fecal coliform test, may be speciated by their ability to ferment D-melizitose and grow at 10 °C. These latter strains (that should be designated as a separate species) have their origins in the aquatic environment, may be the predominant coliform in water pipe biofilm, and are of little sanitary significance.

Because environmental *K. pneumoniae* variants have been isolated from water and nutrient-conducting tissues of trees as well as from the seed embryos (14,15), it is not surprising to detect these coliforms in industrial wastes from wood pulp and paper mills. Other wastes containing significant densities of klebsiellae are textile finishing plants and sugarcane or sugar beet processing operations (16,17). Densities may range from 10^4 to 10^6 *Klebsiella* per milliliter and represent 50 to 90% of the total coliform populations in these effluents (18). As a consequence, surface water and unprotected groundwater receive *Klebsiella* from both environmental and fecal sources in storm water runoff over the water shed and effluents from municipal sewage treatment plants.

Many of the water systems reporting coliform occurrences in their distribution networks have noted that the predominant organism was a member of the *Klebsiella* genus (4,19). Most of these species have been detected in coliform-contaminated public water systems (Table 2). These organisms can be shielded by particulate materials, porous pipe sediments, biological debris, macroinvertebrates, and disinfectant demand products in the water. Furthermore, encapsulation of these coliforms can occur in hostile water environments, triggered perhaps by phosphates and depletion of iron and magnesium salts. This capsular slime coating around *Klebsiella* cells provides a measure of protection from the effects of chlorine and other disinfectants, and the organisms adjust their metabolism to survive by accumulating nutrients (assimilable organic carbon) adsorbed by pipe sediments. Once these organisms become established in the pipe environment, growth beyond meager subsistence eventually creates a biofilm that periodically sloughs cells into the flow of water traversing the pipe network.

Klebsiella colonization in the drinking water distribution system has led to much discussion and controversy about their public health significance in water supply (20,21). No evidence appears to be currently available to suggest that pathogens would similarly grow in these biofilm communities. Nevertheless, the appropriate action is to flush the entire distribution system and apply appropriate disinfection. After all, these are coliform bacteria and their presence suggests either a lack of adequate treatment at the plant or a deterioration in the cleanliness of the pipe network.

Use of a differential test for *Klebsiella* in the total coliform population of a natural water sample can provide evidence of excessive nutrients in source waters or the existence of biofilm sites in water supply distribution systems. Such a medium (M-Kleb agar) containing carbenicillin and adonitol has been used to selectively cultivate (18–24 hours at 35 °C) *Klebsiella* from other species in the total coliform population (12). Thus, parallel testing for profiling total coliform, fecal coliform, *E. coli*, and *Klebsiella* may be performed on a single water sample using appropriate membrane filter tests, and quantitative results can be achieved within 24 hours.

Opportunistic and Pathogenic Coliform Species

Although the vast majority of coliform bacteria in the warm-blooded intestinal flora are harmless, there are some serious exceptions for a few coliform strains. These opportunistic coliforms may present a public health risk to newborns, senior citizens, and immunocompromised individuals in the community. Exposure to some *E. coli* serotypes that are overt pathogens in contaminated water supply would appear to be an even more disastrous event because so many more people become ill in the community.

Opportunistic pathogens are organisms that, when found in large numbers and in the wrong place at the right time, have the potential to cause infection. Potential locations for large densities of these organisms in the water environment include dead ends and slow-flow sections of a water supply distribution pipe network, building plumbing lines that are static from minimal use, and various water line attachment devices (treatment units, humidifiers, faucet antisplash screens, and showerheads). The routes of exposure may be drinking water (ingestion), bathing or swimming (body contact), and inhalation of water vapors (air-cooling devices and fountains). For most people, these types of exposure are of no consequence because the natural defense mechanisms of the human body provide a shield to invasiveness, colonization, and infection.

Opportunistic *Klebsiella*. Among the total coliform bacteria, some *Klebsiella* strains can be opportunistic pathogens and are among the causes of illness reported in hospital records. *Klebsiella pneumoniae*, particularly antibiotic-resistant serotypes, can cause infections of the human respiratory system, genitourinary tract, nose and throat, and occasionally meningitis and septicemia (22,23). *Klebsiella*-caused infections sometimes are of apparent primary etiology, but more often are found in mixed infections or as a secondary invader (24). In the hospital environment, the nosocomial pathogen infection rate was reported to be 16.7 infections per 10,000 patients from 94 hospitals (25). *Klebsiella pneumoniae* was the cause of 1.1% of all nosocomial hospital deaths during the same period. Infections of the urinary system, lower respiratory tract, and surgical wounds were the most frequent cause of *Klebsiella*-associated illnesses or deaths.

Most of the *Klebsiella* in waterborne occurrences are not of fecal origin. In those infrequent situations in which the laboratory analyses reveal a few fecal *Klebsiella* in hospital water supply lines or their attachment devices, efforts must be made to destroy the colonization sites in an attempt to prevent amplification of this opportunistic pathogen to infective dose levels. Infective dose (ID_{50}) values for environmental and clinical isolates of *Klebsiella* have been reported to be between 3.5 and 10^1 to 7.9×10^5

cells per milliliter (26). Therefore, inhalation of moisture from vaporizers using drinking water contaminated with opportunistic fecal *Klebsiella* should be considered a risk to some individuals.

Pathogenic *E. coli.* Primary pathogens in water supply may cause illness among a large number of people in the community and frequently result in deaths among those individuals in a poor state of health (particularly individuals in extended medical care facilities), children, and senior citizens. Other factors to consider include route of exposure, application of water (ingestion, inhalation, or body contact), and dosage (density of pathogen in water). The onset of illness may begin in a few hours or may take several days after a critical exposure to contaminated water supply. The infection may result in no overt symptoms in some individuals, but in the vast majority of people infected there is pronounced illness, often involving diarrhea, bed rest, and lost of normal activity for days.

Most *E. coli* strains are harmless coliforms that live in the intestinal tract of warm-blooded animals including humans, pets (cats and dogs), farm animals (cows, pigs, sheep, and horses), and wildlife (birds, rodents, deer, and so on). However, among the bacterial, viral, and protozoan pathogens that may contaminate an unprotected or poorly treated water supply is a group of pathogenic *E. coli* that causes severe gastrointestinal illness (10). Most common victims are small children in developing countries, who have yet to develop an immunity to these exposures, and travelers to those regions. Symptoms often are watery diarrhea, abdominal pain, vomiting, and in some cases a low-grade fever and bloody stool.

Various pathogenic *E. coli* have been further characterized based on the serological and the virulence characteristics into the following subgroups: enterotoxigenic (producing toxins), enteroinvasive (colonizers of the tissues of the small intestine), or enterohemorrhagic (causing a bloody diarrhea). Incubation period for these pathogens to colonize the intestinal tract and produce symptoms is quite variable, ranging from less then 24 hours to several days, and the duration of the illness varies from three days to several weeks, depending on the virulence characteristics, health status of the person, and effectiveness of medical intervention. In every respect, these *E. coli* are primary pathogens in food and water supply contaminated by domestic sewage, livestock, or wildlife. (Details of these pathogenic strains of *E. coli* are given in E. COLI: PATHOGENIC STRAINS.)

Reassessing Coliform Interpretations

Continuing research into the science of environmental microbiology and numerous field experiences over the years have demonstrated that total coliform bacteria are not always indicators of sanitary significance (27,28). Part of the problem with erratic correlations to pathogen occurrence lies in the greater sensitivity of coliforms to disinfection agents than some waterborne agents. The other factor is that the traditional search for coliforms in water is based on the conventionally accepted protocol to test 100 ml of sample, the reason being that this amount of drinking water represents the average amount ingested at a given time. If no coliforms are found in this test volume, the assumption is that the water quality is excellent and does not provide a risk to public health. In contrast, in the search for pathogens, the sample test size is often a liter for bacterial pathogen agents and 100 liters or more for viruses and protozoan parasites. These test volume differences also apply to the microbial standards established worldwide for water quality in recreational waters, irrigation waters, and municipal wastes.

A reality check suggests that any attempt to increase the size of the test portion to one liter or more for routine coliform analysis would be impractical because increased cost for sample transport from the field to a laboratory would be significant, laboratory processing options for larger samples are limited, and possible increased interference from turbidity and other bacteria in the water sample make coliform detection difficult. Additional concerns include increased laboratory cost for additional equipment and test materials (laboratory hardware, media, and so on) and the need to upgrade operational skills for the average laboratory technician. As a side issue, many water plant operators are fearful that any change in the test baseline or decrease in the percent of coliforms permitted in total samples examined during the month might make the utility out of compliance. Similarly, changes in recreational water quality standards are often resisted by public and local government officials who are fearful that bathing beach closures will be more frequent and unreasonable. These negative concepts suggest that any primary thrust toward improved water quality through refinements in monitoring, revised standards, treatment, and compliance legislation must also include public recognition of the cost-benefit trade-off and a basic understanding of risk acceptance.

The search for a better indicator or at least a major refinement in the coliform indicator concept is in order and long overdue. Other indicator systems, such as fecal streptococci, *Clostridium*, H_2S producers, *Bacteroides*, coliphage, aerobic spore-formers, and heterotrophic bacteria, have been offered as the ultimate answer for specific situations. Each of these candidates has its champion for acceptance, but each appears to fall short of acceptance for different reasons. Considerations in the evaluation of each candidate include exclusive fecal origins, parallel resistance to that of waterborne pathogens, occurrence in sufficient densities to measure treatment process efficiency, easy speciation in the laboratory, rapid-testing capability, and cost-effectiveness in a monitoring program. These requirements are very demanding, and no known indicator system is immune to some weakness that prevents universal acceptance as a stand-alone indicator system.

Water Supply. The most subtle change over the past 20 years of public health microbiology has been the general recognition that the coliform test as used in municipal water supplies is not so much a measure of sanitary significance but more an indicator of treatment operation-effectiveness (28). It is generally agreed that properly operated water treatment systems will inactivate or

remove all coliform bacteria, whether they are of sanitary significance or are merely harmless environmental strains. There is no excuse for coliform bacteria escaping the conventional treatment barrier. Coliform data trends observed in both pilot plant research and field experience have repeatedly shown that this indicator is too coarse a measurement to be used in treatment process adjustments for better barrier protection from intrusions of protozoan agents, viruses, and opportunistic pathogens. The fact remains that many pathogenic agents may penetrate some physical and disinfectant treatment process barriers (that is, coagulation, settling, filtration, and chlorination) that normally provide a safe margin of effectiveness for total coliform removal.

More rigorous tests of treatment-effectiveness must be explored. For example, coliphage mimics many of the properties of viruses and is more cost-effective in the performance evaluation process. *Clostridium* might be another promising surrogate for testing treatment barriers, although their densities are too low in natural waters to observe the desired 6 log removals that are necessary for protection from pathogen incursions. The use of aerobic spore-formers in the evaluation of treatment performance appears to be more promising for several reasons: aerobic spore-formers are common in aquatic waters and very resistant to chlorination, do not multiply in treatment processes as a result of increased assimilable organic carbon (AOC) after ozonation, and are simple to cultivate (29). Furthermore, physical removal of aerobic spore-formers appears to parallel that of particle removals through different treatment configurations and has the added advantage of not breaking apart while passing through various unit processes. These characteristics may provide a critical parallel to the physical entrapment and removal of *Giardia* cysts and *Cryptosporidium* oocysts by various treatment processes.

Attempts have been made to improve the action response to coliform monitoring events in public water supplies. Regardless of the question concerning their poor correlation to some pathogenic agents in water supply occurrences, prompt action must be taken to verify and correct the problem. The new concept involves the use of a test for the presence or absence occurrence of coliforms per 100 ml (30,31). This qualitative approach ignores all concerns for a maximum permissible level of total coliforms in a mean value for all samples over a given month. Instead, frequency limits of 5% are placed on all coliform occurrences during the month.

For years, national regulations on drinking water quality have been based on a mean value derived from total coliform measurements gathered over each month. The limit was established at a geometric mean of one coliform per 100 ml. For many utilities experiencing coliform occurrences, the first reaction, when exceeding this limit, was to increase the number of samples taken over the next few days in an effort to drive the mean value down to below the one coliform per 100 ml limit so as to stay in compliance. Such action may have avoided a noncompliance issue but did not address why there were coliform bacteria at some location(s) in the distribution system. Now, with the opportunity to define water quality in terms of total coliform frequency (presence or absence) over a 30-day period and permitting up to 5% of coliform-positive samples during this interval, all positive samples have equal significance. In other words, a sample with only one total coliform has the same significance as another sample that may have many more coliforms per 100 ml. Unfortunately, the presence or absence procedure obscures the density in a coliform-positive sample, thereby providing no information on the magnitude of the contaminating event.

Recreational Waters. Epidemiological investigations on recreational waters have revealed poor correlations between bather illness and total coliform bacteria (32–35). These facts support the belief that this traditional indicator should be abandoned as worthless coliforms because of the predominance of environmental. More promising relationships may be found with such indicators as fecal coliform/*E. coli*, fecal streptococci/enterococci, and total staphylococci/*Candida albicans*. Much of the evidence points to the need to judge the quality of bathing waters with respect not only to fecal pollution but also to contamination introduced by bathers in close proximity. In fresh bathing waters, fecal coliform/*E. coli* and fecal streptococci/enterococci are the indicators of choice to measure the risk associated with gastrointestinal illness, whereas total staphylococci/*Candida albicans* are useful as predictors of illness associated with the ear, nose, and skin areas of bathers. These later health concerns have poor correlation with fecal contamination in bathing waters.

In marine waters, fecal coliform/*E. coli* may have an accelerated die-off that could distort correlations with pathogen occurrences. This may be the reason investigations of marine waters present some conflicting information on the use of fecal indicator bacteria (fecal coliform and fecal streptococci) as predictors of enterovirus occurrences. Important influences on the perception of safe bathing waters are the more rapid die-off of fecal indicator bacteria (fecal coliforms and *E. coli*) in marine waters, the recirculation of polluted waters near the beach, and the protection afforded to viruses in fecal cell debris.

Coliform bacteria (total or fecal coliforms/*E. coli*) are also a poor measure of body contact risks from opportunistic pathogens that occur in disinfected swimming pools, the exception being fecal contamination introduced into wading pools by small children. There is more interest in the use of enterococci and staphylococci to determine the extent of discrete pockets of epidermal cells and nasal, and saliva contaminants in the surface microlayer of water in the pool before dispersion. Additional useful information on water quality can be obtained by determining the magnitude of heterotrophic bacteria present in relation to the total number of bathers, a factor that is not possible with coliform measurements.

Nutrient Wastes. Extensive use of coliform tests worldwide has identified several disagreements in data interpretation from some types of waste discharges, namely, food-processing discharges, paper mill wastes, and animal feedlot operations (28,36,37). Several public health

concerns must be understood in these situations before drawing conclusions that the fecal coliform concept is invalid. Among these issues are the presence of thermotolerant strains of *Klebsiella*, nutrient waste loading impacts on receiving waters, depression of the natural self-purification capacity of these waters, and concern for extended survival of some bacterial pathogens downstream (38,39).

Sugar Processing Mills. Coliforms (particularly *Enterobacter* and *Klebsiella* strains) are commonly found on both sugar beets and sugarcane crops. These organisms contaminate the crop through application of poor-quality irrigation water, wildlife contact, and land application of farm animal manure if the fields are near cattle feedlots. Wildlife populations in sugar beet–growing areas include meadow mice, pack rats, Norway rats, pocket gophers, prairie dogs, and rabbits. It has been estimated that one acre of farmland may support 300 meadow mice and one square mile of similar agricultural fields can be the habitat for several thousand wild rabbits.

In separate studies of beet soil and beet surfaces from samples collected over five western states, fecal coliform results ranged from less than 2 to 230,000 per gram of material (40). Soil taken from trucks after unloading at the mill gave values of 10.9 to 700 fecal coliforms per gram. River water is used in the mill to wash beets of soil particles. Such feed water receives a substantial quantity of soil and beetroot debris. Fecal coliform levels of 120,000 to 210,000 organisms per 100 ml of spent wash water represent the effect of intermixing many portions of different field soils and beets.

Spent flume water contains a mixture of process makeup water, soil, debris washed from the incoming beets, and juices diffused from the beets in flume water. The resulting composite of pollutants is reflected by total coliform densities that can range from 43,000 to greater than 1,000,000 organisms per ml, with the fecal coliform portion being 1 to 10% of these values. Predominant total coliform species in this population (*Enterobacter* and *Klebsiella*) are particularly stimulated to explosive growth by the nutrient wastes during warm water periods. Most alarming is the protective shield provided by these nutritive wastes to some waterborne bacterial pathogens. A study of the waste from three sugar mills in Michigan during 1966 revealed a total of nine *Salmonella* serotypes, suggesting that this pathogen also can survive in fecal contamination introduced during cultivation, from processing water or sanitary waste in the plant.

Although radically different in appearance, sugar beets and sugarcanes both produce product wastes that contain significant residual sucrose, which is a biodegradable organic for many bacteria. In terms of chemical composition, sugar beet and sugarcane wastes are a complex mixture of various carbohydrates including pectin, pentosans, cellulose, and residual sugars. There are also various purines and related compounds including heteroxanthin, vicin, covicin, betanin, plus betaines, and urea in beet pulp. Vitamin analysis of 100 grams of beet pulp includes vitamin A, ascorbic acid, niacin, riboflavin, and thiamine. With a rich nutrient source such as this, it is understandable why many heterotrophic bacteria, including coliforms and bacterial pathogens, will either flourish or remain viable in the polluted aquatic environment.

These nutrient wastes and their bacterial content can best be reduced through biological activity that consumes the nutrients in waste stabilization ponds that have a long retention time (3–4 weeks). Without paying attention to the nutrient waste reduction before its release to the receiving water, there will be a disastrous collapse of the stream's capacity for self-purification over a river reach extending more than 24 hours flow time downstream (38,39). Bacterial multiplication of coliforms in this zone can exceed 1,000 times the number released from the mill and extend the persistence of fecal coliforms and *Salmonella*. Even under winter conditions, when bacteria multiplication is minimal, there can be an undesirable impact on the quality of receiving streams and lakes.

A field survey on the impact of sugar beet mill waste discharges on the Red River of the northern United States (North Dakota–Minnesota) revealed that the presence of excessive nutrient waste during winter conditions (river temperatures $<5\,^{\circ}C$) depressed stream natural self-purification in a manner such that *Salmonella* in sewage discharges along the river at Fargo, North Dakota, and Moorhead, Minnesota, were detected 73 miles (or 4 days flow time) further downstream than during off-season shutdown of the mill (40–42). In other words, sugar mill nutrient waste became a protective shield to hazardous fecal bacteria and environmental coliforms introduced into nearby receiving waters. This situation does demonstrate that the interpretation of coliform density additions in wastes from sugar mills, as being solely of fresh fecal pollution, may be misleading. Conversely, these events should be viewed as excessive nutrient releases to receiving waters that depress the benefits of a natural purification barrier to pathogenic bacteria passage downstream.

Paper and Pulp Mills. The significance of fecal indicators in discharges of wastewater from paper and pulp mill systems into receiving waters has been a sensitive point for both the industry and environmental regulators for over 40 years (27). The main issue is the quality of wastewater released into rivers and lakes and the impact these organic and sulfur complexes have on receiving water downstream. Unfortunately, both sides to the argument focus on only two aspects — release of indicator bacteria and occurrence of pathogens in the waste discharge. Little attention has been paid to reducing bacterial nutrient loading to receiving waters, which is similar to the same problem as that observed with sugar mill wastes.

Sanitary wastes are often separated from paper mill operational wastewaters, which is essential, but little attention was given to fecal contamination that originates in feed water for mill operations, rodent, and other wildlife contamination of wood chip stock stored in the plant yards, or biofilm formation in process operations. The problem is complicated by the fact that environmental strains of *Klebsiella*, *Enterobacter*, *Citrobacter*, enterococci, and other heterotrophic bacteria colonize vegetation, trees

included. This unique association begins with embryo fertilization of tree flowers. Growth continues in the water- and food-conducting tissues by various bacteria (including *Klebsiella pneumoniae*) and persists throughout the life of the tree (43). Cyclitols or wood sugars are the source of bacterial nutrients in this habitat and remain so even when the trees are reduced to wood chips (44).

Salmonella and additional coliforms are periodically introduced into the huge piles of wood chips in storage yards by rodents and other wildlife that roam the area at night as well as inputs from storm water drainage and feed water used in pulp processing. In a random survey over a nine-month period, seven *Salmonella* serotypes were isolated from effluents of three paper mills discharging into the Raisin River in Michigan (45). These samples also contained 3,700 to 460,000 total coliforms and 700 to 1,100 fecal coliforms per 100 ml. It should be pointed out that the *Salmonella* occurrences in paper mill waste were not continuous over several days of repeated sampling at each site, being unpredictable because of the status of raw material contamination and fluctuating quality of feed water.

Feedlots and Poultry Farms. Agricultural pursuits that concentrate on feeding livestock and poultry in confined feedlots can be a significant contributor of nutrient wastes (partially digested feed) and fecal organisms in the accumulating manure. During storms and subsequent runoff, streams in these water sheds often become impaired with farm animal wastes, if not continually removed by landfills and drainage from storm water runoff diverted into holding lagoons. Considering the fact that cattle feedlots often contain 1,000 to 10,000 heads of cattle over an area of about one square mile, it is reasonable to equate the magnitude of this farm waste with that of domestic waste contributed by a medium-sized city. The problem is also acerbated by the geographic location of many feedlots in regions of low rainfall and small streams. These grasslands are exposed to rainfall patterns that often are heavy cloudbursts that forcefully flush the land surface and dramatically change the stream water quality.

An illustration of this pollution problem can be found in a study of Tierra Blanca Creek and its intermittent tributary, Frio Draw (46). Tierra Blanca Creek is a small stream that has its beginning in the northwestern border area of New Mexico and the Texas Panhandle. From the New Mexico state line, it courses 66 miles toward the dam at Buffalo Lake (30 miles southwest of Amarillo, Texas). This water resource is used for irrigation and as the source water for a multiuse recreational lake that is also a wildlife refuge. The stream's major sources of pollution along its course are the sewage treatment plant effluent from Hereford, Texas, and the storm water runoff from a series of seven large cattle feedlot operations. All of these fecal and nutrient additions occurred within a 10.9-mile reach of Tierra Blanc Creek.

Rainfall for the year averages about 15 inches over the water shed and occurs largely as thundershowers in late April to early June. Following these thundershowers, the stream flow in Tierra Blanca Creek suddenly increases from about 13.7 cubic feet per second (cfs) to temporary flows ranging from 114 to 513 cfs. During the extended dry season, major pollution loading was from the poorly treated sewage plant discharge, which averaged 80,000 fecal coliforms per 100 ml. However, springtime thundershowers suddenly flushed the feedlots, and the municipal sewage treatment processes became overburdened with additional inputs. The net result was a dramatic deterioration in stream water quality, with fecal coliform densities 100 to 1,000 times those of dry weather conditions. This impact on the receiving stream created a severe loss of water quality in the delta area of the multiuse lake, some 6 to 8 miles downstream. In essence, the stream temporarily became a fecal waste conduit, and the excessive nutrient loading depressed any chance of natural self-purification within the stream.

Tropical Waters. Much of the development of coliform and fecal indicator concepts has been done in temperate aquatic environments. Applying these concepts to tropical waters has led some investigators to question their use in the tropical environment as being unrealistic (47–52). These tropical field studies have concluded that coliform and fecal coliform data from tropical streams and bathing waters do not coincide with known sources of fecal contamination. In rural New Guinea, high densities of both fecal coliforms (FC) and fecal streptococci (FS) in drinking water were associated more with domestic animal populations than with the number of people on the water shed. In fact, it was noted that when FC and FS densities were at the lowest, the human population was highest. Unfortunately, no attempt was made to confirm these results, and the implications were that animal populations on the water shed were not a public health issue for water quality. In Sierra Leone, high densities of fecal coliform (40–240,000 organisms per 100 ml) were reported, but no correlation was found between the indicator densities and the presence of *Salmonella*. In Hawaii, FC and FS were found in tropical streams that were not known to be contaminated with sewage. In Nigeria, total coliforms were stated to be quite high in areas upstream of known contaminating sources. In other studies reported from Nigeria, Hawaii, New Guinea, Puerto Rico, Sierra Leone, and the Ivory Coast, high densities of *E. coli* were reported in waters that were stated to be completely free of fecal contamination.

These are several aspects to these conflicting reports that must be understood in the selection, use, and interpretation of indicator systems in the evaluation of water quality in tropical environments:

- Tropical waters are warm waters round the year and often nutrient-laden over the entire drainage basin. These conditions stimulate the growth of many coliform species including environmental *Klebsiella*, some strains of which may be thermotolerant fecal organisms.
- Tropical soils are warm, moist, and high in organic nutrients that support the persistence of various microbes including coliform bacteria from desiccation.

- Sunlight exposures are more intense in the tropics and the UV component is an effective bactericidal agent, particularly for *E. coli*, thereby accelerating the rapid inactivation of this fecal indicator in sunlight-drenched tropical bathing waters.
- All warm-blooded animals (wildlife such as rodents, birds, monkeys, and so on as well as domestic animals including farm animals, dogs, and cats) are important contributors of bacterial pathogens and protozoan pathogens such as *Giardia*, *Cryptosporidium*, among others, and should not be ignored.
- The dense tropical vegetation supports a vast variety of wildlife that will exceed that of the human population in remote areas.
- The frequency of waterborne pathogen occurrences in water fluctuates as a reflection of the population density for infected wildlife, domestic animals, and humans living in the water shed.
- Although tropical waters and soils are host to a much larger variety of waterborne pathogens (that is, *Vibrio* chlorea, fungi, protozoans, and worms) than that encountered in temperate climates, major efforts at water quality characterization must focus on conventional indicators of fecal contamination in drinking water supplies to measure natural barrier and treatment effectiveness.
- Because the threat from recreational bathing in tropical waters and the raw consumption of agricultural produce grown in polluted waters introduce additional risks from tropical parasites, the choice of indicator systems should be expanded to include direct monitoring for endemic pathogens.

For these reasons, it is difficult to interpret the occurrences of total coliforms and fecal coliforms in ambient tropical waters without an environmental impact study or a sanitary survey of activity on the tropical water shed. Perhaps the use of only *E. coli*-testing of tropical freshwaters, augmented with fecal streptococci/enterococci analysis of coastal marine waters, is the only way to avoid the overlay of environmental organisms of no public health significance in these aquatic environments. In the meantime, the search must go on for the "perfect" indicator system that is simple to detect as well as specific to, and universally found in the warm-blooded animal fecal flora. This change in the traditional approach does not exclude the continued use of total coliform and fecal coliform tests in the monitoring of tropical drinking water supplies. In this situation, treated water should not contain any coliform bacteria.

Cisterns and untreated groundwater systems may contain a few total coliforms (<10 organisms per 100 ml) provided there are no fecal coliform/*E. coli* present in the sample. The concern with cistern supplies is poor protection from birds and rodent fecal contamination on the cachement site. Fecal contamination from surface runoff into untreated water wells continues to dictate the need to use a fecal coliform/*E. coli* test to determine the major health risk.

CONCLUSION

Coliform bacteria have long been recognized as one of the major bacterial groups in the intestinal tract of warm-blooded animals. Perhaps no other bacterial group has been studied more in the research laboratory or used more often to characterize water quality. These applications have come with some misgivings. Significant is the realization that the coliform group is an artificial collection of organisms that includes not only those bacteria common to the intestinal tract of warm-blooded animals, humans included, but also environmental strains having no sanitary significance. Most disturbing is the fact that a few coliform strains are either opportunistic bacteria or serious intestinal pathogens.

Further refinements in testing procedures have resulted in the development of a procedure for the subgroup known to be fecal coliforms. Although this subgroup has been used very successfully in a variety of waters and wastes, some nutrient discharges (paper mill, sugar processing, and farm animal feedlots) to receiving waters may distort the magnitude of pollution loading because of the growth of thermotolerant *Klebsiella* of environmental origins in these waters downstream. A specific test only for *E. coli* has also been introduced to exclude these *Klebsiella*. Unfortunately, this more restrictive test also excludes those *Klebsiella* found in the intestinal tract of approximately 30% of the people. These facts illustrate the difficulty in devising a "perfect" indicator system that is selective for all organisms of sanitary significance.

The search for better indicator systems has not yet produced the answer because of a number of conditions that must be met for the "perfect indicator:" identical responses that parallel pathogen incursions and survival in the water system; a simple, reliable, and a rapid test that is cost-effective as a monitoring tool; and occurrence of this indicator system in larger enough densities so that treatment effectiveness can be measured by six log removals. All of these requirements are challenging, and no known indicator system proposed to date is immune to some weakness that prevents acceptance for all classes of environmental waters and wastes.

Intensive investigations have shown that total coliform bacteria do not provide all of the desired characteristics for the ideal indicator. Coliforms are more sensitive to inactivation by disinfectant concentrations recommended for drinking water than are many waterborne pathogens. Most restrictive to any effective use of the coliform indicator system is the traditional requirement to test only 100-ml portions of drinking water. Such a test volume rarely correlates to the possible presence of either virus, *Giardia*, or *Cryptosporidium*, when the same water is examined for those pathogenic agents in 100-liter samples.

The most productive approach is to reassess the interpretation of coliform findings in the light of current information about their place in the ecology of aquatic environments. A review of the subject suggests the following understandings:

1. Fecal pollution concerns in the Tropics must include recognition of the contributions from wildlife and

farm animals on the water shed, not just a focus on human pollution as the sole public health concern.

2. Acknowledgment that pathogen occurrences are not constant in the aquatic environment.
3. Rejection of the acceptance of any coliform in treated drinking water supplies because proper treatment will inactivate these organisms.
4. Abandonment of the historical use of the total coliform test for bathing water quality assessments as being an unrealistic predictor of public health risk in these recreational waters.
5. Recognition that massive growth of *Klebsiella* downstream of some industrial operations is an indication of poorly treated nutrient waste that degrades natural self-purification processes in receiving waters.
6. Response to the sudden appearance of *Klebsiella*, *Citrobacter*, or *Enterobacter* strains in distribution water supply as an indication of biofilm development in the pipe environment that must be suppressed.
7. Awareness that although most coliform bacteria are harmless, there have been waterborne outbreaks caused by a few *E. coli* serotypes that are serious intestinal pathogens.

In conclusion, coliform bacteria may be viewed as a rogue group of organisms used to assess water quality, but the wealth of information on their place in the aquatic environment provides cautious reason for their continued use in lieu of the "perfect" indicator system.

COLIFORM BACTERIA — CONTROL IN DRINKING WATER DISTRIBUTION SYSTEMS

DARRELL B. SMITH
Regional Water Authority
New Haven, Connecticut

The occurrence of coliform bacteria is relatively common in drinking water distribution systems. Most coliform bacteria are generally not harmful by themselves. However, when they are detected, drinking water system operators and public health officials are challenged to determine their source and whether they pose an unreasonable risk to public health. Their presence may signal inadequate treatment, a breach of the distribution system, or may be the result of biofilm that comes about from chronically poor system maintenance. Systems with coliform levels that exceed government standards are in violation of the United States Environmental Protection Agency's (U.S. EPA) Total Coliform Rule (TCR). When this occurs, the water system operator is required to provide public notification, perform additional monitoring, and, in some cases, to develop a coliform bacteria control plan. These actions can be costly and highly disruptive to normal utility operations. Further, periodic or repeated public notification is likely to adversely impact consumer confidence in the local public water supply. Although there does not appear to be a completely effective means to totally eliminate coliform bacteria, practical experience shows that their impact can be minimized using a series of best management practices for treatment, disinfection, and distribution system maintenance.

COLIFORM BACTERIA IN WATER DISTRIBUTION SYSTEMS

Coliform bacteria in water distribution systems have long been problematic for the drinking water industry and regulatory community. The periodic occurrence and recovery of elevated coliforms from water distribution systems has been reported by various drinking water supply systems throughout the United States (1–9). Investigation of such occurrences frequently reveals that the source of the coliforms is not known because there is no evidence of treatment breakthrough or cross-connections in the distribution system.

In theory, one would not expect coliform bacteria to be present in drinking water that has been properly disinfected. In reality, this is not the case. Coliform bacteria are fairly common to some degree in all water distribution systems because drinking water treatment processes and distribution systems are not sterile. When coliform bacteria are detected, the system operator must retest to rule out fecal contamination and, perhaps most importantly, begin to understand and identify their source in order to take appropriate corrective action to prevent further microbial degradation in the water system.

Distribution System Water Quality Deterioration

Before undertaking a discussion of coliform bacteria occurrence in drinking water distribution systems, it is important to become familiar with the concept of water quality deterioration. In a review of the effects of the distribution system on water quality, Clark and coworkers reported that there is increasing evidence that finished water quality may undergo substantial changes as water moves through the distribution system to the consumer (10). Water quality deterioration implies an adverse change in quality between the point of distribution system entry and any point in the system where the change is detected. Although some change in water quality is expected in the distribution system, left unchecked, these changes may result in noticeable aesthetic impacts at the consumer's tap, including the appearance of objectionable tastes and odors, discoloration, and sediments or particulate matter. Adverse water quality changes in the distribution system, which generally go unnoticed by the consumer, include losses in disinfectant residual, excessive microbial growths, and internal corrosion.

Water quality deterioration can result from inadequate treatment, poor system maintenance, or long hydraulic residence times in the distribution system. Examples of inadequately treated water include insufficient disinfection that results in low residuals in the distribution system, poor pH or corrosion control, or the breakthrough of particulate matter as a result of nonoptimized filtration. Foremost among poor distribution system maintenance practices is the failure to periodically flush the system according to a prescribed plan to remove sediments, encrustations, and bacterial growths from the pipe wall. Long residence times that increase the age of water in the distribution system come about in areas where the flow or turnover of stored water is low. Low flow areas occur in dead-end portions of the system where water can stagnate because of poor circulation or in residential neighborhoods where consumer demand is low. Water can also age or become stale in systems with minimal storage tank drawdown.

Unless proper treatment and maintenance is in place, systems that use monochloramine in the distribution system for secondary disinfection are susceptible to a severe form of water quality deterioration know as nitrification. Nitrification is the biochemical conversion of reduced forms of nitrogen to nitrite and nitrate. By and large, nitrification is caused by two groups of bacteria: ammonia-oxidizing bacteria (AOB), which convert ammonia to nitrite, and nitrite-oxidizing bacteria (NOB) that oxidize nitrite to nitrate. Key factors that promote nitrification include increasing water temperature, hydraulic residence times in excess of several days, improper chlorine and ammonia ratios, and biofilm in pipes. For drinking water systems that chloraminate, nitrification can result in severe water quality deterioration in the distribution system, including the loss of chloramine residual, marked increases in heterotrophic plate count (HPC) bacteria, increased nitrite and nitrate concentrations, and possibly difficulty in complying with the TCR (11). (See also NITRIFYING BACTERIA IN DRINKING WATER, this Encyclopedia).

Significance of Coliform Bacteria as Sanitary Indicators

Most waterborne pathogens that impact human health are of fecal origin. Because waterborne pathogens are difficult to measure directly, water suppliers and public health officials rely on the measurement of indicator organisms normally associated with fecal contamination to ensure drinking water safety. One of the most widely used fecal indicator systems is based on the detection of bacteria collectively known as the total coliform group. The total coliform group bacteria include the genera *Escherichia*, *Klebsiella*, *Enterobacter*, *Citrobacter*, and some species of *Serratia*. The overall reliability of this group as an indicator of fecal pollution is somewhat questionable because most strains of coliform bacteria, except for *Escherichia coli*, occur naturally in the environment and are not of fecal origin. The total coliform group is also a poor indicator system for the presence of pathogenic protozoan cysts and some viruses. Conversely, the presence of *E. coli* in drinking water is generally regarded to be of greater public health significance because they are the only members of the total coliform group that are definitely associated with the intestinal tract of warm-blooded animals and humans.

On the basis of a limited study of communities with and without waterborne disease outbreaks, Batik and coworkers cautiously suggested that routine coliform monitoring may be of little help in preventing the transmission of waterborne disease (12). Further, the authors advised public health officials to reevaluate the importance of routine coliform monitoring for the prevention of waterborne disease. Despite this advice, the presence of total coliform bacteria in treated drinking water is unacceptable. Further, their presence without the evidence of a public health threat is indicative of deficiencies in treatment or disinfection that must be corrected.

Sources of Coliform Bacteria in Drinking Water

The presence of coliform bacteria in drinking water distribution systems without the evidence of fecal contamination or operational problems is a general indication of water quality deterioration. Because coliforms can arise from a number of sources and conditions, careful investigation is necessary to rule out fecal contamination. A partial listing of the potential sources of coliform bacteria in drinking water distribution systems is shown in Table 1. While this listing is not all-inclusive, the examples used provide a practical framework to begin the investigation of distribution system coliform occurrence. Experienced distribution system operators typically use these diagnostics to investigate coliform activity and to rule out potentially serious conditions that could pose a threat to public health.

U.S. EPA Total Coliform Rule

The U.S. EPA TCR regulates the presence of coliform bacteria in drinking water distribution systems. The rule is based on the premise that water systems should try to

Table 1. Potential Sources of Coliform Bacteria in Drinking Water Distribution Systems

Source or Cause of Coliform Bacteria	Examples
Inadequately treated water	Treatment interruptions including lapses in disinfection, loss of coagulant feed
Water treatment Deficiencies	Level of treatment not matched to source water quality, e.g., distribution of undisinfected groundwater of low or poor quality
Treatment Breakthrough	Passage of stressed or particle-associated coliforms
Distribution system breaches	Main breaks, construction and service activities including main repairs or new installations, cross-connections
Sanitary Deficiencies	Damaged or missing vent screens or hatch covers on storage tanks, inadequately protected open finished water reservoirs
Sampling and laboratory Errors	Monitoring locations of poor sanitary condition, failure to use aseptic sample collection and handling techniques, contaminated sampling bottles or lab supplies, poorly implemented analytical procedures,
Distribution system Biofilm	Colonization of pipe walls, sediments, or tuberculations in systems prone to water quality deterioration

Table 2. Percentage of US Population Served by Community Water Systems with TCR Violations During 1997

System Size	Population Range	Population Served	Population Receiving Water with TCR Violation
Small	25–3,300	25 Million	4.8%
Medium	3,301–10,000	25 Million	6.6%
Large	>10,001	202 Million	3.5%

achieve drinking water that is free of coliform bacteria because their presence indicates the possible existence of fecal and disease-causing bacteria. The TCR was published in the Federal Register on June 29, 1989 and became effective on December 31, 1990 (13). TCR compliance monitoring is based on testing throughout each month for total coliform bacteria. The number of monthly samples needed for compliance is proportional to the population served by the water system. For example, systems serving a population between 41,001 and 50,000 persons must collect a minimum of 50 samples per month. Large systems that serve a population between 450,001 and 600,000 persons are required to test at least 210 samples per month. Small systems that serve between 4,101 and 4,900 persons must test five samples per month, while systems that serve less than 1,000 persons only test one sample per month or less. Monitoring must be performed according to a state water supply agency-approved sampling plan.

The TCR maximum contaminant level (MCL) is based on monthly coliform presence-absence (PA) levels in the distribution system. Systems that are required to collect less than 40 samples per month are allowed no more than one sample per month to be coliform-positive. Larger systems collecting 40 or more samples per month can have no more than 5% coliform-positive samples in any month.

Whenever a system detects coliforms in drinking water, a set of repeat samples must be collected within 24 hours. Any routine or repeat sample that is total coliform-positive must also be analyzed for the presence of fecal coliforms or *E. coli*. Water systems that exceed allowable monthly levels for total coliform bacteria are in violation of the TCR, which must be reported to the state and the public. A positive result for *E. coli* or for fecal coliform bacteria, which grow at 44.5 °C, constitutes an acute violation of the TCR. It should be noted that testing for fecal coliforms is not always a reliable indication of fecal contamination because some environmental coliform strains of nonfecal origin are also able to grow at 44.5 °C. Conversely, because of their distinct association with the intestinal tract, the presence of *E. coli* conveys a much stronger association with fecal contamination. Any evidence of fecal contamination requires prompt state and public notification.

Systems with chronic coliform occurrence problems because of the presence of biofilm may be granted a variance from compliance with the TCR MCL if the system has no evidence of fecal contamination or waterborne disease (14). In establishing a TCR variance provision, the U.S. EPA created a set of interim criteria to be used by the states as guidelines by which systems could operate without posing an unreasonable risk to health.

Coliform Occurrence in the United States

According to U.S. EPA compliance monitoring records, distribution system coliform occurrence is relatively common among community water systems in the United States. In 1997, the U.S. EPA National Public Water Systems Compliance Report revealed that the TCR was violated by more than 5% of the nation's 54,367 community water systems (15). Further, this statistics represents the highest percentage of maximum contaminant level (MCL) violations for community systems in all size categories during 1997. Populations impacted by coliform MCL violations in 1997, according to system size, are shown in Table 2.

TC-R violations were also problematic in other U.S. EPA public water system classifications during 1997, including nontransient noncommunity and transient noncommunity systems that experienced a TCR MCL violation rate of approximately 4%. Collectively, these systems serve an additional 23 million persons annually.

A survey of 81 U.S. drinking water utilities representing 32 states conducted by Smith and coworkers for the period between 1986 and 1989 revealed that 82.7% of the responding systems reported some level of monthly distribution system coliform occurrence (16). On average, coliforms were detected in these systems six months per year. Slightly more than one-third of the systems reported monthly coliform occurrence levels above 5%.

DISTRIBUTION SYSTEM BIOFILMS (see also BIOFILMS IN NATURAL AND DRINKING WATER SYSTEMS, THIS ENCYCLOPEDIA)

Growths of microorganisms attached to pipe walls and solid surfaces in water distribution systems are commonly referred to as biofilm. Biofilm organisms adsorb nutrients from bulk water and grow as patchy mats. Abrupt hydraulic changes resulting from flow-velocity changes or changes in the chemical environment can trigger the sloughing of biofilms. Coliform-containing biofilms in drinking water distribution systems can result in violations of the TCR when disease-causing microorganisms are not present. Moreover, coliform occurrence that is the result of biofilm is not associated with breaches of the primary treatment and disinfection barriers or contamination within the distribution system. Indications of waterborne disease or evidence of fecal contamination are also absent when coliform bacteria from the distribution system are the result of biofilms. In general, water distribution systems that maintain low disinfectant residual levels throughout the system do not

practice corrosion control and those that do not regularly flush are more predisposed to biofilm formation.

Microorganisms found in biofilms can include a variety of coccoid, rod-shaped, filamentous, and appendaged bacteria, fungi, and higher organisms such as nematodes, and crustacea. While biofilms in drinking water systems are generally assumed to be innocuous, recent research has shown that viruses and parasites such as *Cryptosporidium* can be trapped in biofilms after a contamination event such as a cross-connection (17,18). Noncoliform biofilms that consist mainly of mixed heterotrophs, including iron, sulfur, and nitrogen bacteria, can cause microbially induced corrosion, nitrification in chloraminated systems, and objectionable tastes and odors.

Biofilm microorganisms are known to be associated with distribution system corrosion products and tuberculations (19–22). Tubercle surfaces possess an extremely high surface area that provides an ideal habitat for microbial growth. Unlined cast-iron pipes, present in many older drinking water systems such as the 84-year-old section of heavily tuberculated six-inch main from Milford, Connecticut, shown in Figure 1, can play host to a number of chemical and physical phenomena that favor biofilm growth and affect disinfection efficiency.

Using a scanning electron microscope (SEM), Allen and coworkers found high populations of microorganisms on or in the tubercles of pipe specimens from seven drinking water systems in the United States (23). The investigators concluded that microbial populations are able to successfully adapt to a variety of environmental conditions in a water system that is adequately treated and disinfected. Rod-shaped microorganisms on a tubercle at a magnification of 4,000X, (courtesy of M. J. Allen) are shown in Figure 2.

Microorganisms deeply enmeshed in or on a tubercle are shielded from chemical disinfection by free chlorine because of competing oxidation-reduction reactions that consume the disinfectant before a lethal concentration can penetrate the biofilm. LeChevallier and coworkers noted that biofilms grown on iron pipe surfaces exerted a disinfectant demand that was up to 10 times greater than from biofilms grown on other types of pipe materials (24). Although nutrient concentrations in most treated drinking waters are low, tubercle surfaces are also able to adsorb and store nutrients for microbial growth in an otherwise nutrient-deficient environment. Microorganisms attached to tuberculated surfaces are also protected from the shear forces of water flowing through the pipe.

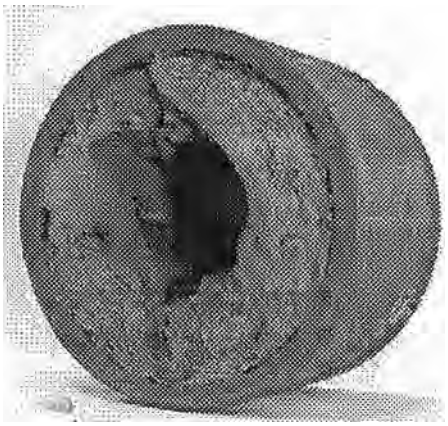

Figure 1. Tuberculated six-inch cast-iron main.

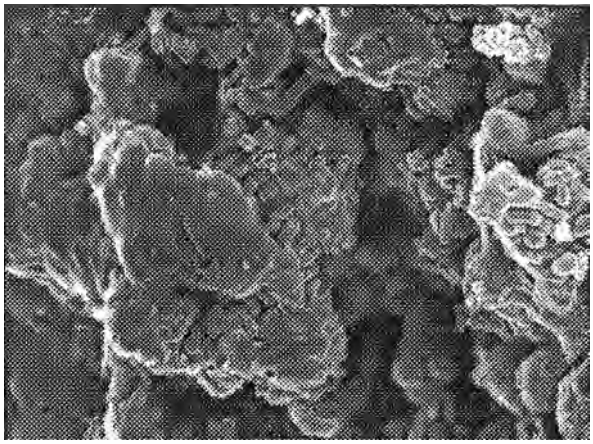

Figure 2. Microorganisms on tubercle surface (4,000 times).

Biofilm Signs and Symptoms

The most outstanding symptom of biofilm is the persistent and widespread recovery of coliforms in the presence of disinfectant residual concentrations typically found in drinking water distribution systems. In a biofilm situation, it is not uncommon for coliform presence-absence to exceed the TCR maximum contaminant level for several days to weeks. Moreover, coliform occurrences due to biofilm may last for several years or more. The highest coliform recovery rates generally occur in the summer and fall months when water temperatures are at or above 15 °C (25). An analysis of 218 coliform-positive samples in the New Haven, Connecticut, distribution system recovered between 1992 and 1998 showed that 73% of all coliform-positive samples occurred between June and November. The mean water temperature during this interval was $17.1\,^{\circ}\mathrm{C} \pm 3.5\,^{\circ}\mathrm{C}$. Between 1992 and 1998, peak coliform levels typically occurred in the month of September, when the mean water temperature was $19.9\,^{\circ}\mathrm{C} \pm 2.6\,^{\circ}\mathrm{C}$. The relationship between seasonal coliform occurrence and water temperature in the New Haven system is shown in Figure 3 for 1992 and 1993.

Traditional water quality parameters such as disinfectant residual concentration, turbidity, pH, and color are not likely to overtly reveal the presence of biofilm. However, difficulty in maintaining an acceptable disinfectant residual in conjunction with excessive HPC bacteria levels may indicate the onset of water quality deterioration that can lead to a biofilm condition.

Biofilm Factors

Biofilms are presumed to result from the complex interaction of environmental, chemical, physical, and distribution system operational factors, including the presence of growth-stimulating nutrients, seasonal changes in water

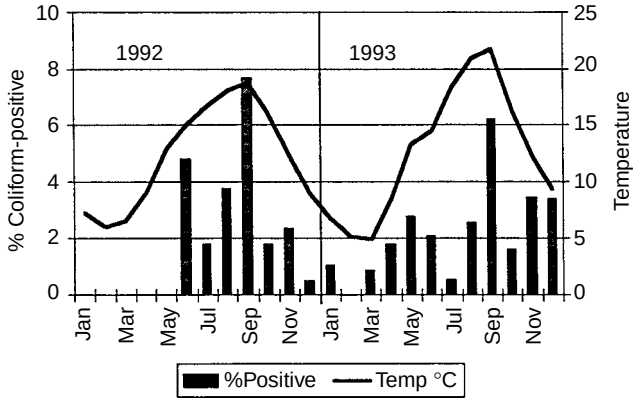

Figure 3. Seasonal distribution system coliform occurrence in New Haven, Connecticut.

temperature, distribution system hydraulics, disinfection practices, and water main corrosion. However, in an 18-month study of 31 North American drinking water systems, LeChevallier and coworkers found that no single factor could account for all observed coliform occurrences (26). Factors evaluated included filtration and disinfection practices, temperature effects, nutrient concentrations, corrosion effects, and operational characteristics. An analysis of system operational characteristics, monthly distribution system coliform occurrence, and water quality data revealed the following findings:

1. Filtration. Four systems in the study used unfiltered surface water and accounted for 64.3% of the positive coliform samples, indicating that filtration may be an important factor in preventing coliform regrowth.
2. Disinfectant Residual Type and Level. Systems that used free chlorine had more coliform bacteria than chloraminated systems. Systems with low disinfectant residuals at dead-end sites, that is, less than 0.2 mg/L free chlorine or monochloramine levels less than 0.5 mg/L, had substantially more coliform occurrences compared to systems that maintained higher dead-end disinfectant residuals.
3. Temperature. On average, the occurrence of coliform bacteria was significantly higher when water temperatures were higher than 15 °C.
4. Nutrient Levels. Systems with assimilable organic carbon (AOC) levels above 100 μg/L tended to have more coliform bacteria than systems with low AOC. Systems with high AOC levels tended to maintain higher disinfectant residuals to control coliform occurrences.
5. Corrosion. Systems using free chlorine with more than 1,000 miles of unlined cast- iron pipe appeared to have a higher incidence of coliform occurrence compared to systems with less than 200 miles of unlined cast-iron pipe. Chloraminated systems showed no apparent relationship between coliforms and the amount of unlined cast-iron pipe present in the system. Systems that used a phosphate-based corrosion inhibitor generally had lower coliform levels.
6. Operational Characteristics. Treatment process and distribution system characteristics associated with increased coliform occurrence rates included:

   - Ozonation without biological treatment
   - Large proportion of storage tanks in the distribution system
   - Lack of a systematic distribution system flushing program
   - Presence of uncovered finished water reservoirs

Biofilm Impacts

Aside from noncompliance with the TCR, distribution system biofilms can

- Interfere with disinfection
- Impact public health
- Provide a habitat for opportunistic pathogens such as *Mycobacterium avium* and *Legionella*
- Increase pumping costs
- Cause corrosion that reduces the life of pipes and other materials in the system
- Produce aesthetic problems including discolored water and objectionable tastes and odors
- Weaken consumer confidence

The South Central Connecticut Regional Water Authority reported expenditures of $875,000 in an unsuccessful attempt to control a sudden systemwide outbreak of distribution system coliforms that began in 1984 (27). The increased operating costs included $750,000 for additional chlorine and overtime labor for extensive flushing of the distribution system. The remainder of this expenditure was used to nearly triple its routine water quality monitoring program. Aside from potential public health implications and operational issues, New Haven's experience underscores the fact that biofilm coliform occurrences can be costly and disruptive to normal utility operations.

DISTRIBUTION SYSTEM COLIFORM CASE STUDIES

Utility response to distribution system coliform occurrence has been varied. Some systems substantially increased disinfectant residual levels and initiated extensive flushing programs in the distribution system. Other systems increased pH levels or changed disinfectant types (i.e., from chlorine to chloramines) or modified corrosion control programs in an attempt to control or eliminate the distribution system coliform occurrences.

To illustrate the impacts and development of various coliform control strategies associated with persistent distribution system occurrence, case studies representing four unique approaches will be presented. The four control strategies to be discussed are

1. Standardization of distribution system maintenance practices in New Haven, Connecticut

2. Year-round flushing combined with a periodic changeover from combined to free chlorine in Greenville, South Carolina
3. Implementation of a corrosion control program in Utica, New York
4. Conversion from free chlorine to chloramine in Hopewell, Virginia

New Haven, Connecticut

The Regional Water Authority, headquartered in south central Connecticut, supplies water to more than 380,000 inhabitants in the 12-town metropolitan New Haven district. The Authority has an average daily demand of 55 MGD (million gallons/day) that is provided by three surface water treatment plants and five wellfields. The distribution system is divided into 19 separate pressure zones and includes about 1,600 miles of water main ranging in size from 4 to 72 inches, 28 storage tanks and 27 pumping stations. Approximately 23% of the distribution system piping consists of heavily tuberculated unlined cast-iron main, some of which dates back to the late 1890s.

In 1984 when distribution system coliform bacteria first became problematic in New Haven, four surface water sources were in use. The surface water facilities included in-line direct, slow sand, and conventional filtration plants along with a high-quality unfiltered supply. The unfiltered surface water provided about 60% of the system's daily demand. A direct filtration plant for this supply was dedicated in 1986. The slow sand filter plant was decommissioned in 1991 after more than 80 years of service.

In the spring of 1984, the Authority unexpectedly began to recover elevated numbers of coliform bacteria from throughout the distribution system. Coliform occurrences peaked in August when the coliform average for the month was 12 times the maximum contaminant level of one colony-forming unit per 100 mL.

Coliform occurrence was systemwide, including areas of the distribution system where water from different finished water sources mixed, as well as in two hydraulically isolated systems. Routine speciation of all coliform-positive samples indicated that there was no evidence of fecal contamination in the distribution system based on the absence of *E. coli*.

After consultation with state and U.S. EPA officials, the Authority immediately increased chlorine residual levels to a maximum of 6–8 mg/L to disinfect the distribution system and insure ample disinfection of the unfiltered surface water source. At the same time, extensive flushing of the distribution system was initiated. This effort, which included all pipe sizes, was completed over an eight-week period. The combined effect of heavy flushing and increased disinfection residual levels appeared to have stimulated biofilm sloughing because the number of coliform-positive samples increased shortly after these changes were implemented. Further, many of the coliform-positive samples recovered during this period showed confluent coliform growth or were too numerous to count on m-Endo agar. Numerous consumer complaints were received through the end of 1984. The bulk of these complaints were related to chlorinous taste and odor because distribution system chlorine residuals were considerably higher than normal. Some consumers also complained of dry skin, hair damage, and the bleaching of laundry items. By the end of 1984, coliform numbers began to subside and this resulted in the gradual lowering of effluent chlorine residuals early in 1985. Chlorine concentrations leaving the treatment facilities were adjusted to maintain a target value of 1 mg/L at all distribution system extremities. To achieve this target value, effluent chlorine residuals averaged 1.9 mg/L (range 1.1 to 3.9 mg/L).

Coliform investigations following the outbreak included intense scrutiny by the State health department and various consultants of past and present water treatment and distribution practices with emphasis on disinfection at the unfiltered supply. These efforts found no major deficiencies in any of the Authority's treatment facilities and were also unable to identify any conditions or practices that could account for the coliform outbreak. Moreover, coliform occurrence rates in areas of the distribution system served by the unfiltered surface water source were found to be comparable to other parts of the system served by filtered surface water or disinfected groundwater. The investigators also found no evidence of fecal contamination or waterborne disease in the Authority's service area (28). A similarly intense review of sampling and laboratory procedures found that the Authority's water quality monitoring program produced accurate and reliable results, and that laboratory errors were not responsible for the unusually high number of distribution system coliforms. Operational and procedural changes made over the next five years following the August 1984 coliform outbreak are summarized in Table 3.

Despite these changes, significant coliform occurrence continued throughout the distribution system as shown in Figure 4. Importantly, this figure reveals that coliform bacteria were present in the distribution system before the 1984 outbreak. However, it is very likely that their significance was overlooked as an indication of biofilm. This is because throughout much of the 1970s and early 1980s, coliform density averages in the Authority's distribution system were generally below the

Table 3. Changes in Treatment and Distribution System Maintenance

Year	Operational Change
1984	Increased free chlorine residuals in all parts of the distribution system
1985	Developed and implemented a unidirectional distribution system flushing program
1985	Expanded raw, finished, and distribution system water quality monitoring
1986	Direct filtration plant online for the unfiltered surface water supply
1988	Increased zinc polyphosphate corrosion inhibitor feed rate from 1 mg/L to 2 mg/L
1990	Implemented periodic cleaning and inspection program for all distribution storage tanks and finished water reservoirs

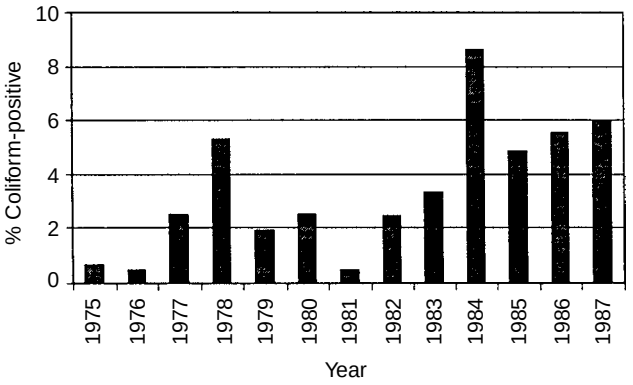

Figure 4. Annual distribution system coliform occurrence in New Haven (1975–1987).

prevailing interim maximum contaminant level, which required monthly distribution system coliform cell density, averages to be less than one colony-forming unit per 100 mL. Further, except for August and September 1984, the cell density–based coliform MCL was never exceeded between 1975 and 1983.

In an attempt to bring the coliform occurrences under control, the Authority began to examine past distribution system maintenance practices. A review of these practices from the mid-seventies through 1981 found that the Authority had no organized distribution system-flushing program and that storage tank cleaning and inspections were performed approximately every 10 years. Any flushing that was performed was limited to customer complaints and the periodic flushing of known trouble spots. In 1982, a short-lived effort was made to develop a more organized distribution system-flushing program. The goal of the program was to flush 100% of all pipes 16-inches or less in diameter on an annual basis. A true unidirectional flushing program was developed in 1985. Over the next five years, an average of 50% of the system was flushed on an annual basis. In 1989, coliform occurrence decreased by about 50% compared with the previous year. Because of this apparent success, annual system flushing averages were reduced to a target level of 25% in 1990. The Authority also adopted a three-year cycle for storage tank cleaning and inspections at this time.

From 1990 through the first half of 1992, coliform occurrence in the distribution system was at a record low since the initial outbreak in 1984. This reduction was thought to be the result of improvements to distribution system flushing, higher disinfectant residuals, corrosion control, and tank maintenance programs implemented between 1985 and 1990. The Authority's apparent success in controlling coliform occurrence was dashed in early June 1992, when coliform bacteria suddenly and unexpectedly reappeared in all parts of the distribution system, which prompted the Authority to apply for a variance from the TCR on June 8, 1992. Flushing was also halted in mid-June 1992 because it initially appeared to track spatially with the appearance of coliforms in the distribution system. A subsequent in-depth review of coliform occurrence patterns from the summer and fall months ultimately showed no relationship between flushing and the appearance of coliforms in the distribution system. Flushing was resumed in 1993 at the 25% level until 1999, when it was suspended because of a drought alert in the region.

The Authority's decision to seek a variance was strengthened by no evidence of waterborne disease in the community, no interruptions in treatment, and no evidence of fecal contamination in the distribution system. As a condition of the variance, the State Department of Public Health Water Supplies Section (DPH) issued the Authority a Consent Order in 1993. The requirements of this Order included continued maintenance of minimum target disinfectant residuals and corrosion inhibitor doses in all parts of the distribution system. Specific mandates for public notification, water quality monitoring, cross-connection control, and performance of an annual independent sanitary survey were also part of the Consent Order. The Order also required the submission of an annual variance report to DPH describing distribution system maintenance completed in the previous year and plans for the following year (29).

In 1993 and 1994, distribution system coliform occurrence continued to be sporadic, with the heaviest occurrence typically appearing in the summer and fall months. After July 1994, monthly coliform occurrence rates were generally well below 5%. Averages of annual coliform occurrence shown in Figure 5 for the period 1995 to 1999 suggest that coliform occurrence had reached what could be considered a normal "background level" for a system of the Authority's size and complexity. Because of these low coliform occurrence rates, the Authority formally petitioned DPH in January 1999 to rescind the Total Coliform Rule (TCR) variance and related Consent Order. DPH lifted the Variance and Consent Order on March 18, 1999.

The factors believed to be responsible for the reduced coliform levels in the Authority's distribution system after 1994 include the maintenance of higher disinfectant residuals throughout the system since the mid-1980s, improved corrosion control and the application of consistent distribution system maintenance practices. Importantly, the events and operational practices chronicled in the New Haven case study suggest that biofilm:

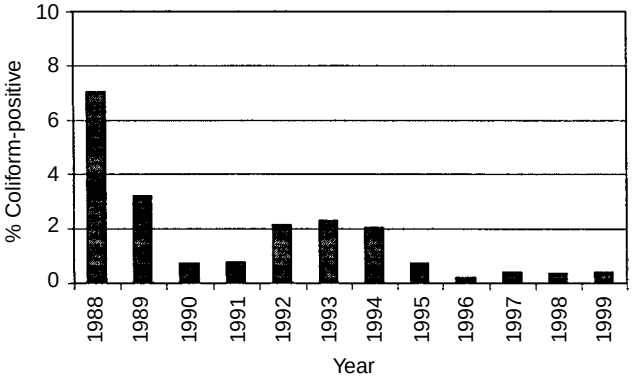

Figure 5. Annual distribution system coliform occurrence in New Haven (1988–1999).

Table 4. Coliform Control Strategy for New Haven, Connecticut

Program Element
Maintain minimum target chlorine residual of 0.3 mg/L in all parts of the distribution system
Annually clean and line 8 to 10 miles of old unlined cast-iron pipe to reduce biofilm habitat
Annually flush a minimum of 25% of the distribution system
Clean and inspect all distribution system storage tanks on a rotating three-year cycle
Apply a corrosion inhibitor to control distribution system corrosion
Maintain an effective cross-connection control program
Perform periodic sanitary surveys of source water, treatment, and distribution system facilities to insure overall system integrity

- likely to have resulted from the cumulative effects of inconsistent and/or infrequent distribution system maintenance practices in the 1970s and early 1980s
- can be held in check by the consistent and systematic application of distribution system best management practices

To ensure that distribution system coliform levels remain low, the Authority has adopted the coliform control strategy outlined in Table 4.

Greenville, South Carolina

The Greenville Water System serves a population of 310,000 residents in greater Greenville, South Carolina. Two high-quality unfiltered surface water supplies and a conventional filtration plant produce an average of 54 MGD. Treatment of the unfiltered supplies is slated to begin in the spring of 2000, when a 75 MGD dissolved air floatation plant comes on-line. The distribution system contains approximately 2,000 miles of water main and 15 storage tanks.

In 1992, the system began to experience persistent episodes of coliform contamination in the distribution system (30). Monthly total coliform bacteria MCL violations occurred three times in 1992, once in 1993, and twice in 1994. Typical of biofilm, peak coliform levels generally occurred between June and September. Distribution system flushing typically occurred only in response to consumer complaints, in areas of the distribution system with low disinfectant residuals, or where coliform bacteria were present.

In the winter of 1994, the Greenville Water System implemented a two-step biofilm control process based on year-round unidirectional flushing and a seasonal disinfectant changeover from monochloramine to free chlorine. The 30-day disinfectant changeover period typically occurs in late March or early April. Sufficient free chlorine is used throughout the system to achieve a 2 mg/L target at all distribution system extremities after flushing. Annual distribution system coliform occurrence data, summarized in Figure 6, indicate that a highly successful approach for controlling biofilm has been achieved in the Greenville Water System. Distribution system flushing crews also reported that the two-step process was responsible for shorter flushing times relative to sediment removal and higher concentrations of free and total chlorine in some areas of the distribution system compared to 1994 levels.

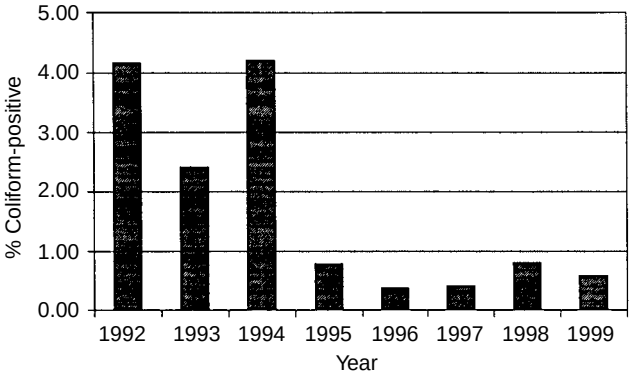

Figure 6. Annual distribution system coliform occurrence in Greenville, South Carolina (1992–1999).

Utica, New York

The Upper Mohawk Valley Regional Water Board serves a population of 126,000 in the greater Utica, New York, area. Before 1992, the system was served by unfiltered surface water from the Hinckley Reservoir. A direct-filtration plant, producing an average of 20 MGD, was dedicated in 1992. The distribution system consists of 625 miles of main and has 25 storage tanks.

Between 1991 and 1994, elevated lead levels and excessive coliform occurrences were common in the distribution system. Ninetieth percentile lead levels at consumer taps, which were the result of highly corrosive source water, were as high as 160 μg/L compared to the U.S. EPA Lead and Copper Rule action level of 15 μg/L. Coliform levels in the distribution system routinely resulted in violations of the TCR. Seasonally, up to 30% of the monthly coliform samples were positive. After the filter plant went online in 1992, distribution system coliform and lead violations continued to occur. This prompted the utility to accelerate modifications and improvements to a previously established corrosion control program, based on the adjustment of pH and alkalinity with lime and soda ash. The utility was also able to demonstrate that the coliform occurrences were biofilm-related and the utility was granted a TCR variance by the New York State Health Department, Bureau of Public Water Supply Protection (31).

Following full implementation of the corrosion control program in 1994, ninetieth percentile lead levels at consumer taps were reduced to below 10 μ/L. The effect of corrosion control on the distribution system biofilm also produced dramatic results with no TCR violations being reported after 1995 as shown in Figure 7.

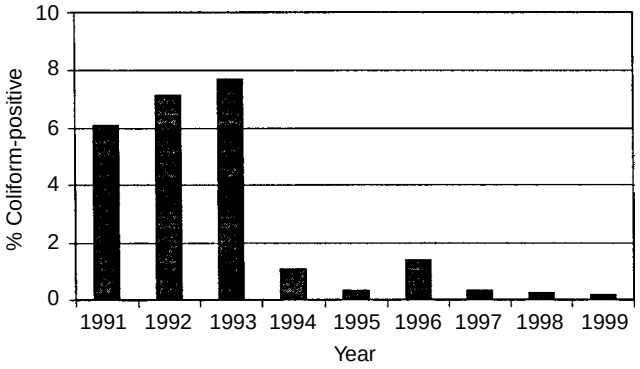

Figure 7. Annual distribution system coliform occurrence in Utica, New York (1991–1999).

Hopewell, Virginia

The Virginia American Water Company serves 15,000 customers in the City of Hopewell, Virginia. Water from the Appomattox River is treated in a rapid filtration plant that is divided into two sections to produce industrial and domestic grades of water. The conventional treatment trains employed in both sections of the plant are identical, except the domestic plant uses post-filter GAC contactors. The combined capacity of the two sections is 33 MGD. Unlike the industrial system, the domestic production is fluoridated and treated with zinc orthophosphate for corrosion control and ammonia is added to form chloramines. The separate industrial and domestic distribution systems contain a total of 162 miles of main. The industrial system contains one storage tank, while the domestic distribution system has two storage tanks.

In 1991, Hopewell began to experience persistent coliforms in the distribution system. In an attempt to control these occurrences, the average free chlorine residual in the distribution system was increased from 0.57 to 2.1 mg/L. Despite this change, the coliform occurrences continued, and total trihalomethane (THM) concentrations exceeded 100 μg/L during the summer because of the higher chlorine residuals (32). Hopewell began using mT7 agar in January 1992 to enhance the detection of injured coliforms (33). Throughout 1992, 22.3% of the distribution system samples analyzed using mT7 agar were positive for coliforms. During the first six months of 1993, 11.7% of the samples analyzed using mT7 agar were positive for coliforms. In May 1993, 5.6% of the distribution system samples were coliform-positive using m-Endo agar (24).

Because adequate distribution disinfectant residuals and pressures were being maintained and there were no coliform bacteria in the treated effluent, the regrowth of coliform bacteria in the pipe network was suspected. These conditions prompted Hopewell to change the domestic distribution system disinfectant from free chlorine to monochloramine in July 1993 (22). One week after chloramination began, all samples taken from the Hopewell distribution system were coliform-negative. Following the changeover to monochloramine, only two coliform-positive samples were detected through the end of 1994. These samples were recovered during the first week after conversion to chloramines and were isolated on mT7 agar. Subsequent coliform monitoring using mT7 agar through the end of 1998 has detected only 12 coliform-positive samples. Further, with regard to chloramines, all samples taken for compliance with the TCR have been negative for coliform bacteria through the end of 1999, and average HPC bacteria levels determined using R2A agar were below 30 CFU/mL.

Monthly THM averages throughout the distribution system did not exceed 100 μg/L during a 15-month period following the conversion to chloramines. Further, the four quarterly running averages for THMs remained below 80 μg/L. Average total haloacetic acid levels decreased slightly from 26 μg/L using free chlorine to 21 μg/L after the conversion to chloramines.

CONCLUSION AND RECOMMENDATIONS

Because some degree of water quality deterioration takes place in all distribution systems, high-quality finished water entering the system is no guarantee that the system will remain free of coliform occurrence. Further, when coliform bacteria become problematic in the distribution system, there is no completely effective means to do away with them. However, the case studies presented clearly demonstrate that the control of distribution system coliforms is possible using a series of best management practices for treatment, disinfection, and distribution system maintenance. These practices include adequate disinfection, filtration to lower turbidity and nutrient levels, corrosion control, and distribution system maintenance. Moreover, the water system operator must consider all of these practices in devising a solution to limit the impact of distribution system coliform occurrences and biofilm. In developing a strategy for coliform control, water system operators also need to be aware of all the potential causes of distribution system coliforms. Each occurrence of coliform bacteria must be evaluated in order to rule out treatment lapses and distribution system contamination before concluding that biofilm is to blame. Failure to investigate any coliform occurrence episode may create an unreasonable health risk if the coliforms are the result of operational problems.

Composting is a technique primarily applied for the stabilization of organic solid wastes, such as municipal solid waste, animal manure, biosolids, and yard cuttings. A new application of composting for bioremediation and biodetoxification is defined as compost bioremediation. Compost bioremediation comprises the remediation and restoration of contaminated soil (soil composting, biopiling), treatment of contaminated sludge and solid waste (composting), and purification of contaminated air (biofiltration). Compost bioremediation applied to landfarming and biofiltration involves the use of tailor-made mature or finished compost, which acts mainly as a source of

microorganisms and cosubstrate for the breakdown of pollutants. Compost bioremediation has proven effective in degrading and sequestering many types of toxic environmental pollutants, such as halogenated aromatics and hydrocarbons, pesticides, petroleum derivatives, explosives, solvents, heavy metals, and odors. Once applied to soil, in addition to alleviating contamination — which is the intrinsic purpose of bioremediation itself, compost has the added value of supplying nutrients and providing soil conditioning for its further restoration. The techniques of landfarming, composting, and biopiling are often collectively designated soil remediation. Landfarming consists of spreading a thin layer of the material that needs to be detoxified over the soil, which then undergoes the traditional agricultural practices of fertilization and irrigation. Mechanical plowing ensures aeration and mixing. Soil composting consists of mixing a polluted soil with compost amendments and bulking agents such as straw, wood chips, plant wastes, manures and, as required, microbial inoculum. Here again periodic turning and aeration are practiced. Biopiling consists of mixing soil with a compost structuring agent at a ratio that is lower than that used in composting. Because turning is not applied, biopiling is less homogeneous and sometimes less effective in removing pollutants than composting. This chapter focuses on the biodegradation of toxic organic compounds commonly found as soil pollutants during composting, with an emphasis on four major families of environmental pollutants: petroleum products, chlorinated compounds, explosives, and pesticides. Landfarming and biofiltration technologies, which are related to the use of compost and not to the composting process itself, are not within the scope of this chapter.

PRINCIPLES OF COMPOSTING

Composting is defined as the thermophilic aerobic decomposition of organic matter (OM) by a mixed microbial population under controlled conditions. Composting is a form of waste stabilization that requires special conditions, particularly of moisture and aeration, to yield temperatures conducive to thermophilic microorganisms (1,2). Compost is the stabilized and sanitized product of composting, which is beneficial to plant growth. The heterogeneous organic substrate has undergone an initial, rapid stage of decomposition and is in the process of humification (3).

Controlled environmental conditions distinguish composting from natural decomposition, which often occurs in open dumps, manure heaps, or field soil. The degree of control also distinguishes composting from other solid-phase bioremediation techniques, such as biopiling and soil farming. The organic wastes, comprising several components, normally have an indigenous population of microorganisms. Once the moisture content of the waste is brought to an appropriate level and the mass is aerated, microbial metabolism speeds up. Energy is obtained by biological oxidation of part of the carbon; some of this energy is used in metabolism, the rest is given off as heat. The end product (compost) is made up of the more resistant OM residues, breakdown products, dead and living microorganisms, together with products from further chemical reactions between these materials (4).

The temperature trend in most composting processes can be divided into four stages:

1. *Mesophilic:* an initial phase lasting one to two days, during which the mesophilic strains of microorganisms start to decompose the readily degradable compounds; heat is given off and the temperature rises. The pH falls slightly as organic acids are produced.
2. *Thermophilic:* the second stage, lasting two to four weeks, when, above 40 °C the thermophilic strains take over. If the temperature rises above 60 °C, the fungi become deactivated, and the reaction is continued by thermophilic bacteria. During this phase, the more readily degradable substances, such as sugars, fats, starch, and proteins, are rapidly consumed and most of the human and plant pathogens are destroyed; the pH becomes alkaline as ammonia is liberated from the proteins. The reaction rate decreases as the more resistant materials are attacked; the compost enters stage 3.
3. *Cool-down:* as the temperature falls, the thermotolerant fungi reinvade the composted material from the cooler environment. These first three stages of composting last from a few weeks to two months, depending on the composted material and technology of composting.
4. *Stabilization and maturation:* requires several months, during which little heat is generated and the final pH is normally slightly alkaline. During this phase, mesophilic microorganisms, as well as macrofauna, colonize the compost. Intense competition for food takes place between the microorganisms, involving antagonism and the formation of antibiotics (5). Humification occurs in the residual OM to produce the stable composted product (2). This process probably includes the polymerization of aromatic compounds, as well as lignin modifications. Thus, it could be important in pollutants detoxification via immobilization in the humic substances.

Thus, the composting of organic wastes is a dynamic and extremely complex ecological process in which temperature, pH, and nutrient availability are constantly in flux.

Different types of microorganisms are active at different times in the composting pile. Bacteria have the most marked effect on the decomposition process, and are the first to take hold. The numbers and species of organisms responsible also change markedly. Thermophilic bacteria, particularly *Bacillus* spp. and *B. cereus* (6), appear to dominate the early phase of high activity, but thermophilic actinomycetes predominate thereafter (7). Fungi, which compete with bacteria for food, play an important role at later stages in the process as the pile dries, as these organisms can tolerate low-moisture environments better than bacteria. Raw compost material contains about 10^6

microbial counts of mesophilic fungi per gram of raw material and 10^3 to 10^6 thermophilic fungi per gram (8). The predominant mesophilic fungi in the raw material are *Geotrichum* spp. (9) and the thermotolerant fungus *Aspergillus fumigatus* (10).

Thermophilic microorganisms prefer temperatures between 45 and 70 °C. Thermophiles generate even greater quantities of heat than mesophiles, and the temperatures reached during this stage are hot enough to kill most pathogens and weed seeds. The thermophiles continue decomposing the feedstock materials as long as nutrient and energy sources are plentiful. As these sources become depleted, thermophiles die, and the temperature of the pile drops. In mushroom compost, thermophilic fungi are responsible for the degradation of lignocellulose (11).

Thermophilic and thermotolerant fungi, which are known to possess cellulolytic and ligninolytic activities, or which have been found growing in compost, have been studied (12): for example, *Talaromyces emersonii*, *Thermoascus auranticus*, *Thermomyces lanuginosus*, and a *Coprinus* sp. (9,10). Chefetz and coworkers (13) purified phenol oxidase (laccase) from municipal solid waste compost during the thermophilic stage of composting. *Chaetomium thermophilium*, a cellulolytic fungus, was isolated from this stage and exhibited laccase activity when grown at 45 °C. The purified laccase exhibited high catalytic activity toward a wide range of phenolic substrates. These fungi may be responsible for the degradation of aromatic xenobiotics during composting.

When the temperature decreases, mesophilic and thermotolerant microorganisms recolonize the compost (8). The fungi that are dominant after peak heating are *Aspergillus* spp. (9) or *T. lanuginosus* (10). Basidiomycotina occurring in compost include *Panaeolus* spp., *Corticium coronilla*, and possibly *Mycena* spp., all of which have been isolated from compost during the cooling and maturation phases, or from mature compost (9,10).

APPLICATION OF COMPOST FOR THE DETOXIFICATION OF TOXIC ORGANIC COMPOUNDS

During composting, the organic contaminants in the raw material are exposed to the activity of microorganisms that are capable of metabolizing some of them to by-products (partial degradation or transformation) and some of them to completion (mineralization). Consequently, composting has been proposed as a means of removing such organic compounds (bioremediation) (14). Of the broad range of common toxic pollutants reported to be degraded in compost, explosives, and more specifically 2,4,6-trinitrotoluene (TNT) and hexahydro-1,3,5-trinitro-1,3,5-triazine or royal demolition explosives (RDX), have been widely studied (Table 1). Other common families of compounds intensively studied include total petroleum hydrocarbons (TPH) such as gasoline, diesel and jet fuels, oil, and grease (15); polycyclic aromatic hydrocarbons (PAH) found in wood preservation, coal gasification, and petroleum refining wastes (16), and the most distinctive family of toxic compounds studied, pesticides (i.e., insecticides and herbicides) (17,18).

In trials for examining the degradation of pesticides in cotton waste chicken manure–based compost, almost complete degradation of carbofuran (a carbamate insecticide) and 99% degradation of simazine (a herbicide of the triazine group) were found after 50 days (19). In Alaska, composting was tested as a means of clearing the soil of fuel pollutants (20). Almost complete degradation of alkylbenzene was registered after 35 days along with a drop in TPH from 1,700 to 120 mg/kg after 70 days. The ability of microorganisms to degrade many dangerous chemical compounds has been proven; among them are compounds that are known to be resistant to degradation, such as benzene, pentachlorophenol (PCP), phthalates, heavy and light fuels, phenols, PAH, mineral alcohols, and polychlorinated biphenyls (PCB) (21). Residues of organochlorines can still be found in composts because of their high recalcitrance to biodegradation.

Table 1. Examples of Organic Compounds from the Four Main Families of Environmental Pollutants Studied for Degradation During Composting

Class of Contaminant	Source	Example
Petroleum products		
TPH	Petroleum industries, vehicle repair workshops, oil-cleaning plants, oil separators: gasoline, diesel and jet fuels, oil and grease	Mainly alkanes, paraffins with 1 to 40 carbon atoms per molecule, and cycloalkanes
PAH	Incomplete burning of coal oil, wood, and garbage; coal gas production; petroleum refining; coal cooking; coal tar manufacturing; wood preservation; aluminum extraction; asphalt; cigarette smoke; fire smoke and residue	Fluorene, naphthalene, anthracene, phenanthrene, pyrene, benzo[*a*]pyrene
Pesticides	Insecticides, herbicides, fungicides	Atrazine, dicamba, diazinon, 2,4-D
Explosives	Military munitions	TNT, RDX, nitrocellulose
Nonvolatile chlorinated compounds	Wood and leather preservatives, pulp and paper manufacturing, production of synthetic polymers, and burning of chlorinated plastics	Polychlorinated dioxins (PCDD) and furans (PCDF), polychlorinated biphenyls (PCB), chlorinated phenols

The degradation of PCP, anthracene, phenanthrene, benzo[*a*]pyrene, and a mixture of benzene, toluene, ethylbenzene, and xylenes (BTEX) during mushroom composting or mushroom compost and soil landfarming was studied on a laboratory scale, using flask respirometers (10 to 100 g), bench composters (1 kg), and environmentally controlled compost bins (40 kg) (22–24). Mineralization of ^{14}C-PCP was observed in composts incubated at 30 °C for 4 weeks, and generally, neither toxic intermediates (e.g., chloroanisoles) nor polymerization products (e.g., dibenzo-*p*-dioxins) were detected. Pre-enrichment using PCP at 500 mg/kg for 3 months on a 30-kg scale induced PCP mineralization activity in composts. Further studies showed that during the thermophilic stage, compost could also be induced to degrade freshly added phenanthrene. The extent of mineralization (65% after 50 days) was greater than in noninduced compost (6%). However, the application of compost did not seem to influence the removal of aged phenanthrene from soil. In contrast to chlorophenols, PAH are strongly hydrophobic compounds that exhibit significant partitioning in the organic carbon of soil, resulting in reduced bioavailability and hence bioremediation potential.

Despite the numerous investigations performed and the wide application of composting in bioremediation, knowledge of the mechanism involved in the degradation of organic compounds during this process is relatively scarce. The following sections provide a detailed description of the four major families of pollutants studied for their degradation during composting: petroleum products (TPH and PAH), nonvolatile chlorinated compounds, pesticides, and explosives.

DEGRADATION OF PETROLEUM PRODUCTS

TPH contaminants consist of several aliphatic and aromatic fractions of crude and treated oil, ranging from simple *n*-alkanes (paraffins with 1 to 40 carbon atoms per molecule) to complex branched and cyclic alkanes, both aromatic and polyaromatic (25). The major sources of TPH discarded to the environment are wastes from petroleum industries, vehicle repair workshops, oil-cleaning plants, and oil separators (see Table 1). *n*-Alkanes, which are easily degraded by soil bacteria, are normally absent or present at low concentrations. The remaining TPH are more difficult to degrade and therefore considered recalcitrant. These include structurally complex alkanes, such as isoprenoids, steranes, hopanes, two- to six-ring PAH, cycloalkanes, asphaltenes, resins, and polar compounds. The many-branched pristane and phytane were used as endogenous tracers to estimate the biodegradability of TPH in several studies (25). TPH-contaminated soils frequently contain 5,000 to 20,000 ppm. Biopiling of soil with mature compost in laboratory-scale reactors resulted in the rapid degradation of even complex TPH within two weeks to two months, compared to the long treatment required with landfarming (up to 6 months) (26,27). The studies found degradation rates of about 375 ppm TPH/day, in contrast to the 40-ppm TPH/day reported for in situ biodegradation (28). However, despite the high extent of degradation reported, a significant amount of bound residue was found. In a field study, Bartusiak (29) reported an oil degradation rate of 110 ppm/day. Kirchmann and Ewnetu (15) studied the biodegradation of oil sludge from petrol stations and petroleum residues from a refinery through composting with horse manure. Paraffin oil was used as a reference. Oil wastes decomposed 78 to 93% within 4.5 months of composting. Mineralization accounted for 37 to 41% of the carbon degraded. Degradation was estimated by measuring total organic carbon (TOC) and total oil content (toc) based on extraction of the organic substances with trichlorotrifluoroethane. Mineralization was determined as the difference between TOC and toc. Volatilization was found insignificant. Brown and coworkers (25) found accelerated degradation of TPH in soil amended with sludge compost. Two- to three-ring PAH degraded more rapidly than others. Among the four-ring PAH, pyrenes degraded more readily than chrysenes. The more recalcitrant PAH within a homologous group were the highly methylated ones.

PAH are composed of several hundred individual compounds containing at least two condensed aromatic rings and represent the more widely studied family of TPH components. Today, anthropogenic combustion of fossil oil is by far the major source of PAH input into the environment (see Table 1) (30,31). PAH with two and three rings are often referred to as low molecular weight (LMW) PAH, whereas those with more than three rings are often referred to in the biodegradation literature as high molecular weight (HMW) PAH (32). Fluorene (two rings), naphthalene (two rings), anthracene (three rings), phenanthrene (three rings), pyrene (four rings), chrysene (four rings), and benzo[*a*]pyrene (five rings) constitute the more extensively studied congeners (Table 2). The recalcitrance of PAH is caused by their limited solubility in water, the requirement for oxygen to initiate oxidation, and their diverse and complex structure (32). In addition, some of the compounds have biocidal properties. The lighter congeners (e.g., naphthalene) are volatile; as the number of condensed benzene rings increases, so do hydrophobicity and resistance to microbial degradation (30,33).

Crawford and coworkers (33) reviewed the potential of composting for the bioremediation of soil contaminated with PAH. Windrow facilities were efficient for the degradation of PAH in compost; however, this increased the volatilization of light and semivolatile congeners. They concluded that both bench- and field-scale studies are needed to further define the variables most conducive to composting processes focused on the degradation of PAH.

Joyce and coworkers (16,40) studied the degradation of a mixture of three- and four-ring PAH during composting of municipal solid waste in a batch-type, in-vessel, laboratory-scale composter. The extent of their disappearance was monitored for 2 months. The results indicated that the major biodegradation occurred during the first 30 days (i.e., active phase). Anthracene, phenanthrene, and pyrene almost completely disappeared, whereas 80% of fluorene's disappearance was because of volatilization. Benzo[*a*]pyrene was completely recalcitrant.

McFarland and colleagues (34,41) reported higher initial rate of bound-residue formation of contaminant carbon

Table 2. Carbon Allocation During Controlled Composting of PAH-Containing Wastes on a Laboratory Scale

PAH	Percentage of Initial Carbon in the Fraction				
	Disappearance	Volatilized	Mineralized	Bound	Adsorbed
Fluorene	90–95	80	n.d.a.	n.d.a.	n.d.a.
Naphthalene	80–95	17	20–60	10–27	45
Anthracene	92–95	n.d.a.	10–30	20–70	4
Phenanthrene	80–95	n.d.a.	38	36	5
Pyrene	50–90	n.d.a.	10–45	15–45	5
Benzo[*a*]pyrene	60	n.d.a.	5–10	20–60	n.d.a.

Note: Adapted from References 34, 35–37,38,39. Data refer to ^{14}C-labeled experiments in soil and compost mixtures or sludge compost. n.d.a.: no data available.

during the first 30 days of composting by inoculating a benzo[*a*]pyrene-contaminated soil composting system with the white rot fungus *Phanerochaete chrysosporium*. Although, fungal inoculation was ineffective in significantly enhancing the extent of benzo[*a*]pyrene degradation within 95 days of composting, the extent of contaminant disappearance was around 63%. However, analysis of the volatile fraction indicated that neither mineralization nor vapor partitioning of benzo[*a*]pyrene (or its chemical intermediates) is significant during the soil composting process. Bound-residue formation was found to be the predominant transformation mechanism for benzo[*a*]pyrene in the microbially active compost systems, accounting for nearly 100% of its removal.

The effect of compost age on the degradation of the four- to six-ring PAH perylene, benzo[*a*]anthracene, and chrysene during composting of municipal solid waste was studied by Martens (42). The author concluded that microbial decay of PAH during composting occurs because no accumulation of PAH concentration in ripe compost was detected inspite of a 40 to 60% weight reduction during composting. In contrast, studies with ^{14}C-labeled PAH indicated that in fresh composts, only minor amounts of PAH are degraded.

The degradation of PAH during composting of artificially contaminated pinewood and naturally polluted pinewood (mixture of waste wood and PAH-polluted soil), mixed with animal manure, was studied at a pilot-scale level (43). PAH degradation in dewar vessels was influenced by the inoculum used. The fastest PAH degradation was achieved by compost addition, but the most intensive CO_2 evolution was measured with PAH-polluted soil as an additive. After 61 days, the PAH content of the wood was reduced from 1,000 mg/kg each to 26 mg/kg of phenanthrene and 83 mg/kg of pyrene. The relationship between microbial wood decay and PAH degradation showed that the detoxification, at least of artificially PAH-polluted wood, requires only partial wood decay. In a pilot-scale percolator, after 27 days of remediation, the portion of residual PAH was higher in the naturally polluted material. The slower degradation in the naturally polluted waste wood may be explained by the lower bioavailability of pollutants relative to artificially contaminated wood. In the former, the degradation rate of PAH depended on their degree of condensation (the higher the number of aromatic rings, the smaller the degradation rate).

Several studies have reported that adding compost to contaminated soil enhanced bioremediation because of the structure of the organic matrix. Kastner and Mahro (35) studied the degradation of naphthalene, phenanthrene, anthracene, fluoranthene, and pyrene in soil and soil and compost mixtures. To evaluate degradation and to distinguish it from sorption, they performed alkaline humic acid extraction of the samples. Kastner and coworkers (36) reported stimulated degradation of ^{14}C-labeled anthracene and hexadecane in soil amended with ripe compost. With compost, 23% of the labeled anthracene was transformed into $^{14}CO_2$ and 42% was fixed to the soil matrix irreversibly, whereas more than 88% of the original anthracene could be recovered from the nonamended control. The formation of nonextractable bound residues was markedly lower with ^{14}C-hexadecane as only 21% of the labeled carbon had become nonextractable after 103 days. Kastner and coworkers (37) also reported that anthracene decomposition in soil occurs in a two-phase process. In the first, the original compound is sequestered in the soil, as reflected by its limited extractability. In the second, PAH metabolites undergo oxidative coupling to the humic substances, forming nonhydrolyzable complexes.

Compost was also reported to enhance the oxidation of aromatic contaminants in soil to ketones and quinones, which eventually further disappear, during the composting of soils and compost mixtures artificially contaminated with coal tar PAH, including N-containing analogs (44,45). Whereas in nonamended soil only aromatics with up to three fused benzene rings were considerably degraded during the first 15 weeks of the experiment, soil supplementation with compost helped enhance elimination of all compounds monitored. After 15 weeks, substantial residues were only found for benzo[*a*]anthracene, chrysene, and benzo[*a*]pyrene. Accumulation of ketonic and quinonic degradation products, such as 9-fluorenone, anthracene-9,10-dione, 2-methyl anthracene-9,10-dione, and benzo[*a*]anthracene-7,12-dione, was observed in nonamended soil material. In mixtures with compost, short-term concentration maxima of such products correlated well with phases of enhanced contaminant elimination.

Soil composting treatment performed on field and laboratory scales was compared for the removal of PAH at mesophilic temperatures (46). PAH degradation was lower in the laboratory trial than in the field trial, and

no self-heating of the soil was demonstrated in the laboratory. The absence of microorganisms was unlikely to have limited the biodegradation of PAH in this study. Composting for the removal of PAH from soil was assessed as a treatment option at a former tar-contaminated site in Australia, alongside conventional land treatment. Soil composting was substantially more effective in removing benzo[*a*]anthracene, benzo[*b* + *k*] fluoranthene, benzo[*a*]pyrene, dibenzo[*ah*]anthracene, chrysene, indenopyrene, and benzo[*gih*]perylene, than the land treatment processes. The extent of removal of these HMW-PAH was at least 50%, over the seven-month treatment period in which composting was used, whereas degradation did not exceed 5% for each of these PAH compounds in the land treatments over the same period (47).

The relationship between biomass growth and PAH degradation in soil, and subsequent toxicity reduction, was evaluated in bench-scale compost units. Whereas all treatments resulted in significant degradation of PAH with two to four rings in their molecular structure (50 to 95%), no reduction in the concentrations of five- or six-ring PAH occurred during the 12-week study (48,49). Rates of PAH removal during the first four weeks of compost treatment correlated strongly with initial PAH concentration but not with the reactor biomass concentration. Several toxicity bioassays were used to evaluate the efficacy with which compost biomass reduces toxicity of PAH-contaminated soil. After composting, no significant genotoxicity was observed in the soil.

Degradation of PAH in aged, creosote-contaminated soil by applying spent oyster mushroom compost was studied in laboratory-scale polyethylene columns (50). Whereas degradation of three-ring compounds was similar, the four- and five-ring PAH were better degraded when soil and fungal substrate were homogenized rather than layered. Fish oil added to the spent mushroom compost (SMC) and mixed with creosote-contaminated soil gave the best degradation of PAH. This treatment, incubated for seven weeks at ambient temperature, resulted in the following removal percentages: 86% of the total 16 PAH, 89% of three-ring PAH, 87% of four-ring PAH, and 48% of five-ring PAH. Whereas numerous studies have been performed on the fate of PAH during composting, very little information is available on their volatility. The LMW congeners, with the higher vapor pressures, are expected to be more susceptible to volatilization. Thus, Silviera and Ganho (38) found 17% volatilization of ^{14}C-labeled naphthalene in laboratory reactors.

Similar to soil, PAH degradation by microorganisms in compost is limited by its availability and by the presence of microorganisms possessing suitable metabolic activities. In contrast to soil, however, composting provides temperature, pH, and redox potentials suitable for their degradation. Sorption and desorption of PAH to and from the organic matrix of compost are crucial to the bioavailability of these compounds. In a recent review on PAH in soil, Wilcke (31) concluded that PAH sorption in soil resembled its partitioning between water and an organic solvent, indicating that sorption is an entropy-driven two-phase process. The first is rapid and probably corresponds to sorption near the surface of the macromolecules. The second is slow and may be explained by diffusion of the PAH to internal binding sites. There appears to be an inverse correlation between the polarity of the organic matrix and the strength of adsorption. Similarly, studying the pattern of pyrene sorption to different types of natural organic matter (NOM), Chefetz and coworkers (51) concluded that the aliphatic moieties of NOM contribute significantly to the sorption of nonionic aromatic pollutants to complex NOM matrices.

The data presented in Table 2 summarize the distribution of the carbon fraction of the most extensively studied PAH congeners during composting under controlled laboratory conditions. As can be seen from the data summarized, covalent binding to the OM seems to be the prevalent path of disappearance, whereas adsorption seems to be a minor one, for all the congeners. Mineralization is significant for the LMW-congeners; however, it is only minor for the HMW-congeners. Volatilization seems to be an important path of disappearance for the low vapor pressure, LMW-congeners, such as fluorene and naphthalene; although, there is not enough data to make a decisive conclusion on the basis of studies performed under composting.

DEGRADATION OF HALOGENATED COMPOUNDS

The toxic halogenated organics, especially chlorinated congeners, described in this section refer to those aliphatic, aromatic, and polyaromatic compounds derived from the use of wood and leather preservatives, pulp and paper manufacturing, production of synthetic polymers, and burning of chlorinated plastics (see Table 1) (52). Volatile chloroaliphatic compounds such as dichloromethane, dichloroethene, trichloromethane, trichloroethene, tetrachloroethene, vinylchloride, and other volatile organic compounds (VOC) are normally treated by biofiltration using, among others, finished compost as a biofiltration packing matrix, rather than composting systems.

Polychlorinated dibenzo-*p*-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) are known to spread through the environment by atmospheric transport and deposition processes (53,54). PCDD and PCDF have been detected in trace amounts as unwanted by-products in final products and residues of industrial production. The sources of PCDD and PCDF can be divided into primary ones, for example the chemical industry, pulp and paper industry, etc., and combustion processes with stationary and mobile sources. The main route for the introduction of dioxins into the environment is via combustion processes, whereby the emitted dioxins may be carried by atmospheric transport to ultimate environmental sinks (55). Such processes lead to the presence of these compounds, albeit at low concentrations, in plant materials and soil, both of which are major components of the raw material used in composting. The fate of PCDD and PCDF during composting, including the more toxic congeners (2,3,7,8-substituted PCDD and PCDF), was studied by Eitzer and coworkers (54). Although somewhat variable, their studies revealed that no significant changes in concentration took place during composting. However, as the average toxic range of these compounds, measured in terms of

toxic equivalents (TEQ), was found to be below the recommended unrestricted level of 5 pg TEQ/g, the final compost was considered safe for agricultural use.

Laine and coworkers (56) applied luminescent bacteria tests to assess the fate of chlorophenols during the composting of sawmill soil and impregnated wood. The assessed toxicity decreased during composting, paralleling the chlorophenol concentrations in the compost piles. Organic chlorine compounds, which appeared in HMW sizes, were neither degraded nor remobilized during composting, although no further polymerization occurred during the composting. Large amounts of PCDD and PCDF were found in the compost piles, but their concentrations did not significantly change during the bioremediation process. As PCDD and PCDF were not degraded during bioremediation, the treatment of PCDD- and PCDF-contaminated wood chips in biopiles is not recommended. However, sampling of airborne particles during the mixing of compost windrows at a wood-preserving site contaminated with chlorophenols and PCDD and PCDF, showed concentrations of PCDD and PCDF in different particle sizes. The congener distribution of PCDD and PCDF in the collected air-particle fractions was similar to that in the compost windrows, and their level was 1,000-fold higher than the atmospheric background values reported previously (57).

Only a few PCB congeners with two or three chlorine atoms are likely to be degraded by composting or addition of finished compost to soil, whereas the higher congeners, with four or more chlorines, are present in finished compost at almost the same concentration as that added or found at the beginning of the process (58,59). The level of PCDD and PCDF and PCB in compost at different degrees of maturation from 21 Brazilian municipal solid waste composting plants was evaluated (60,61). Most PCDD and PCDF concentrations were above acceptable levels (17 ng TEQ/kg), especially for compost from metropolitan areas. For PCB, the average concentrations of six PCB congeners were 28, 52, 101, 138, 153 and 180 μg/kg, which is three times less than the value stipulated by regulations (0.2 mg/kg).

Wastewater treatment sludge and power-boiler fly ash were combined and composted in mixed and static windrows (50-m long, 4-m high, and 6-m wide) (62). The concentrations of PCB and chlorophenol in the final compost were below the levels stipulated by regulations (dioxin concentration of 41 pg/g TEQ). Applying compost to soil improved soil characteristics as measured by a number of parameters, and the dioxin concentration in the final soil and compost mixture was 3 pg/g TEQ, allowing the soil and compost mixture to be classified as agricultural soil. In contrast, Rosenbrock and coworkers (63) reported 28% mineralization of U[^{14}C]dibenzo-*p*-dioxin in soil amended with wheat straw and mushroom compost and up to 50% mineralization by mixing soil with wheat straw precolonized with several strains of white rot fungi.

Straw composting of chlorophenol-contaminated soil, performed at a pilot-scale level, was studied by Laine and Joergensen (64). More than 90% of the chlorophenols were removed during the composting period. Frequent mixing and control of the nutrient level enhanced the chlorophenol degradation activity of the indigenous microbes in the contaminated soil. In a parallel bench-scale experiment, an average 60% mineralization of [^{14}C]-PCP was obtained in four weeks, indicating that a major part of the chlorophenols had been mineralized completely.

Benoit and Barriuso (65) studied the degradation of ^{14}C-labeled 4-chlorophenol (4-CP) and 2,4-dichlorophenol (2,4-DCP) during wheat straw composting on a laboratory scale. After three weeks of composting, approximately 20% mineralization of the chlorophenols was observed, whereas approximately 40 and 70% of 2,4-DCP and 4-CP, respectively, were found bound to compost residue, and 30% 2,4-DCP and only 2% 4-CP to the water-extractable residue. Binding of chlorophenols to humic substances has been explained by polymerization via stable ester-bond formation by extracellular enzymes, accompanied by dehalogenation (66,67). Mineralization of [^{14}C]-PCP was observed in mushroom composts incubated at 30 °C for four weeks, and generally, neither toxic intermediates (e.g., chloroanisoles) nor polymerization products (e.g., dibenzo-*p*-dioxins), were detected (22).

The data presented in Table 3 summarize the distribution of the carbon fraction of the most extensively studied chlorophenols during composting under controlled laboratory conditions. As can be seen from the summarized data, the microbial transformation decreases with the degree of chlorination, and covalent binding to the OM seems to be the prevalent path of disappearance. Adsorption and mineralization are less marked for all the congeners, whereas volatilization seems to be negligible.

Table 3. Carbon Allocation During Controlled Composting of Chlorophenols-Containing Wastes on a Laboratory Scale

	Percentage of Initial Carbon in the Fraction				
Chlorophenol	Disappearance	Volatilized	Mineralized	Bound	Adsorbed

[a] 4-CP: 4-chlorophenol.

[b] 2,4-DCP: 2,4-dichlorophenol.

[c] PCP: 2,3,4,5,6-pentachlorophenol.

DEGRADATION OF PESTICIDES

The use of naturally occurring microorganisms to degrade complex pesticides is not new, and composting is one of the oldest waste disposal systems known to man. Although widely used in the handling of solid wastes, such as agricultural plant residues, the potential of composting in degrading pesticide-laden wastes has only recently been gaining attention. Composting windrows may provide an accessible, low-cost mechanism in which naturally occurring microorganisms can be manipulated to achieve a rapid, cost-effective means of treating toxic wastes. A single windrow may be capable of handling a wide variety of pesticide-laden soils or rinsates simultaneously, or be acclimatized to encourage the dominance of specialized populations of microorganisms to achieve maximum degradation rates (69).

Pesticides vary largely in their chemical nature, and consequently, they vary largely in their ability to break down in compost. Older organochlorine insecticides, for example, toxaphene, break down very slowly (4% within 30 days), whereas other pesticides, for example, trifluraline, degrade more than 80% within the same time frame. Other chemicals, such as 2,4,5-*T*-atrazine, endrin, and PCP, are moderately degradable and are reduced by about 50% in 30 days. Similar variability in breakdown rates is also seen with pesticides in soils (70). In general, organophosphate and carbamate pesticides are at negligible concentrations in composting feedstock, indicating that they are well degraded in the environment. Therefore, most of the degradation studies refer to organochlorine pesticides.

The use of compost for the remediation of high concentrations of released pesticides is considered mainly for two types of applications: (*1*) bioremediation of soils contaminated with pesticides and (*2*) biodegradation of mixed pesticides in rinsates, such as those generated by the washing of sprayers and aircrafts involved with pesticide application. Much of the literature on pesticide transformation in compost refers to the effect of organic amendments, including compost, on the fate of pesticides in soils (71), or to the transformation of pesticides during composting of agricultural or yard waste (18). Neither source is readily relevant to the degradation of pesticides in contaminated soils and rinsates in which pesticides occur at much higher concentrations. Moreover, typical findings in compost-amended soil indicate increased binding and increased stabilization of the pesticides, rather than accelerated degradation (71).

For example, the transformations of eight herbicides (atrazine, simazine, terbutryn, pendimethalin, carbetamide, 2,4-D, metsulfuron-methyl, and dimefuron) in soil after compost addition were monitored during long-term laboratory incubations. Compost addition to soil generally decreased herbicide mineralization and favored the stabilization of herbicide residues. A fraction of the stabilized residues remained extractable and potentially available. However, most of them were nonextractable and formed bound residues. Sorption and desorption could be the first step of kinetically limited biodegradation, mainly for the most highly sorbed herbicides (atrazine, simazine, terbutryn, pendimethalin, and dimefuron). Compost addition had little effect on the less-sorbed herbicides (carbetamide, 2,4-D, and metsulfuron-methyl).

It is important to note that the removal of pesticides by composting is a complex mechanism involving many possible pathways. Most often, the removed pesticides are not actually degraded but their detection becomes impaired by limitations of the analytical analysis. For example, when a pesticide is strongly sorbed to the humic substances in the composting pile, it will still be present in the compost but it may become very difficult to chemically extract, thus its presence can go undetected. However, because of the irreversible nature of some covalent binding mechanisms, the risk to potential acceptors from the bound pesticides is also greatly reduced.

Obviously, complete mineralization to the pesticide's basic, nonhazardous chemical building blocks (carbon dioxide, water, and ammonia) is the best route from an environmental point of view. However, in practice, several other mechanisms normally dominate the removal of pesticides from compost. Some of these mechanisms may include: partial biotic degradation to metabolites; partial abiotic degradation by processes such as hydrolysis or photodegradation; assimilation into microorganisms, uptake by plants, complexation of parent compounds or metabolites with other similar compounds (polymerization) or with humic substances (humification); volatilization into air; leaching into groundwater, or drifting on compost dust in the wind. Volatilization of pesticides has been showed as a major mechanism of removal for a number of pesticides (see review by Buyuksomez and coworkers (17)).

A few studies have reported the disappearance mechanisms and degradation pathways of pesticides during composting using radioactive tracers. Valo and Salkeinoja-Salonen (72) conducted one of the earliest studies on using compost for the degradation of chlorophenol (fungicide) in contaminated soils. Chlorophenol was degraded after 120 days from 200 to 300 ppm to 20 to 30 ppm. Another year of composting reduced the concentration to only 15 ppm, indicating much more difficult removal of part of the aged material. The mechanism of degradation of various pesticides during composting was examined by Lemmon and Pylypiw (73) and by Bugbee and Saraceno (74). They found that 2,4-D is mineralized to carbon dioxide and water, whereas diazinon is partly degraded to water-soluble metabolites and partly to insoluble products. Other studies have shown that composting is a valuable remediation method for soils contaminated with the herbicide dicamba (75) and PCP (76). Racke and Frink (77) found approximately 5% mineralization of carbaryl, a carbamate insecticide, during composting of wastewater treatment sludge in aerated laboratory static piles. They suggested that the main mechanism of disappearance was transformation of carbaryl to 1-naphthol, which in turn binds to the humic fraction of the compost. Reddy and coworkers (78–80) studied the degradation and fate of the [^{14}C]-radiolabeled pesticides diazinon, 2,4-D, and pendimethalin during composting of yard trimmings in aerated laboratory composters. In all cases, volatilization was negligible. After approximately 50 days of composting 47% of 2,4-D and 11% of diazinon were mineralized; the

bound fraction was 49% for 2,4-D (approximately 23% of it was incorporated into humic material) and 51% for diazinon (approximately 19% of it was incorporated into humic material). Only 3% of 2,4-D was found adsorbed, whereas 36% of the diazinon was only hydrolyzed to a secondary product. Pendimethalin was found to be the most resistant to biodegradation, although 13% was mineralized. Rao and coworkers (81) reported complete disappearance and 11% mineralization of [^{14}C]-atrazine after four months of composting of pretreated wood.

The need for appropriate methods to capture and then treat pesticide rinsates generated at pesticide loading, mixing, and wash-down sites is coming to the forefront (69). Pesticide disposal methods based on the principles of bioremediation are not only safe and effective, they are also practical. Several media have been tested as adsorbents for pesticides in rinsates. SMC was tested as an adsorption medium for the removal of pesticides, including carbaryl, carbofuran, and aldicarb, at concentrations of 0 to 30 mg/L from rinsate (82,83). It was found that SMC might potentially be used for on-farm treatment of pesticide rinsate. The rapid equilibrium reached by the pesticide solution and SMC was consistent with a physical type of adsorption mechanism. The adsorption of carbamate pesticides onto SMC exhibited nonlinear, "favorable" adsorption behavior that could be well characterized by the Freundlich isotherm model. In addition, multipesticide adsorption tests displayed the characteristics of competitive behavior. The competitive ability of these three pesticides in multicomponent adsorption followed the order carbaryl > carbofuran > aldicarb, consistent with their adsorbability.

Mullins and coworkers (69,84) developed a system that utilizes lignocellulosic (organic) sorbents and subsequent chemical and microbial-mediated degradation of sorbed pesticide residue. They envisioned this system's incorporation into a pesticide loading, mixing, and wash-down pad facility. By combining or integrating bioremediation with a sorbent and wash-down pad facility, it may be possible to dramatically reduce pollution of surface and groundwater at sites in which application equipment is loaded and cleaned. Furthermore, they constructed and tested several versions of a pesticide disposal system that includes a two-step disposal process: sorption and biodegradation.

Field-scale tests on the disposal of four formulated pesticides using peat moss as the sorbent and composting of the sorbed residues were performed. Thirty-five–gallon volumes of pesticides at concentrations ranging from 1,200 to 1,500 mg/kg were treated. The pesticides mixture included: malathion (Dragon 4E), captan (Captan 50 WP), lindane (Ortho 2.5E), and diazinon (Ortho 4E). The total amount of residue remaining in the treated rinse water and composted sorbent represented less than 2% to as little as 0.003% of the initial amounts of each pesticide contained in the untreated rinse water prior to treatment (69). These results demonstrated the efficacy of using organic sorbents in a large-scale system to remove and degrade pesticides from pesticide-containing rinse water.

Field studies have also demonstrated the degradation of pesticides in a composting environment. For example, very high levels of diazinon can be degraded within a short time. Levels ranging from 4,000 to 32,000 mg/kg were effectively degraded to 1 and 61 mg/kg, respectively (after 8 weeks) and 1 and 7 mg/kg, respectively (after 18 weeks) (85). Bioaugmentation (i.e., inoculation of specialized microorganisms) is likely to enhance the remedial application of solid-state fermentation where difficult-to-degrade pesticides are concerned. More information is needed to establish composting as the method of choice for rinsate disposal. The biggest problem is still the partial degradation of pesticides in the compost pile, which in turn causes large amounts of compost to be defined as hazardous waste because of a high concentration of bound residues.

The data presented in Table 4 summarize the distribution of the carbon fraction during composting under controlled laboratory conditions of distinctive members of each of the families of pesticides commonly applied in agriculture. In contrast to other environmental pollutants, mineralization in general terms is low whereas microbial transformation, followed by binding OM, and adsorption seem to be prevalent path of disappearance. Volatilization seems to be marked in many cases.

DEGRADATION OF EXPLOSIVES

Environmentally unaware practices in areas in which explosives are produced and/or handled have resulted

Table 4. Fate of the Carbon Fraction During Controlled Composting on a Laboratory Scale of Members of the Major Types of Pesticides

in the contamination of soils and sediments with various explosives, including TNT, RDX, octahydro-1,3,5,7-tetranitro-1,3,5,7-tetraazocine (HMX), and methyl-*n*-2,4,6-tetranitroanaline (tetryl).

Until a decade ago, no biological methods were available to mineralize explosives effectively under aerobic conditions without the production of unwanted metabolites (87). As a result, very costly incineration ($300 to $500 per ton soil) was the method of choice for removing explosives from soils (88). In recent years, composting and alternating anaerobic and aerobic biological treatments have been developed and tested on full-scale operations (59,89). The centuries-old technology of composting has been refined to maximize the degradation of hazardous materials such as TNT. The advantage of using compost is associated with the use of compost microorganisms that convert TNT and related compounds into simpler, benign, organic molecules, similar to the way in which they convert organic materials into humus (59). The whole process is based on nature's own ability to decontaminate soils, but under the accelerated conditions existing in the compost pile. The most common type of composting when dealing with TNT-contaminated sites is windrow composting. During such composting, the soil is mixed with compost and spread over a field or other surface in narrow rows called windrows. To facilitate microbial growth, composting material, such as wood chips, straw, alfalfa, manure, or other agricultural products, is added (90). Windrows are kept aerated with occasional turning, and moisture content, oxygen level, and temperature are all carefully monitored. Windrow composting has been found to have a high degree of treatment success; moreover, composting costs far less than incineration and is more environmentally sound. Composting yields compost, which is a valuable material, as opposed to incineration, which yields ash that must itself be disposed of as toxic waste after it has been solidified. Composted material can be revegetated, unlike solidified material. Moreover, composting consumes only very small amounts of nonrenewable energy sources to operate the machinery, whereas incineration uses large quantities of fossil fuel with all the associated environmental consequences.

When the Umatilla Army Depot in Hermiston, Oregon, a Superfund site, composted 15,000 tons of contaminated soil instead of incinerating it, it saved approximately $2.6 million. Risk-based cleanup goals for Umatilla were established at explosive concentrations of less than 30 mg/kg for TNT and RDX. The project exceeded these expectations by achieving undetectable levels of explosives. Contaminant by-products were either destroyed or permanently bound to soil or humus (59).

It is important to note that complete mineralization is not the common biochemical mechanism that acts to decontaminate soils containing explosives. TNT-contaminated soil spiked with radiolabeled [^{14}C]-TNT and treated biologically led to complete immobilization of the reduced TNT in the soil (91). At the end of the treatment process, more than 98% of the initial radioactivity was bound to the soil. Only transformation to the solvent-extractable products, 4-amino-2,6-dinitrotoluene and 2-amino-4,6-dinitrotoluene, and conjugation to cellulosic, humin, humic acid, and fulvic acid was detected in composting of an explosives contaminated soil amended with radiolabeled TNT in a small-scale compost simulation system (92). More than half of the added radioactivity was recovered in the cellulose plus humin fractions. Microbial transformation of TNT usually begins with reduction of one of the nitro groups. Aerobic bacteria are able to reduce two of the three nitro groups of TNT; the reduction of the third nitro group requires anaerobic conditions. Many of the products of TNT biodegradation are highly reactive and covalently bind to cellular components and organic solids (in soil or compost). The latter prevents or prolongs the mineralization process, but also hinders a further spread of TNT contaminants.

Composting can be problematic because the precise fate of explosives is not easily determined. If TNT or its degradation intermediates are bound to the compost mix, these could leach back into the soil. However, extraction experiments with biologically treated soil showed that drastic desorption conditions and even strong hydrolytic agents (0.5 M HCl) could mobilize only minor amounts of the bound residue (<1%). High long-term stability of the reduced and bound radiolabeled TNT in soil was demonstrated in a leaching experiment that was carried out over a period of two years simulating 2,000 mm of rain per year (91). Nuclear magnetic resonance data further confirmed the irreversible binding of the reduced TNT in soil, indicating the safety of the biologically treated soil (91).

Although the Umatilla soil was heavily contaminated with TNT and RDX, no explosives could be detected after composting, and the soil was restored to "a better condition than before it was contaminated" (93). The composting feedstocks used at Umatilla were 30% contaminated soil, 21% cattle manure, 18% sawdust, 18% alfalfa, 10% potato waste, and 3% chicken manure. In other cases, substitutions may be made depending on the cost and availability of ingredients. Composting of explosive-laden soils has been since used in other, geographically varied regions, including the United States Naval Submarine Base in Bangor, Washington; the Navy Surface Warfare Center in Crane, Indiana; the Sierra Army Depot in Herlong, California; the Seymour Johnson Air Force Base in North Carolina; the Louisiana Army Ammunition Plant; Fort Riley in Kansas; and the Hawthorne Army Depot in Nevada.

A different composting approach was reported by Breitung and coworkers (94) and Bruns-Nagel and coworkers (95). Continually aerated compost was compared to compost aerated after an anaerobic prephase of 65 days. The continuous aeration system rapidly degraded 92% of the TNT and contaminating by-products. Although slower, the two-phase system was able to achieve almost 100% degradation of TNT and contaminating by-products (levels were undetectable). The two-phase system works by reducing TNT almost entirely to amino-dinitrotoluene (Am-DNT) during the anaerobic prephase, then using the aerobic phase to degrade the Am-DNT.

Traditional composting presents two major setbacks. First, no more than 30% of the compost pile can be made up of the contaminated soil, which results in an increase in the amount of product that must eventually be landfilled. Second, despite substantial efforts, residual toxicity of the finished compost is still a possibility (87).

To overcome these problems, Grace Bioremediation of Canada developed a proprietary solid-phase composting methodology known as DARAMEND® (89). The technology employs combinations of organic and inorganic soil amendments to modify the physical and chemical conditions in the soil to enhance the rate and extent of microbial biodegradation of organic explosive compounds. The key components of the technology, as applied to soils containing organic explosive compounds, are: proprietary organic amendments, trace quantities of multivalent metals (e.g., powdered iron), physical disruption of soil structure through vigorous tillage, and regulation of soil moisture and oxygen diffusion by irrigation. Typical application rates for the organic amendments are between 0.5 and 2% (w/w) of contaminated soil, thus virtually no bulking of the soil occurs. The number of treatment cycles required to attain the remediation goals varies with the identity of the target compounds, their initial concentrations, and the applicable remediation criteria. DARAMEND® bioremediation technology is currently being implemented full scale on soil contaminated with organic explosives and chlorinated solvents at Naval Weapons Station Yorktown in Virginia. Soil concentrations of organic explosive compounds of 11,350 mg/kg were reduced in 74 days of treatment by more than 99%. Specifically, TNT was reduced to 3 mg/kg, RDX to 4 mg/kg, HMX to below detection limits, and Am-DNT to 1.9 mg/kg (89).

Today, it is clear that the treatment of explosive-laden soils using biological alternatives can compete with the expensive and less environmentally friendly incineration methods.

THE FATE OF ORGANIC POLLUTANTS DURING COMPOSTING

One of the most complicated and controversial aspects of contaminant detoxification by composting is their real fate. Whereas disappearance seems to be very fast (a few hours to a few days, depending on the nature of the contaminants, initial availability, and concentration), the real contribution of biotic degradation or abiotic transformation is more complex and difficult to measure. The ultimate fate of the contaminants depends on the technology of composting, the size of the units, and the duration. For pilot-scale composting studies, a volume of at least 10 to 20 m^3 is required for achieving the typical temperature profiles seen in full-scale piles (17,18,59,96). Furthermore, some of these results depend directly on the chemical analysis and extraction techniques used to monitor pollutants fate. The efficiency and yield of conventional techniques, such as cold extraction and Soxhlet extraction, change during the different stages of composting, as a function of the changes in the solid matrix during humification.

Mass-balance calculations to assess the fate of toxic organic compounds during composting have been reported in lab-scale units, using ^{14}C-radiolabeled material. According to these results, at least in the short term, complete degradation (i.e., mineralization) accounts for only a small portion (10–50% of initial labeled carbon, depending on the type of compound). Biotic mechanisms such as adsorption and binding during humification, which tend to retain the contaminants and/or their metabolites within the solid matrix, appear to be a significant mechanism of transformation (25–40% of initial labeled carbon, depending on the type of compound). Volatilization is also significant; its importance depends on the physical and chemical nature of the contaminants (e.g., vapor pressure), the technique of composting (e.g., forced versus natural aeration, number of turnings), and the size of the composting plant. The schematic distribution rates of the different carbon fractions of the source pollutants of each of the main families of organic compounds reviewed in this chapter are presented in Table 5 (see also Tables 2–4).

The major difficulty in quantifying the fate of contaminants in compost is that lab-scale units (2–15 L) do not provide results similar to field-scale units, in terms of extent of degradation and time scale (59). The time allowed for composting, and especially the length of the

Table 5. Fate of Organic Carbon During Composting of the Organic Pollutants Discussed in This Chapter

		PAH		Nonvolatile		
Fraction	TPH	LMW	HMW	Chlorinated	Pesticides	Explosives
Disappearance[a]	M	H	L to M	H	M	H
Adsorption[b]	L	L to M	L	L to M	M to H	H
Binding[c]	M	M to H	M to H	H	H	M to H
Volatilization	L	M to H	L	L	M to H	L
Mineralization[d]	M	M to H	L	L	L	M

Note: Abbreviations — TPH, total petroleum hydrocarbon; PAH, polycyclic aromatic hydrocarbon; LMW, low molecular weight; HMW, high molecular weight; L: low rate; M, moderate rate; H, high rate.

[a] Disappearance of the source pollutant.

[b] Adsorption refers to the formation of an extractable residue.

[c] Binding refers to the formation of a nonextractable residue.

[d] Mineralization indicates complete degradation to carbon dioxide and water.

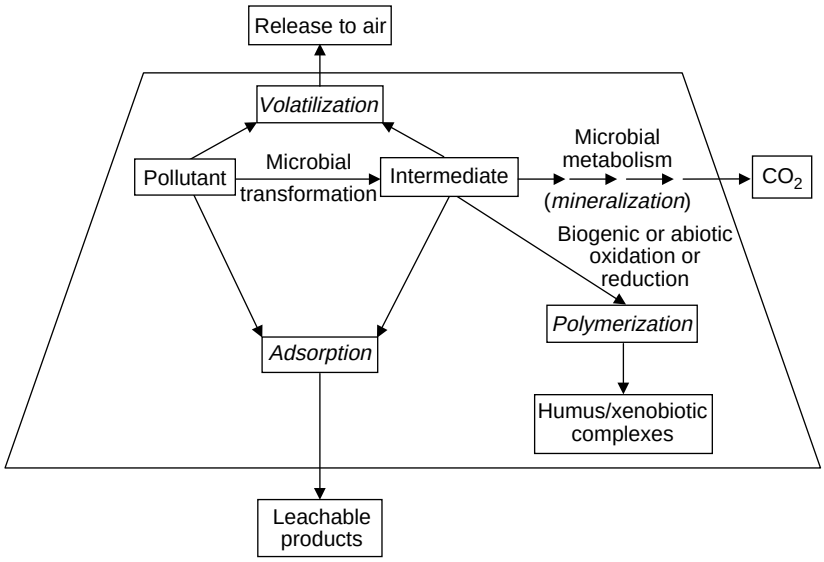

Figure 1. Proposed scheme describing the fate of organic pollutants during composting and its relation to the surroundings. The four main processes occurring are: mineralization (complete degradation), volatilization, adsorption (formation of extractable residues), binding, or polymerization (formation of nonextractable residues). Frame denotes a composting pile.

thermophilic phase, changes drastically from lab to field tests. Volume reduction during composting dramatically affects the residual concentration of the target compounds following the thermophilic phase. More difficult to degrade and less volatile compounds, in fact, concentrate rather than decrease in net reduction. In general, there are not enough data to make a definitive statement on the effect of composting on each particular compound. Moreover, the use of artificial contamination to mimic natural environments, such as soil, or sources of polluted substrates used in composting does not allow, in most cases, a useful prediction of the potential of compost to degrade organic pollutants in natural situations (96).

No remediation technology is appropriate for all contaminants and situations (59). First, the degradation rate of a specific contaminant is affected by the material being composted (97). Second, a relatively low extent of mineralization of aromatic compounds occurs in compost. In some cases, potentially toxic water-extractable intermediates are formed. Compost, as well as other bioremediation techniques, are not efficient enough to degrade highly chlorinated PCB congeners or HMW-PAH congeners (54,56,77). Third, there is the question of whether the formation of nonextractable metabolites is a satisfactory end point of remediation. In practice, loss or lack of extractability by organic solvents is suggestive of binding (39,41,43,77,98). Bound residue, especially to the humic matrix, results from the formation of reactive moieties, such as ester groups, creating low long-term stability. Ether linkages between humic materials and metabolites result in relatively long-term stabilization and decreased bioavailability (39,41,99). Hydroxylated compounds are formed during the degradation of almost all aromatic compounds during composting, which covalently couple to humic substances, resulting in long-term immobilization, but not destruction (30,100). In some cases, coupling of chlorinated compounds to humic material results in dehalogenation (66,67). On the other hand, the high level of OM within the compost matrix enhances adsorption. Adsorption sequesters chemicals temporarily, preventing their further degradation (18). However, adsorbed material eventually leaches. Dubourguier (96) claims that no research has reported on the long-term stability of these humus and xenobiotics complexes for safe use.

A proposed scheme describing the fate of organic pollutants during composting is presented in Figure 1, describing the main biogenic and abiotic processes occurring during composting: mineralization (complete degradation), volatilization, adsorption (formation of extractable residues), binding or polymerization (formation of nonextractable residues).

CONCLUSION

In this chapter have we reviewed various composting processes leading to bioremediation of PAH, chlorinated compounds, explosives, pesticides, and other toxic pollutants. Only a few studies are described on composting per se for bioremediation. However, many processes are based on the principle of composting, such as landfarming and biopiling. In these methods, either fresh OM or compost is amended at various ratios to contaminated soils. Based on the available literature, it may be difficult to conclude upon the optimum composting conditions suitable for specific decontamination treatments as in many cases, the nature and quality of the compost are not well defined. Furthermore, it is important to study bioremediation under more or better controlled environments, which can facilitate the use of tracers, such as ^{14}C-labeled compounds, and the performance of complete mass-balance calculations. It is essential to elucidate the fate of the targeted pollutants and metabolites formed, to assess the mechanism of biodegradation as well as potential residual toxicity.

It can be concluded that composting has some advantages over other in situ remediation technologies.

1. The microbial populations in compost exhibit high activity related to the degradation of organic

material, as well as high diversity of bacteria, actinomycetes, and fungi capable of metabolizing a wide array of organic compounds, including pollutants.

2. The bioavailability of the target compounds seems to be higher in the presence of labile OM, in comparison to soil containing clay minerals, and stable OM, whose interaction with the pollutant could reduce the bioavailability. Moreover, mechanical mixing occurring during composting may improve the physical contact between the different fractions present.
3. The high temperature occurring in the thermophilic phase of composting increases degradation rates although it may promote volatilization of some compounds.
4. The rate of oxidation is higher in compost than in soil because of the continuous supply of air. Furthermore, the extent of oxidation of OM in general, and toxic organic compounds in particular, is improved because of the high oxidation potential of compost compared with soil, as well as enhanced cooxidation because of the array of substrates present.

OM degradation and stabilization are accelerated in compost relative to soil. Thus, composting studies may serve as a model system to predict the potential fate of toxic organic pollutants in long-term processes in soil. Biodegradation of toxic organic compounds in compost exploits a natural process of transformation of heterogeneous OM by mixed microbial populations under controlled conditions. Thus, bioremediation through composting offers an attractive technology for rapid and effective decontamination of solid wastes.

CONDITIONING FILMS IN AQUATIC ENVIRONMENTS

RENÉ P. SCHNEIDER
Universidade de São Paulo
São Paulo, Brasil

ANDREW LEIS
Gerhard Mercator University
Duisburg, Germany

DEFINITION

Organic and inorganic compounds present in the bulk water phase or at the water–gas interface rapidly coat substrata immersed in natural waters (freshwater, marine, or subsurface environments) producing thin films, the conditioning films. These films substitute the surface properties of original substrata by those of the combination substratum/conditioning film. Their formation precedes microbial adhesion and, therefore, influences the interaction of microorganisms with interfaces in aquatic environments. Conditioning films of interest to microbial adhesion and biofilm formation are formed by inanimate substances (colloids, molecules, and ions), of a size significantly smaller than a microbial cell, present in the bulk water phase or at the water–gas interface. These films may also serve as a source of nutrients to organisms in oligotrophic environments.

SOURCES OF ORGANIC AND INORGANIC COMPOUNDS IN ENVIRONMENTAL WATERS

Inorganic compounds in natural waters occur as dissolved cations or anions or as colloids and mineral particles. They enter natural waters by the dissolution of rock minerals, the erosion of surface soils, and atmospheric deposition. Aquatic organic carbon in streams and rivers comprise mostly recent (<30 years old) plant and soil decomposition products (1). In lakes and in the oceans, between 30% (lakes with low hydraulic residence times) and nearly 100% (eutrophic lakes fed by groundwater and oceans) of the aquatic organic carbon is autochthonous (2). Organic carbon in groundwater originates from the weathering of "old" organic matter adsorbed on clay minerals or hydrous oxides of aluminum and iron in soil, and from the release of geologic carbon (kerogen, 3). Aquatic organic carbon is divided into dissolved organic carbon (DOC, the organic carbon fraction that passes 0.45-μm filters) and particulate organic carbon (POC, organic carbon retained by 0.45-μm filters). In many natural waters, however, small particulate organic carbon fragments that pass 0.45-μm filters, such as colloidal matter and nanobacteria, the numerically dominant population of bacteria in natural waters (4), may constitute a significant proportion of DOC (5). The DOC concentrations in natural waters vary from low ppm in oligotrophic environments to tens of ppm in eutrophic waters.

Between 50 and 75% of all aqueous dissolved compounds in natural waters are randomly assembled, high molecular weight, polymeric organic acids known as "humic substances" that form aggregates of 2 to 50 nm diameter commonly associated with clay minerals and oxides of iron or aluminum (1,6). No definite chemical structure can be assigned to these polyfunctional, polyelectrolytic macromolecules whose functionality is dominated by carboxylic acids, esters and amides, aliphatic and aromatic OH, and heterocyclic nitrogen. The generic term encompasses humic acids, fulvic acids, and the relatively insoluble fraction known as humin. Humic acids have molecular weights ranging from 2,000 to 100,000, and constitute some 10 to 15% of DOC in natural waters. They differ from fulvic acids in that they contain fewer carboxylic and hydroxyl functional groups. The remainder of the undefined DOC assigned to the humic group is a poorly understood series of macromolecules known as humin or "hydrophilic acids" with carboxylic, hydroxyl, and carbohydrate moieties (7).

Proteins and their hydrolysis products, dissolved free amino acids (DFAA) and dissolved combined amino acids (DCAA), account for between 2.5 and 5% of DOC in natural surface waters (8). This pool contains material excreted by cells, proteins leached from live or dead organisms, and proteins transformed in the water column by action of extracellular proteases or other compounds. Their size varies from 14 to 66 kDa and their profiles vary both horizontally and vertically in the water column, but their precise identity remains largely unknown. Carbohydrates comprise between 1 and 2% of the total DOC and exist both as free monomers (amino sugars, uronic acids, and aldolases) and as polysaccharides (8). Lipids represent from 10 to 25% of POC in marine surface waters (2) but are only a minor component of DOC. Dissolved lipids consist primarily of *n*-alkanes, pristane, phytane, and methyl esters, ethyl esters, and propyl esters of fatty acids, whereas triacylglycerols, free fatty acids, and phospholipids dominate the lipid pool of the particulate phase. From a mechanistic perspective, interactions between microbial cells and inanimate components of natural waters are mediated by the functional groups present in the molecules. In the case of inorganic compounds, these functional groups are predominantly free solvated ions and, in the case of colloids, oxides of silicium, iron, or aluminum. Most functional groups associated with organic matter are either charged or capable of undergoing polar type of interactions (e.g., hydrogen bonds) (Table 1). It is, however, important to note that many organic macromolecules have extensive hydrophobic domains in their structure. If this hydrophobic character predominates, then the molecule will be expelled from the bulk water phase and accumulate either at solid–liquid interfaces or at the water–air interface.

INVESTIGATING CONDITIONING FILMS

Conditioning films by their very definition are thin surface coatings. Their study therefore requires analytical techniques appropriate to the task and sample handling and manipulation methodology that avoids contamination with materials not present in the water sample or those materials from the water sample that are not part of the

Table 1. Functional Groups Present in Natural Organic Matter

Functional Group	Structure[a]	Occurrence
	Acidic Groups	
Carboxylic acid	R–CO_2H organic carbon	90% of all dissolved organic carbon
Enolic hydrogen	R–CH=CH–OH	Aquatic humic substances
Phenolic OH		Aquatic humic substances, phenols
Quinone		Aquatic humic substances, quinones
	Neutral Groups	
Alcoholic OH	R–CH_2–OH	Aquatic humic substances, sugars
Ether	R–CH_2–O–CH_2–R	Aquatic humic substances
Ketone	R–C=O (–R)	Aquatic humic substances, volatiles, ketoacids
Aldehyde	R–C=O (–H)	Sugars
Ester, lactone	R–C=O (–OR)	Aquatic humic substances, tannins, hydroxy acids
Core aromatic unit		Aquatic humic substances, hydrocarbons
Aliphatic unit	R–CH=CH–CH_2–CH_2–R	Aquatic humic substances, hydrocarbons
	Basic Groups	
Amine	R–CH_2–NH_2	Amino acids
Amide	R–C=O (–NH–R)	Peptides

Note: [a] at pH 7

conditioning film. Vessels for sample collection and storage should, whenever possible, be made of glass and have volumes sufficiently large to avoid significant alteration of the chemical bulk water composition by materials either adsorbed onto or leached from vessel surface polymers. It is also important to process water samples either by membrane filtration or by centrifugation before storage, to separate particulate biotic and inanimate matter. Again, it is important to avoid contamination of the samples with material leached from the membranes or the centrifuge tubes. In this sense, it is advisable to discard the first 100 mL of filtrate, or even better, to determine empirically at which filtration volume the amount of organic or inorganic matter contributed by the filter to the sample becomes negligible. The pore size cutoff of the membranes should be such that it allows passage of small colloids and high molecular weight organic matter but retains even the smallest bacteria. Filters with pore sizes around 0.1 μm are adequate for conditioning film studies. Samples should be stored in refrigerators but not frozen because this would cause aggregation of dissolved macromolecules into colloids during the freezing process.

It is important to ensure thorough removal of bacteria from water samples before conditioning film studies. Depending on the parameters investigated, small numbers of bacteria on substrata could significantly bias conditioning film analysis. If it is assumed that conditioning films are thin films with a thickness of approximately 80 nm (corresponding to a mature conditioning film, 9), with a density similar to that of bacteria, and that these films homogeneously coat a surface, then the material contributed by a globular microbial cell with a diameter of 1 μm (water content approximately 80%, density of organic matter approximately 1 g/cm^3) would correspond to a conditioning film of approximately 6.5 μm^2. If it is stipulated that contamination by microbial compounds should be less than 1%, then a substratum cell density of less than 1 cell per 650 μm^2 would be tolerable. Substratum cell densities observed when substrata are exposed to unfiltered surface waters rapidly reach values well above this threshold. This problem is particularly important when analyzing the chemical composition of conditioning films using extractive techniques or direct in situ analysis methods. It is of lesser importance when determining conditioning film thickness by ellipsometry, for example, because irregularities on small patches of surface do not significantly impact averaged data.

CONDITIONING FILM ANALYSIS

The comprehensive set of data required for conditioning film characterization cannot be obtained with a single analysis method. A brief assessment of the utility of the

most important methods for conditioning film analysis is given in Table 2.

Contact Angles

Contact angles formed when drops of diagnostic liquids spread on substrata are one of the few analysis techniques with good sensitivity for the very top layers of surfaces (Fig. 1). At equilibrium, the relationship between the liquid–vapor (γ_{LV}), the solid–vapor (γ_{SV}), and the solid–liquid (γ_{SL}) interfacial free energies converging at the drop edge/solid/air interface is described by the Young equation (Fig. 1, 10):

$$\gamma_{LV} \cos\theta = \gamma_{SV} - \gamma_{SL} \quad (1)$$

γ_{SV} in Equation (1) may be influenced by adsorption of liquid vapor to surfaces but the consensus in the literature indicates that for contact angles greater than 10°, the spreading pressure caused by the vapor film can be neglected. Under these circumstances, the solid–vapor interfacial free energy in Equation (1) can be replaced by the surface free energy of the solid surface, γ_S (10):

$$\gamma_S = \gamma_{LV} \cos\theta + \gamma_{SL} \quad (2)$$

Solving Equation (2) would theoretically allow one to determine the surface free energies of the substratum γ_S and of the particle γ_P, two parameters required for calculation of the solid–particle γ_{SP}, the solid–liquid γ_{SL}, and the particle–liquid γ_{PL} interfacial free energies that

Table 2. Methods Available for Conditioning Film Analysis

Method	Contact Angle	Mercury Drop Electrode	Chemical Hydrolysis
Information provided	Wettability surface free energy	Surface potential	Monomeric composition of conditioning film components
In situ capability	Yes (bubble contact angle techniques) No (all other techniques)	Yes	No
Surface resolution	Macro (mm^2)	Macro (mm^2)	Macro ($mm^2 - cm^2$)
Analysis type	Physicochemical	Physicochemical	Molecular
Characteristics	Relatively simple Fast Surface layer sensitive	Fast Simple	Relatively simple
Disadvantages	Requires air/water/solid interfaces no consensus about most appropriate thermodynamic models for calculation of surface free energy diagnostic liquids may alter constitution of conditioning films	Only one type of (toxic) substratum substratum not suitable for subsequent microbial adhesion studies	Destructive variability of the efficiency of hydrolysis of different polymers requires complex laboratory set-up for monomer analysis and identification impossible to reconstitute polymeric structure of macromolecular conditioning film components.

Disadvantages	Tip/sample interactions may distort results Flat surface (at nm scale) required to achieve good vertical resolution Nonrigid conditioning film molecules may distort from lateral tip forces	No definitive identification of conditioning film components possible Resolution currently less than SFM Small depth of field

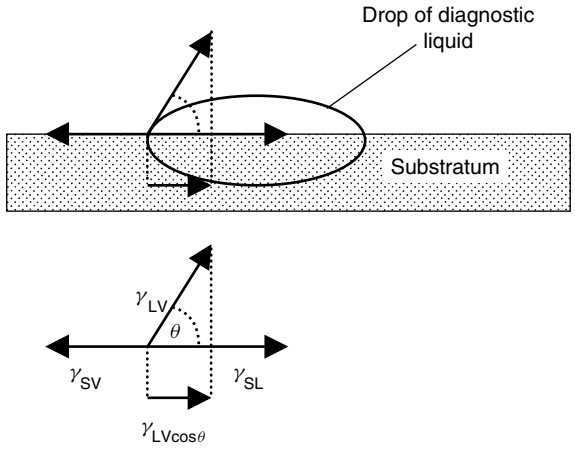

Figure 1. Surface energy equilibrium diagrams in contact angle analysis. γ_{SV} : solid–vapor interfacial tension, γ_{LV} : liquid–vapor interfacial tension, γ_{SL} : solid–liquid interfacial tension, and θ : contact angle.

determine the free energy of adhesion of a particle (or molecule) to a substratum:

$$\Delta F_{adh} = \gamma_{SP} - \gamma_{SL} - \gamma_{PL} \quad (3)$$

Of the four parameters contained in Equation (2), only θ and γ_{LV} can be determined experimentally. The remaining terms need to be estimated based on theoretical models (10). Unfortunately, there is no consensus in the literature about which of the plethora of thermodynamic models proposed to calculate the different physicochemical surface properties from contact angles produces correct estimates for the respective parameters. An evaluation of the most commonly used thermodynamic models for contact angle analysis revealed that the Lifshitz van der Waals acid-base approach with the diagnostic liquids water, diiodomethane, and formamide provided the most consistent results for conditioning film analysis (11).

Contact angles may be measured in static or dynamic mode using a variety of techniques (12). In the dynamic mode, the volume of the droplet of diagnostic liquid is continuously changed either by increasing the amount of liquid (advancing contact angles) or by retrieving liquid from the droplet (receding contact angle). Advancing contact angles wet new areas of the solid surface constantly, whereas receding angles develop over already wetted areas. Continuous desorption of conditioning film components by advancing contact angles may lead to accumulation of an organic film at the advancing edge of the drop. Receding angles on conditioned substrata certainly probe surfaces, the composition of which has been altered by the advancing angle, and thus produce results of questionable significance to the original conditioning film. Dynamic contact angle measurement should be avoided when assessing conditioned interfaces. Contact angles may also be measured in situ by placing the substratum face down in a measuring chamber filled with liquid and analyzing the contact angle of an air bubble with the coated surface (13). Care is required in the interpretation of the results obtained with this method as well. It is well known that passage of an air–water interface across a surface exerts shear forces strong enough to detach firmly bound cells (14). A similar process may occur with adsorbed macromolecules when an air bubble spreads on a conditioned surface.

Sessile contact angles need to be measured as fast as possible after deposition of the droplet on the test surface. The solvent action of many diagnostic liquids may remove adsorbed conditioning film components and thus contaminate the liquid. In addition, vapors of the diagnostic liquid may deposit at the solid–vapor interface in front of the droplet. Both processes would change the value of the contact angle. It is important to consider that macroscopic analysis with contact angles provides essentially averaged values for surface properties. For example, on a hydrophobic porous substratum, a diagnostic liquid may fill pores and create patches of liquid–liquid interfaces, whereas on a hydrophilic surface, the liquid may rest on a plane surface composed of solid and air. Averaged results such as provided by contact angles in both of these cases (or on inhomogeneous surfaces) would not be representative of the conditioned surface. The drop size of contact angles needs to be uniform because of the effects of gravity and drop cohesion on drop shape. Substratum roughness also affects contact angles, but this effect is of not much significance when the same surface is compared in the coated and in the clean state. Contact angles in air cannot be measured on fully hydrated films. It is well known from analysis of hydrated biological surfaces that contact angles change progressively from a fully wetting condition during dehydration until they reach a stable plateau value, which is claimed to be a thermodynamically significant measurement (15). However, it has recently been demonstrated by the authors of this chapter that bacterial adhesive properties of conditioning films in this partially dehydrated state are the same as those of the in situ film.

Mercury Drop Electrode

In the mercury drop electrode, the convective streaming created by the gradient in surface tension at a liquid–liquid (water sample/mercury) interface generates a measurable increase in the reduction current of mercury (II), which is manifested as a polarographic maximum (16). Dissolved organic molecules (and micelles) adsorbed at the mercury–water interface reduce the gradient in surface tension and slow down the convective streaming, which is detected as a suppression of the maximum current measured. Surface-active materials present in conditioning films can be quantified with this methodology.

Fragmentation Techniques

Conditioning films can be chemically hydrolyzed and the hydrolysis products analyzed by standard chemical analysis techniques (17). The results need to be interpreted with care because it is impossible to reconstitute the macromolecular composition of a conditioning film from analysis of the monomers. Moreover, it is important to avoid analytical bias toward more readily identifiable compounds

of biological origin such as amino acids, sugars, or lipids. Molecules from the humic group are less amenable to assessment by standard methods and are often overlooked in these studies. Conditioning film components may also be fractionated directly from the surface by pyrolysis (18), where the fragmentation pattern depends on the nature of adsorbed polymers and on the number of attachment sites of each polymer with the substratum. It is, therefore, difficult to obtain definitive data on macromolecular composition of conditioning films by this method.

Electrokinetic Techniques

Electrokinetic techniques exploit the fact that movement of charged particles in electrolytes depends on their surface charge (19). Any one of the four electrokinetic effects electrophoresis, streaming potential, electroosmosis, or sedimentation potential may be employed to determine the electrokinetic or zeta potential of a conditioned interface. In reality, the electrochemical plane of shear separating the moving particle from the solution is located at some distance from the substratum surface because of the electric double layer that forms on surfaces in electrolytes. The zeta potential measured with electrokinetic methods therefore represents an approximation of the electrostatic potential at the edge of the diffuse part of the double layer (Fig. 2). In practice, only two of the electrokinetic effects have found widespread use, electrophoretic mobility measurements on small particles in electrolytes and streaming potential, where fluid is forced through a capillary tube to generate a measurable potential at the test surface. These methods do not provide strict chemical identification of conditioning film components. Electrophoretic mobility versus pH curves of surfaces are electrophoretic titrations of ionizable surface functional groups. Thus, pK values and putative identities of acid-base functional groups in conditioning films can be investigated with carefully designed electrophoretic titrations.

Mass Spectrometry

Recent developments in mass spectrometry have greatly increased its applicability to conditioning film analysis (20). Volatilization and ionization of macromolecules can now be achieved readily with techniques such as the application of a strong electric field to the sample (field desorption), bombardment of the sample with energetic ions or atoms, the formation of ions directly from small, charged liquid droplets (thermospray ionization), electrospray ionization, and bombardment with short duration, intense pulses of laser light (laser desorption). Modern time-of-flight mass analyzers allow for true macromolecular analysis of ions with masses in excess of 100,000 Da (21). In these detectors, ions generated by pulsed beams controlled by precision timing are accelerated in a magnetic field and then allowed to drift in a field-free tube where they separate into a series of spatially discrete individual ion packets, each traveling with a velocity characteristic of its mass. Assuming that all ions have the same energy, heavier ions take comparatively longer to reach the detector. The velocity of the ions is proportional to the mass-to-charge ratio of a particular ion species.

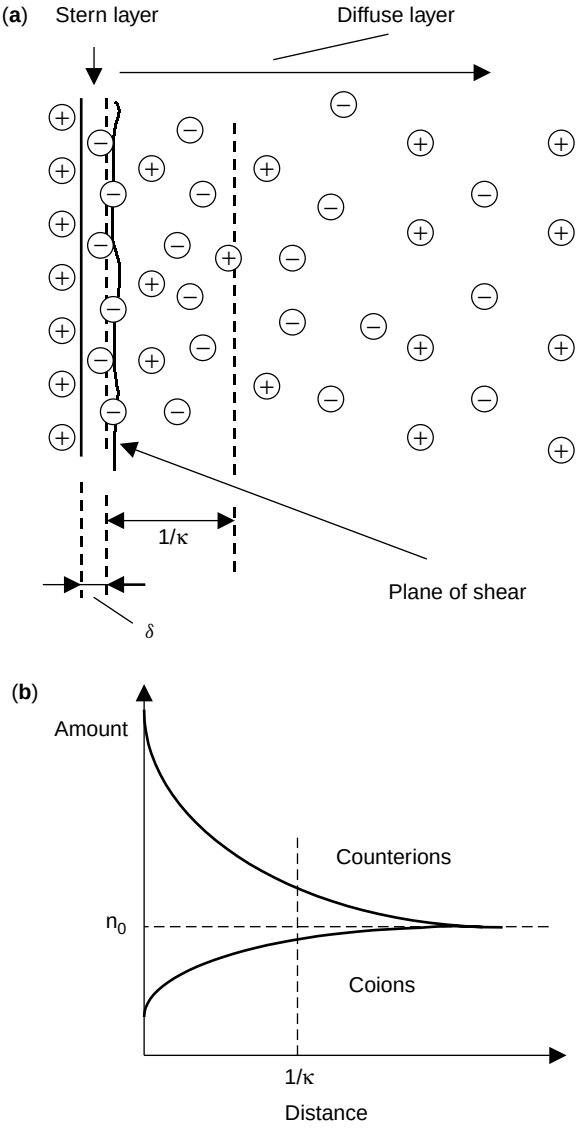

Figure 2. (**a**) Schematic representation of electric double layer. Δ : thickness of Stern layer (ions tightly bound to the substratum surface) and $1/\kappa$: thickness of electric double layer. (**b**) Concentration profile of coions and counterions in the electric double layer. n_0 : equilibrium concentration in solutions without charged surfaces.

Time-of-flight secondary ion mass spectrometry (TOF-SIMS) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) are the two truly surface-capable MS techniques (22,23). In TOF-SIMS, the sample surface is bombarded with a focused primary ion beam of O_2^+, Cs^+, or Ga^+ with an energy of 0.5–2.0 keV. The shock wave generated by the penetration of the highly energetic ions into the surface desorbs and ionizes adsorbed matter generating secondary ions that are injected into a TOF mass analyzer. The current state of the art of TOF-SIMS allows only for the generation of secondary ions of up to 10,000 Da. New developments may extend this mass range considerably in the near future (24). In MALDI-TOF MS, the sample is

mixed with an energy-absorbing matrix, irradiated with a laser, and analyzed using a time-of-flight mass analyzer. The sample probe is commonly stainless steel or silver, sometimes with a roughened sample application area to promote nucleation. Ionization and volatilization can be achieved with many different lasers, the most popular being nitrogen lasers with a wavelength of 337 nm and IR lasers with a wavelength of 10.6 μm. The matrix is believed to serve two major functions: absorption of energy from the laser light (hence, the requirement for a high molar absorbance at the wavelength of the laser) and isolation of the biopolymer molecules from each other. Low molecular weight aromatic compounds with extended electron conjugation readily meet these requirements. Typical matrix : sample ratios of $1,000:1$ to $5,000:1$ are optimum for ion production. The choice of appropriate matrix compounds is still largely empirical and one cannot predict a priori if a matrix compound will form a homogeneous solution with a given analyte molecule. Proteins and oligosaccharides can be analyzed readily by MALDI-TOF but routine analysis of humic acids and polysaccharides requires further methodology development.

Electrospray ionization (ESI) mass spectrometry is a rapid and accurate technique for the analysis of a wide range of polar compounds (25). Electrospray ionization operates by the process of emission of ions from a droplet into the gas phase. A solvent is pumped through a stainless steel capillary that carries a high potential, typically 3–5 kV. The strong electric field generated by this potential causes the solvent to be sprayed from the end of the capillary. The aerosol contains highly charged droplets. As the droplets evaporate, the ions within them also evaporate. A flow of warm nitrogen gas through the source helps the evaporation process and removal of the solvent. There is usually no fragmentation, and the spectrum contains only the pseudomolecular ion. The method is useful only for analysis of desorbed conditioning film components.

X-ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy, also known as electron spectroscopy for chemical analysis (ESCA), is a truly surface-capable method of elemental analysis (26). Irradiation of a sample with X-rays of known energy results in the emission of electrons of (lesser) binding energy. The kinetic energy of these electrons is measured by a spectrometer. The spectrum is a composite of the single-core electron (i.e., photoelectron), and an Auger electron, which is ejected following reorganization within the atom. The technique allows depth profiling of the elemental composition of conditioning films by variation of the angle of incidence of X-rays on the sample surface (27). One of the drawbacks of this method is the ultrahigh vacuum required in the sample chamber, which allows for analysis of only tightly bound, dehydrated, and nonvolatile conditioning film components.

Fourier Transform Infrared Spectroscopy

Infrared (IR) spectroscopy is one of the principal methods for identification of compounds used in chemistry. It provides extensive information about vibrational modes of atoms and functional groups in molecules. The same information can be obtained at much greater speed and sensitivity using Fourier transform IR spectroscopy (FTIR). There are many variants of FTIR (28). The ones most relevant for conditioning film analysis are specular reflectance FTIR and grazing angle FTIR, both restricted to analysis of dried films, and attenuated total reflectance FTIR that allows the study of conditioning films in situ, for example, directly in the aquatic phase (29). Specular reflectance FTIR involves the analysis of IR radiation totally reflected at mirror surfaces when the angle of reflection is equal to the angle of incidence. The amount of light specularly reflected depends on the nature of the surface and the refractive index of the substratum. In the "low reflectance" or "high absorption" variation of the technique, most of the radiation is absorbed and dissipated within the bulk of the sample. The spectrum obtained represents changes of refractive index of the sample as a function of wavelength, and the signal is usually weak. In the "high" or "absolute" reflectance mode the sample is deposited on a highly reflecting surface. Incident radiation passes through the sample, is reflected at the mirror surface, and passes through the sample a second time. The small amount of radiation reflected from the front of the sample can be used to estimate epitaxial film thickness. In grazing angle FTIR, the IR beam is directed at the specular surface at a high angle of incidence to the normal, such that the beam interacts with the coating, but not with the substratum. The grazing angle effectively increases the path length of the beam through the sample. The use of a polarizer dramatically enhances the sensitivity of the measurement because only plane-polarized light will interact with the coating. Films too thin for conventional specular reflectance (e.g., Langmuir-Blodgett films) can be analyzed by grazing angle FTIR (30).

In attenuated total reflectance FTIR, the IR beam channeled through an IR transmitting crystal of high refractive index reflects off the crystal walls many times generating an evanescent wave, which penetrates into the surrounding medium producing a spectrum of the sample in contact with the outer surface of the crystal. The depth of penetration of the evanescent wave depends on the wave number and angle of incidence of the radiation as well as on the ratio of the refractive index of the solution to the refractive index of the crystal. Wavelength scanning over a range of wave numbers produces the spectrum. Thus, crystals of different refractive index have to be used to vary depth of penetration of the evanescent wave at particular wave numbers. For example, the depth of penetration for the amide I band ($1{,}650\ \mathrm{cm}^{-1}$) is 0.14 μm for Ge or 0.17 μm for ZnSe, the most suitable materials for analysis of aquatic samples. The best performance of ATR-FTIR can be obtained with cylindrical crystals placed in a circle cell. A large number of internal reflections in the IR-transmissible crystals and a high refractive index maximize the signal from adsorbed species, minimize spectral distortions, and ensure small penetration depths into the sample that minimize interference from compounds present in the bulk solution. ATR cells have been designed to ensure

laminar flow with all areas of the surface reached by the flowing liquid. Water can be accurately computer-subtracted to obtain spectra of substances in a hydrated state and can thus analyze the composition of conditioning films deposited in situ (31).

Fourier Transform Raman Spectroscopy

Raman spectroscopy detects changes in scatter of IR radiation, rather than in absorption like FTIR spectroscopy (32). The two techniques are thus complementary. Raman spectroscopy is useful for detecting the bonds of weakly-absorbing IR species, such as C=C bonds or aromatic carbon functionalities. Raman has also proved useful in characterizing strongly IR-absorbing compounds, including amino acids and dye molecules adsorbed onto roughened metal substrata. In surface-enhanced Raman spectroscopy (SERS), the coupling of the radiation field with the oscillating, delocalized electrons of the metal substratum leads to enhanced signals from adsorbed compounds such as amino acids, peptides, and proteins (33). The principal advantages of Raman spectroscopy over FTIR are the complete lack of interference from water, and the smaller "spot-size," typically on the order of $1-3\ \mu m$ of Raman microscopes compared to $5-10\ \mu m$ for FTIR. The main disadvantage is that Raman spectroscopy is sensitive to fluorescence, a property inherent to aromatic amino acids and humic substances. For every Raman photon that is detected, about 10,000 fluorescence photons are detected.

Ellipsometry

Ellipsometry, a technique based on the principle that the state of polarization of monochromatic light incident on a specularly reflecting surface will differ following the adsorption of material onto that surface, is widely used for analysis of the thickness of adsorbed films (34). Collimated unpolarized or circularly-polarized monochromatic light is directed through a telescope that polarizes the light incident on the surface (35). The polarization state of the reflected light is subsequently analyzed. Although several variations in optics and analyzers exist, the most commonly used instrument is the "null" ellipsometer. In its most basic form, rotation of the analyzer components results in the refringent light being totally extinguished. Photoelectric detectors achieve the null condition by varying the output current or voltage. Film thickness is analyzed based on the estimation of the film's optical constants under the assumption that the film is completely transparent for the ellipsometer beam. The technique is very sensitive to surface imperfections, such as surface roughness, oxide layers, contamination, and surface damage.

Near-Field Optical Microscopy

Near-field optical microscopy overcomes the limitation of conventional optical microscopy techniques by scanning a subwavelength light source very close to the sample and building an optical image, pixel by pixel (36). In scanning near-field optical microscopy, the light source is connected to an optical aperture of 25 to 100 nm diameter fabricated into the apex of an aluminum-coated optical fiber. Using force-feedback, the tip of the probe maintains a constant separation from the sample (5 nm). As the light emanates from the tip, it only illuminates a volume of the sample of similar dimensions to the aperture. Hence, resolution is limited to the size of the aperture and not by the wavelength of the light. Near-field optics have produced the highest optical resolution to date, and can now be added to any conventional microscope. The technique is capable of generating topographical data (i.e., vertical, z-dimensions and lateral, x-y-dimensions), therefore, placing it in the same family as other scanned probe techniques. By controlling the polarization state of the laser light at the aperture and by using polarizers and filters of the collected signal, the same contrast mechanisms used in far-field imaging can be used, for example, fluorescence, absorption, reflection, or polarization.

Scanning Probe Microscopy

The variants of scanning probe microscopy (SPM) most suitable for conditioning film analysis are scanning tunneling microscopy (STM) and atomic force microscopy (AFM). The common features of both techniques are a laser-activated scanner and a sharp tip, or "probe." SPM scanners are made from piezoelectric ceramics that expand and contract proportionally to an applied voltage. A variety of probe materials are available depending on the type of measurement to be performed. STM tips are generally platinum-iridium or tungsten. AFM tips are fabricated from silicon or silicon nitride (chemically-etched or oxide-sharpened). The much stiffer silicon tips are more common for resonating probes that minimize contact-induced film damage. Cantilevers with high resonant frequencies are not suitable for solution-state work.

Scanning tunneling microscopy (37) is capable of true atomic-scale resolution. As the tip scans the sample, it encounters sample features of different heights, resulting in an exponential change in tunneling current as a function of separation distance. A feedback loop is used to maintain a constant tunneling current during scanning by vertically moving the scanner at each (x, y) data point until a "set point" current is reached. The vertical position of the scanner at each data point is recorded to form a topographical image. This technique is limited to conductive and semiconductive substrata, although the short tunneling distance allows its use in aqueous media.

Atomic force microscopy (38) uses the same general instrument layout as the STM, but the probe is a pyramidal tip attached to the end of a long, low-spring-constant cantilever. Monitoring the deflection of a laser from the top of the cantilever as it scans across the substratum produces topographical or other images. The process is therefore mechanical, and does not depend on sample conductance. There are three primary modes of AFM, which are defined according to the nature of the tip-substratum interaction. Ideally, the tip would not touch the substratum. This is the basis for "noncontact" AFM. Unfortunately, long-range van der Waals interactions are extremely weak in liquid solutions, and conditioning film images obtained with this technique are often

poor. Sometimes, experimental conditions allow for the acquisition of satisfactory imaging data of adsorbed macromolecules (39). The basic principle for "contact" mode AFM is to drag the tip across the substratum. Force curves are used to determine the minimum tip force, which can be applied without retracting the tip from the substratum, and to measure attraction, repulsion, and adhesion between the tip and sample. Force curves may also be acquired in resonating probe AFM to view changes in amplitude and phase with tip-sample separation. The probe assembly is oscillated at or near its resonant frequency such that tip-sample contact is minimal because the tip only contacts the substratum at the end of each oscillation cycle. The free-air amplitude of oscillation is reduced ("damped") by the substratum/sample, and the AFM uses this change in amplitude to map the topography. The feedback loop usually maintains the oscillation amplitude constant. Operation can take place in ambient and liquid environments. In liquid, the oscillation need not be at the cantilever resonance. When imaging in air, the typical amplitude of the oscillation allows the tip to contact the surface through the adsorbed fluid layer without being stuck.

Topographical measurements made with an SPM are a convolution of tip-sample interactions. For this reason, SPM is a mechanical, rather than an optical technique, and the tip composition and construction are the major limiting factors determining lateral resolution. The most important tip parameters are the radius of curvature (sharpness) and the angles of the tip sidewalls. An ideal tip would end in a single atom. For atomically flat substrata, this permits atomic scale resolution. Conditioning films, however, are never atomically flat. For the tip sharpness to be effective for these samples, it would need to extend vertically for the maximum height of the sample. In other words, the tip would ideally be a needle, rather than a pyramid, and even then, the accessible sample area would be still limited to 90°. When the substratum has raised or lowered areas with gradients greater than the tip angle, the trajectory of the tip over the corrugated substratum is an indication of the tip shape, rather than the true surface topography. Contamination of the tip with debris from the substratum or from adsorbed matter (in fluid) effectively dulls the tip. This does not necessarily distort the vertical resolution, but the lateral resolution can be affected drastically. Vertical resolution is determined by the resolution of the scanner movement, typically less than 0.1 nm.

PHYSICOCHEMISTRY OF CONDITIONING FILM FORMATION

The transport of conditioning film components from the bulk liquid phase to the substratum surface depends on mass-transfer processes with hydrodynamic shear as an important force field to be considered when surfaces are exposed to flowing media. At distances below 10 to 50 nm from the surface, molecular forces replace the hydrodynamic forces. At a molecular level, up to 17 different types of repulsive or attractive interactions between particles in liquid media listed in the literature can be combined into a set of five primary types of interactions (40): Brownian motion, electrodynamic or Lifshitz van der Waals forces (includes London, Debye, and Keesom forces), electrostatic forces (Coulombic forces), polar interactions (includes Lewis acid-base interactions, hydrogen donor–hydrogen acceptor interactions, hydrogen-bonding forces, and electron acceptor–electron donor interactions), and chain elasticity when layers of adsorbed polymers overlap (such as in the case where a cell attaches to a substratum surface conditioned with a macromolecular film). The terms pressure, force, and interactions, all widely used in the literature interchangeably, really mean energy and should be understood as such.

Brownian Motion

Every molecule or particle immersed in liquid medium, irrespective of its size, has a Brownian energy of approximately $1\,kT$ ($k = 1.3805 \times 10^{-23}\ \mathrm{JK}^{-1}$, T = temperature in Kelvin). This energy keeps particles in suspension, provided the energy of attraction between similar molecules or particles (substrata) is less than $1.5\,kT$ per pair. Brownian motion, therefore, plays an important role in the solution stability of small molecules.

Lifshitz van der Waals Electrodynamic Interactions

In aquatic systems, all the three types of Lifshitz van der Waals electrodynamic interactions behave similarly and decay at the same rate at distances of 5 to 10 nm from the particle or molecule surface. The decay rate for energies per unit surface is inversely proportional to the square of the distance (L^{-2}). The van der Waals-Debye interactions where a molecule with a permanent dipole induces a dipole in a neighboring molecule by polarization and the van der Waals-Keesom forces (interactions between molecules with permanent dipoles) are not subject to retardation at distances beyond 5 to 10 nm from the particle surface and are of minor importance in condensed media such as water. The London van der Waals forces (instantaneous dipoles induced by the motion of electrons in a molecule) represent more than 95% of the electrodynamic forces in liquids. They decay at a rate proportional to L^{-3} at distances beyond 5 to 10 nm from the particle or molecule surface. Lifshitz van der Waals interactions can be attractive or repulsive, depending on the properties of the interacting surfaces.

Electrostatic Interactions

Most surfaces in natural waters are negatively charged. Electrostatic interactions between them are therefore usually repulsive; their intensity depends on the electrokinetic potential of the interfaces. The interaction energy decays exponentially with distance L, as $\exp(-\kappa L)$. $(1/\kappa)$, the Debye length, is the thickness of the Gouy-Chapman electric double layer and varies with the ionic strength of the medium. The interactions between two negatively charged surfaces can be attractive when the values of their surface potentials differ significantly or when bridging compounds such as divalent cations are present in the medium.

Polar Interactions

Polar interactions between molecules or particles in aqueous phases are generally of much higher energy than Lifshitz van der Waals or electrostatic interactions. Polar interactions, on a generic level, comprise all types of electron donor–electron acceptor interactions including hydrogen-bond interactions and hydrophobic interactions. Hydrogen-bonding interactions in water between very hydrophilic materials tend to be repulsive, whereas the same interactions between more hydrophobic surfaces tend to be strongly attractive. Polar interactions decay exponentially with the distance L from the surface, as $\exp(-L/\lambda)$, where λ is the decay length characteristic of the medium (somewhere between 0.2 and 1.0 nm for water).

Chain Elasticity

Chain elasticity comprises a series of forces that apply when a polymer is compressed or stretched (41). A bacterium approaching a surface conditioned with macromolecules will initially interact with the polymers by physisorption processes. Further reduction of the bacterium-substratum distance will depend on the contraction and/or conformational alteration of the conditioning film macromolecules and of the polymers at the bacterium surface.

Other Interactions

The remaining interactions listed in the literature are disjoining pressure, hydration pressure, structural forces, depletion flocculation, depletion stabilization, entropy-driven interactions, enthalpy-driven interactions, cross-binding interactions, steric interactions, specific interactions, and osmotic pressure. All of these interactions are either part of one of the primary interaction groups identified earlier or the result of combinations of these groups (40).

Adsorption of Macromolecules

A prerequisite for adsorption of a compound to a surface is the decrease of the Gibbs free energy:

$$\Delta_{ads}G = \Delta_{ads}H - T\Delta_{ads}S \quad (4)$$

where H, S, and T are enthalpy, entropy, and absolute temperature, respectively, and Δ_{ads} indicates the change of the thermodynamic functions resulting from the adsorption process. For adsorption to be thermodynamically favorable, $\Delta_{ads}G$ has to be exothermic, for example, less than zero. With macromolecules, exothermic adsorption is often achieved at the expense of conformational alteration. The polymers most likely to be found in conditioning films from natural waters are humic compounds, polysaccharides, and proteins. Little is known about the conformational changes of humics or polysaccharides upon adsorption, but a great deal of information is available about these events in proteins, which adopt three types of structures in solution. The expanded-coil structure is highly solvated and flexible. Fibrillar proteins have a regular structure of α-helices or β-sheets. Globular proteins may contain a combination of α-helices, β-sheets, and random parts folded into a compact entity. Most proteins belong to the fibrillar or globular classes.

Norde and Lyklema (42) classify proteins as "hard" or "soft" depending on their resistance to structural modification on adsorption. "Hard" proteins are structurally stable because of their strong internal coherence. Hydrophobic groups are buried in their interior and most of the charged or polar groups are located at the protein–water interface. Internal charged groups occur as ion pairs because the reduced local dielectric permittivity inhibits dissociation. Adsorption of "hard" proteins is governed by electrostatic interactions and partial dehydration of both the substratum and protein surfaces. Calculations of the energy balance of dehydration of a polystyrene substratum (42) by a protein of 50 kDa adsorbed with a surface coverage of 2 mg/m^2 indicate a moderately exothermic reaction suggesting that dehydration of interacting interfaces alone can facilitate macromolecule adsorption. Globular proteins do not unfold significantly upon adsorption, but a modification of secondary structure into a more random configuration causes an increase in entropy sufficient for spontaneous adsorption (42). "Soft" proteins undergo structural modifications upon adsorption that result in increased entropy of the adsorbed species. The partial or even total denaturation of these proteins at interfaces leads to the establishment of many contact areas between the adsorbed macromolecule and the substratum. This considerably increases the stability of the sorptive interaction.

Electrostatic charge is another important factor that determines the rates of protein adsorption to surfaces. Adsorption of negatively charged proteins to positively charged substrata is usually rapid and diffusion-limited. Protein adsorption is maximal at pH values around the isoelectric point, where the protein has a more compact, globular, conformation. At other pH values, net positive or negative protein surface charges lead to more extended protein configurations as a result of the intramolecular electrostatic repulsion. In addition, the net charge of the protein generates an electric double layer. In most circumstances, the charge of the substratum will be of the same sign as that of the protein and the electric double layers on both of these surfaces will increase the energy barrier for adsorption.

COMPOSITION OF CONDITIONING FILMS

The predominance of glycoproteins in conditioning films from natural waters has been inferred from the presence of amide and polysaccharide adsorption bands observed in ATR-FTIR spectra obtained in some of the pioneering investigations (43). These two bands are certainly indicative of the presence of proteins and polysaccharides on the substratum surface but because unfiltered water samples were exposed for several hours or even days to substrata, it is more likely that the results obtained represent the colonization of the surfaces by microbial biofilms. Furthermore, the presence of polysaccharide and

amide adsorption bands on FTIR spectra does not imply that these compounds occur in the same macromolecules. Similar results were reported by Kristoffersen and coworkers (17), who found amino acids, sugars, myristic, palmitic, oleic, and stearic fatty acids in material hydrolyzed from surfaces exposed to raw seawater for two hours in flow cells. Electron micrographs, however, suggest the presence of a significant amount of material of microbial origin on the exposed surfaces. The patch wise distribution of lectin-binding material (polysaccharides or glycoproteins) on substrata exposed for between one and three days in seawater and its absence in areas without cells is indicative of the close association of these materials with microbial cells (44). Evidence for the presence of humic substances in conditioning films deposited from marine waters was first reported by Loeb and Neihof (9) and has been recently conclusively demonstrated by Leis and coworkers (24). The composition of conditioning films in subsurface environments is largely unknown, but it can be assumed that these films will be dominated by humic-like substances derived either from kerogen or transported into the subsurface in addition to inorganic components deposited from solution.

MODIFICATION OF SUBSTRATUM SURFACE PHYSICOCHEMISTRY BY CONDITIONING FILMS

The surface charge of particulate matter suspended in natural surface waters is always negative as a result of adsorption of organic components of conditioning films (9,45–49). Oxidation of organic matter by UV removes the ability of the coatings to modify substratum surface charge. Both large and small molecular weight compounds contribute to the surface charge of the films (50) whose major ionizable groups are carboxylic and phenolic –OH groups (48). The surface charge imparted by conditioning films on substrata appears to vary between sites, for example, the organic composition of the films seems to be specific for the sampling location (9,48). Every water sample was found to contain dissolved organic and colloidal matter that generated conditioning films, which modified surface free energy and its components (Lifshitz van der Waals, electron donor and electron acceptor) on most substrata. The effects were, however, substratum-specific and site-specific and there were no general unifying trends discernible (51,52).

KINETICS OF CONDITIONING FILM DEPOSITION

Conditioning films accrue at a rate of approximately 1 nm/s during the first few seconds of exposure, but the accumulation rate slows down rapidly till they reach their terminal thickness of between 20 and 80 nm after approximately 20 hours (53). Under optimum adsorption conditions, the surface coverages may reach 50% within the first few seconds (54). Conditioning films more than approximately 20 nm thick most probably comprise several layers of adsorbed molecules. Even after growing to a steady state thickness, the molecular composition of the films continues to change by the replacement of macromolecules with low affinity by others with higher affinity for the substratum (52,55). In analogy to the effects of conditioning films on bacterial adhesion, the first conditioning layer will influence the adsorption of the subsequent layers (56).

EFFECTS OF CONDITIONING FILMS ON MICROBIAL ADHESION

Conditioning of a surface with macromolecular organic matter should result in the formation of a coating with physicochemical properties different from those of the original surface. Such a coated surface should, therefore, retain organisms in a manner different to that of the original substratum. Studies with model compounds such as proteins have firmly established that conditioning films do influence microbial adhesion to inanimate substrata. Concentrations of dissolved organic compounds in the grams per liter range employed in these studies are well above the low parts per million (ppm) range typically encountered in most natural waters. Systematic evaluation of the effects of conditioning films from natural waters representative of freshwater, marine, and subsurface environments (52,57,58) revealed that microbial adhesion was modified on about 60% of substrata tested. The film-specific and substratum-specific effects were caused by the high molecular weight components of the films. Stripping of volatile compounds from the samples did not modify the adhesive properties of films, and films deposited from material that passed filters with a nominal pore size of less than 30,000 Da did not affect adhesion of the test organisms. Despite the low concentration of organic matter in natural waters and of its diverse nature, a few of the samples investigated produced films on four different substrata to which microorganisms attached in similar numbers, for example, the films appeared to completely mask the adhesive properties of the underlying substratum. On other occasions, however, substratum properties appeared to be somehow relayed to adhering bacteria across the conditioning film. In the case of the thin films deposited from natural waters, this may be caused by patchiness of surface coverage, for example, there may be areas of the substratum not entirely covered by macromolecular material. Substratum properties could also be relayed to bacteria if conditioning film material is removed from the bacterium–substratum interface in the early phases of attachment. Comparison of adhesion of carbon-limited and nitrogen-limited phenotypes revealed that conditioning films could modify the selectivity of substrata for microbial phenotypes (52,57,58). Adhesion of the test organisms to conditioned substrata correlated only occasionally with surface physicochemical parameters determined with contact angles (59).

The identity of the macromolecules from natural waters that affect bacterial adhesion to conditioned substrata is not known. Conditioning of a hydrophilic (stainless steel) and a hydrophobic substratum (polypropylene) with organic matter from six different fractions (hydrophobic-base, hydrophobic-neutral, and hydrophobic-acid as well as hydrophilic-base, hydrophilic-neutral, and hydrophilic-acid) of a freshwater and a marine water did not improve the consistency of the effects of the films on

microbial adhesion relative to the results obtained with the unfractionated water samples (52). Coatings from hydrophobic fractions were as effective in modifying adhesion as coatings from hydrophilic fractions. In addition, variation of the concentration of the material from the fractions in the conditioning film solutions and of the exposure time revealed that both factors influenced the adhesive properties of the conditioning films. Clearly, adsorption of the microbial adhesion-modifying macromolecules from natural waters to surfaces is a complex and dynamic phenomenon.

CONDITIONING FILMS AS SOURCES OF NUTRIENTS FOR BACTERIA

Ever since microbiologists realized that surfaces in natural environments are colonized by microorganisms, there has been speculation about the ecological advantages of the attached forms of life to microbes. Because most aquatic environments are oligotrophic, for example, low-nutrient ecosystems, one possible reason for the high affinity of bacteria for surfaces is the potential role of conditioning films as sources for nutrients (60). It is now well established that microbes have evolved a diversity of strategies to access adsorbed nutrients (60). These include reversible adhesion followed by detachment of either the mother cell or of a daughter cell once available adsorbed food sources are exhausted (61) and some sort of reversible attachment with surface movement such as crawling (62) or other forms of lateral displacement (63). Small molecular weight hydrophobic compounds such as stearic acid sorb tightly to substrata but can be accessed readily by microorganisms (62,63). It is even possible to isolate microbes targeted at the biodegradation of adsorbed small molecular weight compounds (64). The digestibility of adsorbed macromolecules by exoenzymes will depend largely on the conformation of the adsorbed species, which in turn varies depending on the surface chemistry of the substratum. Samuelsson and Kirchman (65) studied the growth of Pseudomonas S9 on adsorbed ribulose 1,5-bisphosphate carboxylase (rubisco). They found that although a larger amount of rubisco adsorbed to hydrophobic surfaces, hydrolysis of the protein was faster on hydrophilic surfaces probably because of the easier access of the exoprotease to the adsorbed protein. Growth of microorganisms was also initially faster on hydrophilic surfaces but more rapid depletion of available substrate led to higher growth rates on hydrophobic surfaces after six hours. The relevance of these results to conditioning films from natural waters depends on the following issues:

1. *The Nature of the Components of Conditioning Films from Natural Waters*. All of the studies in which bacterial growth and utilization of adsorbed organic compounds has been demonstrated employed compounds such as proteins, fatty acids, or hydrophobic pollutants, which are not likely to be significant components of conditioning films in natural waters. The compounds were used in a pure form, for example, the surface concentration of the particular substrates was very high. However, in natural waters, easily degradable organic carbon ("labile carbon") represents only between 10 and 30% of DOC (8). Furthermore, this scarce, labile fraction comprises small molecular weight compounds that either do not adsorb to surfaces or adsorb only weakly (60). The remainder of the DOC pool is constituted of recalcitrant organic matter with turnover times of up to 6,000 years (8).

2. *The Ease of Biodegradation of These Components*. The humic compounds that represent the largest fraction of natural water DOC and which have been demonstrated to be part of conditioning films, are thought to be rather recalcitrant for biodegradation by bacteria (66). Growth yields on these compounds are likely to be significantly smaller than those obtained with sugars, amino acids, or fatty acids. It is, therefore, very unlikely that the conditioning film material from natural waters present in the contact area of a microorganism with the substratum would support the production of biomass required for cell replication.

3. *The Geometry and Contact Area of the Bacterium-Conditioned Substratum Interface*. The contact area of a microorganism with a conditioned substratum is very small. Most cells are curved, and only a very small part of the curved section is in direct contact with the substratum (67). The immediate contact area of cells with conditioning films, therefore, does not represent a significant source of food for attached microbes. Rhouxhet and Mozes (68) calculated that if a disaccharide was adsorbed as a monolayer and the cell was actively respiring at rates typically encountered in growing organisms, the compounds adsorbed in an area corresponding to the surface occupied by the cell would be consumed within 10 seconds. Alternatively, one could estimate the area of conditioning film required to supply a cell with its organic carbon in sufficient amounts for the synthesis of the entire cell organic carbon. If the following assumptions are made:

- the cell is assumed to be a sphere with a diameter of 0.5 μm
- cells consist of 80% water and 20% organic matter (density of 1 g/cm^3)
- rubisco adsorption data from Samuelsson and Kirchman (65) are adopted as reference (maximum of 0.45 μg/cm^2)
- yield of biomass production with rubisco is assumed to be one (1 g of cell mass formed per gram of rubisco utilized)

then it becomes clear that the cell would need to scavenge the entire rubisco adsorbed in an area of approximately 2.9 μm^2, which is approximately 15 times the projection area of the cell diameter on the substratum surface. Clearly, organisms need to scavenge comparatively enormous areas to satisfy their food requirements if the only source of nutrients were the conditioning films, even when these films consist of easily degradable substances. Growth yields on films from natural waters are likely to be much lower because the cells would have to produce a wide range of extracellular enzymes and the substrates of the individual exoenzymes would be dispersed over a much wider

area than was calculated for rubisco. Surface displacement is the only means by which microbes would obtain sufficient nutrient sources from adsorbed films for growth.

4. *The Specific Physicochemistry of Surfaces*. Most organic compounds available to microbes in oligotrophic natural waters are macromolecules. These substances may adsorb to surfaces tenaciously forming many contact points and may even be denatured. These processes may render many of them unavailable for breakdown by exoenzymes thus restricting even more nutrient availability to microbes.

Points 1 to 4 illustrate that the content of easily degradable organic matter is low in conditioning films from natural waters. Depletion of these components from the films would facilitate their replacement by the dominant recalcitrant organic molecules in the pool. Conditioning films from natural waters are, therefore, not significant sources of organic carbon for bacteria in oligotrophic environments.

CONCLUSION

The composition of conditioning films from natural waters, the dynamic processes that occur during their formation, and their exact role in microbial adhesion and biofilm formation are still largely not known. The following list includes some of the most important issues that need to be researched to better understand the interaction of environmental conditioning films with environmental microbes:

- What are the components in conditioning films that influence microbial adhesion, either positively or negatively?
- How far into the development of microbial biofilms do conditioning films influence the process?
- Which components of conditioning films, if any, are food sources for microorganisms and what growth rates and yields can be achieved by microbes growing on these compounds?
- Does the ability to utilize conditioning film components as food source provide an advantage for microorganisms colonizing inanimate surfaces in natural environments?
- What is the exact role of conditioning films in microbial attachment?
- Do microbes attach to surfaces via the establishment of connections between their cell surface adhesive biopolymers and conditioning film components or, alternatively, do conditioning films only play a role in initial, reversible adhesion, with firm linkages between microbe and substratum established after displacement of conditioning film components from the interface between microorganism and substratum

Novel surface analysis techniques and improvements in mass spectrometry procedures that allow for analysis of entire macromolecules provide a novel set of tools for the study of conditioning films. These methods, in combination with state-of-the-art molecular biology and microbial physiology procedures, will greatly improve our understanding of the interactions of conditioning films with microbes.

CONTROLLING THE MICROBIAL QUALITY OF DRINKING WATER IN DISTRIBUTION SYSTEMS

EDWIN E. GELDREICH
Cincinnati, Ohio

The existence of man is dependent on water supply and it is an essential element in community life. Ancient civilizations evolved around rivers, lakes, and ground water outcroppings as springs. Catchment basins or open-dug wells were developed to catch rainwater, and open channels were created to divert water resources to village fountains, public baths, and agricultural fields. The ancient Greeks constructed clay pipes for water transport (1), and early Romans became the master engineers who created massive aqueducts for the purpose of bringing water supply from the mountains to distant cities (2). These achievements were followed by the Moorish civilization that extended water delivery systems to create marvels of water fountains in the arid lands around the Mediterranean coastal areas of Spain. In the Americans, the various centers such as the "lost Inca city" of Machu Picchu (Peru) and the Mayan cities in ancient Mexico attest to the management of water for the survival of these great centers of civilization. Today, the very existence of many villages in remote areas of the world are tied to a water source within less than two hours walking distance because water supply must be carried in buckets by women and children to their homes. From these basic discoveries of how to collect, protect, conserve, and provide water in a community, there has evolved the present day complex structure of a distribution system.

The intent of a modern distribution system is to supply water on demand to individual homes, public buildings, offices, hotels, schools, and industries for five basic purposes: safe water to drink, sanitation necessities (baths and toilets), processing food, creating manufactured goods, and fire control. These uses require a complex engineering operation that includes storage of water supply, pumping stations to move water in large mains throughout the pipe network, standpipes to afford relief from surges of water pressure in the pipelines, valves to isolate sections of the system, booster chlorination stations

and fire hydrants; all of which are connected together by miles and miles of pipes laid under the streets to reach all customers in the community. Added to this complexity are numerous water-attachment devices connected to building and home plumbing systems for a variety of uses. As a consequence, it is not surprising that water entering the distribution system from the treatment plant may be altered in quality during its passage. These quality changes are most often detected in taste, odor, and color that affect the appreciation of a pleasant drinking water. More serious are the intrusions of microbial and chemical agents that are of health significance (3). Protecting the quality and quantity of a water supply in distribution within the community is a complex engineering operation that never stops.

Basic Concepts in Distributing Microbially Safe Water

Rare has been the opportunity to design a water distribution system before a community is built. More often, its growth anticipates or follows urban sprawl in every progressive community. Water supply distribution systems in cities created over two hundred years ago were relatively simple in design because the cluster of human activities was close together. As these cities grew into urban sprawls and with increased diversity of activities, the demand for water intensified. In many cases, additional sources of water had to be found. Often the solution was met through the development of more wells or for other utilities; long transmission lines were laid to large distant surface waters in an effort to increase the availability of raw water. To keep up with the demand and to provide a water supply reserve for fire control, treated water was stored in additional reservoirs located at strategic sites further out in the pipe network. As a result of these pipe network expansions, gravity movement of the water supply over hilly terrain was found to be inadequate and pressure pumping was introduced to move the water to far reaches of the system. Today, progressive water utilities have developed strategies to keep pace with the anticipated expansion of the metropolitan area over the next decade or two. Implementing these plans must proceed carefully, however, to avoid oversizing the distribution system too early. When supply far exceeds demand, there is long retention of water supply in the pipe and in the reservoir storage tanks. The net result is that water supply stagnates and there is a rapid deterioration in quality. Whenever possible, it is desirable to keep water supply moving throughout the distribution system for short retention times and minimal quality changes.

Storage of treated water supply is mandatory in every community system to meet periods of peak demand and to provide a buffer during emergency shutdown of water treatment production. These reservoirs of drinking water supply may be held underground, at ground level, or in elevated tanks. Underground reservoirs are generally constructed as cement vaults, but older basins still in use were created with masonry or stone and are lined with concrete, asphalt, or butyl rubber to prevent surface leakage or groundwater contamination into the supply. Elevated storage tanks are constructed of steel or reinforced cement materials and sealed with an epoxy coating to deter water loss through leakage. Impounded storage of drinking water at ground level should be covered to minimize contamination from storm water runoff, birds, dust, human contact, and adjacent road spills. Over time, sediment and biofilm accumulate in these storage structures. For these reasons, it is desirable to take storage reservoirs off line every three to five years to flush out this microbial habitat, repair any structural defects, and apply a new coat of epoxy sealer.

Maintaining Distribution System Integrity

Integrity of the system is of utmost importance. This places emphasis on maintaining pipelines with minimal leaks and a positive pressure of 20 psi (pounds per square inch) to prevent backflows during cross-connections. Materials used in the manufacturing of pipe must be stable over the years of service life to resist collapse from movement in the pipe bed during ground heaving in the winter, vibrations created from road traffic, or nearby construction activity, and earthquakes. Pipe networks should be designed to minimize numerous dead-end lines by incorporating continuous loops that nullify the creation of static water areas.

The service life of pipes is not infinite. Various materials have been used for water supply pipes including cast iron, ductile iron, cast iron lined with cement, steel, reinforced concrete, asbestos combined with Portland cement, and three plastic materials: polyvinyl chloride (PVC), polyethylene, or polybutylene. Pipe material in building plumbing networks are most often copper or plastic, but occasionally, black and galvanized iron may be encountered in older homes. Pipe service life is also affected by both external and internal corrosion. External corrosion results from the intimate contact with aggressive soil environments. Some of these factors include soil resistivity, soil pH, presence of sulfate-reducing bacteria, and differences in soil type along the pipeline. Pipes laid in areas of landfill or across industrial sites may also be exposed to accelerated external corrosion. In these cases, some form of external coating or a sleeve is needed to provide substantial protection from accelerated lost of integrity.

Internal corrosion is the result of water aggressiveness in unlined metal pipe that is often aided by microbial activity of both sulfate-reducing organisms and other aerobic heterotrophic bacteria (4,5). Additional factors that cause water to become aggressive on metal pipe materials include low pH, low alkalinity and hardness, high chloride, or high sulfate in some interrelationships. These exposures lead to formation of an irregular, porous deposits (tubercles) that are suitable for microbial habitation and attack on the metal surface. Over time, the interior pipe surface becomes pitted as microbial and chemical mediated corrosion slowly reduces wall thickness and strength.

Combating corrosion is critical because deposits of rust accumulating in the pipe begin to restrict water flow, bacterial colonization of tubercles expand, and customer complaints of taste and color in the water increase (6). Strategies for pipeline salvage may vary depending on the status of the corrosion problem. Severe accumulations of

tuberculation will require mechanical scrapping of the pipe to loosen these rock-like deposits. Less severe corrosion deposition may be removed by forcing a plastic plug (termed a *pig*) through the line to sweep the material ahead and out of the pipe. Following such action, the line is flushed to remove sediments and other debris. In more serious situations, lining the pipe section with cement may be cost effective and desirable to combat biofilm development and stop loss of water through corrosion pinholes that may develop in the pipe wall.

The immediate response to a line break is to repair the fractured pipe sections or to replace. To expedite repairs at streets with high-volume traffic, pipes with longitudinal splits are often patched with metal straps. A more permanent repair approach is to cut out the broken section and replace it with new pipe. Once the repair is made and tested for leakage, on-site disinfection of the repaired section is essential to prevent the introduction of microbial contamination from drainage around the site. Generally, this procedure consists of the application of a heavy chlorine dose (50 mg/L HOCl), usually in the form of liquid chorine, calcium hypochlorite granules or tablets, or sodium hypochlorite solutions. The disinfected standing water is held in the pipe section for 24 hours after that a bacterial test for heterotrophic bacteria is made. If the bacterial density is less than 500 organisms per ml, the pipeline is accepted for return to service, if not, the disinfection procedure is again applied and the water tested for residual contamination. Any repeated contamination will require an inspection of the repair job for a cause to the loss of pipeline integrity. Frequent line breaks in the same area increase the probability of a breakthrough of microbial contamination. Repeated breaks in the vicinity should be viewed as a signal for prompt rehabilitation of that part of the pipe network.

Managing Water Quality

Maintaining the integrity of the distribution system requires a dedication to preventive maintenance of all component parts to optimize their service life and function. Cast iron and ductile iron pipe appear to have a service life of approximately 100 years; reinforced concrete, 50 years; and asbestos cement pipe, 30 years. Although thousands of miles of nonmetallic water pipes and service lines have been installed, little can be said about their service life because these materials are a relatively recent development.

Every water utility has a history of some unpredictable water loss that occurs because of slow leaks, pipeline breaks, and unmetered service to their customers. In reality, the distribution pipe network is never completely watertight but with good management, losses from slow leaks should not exceed 15%. It is important to not only minimize these water losses as a matter of water conservation and lost revenue but also to reduce possible soil contamination opportunities. A dangerous contamination pathway may be created in unchecked water loss situations and to cross-connections and back-siphonage in water attachment devices, interconnection of private and public water supplies, or lack of backflow prevention in lawn watering systems, fire control sprinklers, and car wash operations.

Back-siphonage is the movement of drainage water back against the direction of normal flow or positive water pressure. This is the reason why water supply utilities must maintain a positive pressure of at least 20 psi in all areas of the distribution pipe network. Such a policy provides significant protection from passage of storm water runoff and sewage drainage in the pipebed to a fractured pipeline, a poor pipe joint or cross-connections to various water-use devices in plumbing systems. Any large-scale reduction in water pressure is an opportunity for microbial contamination to overcome the integrity of a safe distribution system.

For those utilities that have very aggressive water, inclusion of a treatment to suppress corrosion is essential to reduce chemical and microbial mediated activity on the pipe walls (7). An effective corrosion control protocol is sometimes difficult to achieve because only certain nontoxic substances at low dosages can be employed for health reasons. With this limitation in mind, corrosion treatment has focused on raising the pH and alkalinity during water processing or adding corrosion inhibitors (carbonates, polyphosphates, blended phosphates, or sodium silicates) to form protective films on pipe walls. Unfortunately, attempts to create a passivating film of inhibitors on pipe walls may result in excessive depositions in mixing zones where the water flow shifts back and forth. The net effect is an unstable shifting between deposition and dissolution by changes in water quality and reversals of flow. This instability often results in the unpredictable release of sediments and entrapped bacteria into the bulk flow of water.

Cross-connections and back-siphonage are always a threat to water quality in the distribution system. Much of this threat is from attachment devices or poor plumbing practices that do not isolate the water supply from backflow of drainage in the device. What is also dangerous is the illegal tap-in on public water supply lines and the interconnection of a private well or cistern supply with the municipal water system. These unauthorized actions by private citizens provide opportunities for incursions of fecal bacteria, viruses, and protozoan pathogens from surface runoff around the wellhead or from bird and rodent feces on the cistern rainfall collecting surfaces.

Maintaining a disinfection residual that can inactivate pathogens associated with contaminants seeping into large volumes of high-quality water supply does provide some protection from these incursions (8). Obviously, there are limitations to this protective barrier. Chlorine residuals in distribution water often range from 0.1 to 0.3 mg/L and these concentrations will not be effective during massive intrusions of gross contamination characterized by odors, color, and milky turbidities. Fortunately, replenishment by the inflow of fresh, chlorinated water will provide significant dilution and dispersion of these contaminants to improve the potential for inactivation of microorganisms by the available disinfectant residual.

Microbial Flora of Drinking Water

Drinking water is not sterile nor does it need to be for a safe supply. The objective of water utilities is to

provide the community with a water supply that presents a minimal health risk from the invisible threats of microbiological, chemical, and radiological contaminant. Also of concern with dubious safe water is the general appearance (turbidity) and palatability (taste and odor). These conditions are often linked to the metabolic activity of microorganisms within the distribution pipe network.

Profiling the organisms found in potable water reveals a mixture of microorganisms whose origins are varied (3). They may have been introduced in the source water, survived treatment and established themselves in the distribution system, or entered during line breaks or cross-connections (9). Ecological dominance of some species is a reflection of their ability to rapidly colonize corrosion sites, low flow areas of the system, stratified water-storage tanks, and attachment devices in building plumbing networks.

Inspection of the bacterial population of microorganisms in drinking water reveals many gram-negative and gram-positive bacteria, spore-formers, acid-fast bacilli, pigmented organisms, fungi, yeast, and free-living amoeba and nematodes. Most of these organisms are ubiquitous in the aquatic environment and of no public health significance. The exceptions are those organisms in the population of innocuous organisms that may become opportunistic pathogens or transfer antibiotic resistance factors to the human intestinal flora. By contrast, fecal contamination introduces the chance occurrence of intestinal pathogens (bacterial, viral, and protozoan). The routes of exposure may not only be ingestion but also body contact with the water during bathing or inhalation exposure to indoor climate control devices. An overview of some microbial groups in potable water reveals the presence of coliforms, antibiotic resistant bacteria, opportunistic pathogens, pigmented bacteria, ultramicrobacteria, and macroinvertebrates.

Coliforms. A variety of coliforms may be found occasionally among the heterotrophic bacteria in potable water supply (4). Their occurrence fits no set profile but some species are more common that others, perhaps because they are more capable of colonizing the Spartan environment of the distribution system. These organisms include *Klebsiella pneumoniae, Enterobacter aerogenes, Enterobacter cloacae*, and *Citrobacter freundii*. Among the coliforms, *Klebsiella* occurrence must be viewed cautiously even though the vast majority of this genus are environmental coliforms of no public health significance (10,11). Approximately 30% of all human intestinal tracts contain some *Klebsiella* strains, however, *E. coli* is the predominant coliform species of the fecal flora of warm-blooded animals. Because *E. coli* does not normally persist in the potable water environment, any occurrence of this organism suggests an immediate presence of fecal contamination. However, in recent years a mutant *E. coli* strain has been found to colonize greensand (used in water-softening treatment). This contaminant is difficult to eradicate with disinfection, because the strain develops a protective mucoid characteristic. Another strain, *E. coli* 0157 : H7, has recently emerged as a serious hemorrhagic pathogen. This organism is a slow fermentor of lactose and appears to be able to form a tenacious film over the inner surface of bottled water containers with survival for more than 300 days (12).These observations suggest that *E. coli* strains are emerging with new and dangerous characteristics for survival.

Antibiotic-Resistant Bacteria. The transfer of antibiotic resistance factors among the heterotrophic bacteria in water to the flora of the intestinal tract may be a contributing factor in the declining efficacy of an increasing number of antibiotics used in medical therapy. Antibiotic resistance factors (R-factor in plasmid transfers) occurring in bacterial populations originate in surface water sources containing rural storm water runoff from animal feedlots and in upstream municipal sewage effluents. Farm animals in particular, often receive continuous doses of antibiotics in animal feed and become generators of a variety of antibiotic resistant bacteria. Wastewater and water supply process basins provide the mixing chamber for R-factor transfers and the chance for some organisms to acquire multiple resistances to different antibiotics. Many of these transformations occur in the biofilm established on process basin compartment walls, agitators, and sand or mixed media filters (3,4). Receptor organisms may include *Pseudomonas Alcaligenes, Acinetobacter, Moraxella, Staphylococcus*, and *Micrococcus*. In the water supply of Cairo Egypt, 40–70% of the heterotrophic bacteria could be expected to have antibiotic resistance factors (13). Perhaps, part of this high percentage may be a consequence of indiscriminate use and easy access to antibiotics in the metropolitan area.

Opportunistic Pathogens. Some of the microorganisms (bacteria and fungi) that survive treatment and colonize the distribution system may in turn become colonizers of the susceptible human (individuals with underdeveloped or impaired immune systems), generally, the very young and senior adults in the community as well as patients on chemotherapy, dialysis, severe burn injury repair, and individuals receiving organ transplants (14). At least 5% of new patients in hospitals acquire nosocomial infections and 1% may die as a direct result of these exposures. The source of many of these opportunistic pathogens is water and water-attachment devices; others are introduced in salads and by hospital staff or visitor contact (15).

Bacteria, common to the water environment may present a health risk to susceptible individuals if high densities (10^6 per ml) occur (14,15). Amplification of these potential opportunistic organisms in static water locations of the building plumbing system or in an attachment device is necessary for the organism to achieve infective dose levels in healthy children and adults that approach 1×10^{10} cells per exposure. Infective dose for those individuals most at risk in the community would be several magnitudes less. Although the number of cells necessary to achieve an infective dose may seem unlikely to occur often, the volume of water used to take a shower or bath can easily supply this accumulative density during a given exposure period. Some of the bacteria most often found to be the cause of nosocomial infections associated with

contaminated potable water are *Pseudomonas, Acinetobacter, Mycobacterium, Flavobacterium, Legionella*, and *Klebsiella* (16,17).

Fungi are another group of organisms in water that, when present in certain situations, may colonize the human body and become opportunistic pathogens (18). The most frequent complaint is from allergenic reactions: (sauna taker's disease), mycotoxin, and infections of the skin, nails, hair, and genitalia. Very often the contact exposure route is with some water attachment device used in the home, hospital, or health spa.

Filamentous fungi (*Penicillium, Cladosporium, Phyma, Acremonium, Sporocybe, Aspergillus*, among other) are common to the aquatic environment. Hence, it is not unusual for mycelial fragments and spores to be present in source water. Passage through coagulation, sand filtration, and disinfection will lead to some reduction in fungal densities but are quite variable in their effectiveness. Aquatic fungi find many areas (pipe joints, gaskets, joint seal compounds, and biofilm sites in areas of corrosion and sediment) of the distribution system to be a satisfactory environment for colonization (3,4).

Profiles of filamentous fungi in water supply are variable, being a reflection of seasonal water temperatures, source water quality, treatment patterns, and methods used to isolate these organisms in the laboratory. Fungi densities in potable water supplies are usually less than 10 organisms per ml (3). Any greater numbers in water supplies often result in customer complaints of poor taste and musty odors.

Yeasts are found in water supply (19). Although little is known about their profiles, frequency, density, and regrowth characteristics, one species, *Candida albicans*, is an important example of an opportunistic strain of yeast. This yeast may cause secondary infections to individuals stressed from diabetes, cancer, and immunological defects associated with AIDS, organ transplants, and the application of broad-spectrum antibiotics. Water treatment will remove 90 to 99% of yeast in raw source waters but only ozonation rather than conventional chlorination is effective in their inactivation (3). Finished water coming from the treatment plant may have very few yeast per liter but these scant occurrences may be amplified a thousand fold in old pipe sections, dead ends, and other stagnant water sites in the pipe network.

Pigmented Bacteria. Some of the bacteria found in water supply have the ability to form nonphotosynthetic and nondiffusible pigments (yellow, orange, pink, purple, brown, and black) (20). This characteristic may be observed on plate cultures if the incubation time is extended beyond three days. Such organisms (strains of *Flavobacterium, Mycobacterium, Serratia, Corynebacterium*, and *Chromobacterium*) appear in greatest abundance in waters of high quality such as public water supplies, bottled water, and product water from a variety of attachment devices such as ice machines, point-of-entry treatment packages, humidifying units, and hemodialysis equipment (3). Their origins are in source water and soil contaminants introduced in line breaks. Disinfection of water supply has little impact on pigmented bacteria (3). Of this group of organisms, nontuberculous *Mycobacterium* and *Serratia* species may be the major representatives of those pigmenters that can be opportunistic, causing skin lesions, septicemia, and postsurgery complications in the hospital.

Although pigmented bacteria entering the distribution system may be only a few organisms per liter, this density changes significantly in static pipe sections of the distribution network. Yellow-pigmented and orange-pigmented strains follow different seasonal patterns of dominance. For instance, yellow-pigmented bacteria occur in higher densities during the summer, whereas orange pigmenters are more frequent in the winter (3). Little is known about the mechanism that stimulates these cyclic growth patterns in the distribution system.

Ultramicrobacteria. This group of very small heterotrophic bacteria (less than 0.3 μm in size) is "normal"-sized aquatic bacteria that have adjusted to the harsh environment of the distribution system through gradual starvation (21). As part of their survival mechanisms, some of these ultramicrobacteria develop encapsulation and enhanced adhesion to pipe walls, tuberculations, and storage tank surfaces. As a consequence, these organisms are capable of surviving for extended periods of slow water movement during storage in static reservoirs and in bottled water stockpiled for use during natural disasters (22).

Some of these ultramicrobacteria include strains of *Klebsiella, Escherichia, Bacillus, Micrococcus, Staphylococcus*, and *Vibrio*. Pathogenic bacteria may also become minaturized in structure and metabolic activity under these circumstances and may be difficult to detect unless very dilute media are used for their cultivation with extended incubation times (3). On resuscitation in the laboratory, these organisms often return to normal size and typical metabolic functions.

Macroinvertebrates. Drinking water also contains a diverse population of free-living organisms that feed on bacteria and fungi. These are the amoebas, amphipods, copepods, and the nematodes common to surface waters (23). In water treatment, many of these organisms become entrapped in the filter media but some pass through treatment barriers, including disinfection exposure. Migration into the distribution system occurs in the search for food (bacteria and fungi) at tuberculation sites of biofilm or in areas where water flow is slow and colonized bacteria occur in the sediments. Although these organisms are not known to cause a health risk, they may become a transporter of viable coliforms, *Legionella*, and other bacteria into the distribution system (3,4). When the macroinvertebrates burst open, the engulfed bacteria are released. In some instances, excessive colonization by macroinvertebrates in old pipelines may lead to public complaints about water palatability and aesthetics because of their presence in the drinking water.

Biofilm and Water Stability

Water supply biofilm is a microbial event created by a consortium of organisms at some site within water treatment, distribution, or plumbing systems. Circumstances that

are conducive to their growth occur under challenging conditions that include adequate nutrients, a protective habitat, and favorable water temperature. Adversities to biofilm development are disinfection, unstable sediment substrate, and the shearing effects of water movement under pressure. These habitats may occur in water process basins, distribution pipes, storage tanks, stagnant plumbing lines, and attachment devices. Key requirements for successful biofilm development are the ability of organisms to adjust their metabolic activity to a limited nutrient base, form a slimy matrix of extracellular organic polymers for adhesion to pipeline surfaces and locate in an area of minimal exposure to disinfection residuals.

Upon entering the distribution system, microorganisms may follow one of several scenarios: (*1*) die in the harsh water environment for lack of suitable nutrients or from exposure to disinfectant residuals, (*2*) sustain meager survival by successfully attaching to some pipe material then take on an ultramicrobacterial existence, or (*3*) rapidly adjust to the water environment and actively colonize quiescent sites in the pipe network (24).

Biofilm development in the distribution system is a progressive process (25). Initial microbial colonization occurs among those organisms that either become embedded in the sediments or quickly produce a slimy matrix of extracellular organic polymers that adhere to the pipe surfaces. This matrix is interlaced with water channels that have been reported to constitute as much as 40 to 60% of the total biofilm volume (3).

Biofilm in Water Distribution. The adverse effect of biofilm development in the pipe network is the sudden, erratic release of coliforms and other heterotrophic bacteria into the bulk water flow that has nothing to do with a treatment barrier failure, cross-connection, or line break. The problem is most often associated with systems using surface water. These occurrences are stimulated by warm water temperature ($>15\,^{\circ}C$) in the pipe network and the accumulation of assimilable organics above a critical mass. During these episodes, coliform positive samples are detected in an almost random fashion throughout the pipe network. Coliform speciation from these positive water samples during a biofilm release period often reveals that one of several coliform species predominate (*Klebsiella pneumoniae, K. oxytoca, Enterobacter agglomerans, E. cloacae*, or *Citrobacter freundii*). Perhaps this is the reason why only *Klebsiella* and *Enterobacter* strains are most often identified as the coliforms involved in public water supply noncompliance problems (3).

Coliform releases in biofilm fragments may not be of public health significance per se but should not be ignored because of perpetual concern for a hidden fecal contaminating event (3). These biofilm releases could be masking other more serious situations that suggest (*1*) a possible partial loss in treatment barrier effectiveness, (*2*) backflow of contaminated water into a distribution line, or (*3*) accumulation of assimilable organics in slow flow pipe sections that support expanded microbial growth in localized areas and interference with disinfectant residual effectiveness.

Within the potable water distribution system, there are many safe havens for biofilm development. Foremost among these sites are areas of corrosion and slow flow where sediments accumulate and water movement is not sufficient to disrupt the development of colonization on iron pipes (9). This action is followed by tuberculation in the pipe that not only impairs water flow but also becomes a protected microbial habitat for cell attachment within the porous structure of these corrosion deposits (25–27).

Although cement pipe and PVC pipe materials are not subject to this type of corrosion attack, water characteristics may change the surface structure of asbestos/cement mains and biological activity will eventually create pitting of plastic pipe materials and splaying of cement surfaces. It is important to note that not all pipe sections may show evidence of deterioration even after 50 years or more of service: the reason being the nature of the system's water chemistry and the continuous movement of water supply through the pipe network in high-demand areas. Water storage reservoirs and standpipes may also accumulate biofilm deposits on sidewalls and in tank bottom sediments as a result of slow water exchanges and stratification. This near static situation provides opportunities for enhanced anaerobic growth of various nuisance organisms that cause taste and odors.

Growth of pioneering microorganisms in the distribution system initially proceeds slowly as the organisms adjust to the constraints of this aquatic environment (3). Eventually, other organisms traversing the bulk water movement become entrapped in this material and introduce diverse metabolic pathways and unique by-product releases. With the synthesis of more complex organics and unique by-product releases, additional organisms with specialized nutrient requirements such as *Legionella* become established in the microbial community. Thus, as the pioneering biofilm reaches maturity, the microbial community becomes a site for progressive diversity of bacteria, protozoans, nematodes, and worms.

This consortium of organisms is a dynamic entity, with profiles shifting to reflect establishment of newcomers to the habitat, impact of antagonistic organisms in the community, and changing dominance by more aggressive organisms. All of these microbial profile changes are a reflection of warm water temperatures, available organics and nitrogenous compounds, and the impact of disinfectant exposures. Portions of the biofilm may eventually slough off into the bulk flow of water, as the thickness of the biofilm is held constant by the shearing effects of water flow. Other cases of biofilm release are water pH changes that effect pipe sediment stability and mechanically scraping of pipelines to reduce tuberculations.

Although the profile of transient organisms may vary with seasonal factors in source water, the permanent flora that comprises biofilm may be expected to be more stable. Organisms such as *Pseudomonas, Flavobacterium, Proteus, Bacillus, Actinomycetes*, coliforms, fungi, and bacterial predators are often the major contributors to the permanent biofilm community (3). The bacterial pathogen *Salmonella* has also been

demonstrated in biofilm but its persistence may be tenuous because of competition from other organisms that have been estimated to be 2,400,000 total organisms per milliliter.

Drinking Water Stability. Drinking water stability can only be achieved by keeping the system clean so that there are minimal progressive changes in the microbial quality (28). Source water constituents (assimilable organics, humic substances, and turbidity), treatment configuration, poor line-flushing practices, and water stratification in storage tanks provide opportunities for the gradual accumulation of sediments and microbial presence in the distribution system. These elements provide either a source of nutrients or contribute to a protective habitat.

Essential nutritive substances for microbial subsistence and growth in this situation are nitrogen, phosphorus, trace metals and biodegradable organics. Of these substances, reduction of organics is the most cost-effective approach to bring biological stability to the water system as critical inorganic materials are ubiquitous in the aquatic environment (29). Specific treatment options include biological treatment (ozonation followed by biological removal in carbon filters), granular carbon filtration, and enhanced coagulation. These processes provide destruction of recalcitrant organics in ozone treatment, improved extraction in the filter media bed and more effective physical entrapment in the coagulation process. The net result is that less organics pass into the distribution system and become available to organisms that have become entrenched in the pipe or storage tank environment. As a consequence, microbial activity becomes limited even in the presence of warm water conditions (9,17) and biofilm expansion is held in check. As an additional benefit, chlorine demand is reduced in the pipe environment that, in turn, improves the protection provided by disinfectant residuals in the pipe network.

Biological stability in the distribution system is most often measured by determining the assimilable organic content (AOC) or the biodegradable dissolved organic carbon (BDOC) concentration. The AOC test is based on a bioassay of two test strains (*Pseudomonas fluorescens* strain P17 and *Spirillum* strain NOX) with growth in the test sample compared to calibrated growth curves established on known concentrations of standard organic compounds (acetate and oxalate) for these organisms (30,31). The BDOC procedure evaluates the reduction in the dissolved organic carbon concentrations (DOC) over time. In the procedure, an inoculum of heterotrophic bacteria in a sample taken from the filter bed is then added to the filter-sterilized test sample (32,33). Sterilization of the test sample removes any overlapping response caused by the original flora in the test portion. DOC testing of the incubated sample is done daily till the DOC measurements reach a stable value over several days. The difference between the initial and final DOC concentrations is the biodegradable organic carbon fraction of the test sample.

Using these methods, the threshold at which drinking water supply may be considered biologically stable is less than 10 μg/L of AOC or 0.15 mg/L carbon in a BDOC test. Unfortunately, low nutrient concentrations alone do not ensure coliform-free water supply because of the potential threat of a contamination breakthrough (34,35).

Monitoring Microbial Quality

Monitoring the microbial quality of drinking water supply is a regulatory requirement established by the Federal Drinking Water Act that was enacted to protect public health (36). The regulations in this legislation are enforced by the United States Environmental Protection Agency and revised periodically as new information on causes for waterborne risks are discovered, faster and more specific methods for analysis are developed and innovations in treatment are field tested to improve barriers to chemical, radiochemical, and microbial contamination. The overall goal is to reduce the health risk that might be found in public water resources, nationwide. In Europe, the European Community Directive on the Quality of Water for Human Consumption has established guidelines for drinking water quality throughout the member states but the interpretation and implementation of the directive can be different from country to country (37).

Monitoring production of water at the utility and throughout the distribution system provides managers with vital information on continued effectiveness of treatment schemes to process the varying qualities of source waters and evaluating the integrity of water supply in distribution. It must be remembered that collection and subsequent analysis of water samples only provides information on the quality of water in the distribution system and does not in itself improve the water quality. Continued monitoring without an action response to correct the problem does not solve the problem.

Pioneering development of national standards for public water quality by the U.S. Public Health Service focused on characterizing the sanitary quality of public water supplies (38). Although coliform bacteria are found in high densities in the intestinal tract and are readily detected by conventional laboratory procedures, this group of bacteria became the chosen indicator of sanitary significance. By definition, these organisms are an artificial grouping of various gram-negative bacilli. Because they generally ferment lactose sugar, this characteristic became the bases for their detection. Like all indicator systems, there are some weaknesses in this interpretation.

In the case of the total coliform indicator group, many of these organisms are dominant environmental strains in the aquatic environment. Their die-off does not closely parallel that of virus persistence in fecal cell debris or the extended survival of pathogenic protozoan cysts or oocysts. With a coliform standard set on a test volume of 100 ml (approximate capacity of a glass of water for drinking) and the search for bacterial pathogens, virus, and protozoans based at 1-, 10-, or 100-l test portions, respectively (low density occurrences in contaminated drinking water), there is little opportunity for many parallel correlations. Regardless of these shortcomings, the total coliform test has amassed an impressive record of serving as an indirect indication of a microbiologically safe water supply and providing useful information on treatment effectiveness.

Monitoring frequency for water quality in the distribution system is based on the population served by the utility (3). The rationale for this approach is based on the recognition that as population increases so does the size and complexity of the system and the potential for cross-connections and back-siphonage. Unfortunately, the one major weakness in this approach is that small water systems (serving fewer than 10,000 people) are infrequently monitored. Small water systems (that often have the most water quality problems) are only obligated to monitor water quality a few times per month in an effort to reduce the burden of laboratory costs. To counter this loss of critical information, small water utilities should be subjected to a periodic sanitary survey of all operational practices by the State Water Authority. This review would help identify faults in water quality protection. Other factors to consider in maintaining a responsive monitoring program for all water utilities are pipeline break frequency, low-water pressure problems, areas of no disinfectant residual, and historical patterns to all coliform occurrences. Every water distribution system has unique characteristics so that the frequency of monitoring and locating of sampling sites must be flexible and responsive to changing water quality conditions.

Case Studies on Pathogen Incursions

Adequate protection of the distribution system is essential to prevent the incursions of pathogens into the safe water supply. Waterborne outbreak events because of the problems in the distribution system may start from line breaks in contaminated soils, sudden loss of water pressure, and wildlife contamination around open reservoirs of finished water or bird habitation inside storage tank structures that have deteriorating covers (3). A study of distribution system deficiencies for water supplies in the United States for the period from 1971 to 1998 that have lead to waterborne outbreaks (Table 1) reveals the importance of careful management of the distribution system and an effective community plumbing ordinance to avoid the risk of drinking water contamination. Field investigation of these outbreaks has uncovered a wide range of intestinal pathogens as the causes for these community disasters (Table 2). It is important to note that there still are reports of a larger number of outbreaks for which a pathogen was never detected in the water supply. Part of this problem is because of not recognizing a contamination problem until it has passed through the water system, lack of

Table 1. Distribution System Deficiencies Causing Outbreaks (1971–1998)

Deficiency	Community Outbreaks	Systems Percent	Non-Community Outbreaks	Systems Percent
Cross-connection/Back-siphonage	45	50.6	15	62.5
Corrosion/leaching of metals	12	13.5	1	4.1

rapid screening techniques for waterborne pathogens, and the sudden emergence of new pathogens that have not previously been found in water supply (3,4,39).

Several scenarios can be cited to illustrate a public health disaster that might have been avoided with better attention to distribution system operations. In all of these case histories, a waterborne outbreak occurred because of the presence of a specific pathogen. It is likely that other pathogens could also take the same pathways during an outbreak but may be overlooked in the search that is focused on the first pathogen detected in the water supply or found in the feces of several illness cases.

Line Breaks and Service Meter Repairs. Loss of protection in the pipe network from storm water runoff or sewage migration into the pipeline bed is always a threat whenever there are line breaks and repairs as well as service meter replacements. One example to cite is a waterborne outbreak involving the pathogen *E. coli* 0157 : H7 that occurred in the small farm community of Cabool, Missouri (population 2,090) during the period from December 15, 1989 to January 20, 1990 (39). This event resulted in four deaths, 32 hospitalizations, and a total of 243 known cases of diarrhea. The pathogenic agent was found in the bloody feces of some of the hospital patients.

Public water supply became the prime suspect after field epidemiologists ruled out contaminated raw beef and tainted milk. Further investigation revealed that persons living inside the city (using municipal water) were 18.2 times more likely to develop bloody diarrhea than those people living outside the city and using private well water supplies.

A study of the water utility records revealed that the groundwater aquifer used as untreated drinking water had a long history of meeting the bacteriological quality standard. However, several events occurred in the distribution system prior to the waterborne outbreak that may have been the major contributing factors. Weather conditions proceeding this outbreak reached record low temperatures that caused freeze blockages in 43 service meters and two major distribution line breaks that were within days of each other at two residential locations. Some meter boxes were reported to be partially submerged during replacement that could have introduced contamination. On the basis of customer recollections, the two-line breaks did not reduce water pressure systemwide although localized low pressure created opportunities for back-siphonage overnight before the breaks were repaired. In both the line breaks and service meter repair situations, line flushing with fresh water supply was done but the lines were not disinfected prior to service.

The source of contamination was though to be sewage from the municipal collection system that was undersized in pipe capacity and becoming overloaded with storm water runoff that leaked into the waste transport system. There were continual complaints from some residences of periodic overflows from nearby sewage distribution boxed into their yards, even though storm water runoff was drained by open ditches along the streets. These complaints were verified during heavy rains by observation of various paper products associated with sewage being released at several distribution boxes. Such situations provided opportunities for soil contamination and a pathway for sewage or surface runoff to intermingle with water supply at line break areas and service meter repair sites.

The pathogenic agent was not recovered in the water supply probably because a specific search for the organism in water samples was not done during the outbreak period. Additional circumstantial evidence was found in several water samples: detection of *E. hermanii*, an associate *Escherichia* strain, and several tetracycline-resistant coliforms that share characteristics with the outbreak strain *E. coli* 015 : H7. Such findings suggest that these organisms and the outbreak strain originated from a common source of contamination. At this point in the investigation, no pathogenic *E. coli* was detected in any of the samples although coliforms were present in some of the distribution samples taken at the ends of the pipe network yet there was never a report of coliforms being in the groundwater supply. The next step was to create a hydraulic mode of water flow patterns in the distribution system. The purpose was to plot a simulation for contamination movement entering the line breaks and meter repairs. The result of this study showed that by combining the main break dates with the illness start dates and resident locations, 85% of cases could be linked to the direction of first incursion of contaminated water in the distribution system. The outbreak subsided with the consumption of boiled water. Since then, the system has utilized disinfection on a permanent basis and there has been no more water associate illness reported in the community.

Water Pressure Interruptions and Illegal Tap-Ins on the Pipe Network. Water losses from perpetually leaking pipes represents not only a loss in revenue for the utility (unaccounted water losses are often between 30 and 60%) and a waste of resources but also a potential health risk from incursions of contaminates. Such a situation is often a serious problem in many third world nations. Compounding factors are problems with utility infrastructure deterioration in treatment or distribution and scheduled interruptions in pumping water throughout the system to reduce the cost of electricity. With sewage collection systems that are also in need of infrastructure repair and capacity expansion, it is not surprising to find sewage overflows linked to deteriorating water supply distribution networks. Once a waterborne outbreak begins to form in a community, defective sewage collection systems reinforce the risk and intensify the spread of contamination. This was one aspect to the rapid development of the cholera outbreak in much of South America in 1991 (40,41).

The city of Lima, Peru, obtains its water supply from a surface water source that is augmented by a series of wells in various locations throughout the city (3). Considering the gross nature of the surface source water during seasonal flash floods, it is remarkable that the water utility is capable of producing a water quality that meets international drinking water standards of less than one coliform per 100 ml. *Vibrio cholerae* was never detected in the finished water from the plant during the outbreak.

Unfortunately, the microbially safe water supply produced at the plant did deteriorate in distribution during the cholera outbreak based on a special study of 183 water samples collected from the pipe network and promptly tested. Fecal coliform bacteria were found in 18.7% of all samples. One sample had a maximum fecal coliform density of 240 organisms per 100 ml, and the fecal coliform occurrences increased with distance from the water plant. None of these samples contained cholera in the 100-ml test portions, however this pathogenic agent was detected in earlier tests from two wells supplying water to the distribution system.

There are a variety of factors that contributed to this loss of water quality. Because of a limited operational budget, sustained water pressure in the pipes was limited to restricted hours each day (4–6 hours) in different areas of the city in an effort to cut pumping cost for electricity. This action resulted in the failure of numerous building water supply tanks to fill with new water. In other situations, this loss of water pressure contributed to back-siphonage from attachment devices and encouraged some citizens to augment their water supply by interconnecting lines between private wells and the public water supply. The condition of widely fluctuating water pressures also provided many opportunities for reversals of flow and suction that mixed good quality water with contamination pathways wherever they existed in the pipe network from leaking pipes and cross-connections. Adding to the problem was a nonexisting flushing program for the distribution network because water production at the water utility barely met the demand and no funds were available to repair all of the pipe leakages in the system. These negative impacts also made it impossible to maintain a protective disinfectant residual because of significant disinfectant demand from the contaminants in most of the pipe network. As a result of the enforced low water pressure and inadequate system maintenance, integrity of the pipe network was lost to an increased health risk.

Bird Habitation in Drinking Water Storage Tanks. Wildlife habitation (sea gulls, ducks, and geese) in open, reservoirs of drinking water supply has long been recognized as a significant contributor to fecal contamination and the source of some waterborne outbreaks. The obvious solution is to enclose large, open reservoirs whenever possible, but cost considerations in engineering a cover over huge water surface areas make this approach unfeasible. Thus, it is a common practice to inject additional chlorination (booster chlorination) to water at the outlet from these open reservoirs prior to water entry into the distribution system in an effort to inactivate any bird contamination and to replace a loss in disinfectant residual from sunlight exposure.

Smaller capacity, covered water storage tanks spaced at appropriate locations within the service area are a more practical solution. Water pressure can be established more uniformly everywhere and individual tanks can be taken out of line for repair and cleaning while other tanks serve as backup. These covered storage tanks also slow the decay of chlorine residual because sunlight exposure is not a factor. Unfortunately, when preventive maintenance of the tank structure is infrequent, corrosion of the tank begins to accelerate. The most common concern is that the protective screen cover over air vents may be breached because of the action of corrosion or wind damage. This situation provides opportunities for birds to enter the tank structure to find shelter from the winter weather. Such was the case when pigeons invaded openings in water supply tanks at Gideon, Missouri (42).

The community outbreak of diarrhea, caused by *Salmonella typhimurium*, occurred during November and December 1993. It was estimated that 44% of the community (1,104 population) became ill. Two of the hospitalized patients died. A sanitary survey of the water supply revealed that water supply was derived from two wells driven 1,300 feet into an aquifer. At the time of the outbreak, the water supply was untreated because the aquifer quality met the coliform standard for a safe water supply. Water pumped from these wells was stored in two water tanks (50,000 and 100,000 gal. capacity) and satisfied customer demand in this small community. In addition, a private water storage tank of 100,000 gal. capacity (used for fire control in a cotton baling plant) was also connected to the system for filling but separated by a backflow prevention valve.

During field investigation, a large number of pigeons were observed roosting on the two 100,000 gallon tanks. Physical inspection of the water storage tanks revealed the consequences of minimal maintenance to arrest corrosion and maintain a protective barrier screen at all air vents. The tank inspector found that all tanks were deteriorating from long-term corrosion. There were holes in the top of the privately owned tank and numerous bird feathers and droppings were floating in the water supply at all the three tanks. Not surprising was the detection of *Salmonella typhimurium* in the sediment from the private water storage tank.

A combination of events set the stage for passage of the pathogenic agent into the distribution pipe network. In early November, there was a sharp climatic change in weather with air temperatures falling to record lows. This persistent and dramatic event caused destratification of the water supply in the storage tanks. The resultant mixing of stratified tank water resulted in a variety of taste and odors and an increase in complaints from customers.

Immediate water utility action was to flush the entire water supply lines over a 12-hour period. Each of the 500 hydrants was flushed for 15 minutes at a rate of 750 gal./min. This vigorous action brought much of the water out of the storage tanks thereby further mixing the contaminants and passing them into the pipe network. Not surprising was the detection of *Salmonella typhimurium* during the outbreak period at a fire hydrant nearest to one of the public water supply storage tanks.

Applying a hydraulic model simulation of water movement in the system revealed that the earliest cases of salmonellosis and the location of the fire hydrant at which this pathogenic agent was recovered, were situated primarily around the 100,000 gallon tank. This finding supports the belief that the pathogenic agent was pulled into the pipe network during the vigorous flushing program that focused in the area around the tanks.

In retrospect, the systemwide flushing program should have begun with good quality water at the wells then followed by progressive draining of system water outward to the ends of the pipe network. This strategy might have provided more protection to part of the population served; although, this was difficult to achieve because of cyclic reversals of flow in some parts of the pipe network. Lack of funding for repair and maintenance of storage tanks was a major contributing factor associated with this outbreak. The outbreak finally was brought under control with a community order to boil drinking water until tests revealed that disinfection residuals were occurring consistently throughout the entire distribution system.

CONCLUSION

Drinking water quality in the distribution system must be safe from a variety of pathogenic agents that may be present in sewage, storm water runoff, and poor quality source waters. There is a growing awareness that subsets of the population are at increased risk from exposure to opportunistic pathogens through ingestion, inhalation or body contact, whereas a greater number of consumers may be sensitive to the sudden advent of taste and odors associated with microbial activity in the pipe/tank environment. This condition need not imply that drinking water supply must be treated and delivered as a sterile product to the consumer. Rather, the solution lies in achieving a biologically stable water to minimize microbial activity.

The quality of water supply entering the distribution system will change over time as a function of system integrity, retention time in the pipe–storage tank network, and microbial response to this environment. To combat these changes in quality, every water utility must maintain a permanent program for systemwide flushing. Identify and correct water loss through leak detection, revamp the pipe network pattern to reduce dead-ends through continuous pipe loops, replace lines with a history of frequent pipe breaks, and institute triennial inspections of storage tanks that must be taken off-line for cleaning, resealing, and repair.

Each public water system is unique in some aspect, so it is important to focus on those unique features that have the potential for degrading water quality during distribution. This means that the water authority must implement an effective, routine microbiological monitoring program for the distribution system with an action response to various scenarios of quality change. Furthermore, a public awareness initiative must be in place to inform consumers about the quality of their water supply during adversities and disclose strategies for improvement.

CYANOBACTERIA

JOANN M. BURKHOLDER
North Carolina State University
Raleigh, North Carolina

Cyanobacteria, also known as chloroxybacteria, blue-green algae (cyanophytes, blue-green plants — formerly myxophytes or "slime plants"), cyanochlorontans (blue-green organisms), and prochlorophytes, are prokaryotes with the universal plant pigment, chlorophyll a, and with "higher plant" or oxygenic (oxygen-producing) photosynthesis, wherein water is split for the electron source and oxygen is emitted. They are evolutionarily the oldest oxygenic photosynthetic organisms (1,2). Cyanobacteria were the dominant forms of life on earth for more than 1.5 billion years, and their earliest fossil record is from about 3.5 billion years ago (2). Many species have retained the ability to fix atmospheric nitrogen (dinitrogen gas) and, in fact, cyanobacteria have been estimated to fix approximately 75% of the nitrogen (N) attributed to natural sources worldwide. They were abundant in the ancient oceans and were also the earliest terrestrial autotrophs, helping to create and enrich the soil (2). In present times they remain ubiquitous, covering the air-water interface across lakes and oceans, endolithically within desert rocks and as crustose forms in the "black zone" of the high rocky intertidal worldwide; at depths down to at least 100 m in the dimly lit oceans, beneath more than 30 m of Antarctic sea ice (2), in light-free caves and tombs (3), in hot springs at temperatures up to approximately 75 °C (2), and in the lungs and digestive tract of an array of homeothermic organisms, including humans (4,5). Cyanobacteria are significant to evolution not only because of their biogeochemical importance in forming the oxygen-rich atmosphere but also because they are the likely progenitors of the chloroplasts of red algae (Rhodophyta), which are the dominant macroalgal flora of the intertidal or subtidal and of soft-water streams in various geographic regions (1). Certain species (the chlorophyll $a + b$ organisms) are also considered the progenitors of the chloroplasts of green algae (Chlorophyta) and higher plants.[1] This article provides an overview of cyanobacteria taxonomy, systematics, phylogeny, cell biology, ecology, and evolutionary significance.

TAXONOMY, SYSTEMATICS, AND PHYLOGENY

The Fossil Record

Schopf (2) wrote, "The best documented early branch of the Tree of Life is the cyanobacterial lineage, represented in the Precambrian fossil record by ensheathed solitary and colonial unicells (represented in extant taxa by the Chlorococcaceae) and cellular microscopic filaments [(mostly members of the) Oscillatoriaceae, taxonomically the most diverse cyanobacterial family]." Most Precambrian cyanobacteria-like fossils, both older and younger than 1.5 billion years (Ga), are referable to extant genera within the Chlorococcaceae and the Oscillatoriaceae. Schopf (2) described 37% (26 of 70) of coccoidal taxa in the fossil record as older than 1.5 Ga and 28% (31 of 109) of those younger than 1.5 Ga as indistinguishable from extant species. Moreover, 35% (18 of 51) of filamentous cyanobacterial taxa in the fossil record older than 1.5 Ga and 37% (56 of 152) of those younger than 1.5 Ga are virtually identical to extant species in the Oscillatoriaceae. No discontinuity has been detected in cyanobacterial community structure, biotic composition, or environments inhabited since 1.5 Ga years ago. The oldest cyanobacterial fossils known to date were found in the 3.5-Ga-old conglomeratic Apex chert (basalt), a geologic formation in northwestern Western Australia (1,2).

In that assemblage, 7 of 11 species (ca. 63% of measured specimens) are similar in cellular organization, size range, median dimensions, and pattern of size distribution to oscillatoriacean cyanobacteria, and several are indistinguishable from extant species. At that time, there were extensive shallow seas, with volcanic islands fringed by sedimentary debris (river gravels, sands), mud flats, and interspersed evaporitic lagoons. Isotopic compositions of organic and carbonate carbonate in the Apex chert indicate the occurrence of photosynthetic carbon dioxide fixation similar to that of extant cyanobacteria grown in carbon dioxide-rich environments. Other lines of evidence support these findings of 3.5-Ga-old cyanobacteria. Among prokaryotes, oxygenic photosynthesis is unique to cyanobacteria (2). The Apex sequence and coeval geologic units contain evidence of both the reactants required for oxygenic photosynthesis (H_2O, CO_2) and the products (reduced org. carbon and O_2). Evidence of carbon dioxide occurs as calcium carbonate–rich limestones, deposited as a result of the aqueous reaction between Ca^{+2} (from weathering of the land surface) and HCO_3^- (from dissolution of atmospheric CO_2).

Graham and Wilcox (1) wrote, "The rise to dominance of cyanobacteria ... has been described as the single most significant evolutionary event in the history of life on earth, for without it, subsequent origin of eukaryotic life would have been impossible." Evidence for free molecular oxygen (g) 3.5 Ga ago, and its origin predominantly from cyanobacteria, is provided through several lines of evidence. The earth's atmosphere mostly formed from volcanic outgassing of the planetary interior over geologic time (2). Unlike other components of the atmosphere (N_2, H_2O vapor, CO_2), oxygen is not released from heated rock. The presence of free oxygen is indicated by iron oxide–rich sedimentary deposits called banded iron formations (BIFs, the world's major source of iron ore), which are widespread in geologic terrains that are more than 3.5 to 1.9 to 2.0-Ga old (2). The oxygen content of the atmosphere increased dramatically between 2.2 and 1.9 Ga ago (from $\leq$ 1% to $\geq$ 15% of present levels). Nonbiological sources (e.g., thermal dissociation or UV-induced photodissociation of water vapor) would not have been sufficient to account for the massive quantity of oxygen that was added. Thus, oxygenic photosynthesis is the only quantitatively plausible source for the enormous quantities of oxygen that were sequestered in Precambrian BIFs (2).

Other evidence for ancient oxygenic photosynthesis from cyanobacteria has been obtained from 2.7 Ga-old stromatolites (layered, calcareous, mound-shaped structures) in the Tumbiana Formation of Western Australia (1,2). Stromatolites are abundant in Precambrian deposits from shallow and deeper waters worldwide, and are believed to have been produced by photosynthetic cyanobacteria that trapped sediments along with layered deposits of calcium carbonate that precipitated from the photosynthetically increased pH in the surrounding medium. The low sulfate content of many ancient stromatolites indicates that they developed in freshwater lakes as a result of oxygenic, rather than anoxygenic (anaerobic process, without oxygen production), photosynthesis. The maximum number of ancient stromatolites occurred in the late Precambrian

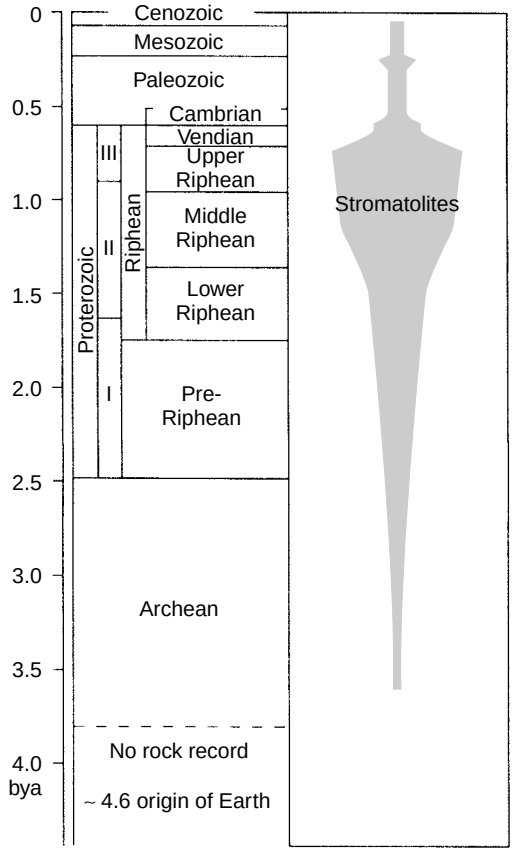

Figure 1. Stromatolite occurrence on Earth, which gradually increased throughout the Precambrian to maximum abundance approximately 800 Ma ago, after which they declined to present-day numbers. Modified from Tucker and Wright (1990), and reprinted from L. E. Graham and L. W. Wilcox, *Algae*, Prentice-Hall, Upper Saddle River, N.J., 2000, with permission from the authors and Prentice-Hall.

approximately 0.7 to 0.8 Ga ago, followed by a sharp decline during the Cambrian (Fig. 1; 1). The decrease may have been related to an increase in herbivorous gastropods that grazed on cyanobacteria-containing microbial biofilm layers or mats before they could accrue form stromatolites. Burrowing organisms that also appeared in abundance may have disrupted the growth of cyanobacterial mats, and increasingly abundant red and green calcareous seaweeds and metazoans may have competed with cyanobacteria for suitable substratum. Present-day cyanobacterial mats usually form in habitats with little or no metazoan grazing activity, such as coastal tidal sand flats, protected coastal lagoons and inland saline ponds, lakes, and seas, hot and cold deserts, caves, and geothermal springs. In habitats devoid of gastropods and other grazers, extant cyanobacteria also remain active in stromatolite formation (i.e., in hypersaline, shallow tropical habitats throughout the world, and also in permanently ice-covered Antarctic lakes) (1,2).

Blue-Green Algae, Blue-Green Bacteria, or Other Names?

The list of division-level names spanning botanical to bacterial nomenclature illustrates the major controversy

that has plagued the systematics of these organisms for nearly 30 years (6–8)—Should they be considered as primitive plantlike algae or as bacteria? They are prokaryotes with many ultrastructural and biochemical bacteria-like features; yet they share the same basic photosynthetic biochemistry of eukaryote algae and higher plants, and they share the "universal plant pigment," chlorophyll *a*, which is the pigment that participates directly in oxygenic photosynthesis and is structurally distinct from bacteriochlorophyll (1). The general view of some ecologists and phycologists can be summarized by Lewin's (6) argument in favor of blue–green algae (division cyanophyta under the International Code of Botanical Nomenclature), paraphrased as: Why combine all prokaryotes together, when they are so strikingly distinct in basic photosynthetic biology, pigments, and certain ultrastructural traits such as phycobilisomes? Should we then combine all eukaryotes together as well, for example, flowering plants in the same group as humans, because they have a nucleus? Golubec (8) similarly argued that many algae and even angiosperms show heterotrophic capacity, and that blue–green algae generally act as primary producers, not as decomposers.

Molecular and microbiological specialists, in contrast, favor placement of these organisms under the bacteriological code, in recognition of the fact that cyanobacteria represent an "undisputed distinct phylogenetic line of the eubacteria" (9). As a result, cyanobacterial publications in taxonomy and systematics have become widely scattered across bacteriological, medical, microbiological, and botanical literature. Recently, as a further complication, small prokaryotes that are green ("apple–green") in color, having chlorophyll *b* rather than blue–green algal phycobiliproteins as accessory pigments in photosynthesis, have been removed by various specialists from a previously separate algal division under the botanical code, the Prochlorophyta (10), and added to the cyanobacteria under the International Code of Nomenclature of Bacteria. Like most aspects of the taxonomy of prokaryotes with "higher plant" photosynthesis, the phylogenetic position of the chlorophyll $a + b$ prokaryotes is still in debate, and phycology texts reflect both sides (2,11). Indeed, some specialists use the terms Cyanophyta and Prochlorophyta [the latter, designated as an artificial (not phylogenetically coherent) division of "green cyanophytes"] from the botanical code, although placing these organisms within the Kingdom Eubacteria (12). The division Prochlorophyta has been described as artificial on the basis of molecular data (16S ribosomal RNA sequences) indicating that the three known genera are only distantly related (13). Other molecular data (e.g., sequences for a DNA-dependent RNA polymerase, *rpo* C; and partial sequence of the ribulose-1,5-bisphosphate carboxylase/oxygenase enzyme or Rubisco) indicate that two of the three genera (*Prochloron, Prochlorothrix*) are close relatives, whereas the third (*Prochlorococcus*) is more closely related to γ-purple bacteria (14,15) (Fig. 2; see article by Campbell in this Encyclopedia).

Operationally, species in cyanobacteria vary greatly depending on the classification scheme, and no complete comprehensive coverage of cyanobacterial species is yet available. The species concept in cyanobacteria is, in fact, uncertain and presently in a state of major flux. The difficulty stems, in part, from the fact that cyanobacteria lack gametes or sexual structures, which precludes definition by the biological species concept (i.e., two taxa belong to the same species if they interbreed and have viable offspring; 11). Cyanobacterial taxonomy began in the 1700s and the system that was developed through most of the 1900s was under the botanical code. Identification was based almost entirely on morphological traits (e.g., see Geitler (16) and the Frémy series given in (2)), but it was later realized that many of these traits are polymophic, depending on environmental conditions. For example, in the blue-green prokaryotes with oxygenic photosynthesis, hormogonia (specialized cells used to fix dinitrogen gas into inorganic N; see following text) form in low-N environments; phosphorus limitation tends to alter the degree of filament tapering and pattern of false branching; sheath color/thickness depend on the abundance of certain micronutrients and the turbulence, and so on (17,18). Less information is available on polymorphism among the "green" prokaryotes with oxygenic photosynthesis. Some morphologically distinct isolates of symbiotic coccoid organisms, *Prochloron didemni*, have been evaluated as very closely related on the basis of molecular data, implying that different physiological states of *P. didemni* in different hosts affect their morphological appearance (2).

As a proposed solution, Drouet and Daily [series given in Castenholz (9)] relied upon several simple morphological features to combine more than 2000 previously described species within more than 150 genera to 24 genera and 62 species for all known cyanobacteria. However, many of their analyses had relied on dry herbarium material that would have led to inaccurate morphological descriptions; live strains were not subjected to environmental gradients to verify polymorphic traits; and genetic information was not available. More recently, the cyanobacteria were regrouped at the family and genus level by Komárek, Anagnostidis, and Kann (2), still as blue-green algae under the botanical code. Their most recent definitive contribution of Komárek and colleagues presents a detailed, logical arrangement of the Chroococcales, considering cell shape, patterns of cell division, and cell organization within sheaths and/or mucilage (19).

Stanier and coworkers (7) and Rippka and coworkers (17,20) proposed removal of this entire group of organisms from the botanical code and placement under the bacterial code. However, at present, taxa described under either code are considered in accounts prepared under the other code (2). Descriptions at the order level (21) are similar to those in historical botanical systems. The cyanobacterial taxonomy was first to rely upon other characteristics in addition to morphology (e.g., optimum temperature for growth, fatty acid composition, motility, heterotrophic potential, DNA base pair composition, gas vacuoles, etc.). By that taxonomy, the organism formerly known as *Microcystis aeruginosa* would be called *Microcystis* strain number, followed by series of + and − signs indicating presence/absence of certain morphological, physiological,

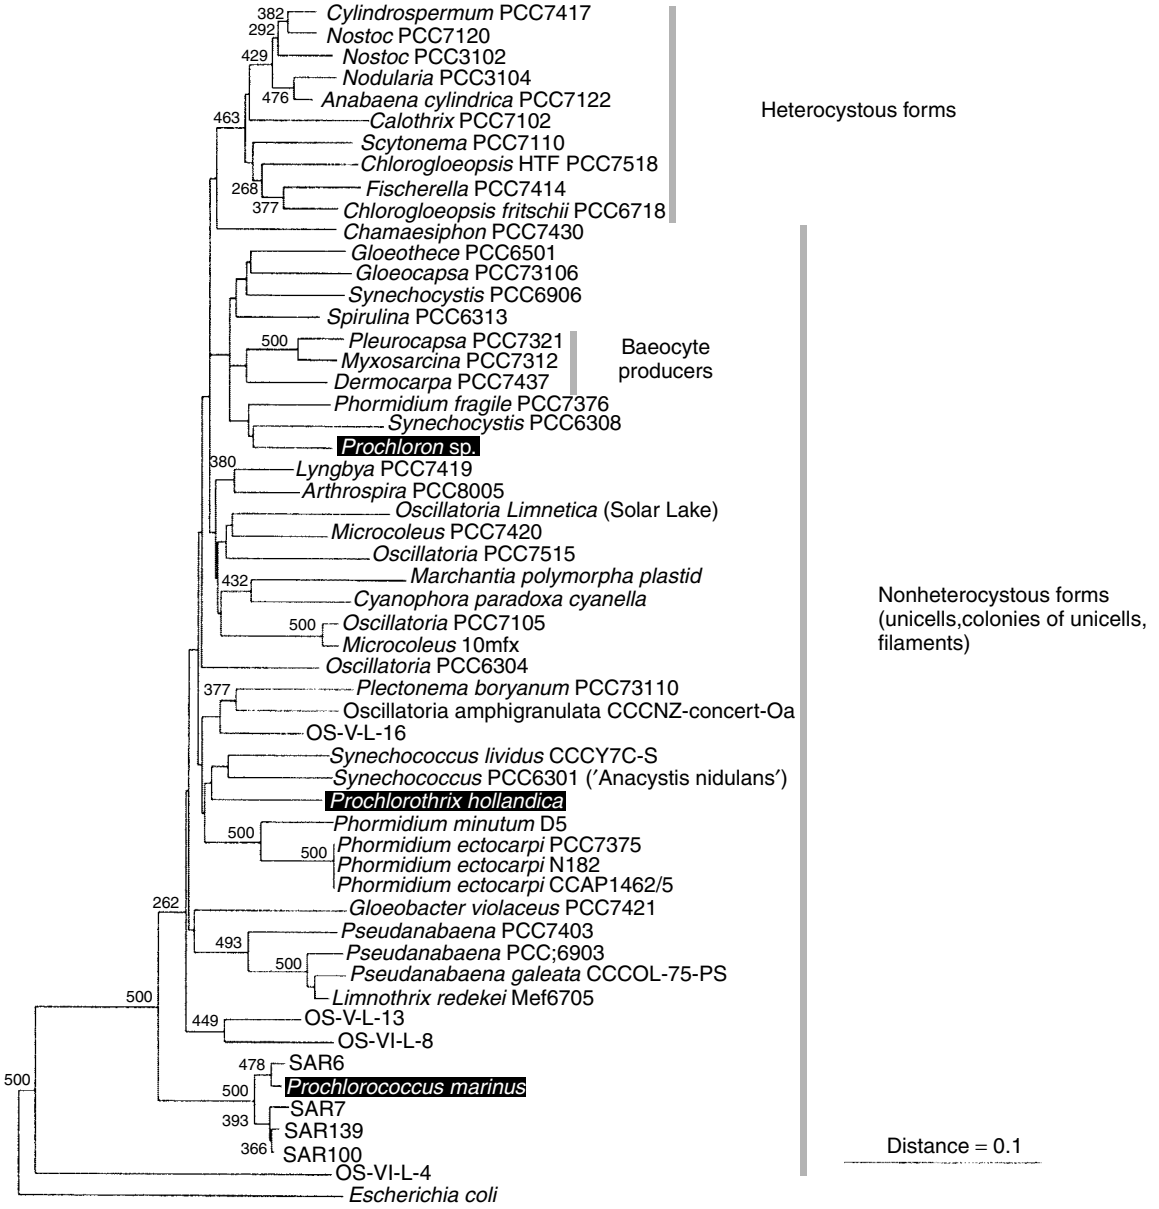

Figure 2. A phylogenetic tree of the cyanobacteria (and plastids, represented by the liverwort Marchantia and the glaucophyte Cyanophora) inferred from 16S rDNA sequences. Note that taxa with heterocysts form monophyletic groups, whereas other types of cyanobacterial morphologies appear to have arisen multiple times. Also, note the polyphyletic nature of the chlorophyll b-containing prokaryotes with oxygenic photosynthesis (Procholoron, Prochlorothrix, Prochlorococcus). Organisms listed as a series of letters and numbers are not yet named, and are known only from sequences obtained from environmental samples. The numbers on the branches represent bootstrap values (refers to a modeling procedure that estimates how closely the taxa are related evolutionarily) based on 50 resamplings of the data. After (A. Wilmotte, in D. A. Bryant, ed., *The Molecular Biology of Cyanobacteria*, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1994, pp. 1–25), reprinted from (L. E. Graham and L. W. Wilcox, *Algae*, Prentice-Hall, Upper Saddle River, N.J., 2000), with permission from the authors and Prentice-Hall.

and other traits. Thus, older botanical generic names, but not species names, were retained whereas phenotypes were reordered to define genera based on clusters of characteristics. Limited attempts have been made to assess species status under the bacteriological code using additional genetic traits (e.g., molar guanine + cytosine ratios in DNA, DNA-DNA reassociation rates, thermal stability values of DNA-DNA hybrids, PCR fingerprinting with primers from randomly repeated elements, 16S rRNA sequences from variable regions V6–V8, amplified ribosomal DNA restriction analysis of the internally described spacer, and genome size) (2,9). The present review honors

the "cyanobacteria" of the bacteriological code, but treats them as primitive plantlike (algal) organisms in ecological contexts. Although (botanical) species names technically should not be used for cyanobacteria, they were retained here to facilitate comparison with other literature, because clonal cultures and strain numbers are not yet available for many previously designated species.

Molecular analyses based on various gene sequences have demonstrated that cyanobacteria are a major eubacterial clade (phylum). The basic traits shared in common between cyanobacteria and (other) eubacteria are prokaryotic ultrastructure, common presence of mucilaginous sheaths (although frequently found in eukaryote algae as well), simple binary fission, absence of the histone proteins associated with eukaryotic DNA (also missing in certain other eukaryote algae), and 70S ribosomes composed of 16S and 23S subunits.[1] Applying Stanier and coworkers' (7) scheme, and on the basis of strong molecular evidence (14,15), the "apple–green" prokaryotes that were designated as prochlorophytes under the botanical code (10) are considered as members of the cyanobacteria as mentioned (1,2). This schematic ignores the presence of both chlorophyll *a* and *b*, starchlike food storage product similar to that of higher plants (13), and stacked thylakoids in prochlorophytes but not in other cyanobacteria (1,12). These historically had been regarded as taxonomically reliable characters, especially the chlorophyll composition, in distinguishing among eukaryote algal divisions. However, among the cyanobacteria, recent findings suggest the presence of all four chlorophylls ($a - d$) (or, if the prochlorophytes were to be considered separately, then the cyanobacteria still would have three of the four chlorophylls represented) (1), creating challenges for botanical systematists and phylogeneticists that might be more consistently addressed using certain molecular traits.

Modern approaches are increasingly based almost entirely on characteristics of pure cultures and instead of a specific epithet, a strain number is commonly used (9). However, there is a serious problem inherent in use of pure cultures over time, that is, pure cultures often have aberrant physiological, morphological, and genetic (especially ploidy) traits from field material that become more pronounced over time (18). It is also important to note that in some cyanobacteria, field material with different morphologies often yields distinct cultures, indicating that data based on the morphotype of field material can be of value (22). Clonal cultures do not yet exist for many cyanobacteria. Castenholz (9) estimated that fewer than 10% of what may eventually be recognized as genera (using Stanier and coworkers' system, expanded in the "Stanier/Rippka system" to include biochemical and ultrastructural features, and limited genotypic characters) have corresponding clonal isolates in culture, and that probably far less than 5% of the "species" are known in culture. Some of the more common species from nutrient-poor (oligotrophic) waters such as various tropical *Trichodesmium* spp. have been difficult to culture (9). The prospect remains that many, if not most, of the thousands of species that were historically described and then regrouped may be ecological phenotypes (ecophenes) of relatively few genotypic clusters (9). This question can only be resolved when many more quality cyanobacterial clones become available and when aberrancies that develop over time as an artifact of culture conditions can be distinguished from traits expressed under natural conditions.

Principles of phylogenetic systematics are increasingly being used to define cyanobacterial taxa as true for eukaryotic algae, especially rRNA sequence data (Fig. 2; 9). For example, genera that previously were grouped together on the basis of more complex morphology have been divided into related clusters or branches, considering similarities in rRNA nucleotide sequence. Structurally cryptic variants distinguishable at the molecular but not the morphological level occur among the cyanobacteria. However, polyploidy (occurrence of multiple genomic DNA copies per cell; see following text), coupled with possible variation among these multiple genomes, and the occurrence of horizontal DNA transfer (uptake and genomic incorporation of foreign DNA, resulting in formation of genetic chimeras), may complicate attempts to characterize cyanobacterial species by nucleotide signatures (1,9).

Diagnostic Characters Under Light Microscopy

Basic cyanobacteria morphotypes include coccoid unicells or colonies and unbranched or branched filaments [cells of the filament, not considering the sheath, are collectively called a trichome (1); Fig. 3]. Filaments may have true or "false" branching, wherein true branches develop by continued division by a cell at an angle to the main filament axis. False branches are outgrowths of filaments adjacent to a dead cell or a specialized cell (e.g., a heterocyst, see following text). Filaments may be uniseriate or multiseriate, consisting of one or more than one row of cells, respectively. Presence or absence of reproductive cells can be helpful in identifying cyanobacteria, including baeocytes (endospores) produced by subdivision of a cell into multiple cytoplasmic units**;** exospores, which bud from the apex of a filament; and akinetes that are thick-walled, food reserve–packed resting stages of vegetative cells. Other useful structures include the presence/absence of a mucilaginous sheath, heterocysts, and hormogonia (the latter are short filaments separated from longer filaments, which can act as a form of vegetative propagation). In addition, the prokaryotic cyanobacteria have no organelles, so their pigments are not compartmentalized and cells appear uniformly pigmented in light microscopy. The cells generally are small (ca. 0.4–3.0 μm, biovolume $<1–10 \mu m^3$), but some unicellular and colonial coccoid taxa have much larger cells (maximum dimension up to 60 μm, biovolume $>10{,}000\ \mu m^3$) (1,2). As Whitton and Potts (2) pointed out in their excellent overview, the depth and detail of the information needed to identify cyanobacteria to "botanical species" have become so great that they might be most effectively accessed from a formalized, continually updated database. Such a database has been created for the 320 botanical species from the British Isles, with most of the morphological and ecological data expressed in 113 characters or character states (23). It was estimated that about 150 characters would be sufficient to encode the information for all described cyanobacterial species. In

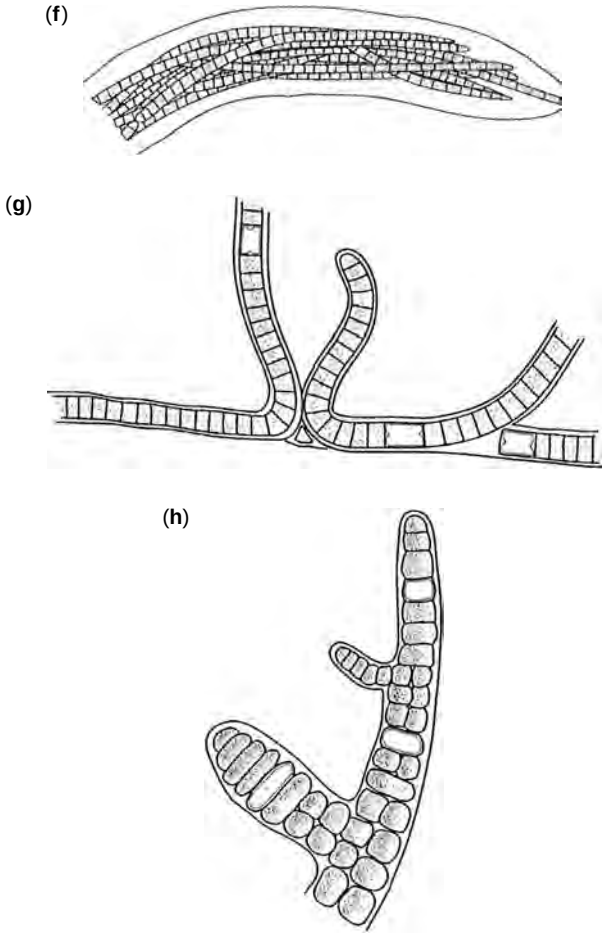

Figure 3. (*Continued*)

related work within the bacteriological nomenclature, *Anabaena* strains have been described in a detailed similarity matrix (24).

Most botanical classification schemes for the cyanobacteria are based on light microscopy. These schemes have combined unicellular and colonial cyanobacteria within the order Chroococcales, and grouped unbranched filamentous taxa lacking specialized cells within the order Oscillatoriales (14,15). However, these groupings are not consistent with recent molecular evidence, and the order Pleurocapsales is also in question (12). On the other hand, inclusion of all heterocyst-producing cyanobacteria within one order (Nostocales) is supported by molecular evidence (Table 1; 12). Molecular research is underway to clarify relationships among cyanobacteria to construct more evolutionarily meaningful classification schemes (1).

Some Genetic Features

Because rRNA sequences (especially 16S rRNA sequences) have been used to assess relationships within the cyanobacteria, and between cyanobacteria and chloroplasts, ribosome composition has become an important feature in cyanobacteria systematics (12). Cyanobacterial ribosomes consist of three types of structural RNA,

Table 1. List of Features in the Orders of Cyanobacteria. After Castenholz and Waterbury (1989), Modified from [(B. A. Whitton and M. Potts, eds., *The Ecology of Cyanobacteria—Their Diversity in Time and Space*, Kluwer Academic Publishers, Boston, Mass., (2000)]. Reprinted with permission from the authors and Kluwer Academic Publishers

NONFILAMENTOUS	
	Order Chroococcales
	Unicellular or nonfilamentous aggregates of cells held together by outer wall or gel-like matrix; binary division in one, two, or three planes, symmetric or asymmetric; or by budding. Rarely form thick-walled resting cysts (akinetes)
	Order Pleurocapsales
	Unicellular or nonfilamentous aggregates of cells held together by outer wall or gel-like matrix; reproduction by internal multiple fissions with production of offspring cells smaller than parent; or by a mixture of multiple fission and binary fission. Rarely form akinetes
FILAMENTOUS	
	Order Oscillatoriales
	Binary division in one plane giving rise to uniseriate (1 column of cells) trichomes, sometimes with false branches; do not form heterocysts. Akinetes apparently not known
	Order Nostocales
	Binary division in one plane giving rise to uniseriate trichomes, sometimes with false branches; one or more cells per trichome differentiate into a heterocyst (at least when concentration of inorganic nitrogen is low). Some also produce akinetes
	Order Stigonematales
	Binary division periodically or commonly in more than one plane, giving rise to multiseriate trichomes or trichomes with true branches or both; apparently always have the ability to form heterocysts. Some also form akinetes

each associated with a protein, including "large" 23S ribosomal RNA, "small" 16S ribosomal RNA, and "very small" 5S ribosomal RNA (ca. 2,900, 1,540, and 120 nucleotides, respectively; S = Svedberg Unit, measure of sedimentation rate when ultracentrifuged). Cyanobacterial ribosomes are smaller than eukaryote cytoplasmic ribosomes, but similar in size to ribosomes of other eubacteria and to ribosomes of eukaryote mitochondria and chloroplasts (12).

The basic morphotypes of cyanobacteria have been retained for at least 2.8 billion years, as mentioned (1,2). It is unknown whether this apparent stasis has occurred because of ecological equilibrium (unlikely, given changes on earth over geologic time) or genetic homeostasis. Many "species" or strains of cyanobacteria have apparently been selected for tolerance of widely varying environmental conditions (2). Cyanobacteria have long generation times (days to months) in comparison to many heterotrophic bacteria (9). Furthermore, genome size may be larger in the more morphologically complex (filamentous) cyanobacteria than in unicellular eubacteria and unicellular coccoid cyanobacteria (among c. 128 strains, c. 1.6×10^9 daltons in unicellular coccoid cyanobacteria, up to 8.6×10^9 daltons in filamentous taxa) (9). On the other hand, these differences in total DNA may reflect polyploidy, which is common in the relatively few cyanobacteria examined. Thus, the coccoid unicellular taxa, *Cyanothece* (formerly *Synechococcus*) and *Synechocystis*, can have up to six identical chromosomes; and in *Synechocystis* PC 7942, polyploidy can involve up to 10 identical DNA molecules (9). The entire genome of *Synechocystis* PCC 6803 has been sequenced and includes 3,573,470 base pairs and 3,168 genes (*http://www.kazusa.or.jp:8080/cyano/*, the CyanoBase database) (2). Similar projects have been undertaken for *Prochlorococcus* and *Anabaena* (2).

Genetic recombination (donation of short DNA fragments from other strains or "species") is of recognized importance in bacterial evolution, but the frequency of horizontal translocation of DNA in natural cyanobacterial populations is unknown. Transfer of short DNA fragments has been documented in some rapidly growing, unicellular culture strains (9). However, the mechanism(s) for DNA uptake has not been determined, and no confirmed example of transduction or conjugation (mating) is yet available (1,9). In addition, because of difficulties encountered in attempts to recover mutant strains, little is known about spontaneous mutation rates in cyanobacteria.

Ultrastructure and Photosynthetic Pigment Complement

The fine structure of cyanobacterial cells is consistent among phycobiliprotein-containing taxa, but somewhat distinct from that of the chlorophyll $a + b$ organisms (Fig. 4; 12). Many prokaryotic traits are shared between the two "subgroups," including absence of organelles and presence of the following inclusions: a four-layered cell wall with murein as a structural component (peptidoglycan with peptide side chains attached to linked, alternating residues of N-acetylglucosamine and N-acetylmuramic acid); thylakoids containing chlorophyll **a**; cyanophycin granules [multi-L-arginyl-poly(L-aspartic acid), nitrogen storage reserves, diameter approximately 500 nm, consisting of polymers of amino acids arginine and asparagine]; polyphosphate bodies (or volutin granules of highly polymerized phosphate, diameter 0.5–2 μm; function to some extent as P storage reserves; found in [other] bacteria, fungi, and eukaryote algae); and carboxysomes (polyhedral bodies, diameter 200–300 nm; contain the photosynthetic Rubisco enzyme system; Table 2) (1,12).

However, there are also important differences between the "blue-green" and "green" prokaryotes with oxygenic photosynthesis. The blue-green organisms have cyanophycean starch (α-1,4-linked polyglucan, similar to glycogen and to the amylopectin component of higher plant starch) as their major reserve polysaccharide. In

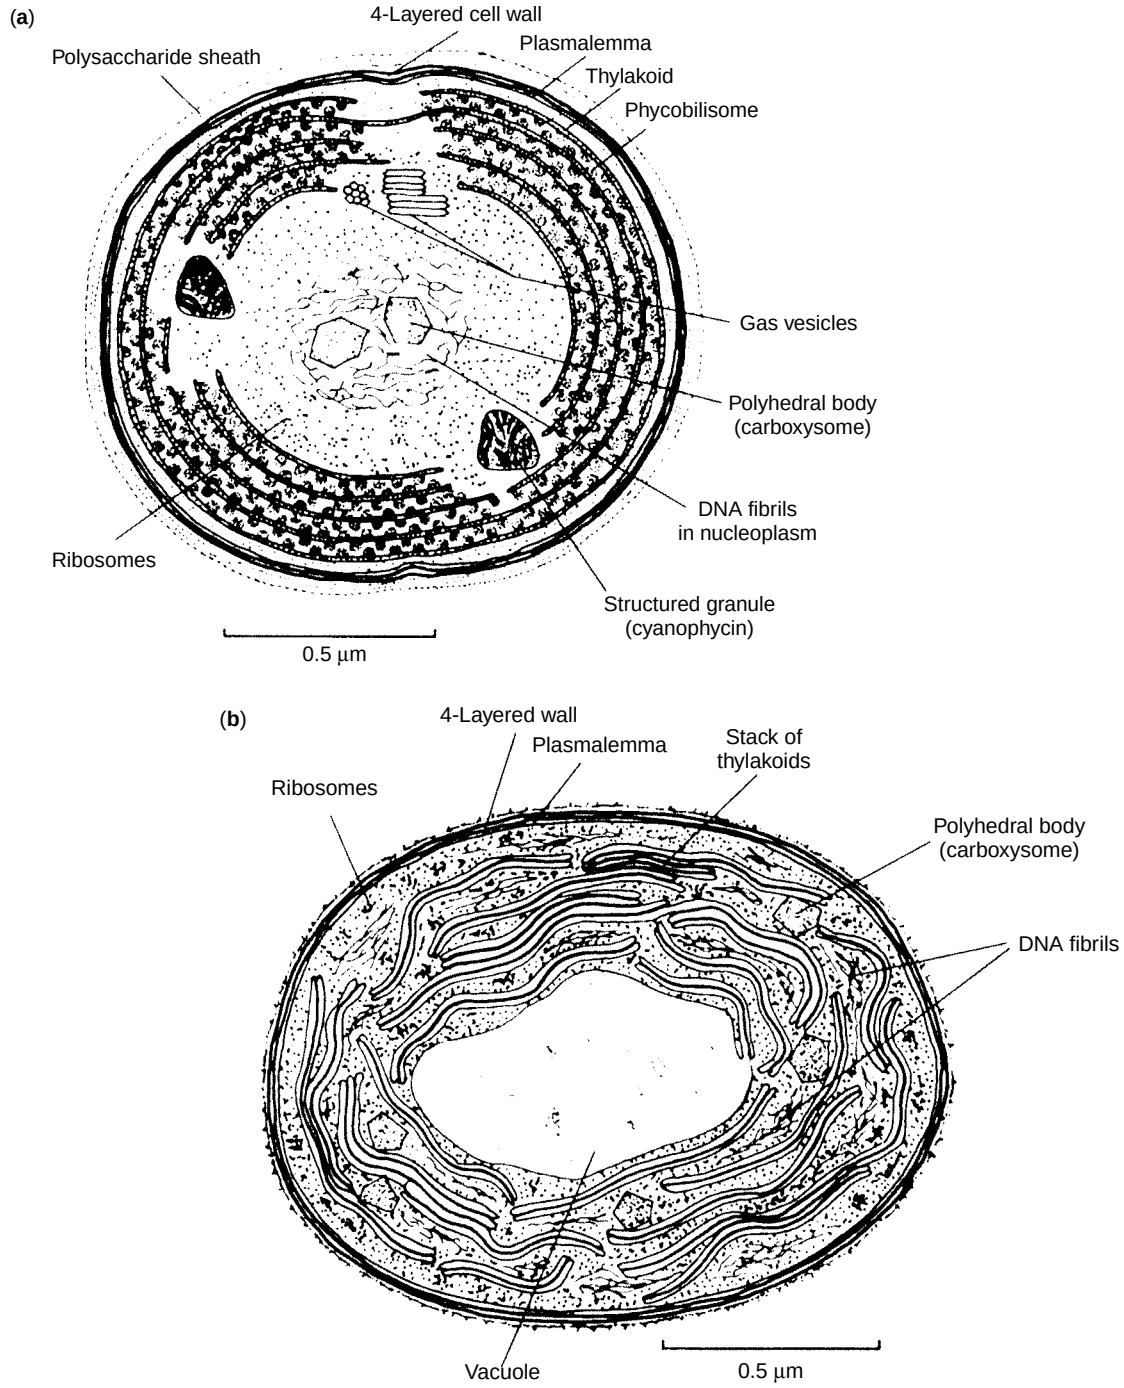

Figure 4. Diagrams comparing the ultrastructure of (**a**) the "blue-green" coccoid prokaryote, Synechocysis-tis and (**b**) the "green" coccoid prokaryote, Prochloron. Reprinted from (C. van den Hoek et al., *Algae—An Introduction to Phycology*, Cambridge University Press, Cambridge, U.K., 1998.) with permission from the authors and Cambridge University Press.

contrast, the green taxa have higher plant starchlike reserves with both amylose (β-1,6-linked polyglucan similar to amylose, and α-1,4-linked amylopectin) (12). The blue-green taxa are also strikingly distinct from the green prokaryotes in their pigment composition, especially the accessory pigments involved in photosynthesis. The blue-greens contain water-soluble phycobiliprotein pigments (the chromophores of which are called phycobilins) organized within complex, efficient light-harvesting structures called phycobilisomes [see following text; note that there is no structure of equivalent complexity known in (other) eubacteria]. The phycobiliprotein pigments are also highly significant in the ecology of these organisms (see following text). In contrast, the green prokaryotes

Table 2. Comparison of the "Blue-Green" and "Green" Prokaryotes with the Universal Plant Pigment, Chlorophyll *a*, and Oxygenic Photosynthesis. ***These organisms recently have been considered by some specialists (on the basis of molecular data, but ignoring pigment complement and certain distinct aspects of the fine structure which are regarded as major taxonomic characteristics in phycology) to be two subgroups within the cyanobacteria (1,12).***

Feature	Commonalities	Distinctions	
		"Blue-Green" Taxa	"Green" Taxa
Morphology	Coccoid, filamentous	Some colonial or with branched filaments	No colonial taxa, No filament branching
Color(s)	—	Blue, olive green,	Red bright green
Main photosynthetic pigment[a]	Chlorophyll *a* in thylakoids[b]	—	
Accessory pigments	—	Phycobiliproteins, in phycobilisomes; a few with chlorophyll *c* or *d*	Chlorophyll *b* (no phycobilisomes)
Light-harvesting proteins	Similar[c]	—	—
Major xanthophyll	Zeaxanthin	—	—
External mucilage (sheath)	Similar[d]	—	—
Cell wall[e]	4-layered, with structural murein	—	—
Gas vesicles	Present (some plankters)	—	—
Thylakoid arrangement[f]	—	Occurring singly, equidistant	Grouped (2-several per stack)
Reserve polysaccharides	—	Cyanophycean starch (polyglucan similar to glycogen)	Higher plantlike starch
Other reserves	Cyanophycin (N), polyphosphate bodies (P), lipids	Poly-β-hydroxy-butryic acid[g]	
DNA location	—	Concentrated in center of cell cytoplasm	Diffuse distribution throughout cytoplasm
Nitrogen fixation	?	Present in many	?

Note:
[a] Chlorophyll *a* is distinct from bacteriochlorophyll and chlorobium chlorophyll, the two chlorophylls found in other (nonoxygenic) photosynthetic bacteria (1).
[b] The exception is the blue-green prokaryote, *Gloeobacter violaceus* PCC 7421, which contains chlorophyll *a* but lacks thylakoids, suggesting that this taxon is relatively primitive (also supported by some molecular evidence) (1).
[c] The chlorophyll *a*/*b* binding proteins of these green prokaryotes are closely related to blue-green prokaryote light-harvesting proteins, rather than to eukaryote chlorophyll *a*/*b* proteins (1).
[d] A mucilaginous sheath is often present, composed primarily of complex polysaccharides with fibrillar appearance in electron microscopy (12).
[e] The cell wall is similar to that of gram-negative bacteria, and can be destroyed by lysozyme. The murein layers (peptidoglycan) typically is perforated by small pores with cytoplasmic extensions. The cell wall layers outside the murein layer consist mostly of lipopolysaccharides (12).
[f] Note, however, that thylakoid stacking has been documented in a genetically altered *Synechocystis* species lacking phycobilisomes, suggesting that thylakoids may stack when there is no spatial interference (here, phycobilisome structures) (25).
[g] Lipid droplets have been found in both blue-green and green prokaryotes; and several blue–green taxa have contained poly-β-hydroxybutryic acid (in vesicles ca. 200 nm in diameter; found in many [other] bacteria) (12).

have water-insoluble chlorophyll *b*, rather than phycobiliproteins, as their accessory pigment in photosynthesis.

HABITATS

General Distribution

The extant "blue-green" cyanobacteria are a diverse, ubiquitous group as mentioned. In contrast, only three monospecific genera of "green" prokaryotes with oxygenic photosynthesis are known (but note that *Prochloron* may possibly include two to three different "species") (2,15). *Prochloron didemni* was first described in the mid-1970s, and occurs as intra- and (mostly) extracellular symbionts of tropical and subtropical ascidians (sea squirts; temperature 21–31 °C). *Prochlorococcus marina* is an abundant picoplankter at 50 to 100 m depth in the open oceans, and was first detected in the early 1990s using flow cytometry (1,12). Two ecotypes have been determined (differing from one another by 2% in SSU rDNA sequence), one of which grows maximally at light levels that completely photoinhibit the other (1). *Prochlorothrix hollandica* is the only known filamentous "green" prokaryote and forms major blooms in shallow, eutrophic (nutrient-rich, highly productive) freshwater lakes of the Netherlands (12).

Cyanobacteria are widespread in neutral and alkaline waters, but do not thrive at pH less than or equal to 4. They often dominate the late summer plankton of temperature-stratified eutrophic lakes and slowly flowing lower rivers, where colonial coccoid and filamentous species such as *M. aeruginosa*, *Anabaena flos-aquae*, *Anabaena circinalis*, *Aphanizomenon* spp., *Cylindrospermum raciborskii*, and many others, form major water discoloration from noxious blooms up to 10^9 cells/mL in freshwaters worldwide (see following text) (2,5). Many of these species are capable of dinitrogen fixation, affording a significant competitive advantage over other phytoplankton. Many also produce potent toxins (see following text) that make them unpalatable to certain zooplankton grazers (2,5). The blooms commonly deplete dissolved oxygen concentrations from their high respiration during the night, causing massive fish kills (26). Filamentous and colonial coccoid cyanobacteria can also dominate the phytoplankton of shallow, polymictic, eutrophic reservoirs that sustain episodic, high sediment loading, alone or with phosphate (P) enrichment (27). Estuaries of Australia and in the Baltic Sea sustain massive blooms of the toxic cyanobacterium, *Nodularia spumigena* (28). Blooms of another filamentous, colonial cyanobacterium, *Trichodesmium thiebautii*, form "sawdust-like" patches in open-ocean blooms worldwide that were noted by Darwin and certain early explorers (29).

In the subsurface plankton of oligotrophic and mesotrophic lakes (with low and moderate productivity, respectively) and the oligotrophic oceans (to >100 m depth), cryptic, picoplanktonic cyanobacterial unicells (0.2–2.0 μm) contribute significantly to carbon production and ecosystem function (2). Their physiological ecology appears similar across oligotrophic freshwater and marine systems. In addition, picoplanktonic, coccoid unicellular cyanobacteria (*Cyanothece aeruginosa* and others) cover most lakes, slow-flowing rivers, and the oceans (2,30). And, colonial coccoid cyanobacteria (cell diameter 0.5–3.0 μm) are abundant in shallow eutrophic lakes (2) and turbid, eutrophic estuaries during summer. The abundance and major contributions of picocyanobacteria to the ecology of most of the aforementioned aquatic systems had been completely missed until the 1970s (30), and until the early 1990s their dominance of the summer plankton in turbid, eutrophic estuaries had been overlooked [e.g., Neuse Estuary, North Carolina, where this phenomenon was first reported by Fensin (31); Fig. 5; later by Paerl and coworkers (32)].

Within the benthic biofilm communities of oligotrophic lakes, pico-cyanobacteria (mostly coccoid colonial forms and unicells) can predominate throughout the growing season, contributing significantly to total community biovolume and cell number (Fig. 6; 33). These and/or larger cyanobacteria [including some toxic taxa (2)] can also become abundant in benthic habitats of eutrophic lakes and shallow, eutrophic rivers. Planktonic, filamentous cyanobacteria are stimulated to produce extracellular polysaccharides in response to episodic sediment loading, which results in coflocculation and settling to benthic habitats (34). There, they can thrive and provide an inoculum for other planktonic blooms (35;

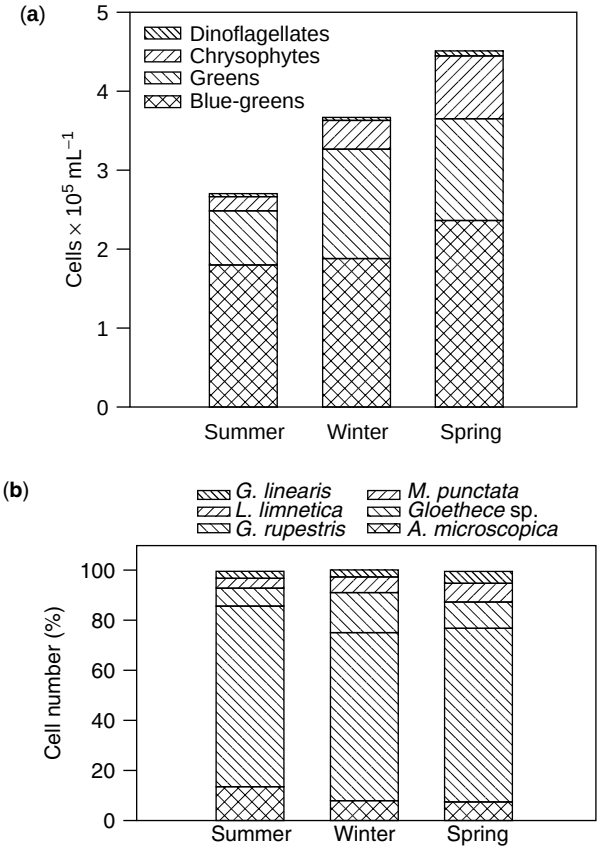

Figure 5. Cyanobacteria in the Neuse Estuary, North Carolina, United States, including (**a**) total abundance (designated as blue-greens) and (**b**) relative abundance (percentage of total phytoplankton cell number) of cyanobacterial taxa, with picoplankters including Gloeothece (G. linearis, G. rupestris, Gloeothece sp.) and Microcystis spp. (especially, M. punctata) contributing 50% or more of the total phytoplankton cell number during all seasons. From (E. E. Fensin, Population Dynamics of Pfiesteria-like *Dinoflagellates, and Environmental Controls in the Mesohaline Neuse Estuary, North Carolina, U.S.A.*, M.S. thesis, Department of Botany, North Carolina State University, Raleigh, N.C., 1997.) with permission of the author.

Fig. 7). Benthic *Phormidium* mats can be seasonally dominant or subdominant macroalgae in third-order, softwater streams of New England and the southeastern United States (36,37). Thus, cyanobacteria are important members of the flora of both open-water and benthic habitats in many aquatic ecosystems.

Success in Extreme Environments

Geothermal Springs. Hot springs, with characteristically high temperature in combination with high sulfide or acidic conditions, are scattered throughout all continents (except Antarctica, with fumaroles) and many islands, often separated by substantial distance. It has been hypothesized that there should be endemic species of thermophiles, restricted to certain hot spring clusters by geographic isolation and, perhaps, evolutionary divergence (2). Some of the major cyanobacterial taxa found in geothermal springs, such as *Cyanothece* spp., appear to

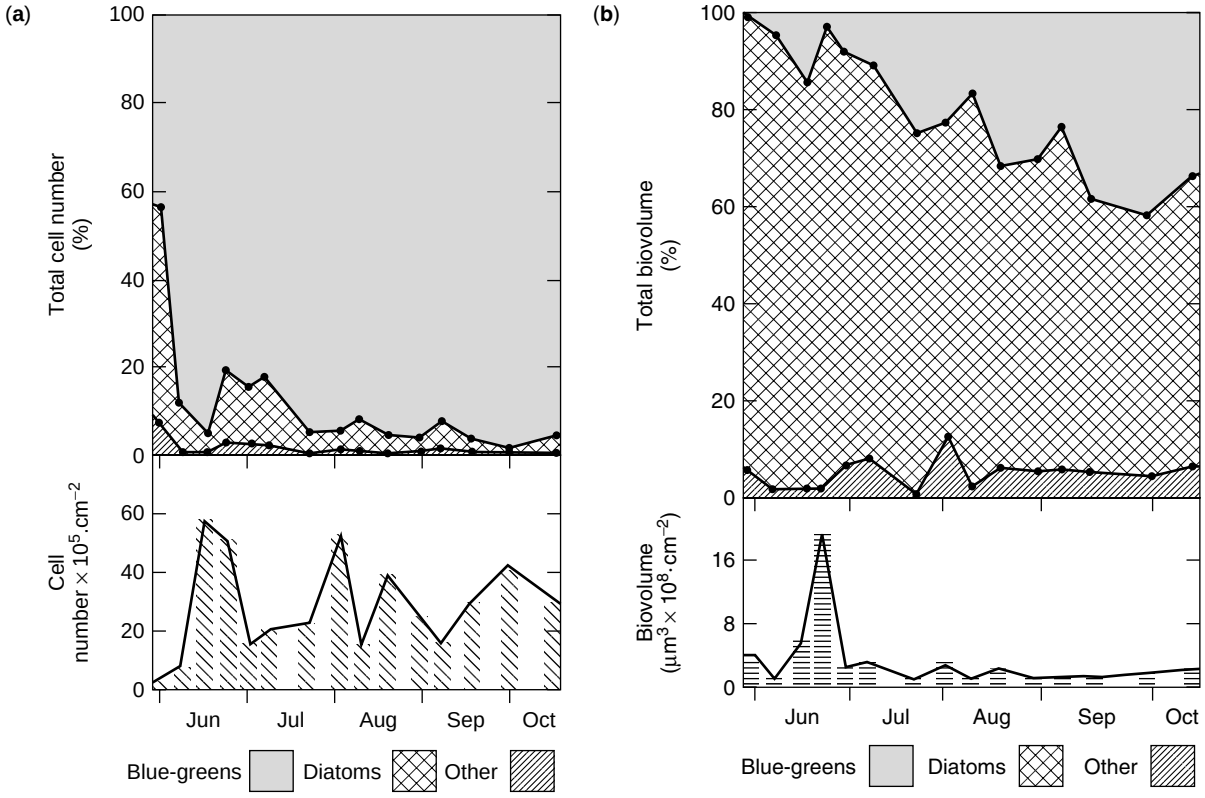

Figure 6. Epiphytic microalgae [here, including abundant pico-cyanobacteria as blue-greens; e.g., Gloeothece linearis, Cyanothece (Synechococcus) Aeruginosa, *Chroococcus minor*, *Aphanothece microspora*, *A. gelatinosa*, *A. nidulans*, and *C. minor*] on the outer leaves of *Scirpus subterminalis*, the dominant rooted, submerged plant in the littoral zone of a hardwater, P-limited, north temperate lake, including relative abundance (percentage of total phytoplankton) as (**a**) cell number and (**b**) biovolume. From (J. M. Burkholder and R. G. Wetzel, *Arch. Hydrobiol. Suppl.* **83**, 1–56 (1989).), reprinted with permission from E. Schweizerbart'sche Verlagsbuchhandlung.

be restricted by geographic distribution, whereas others such as *Mastigocladus* cf. *laminosus* and "*Chlorogloeopsis*" [taxonomy uncertain; formerly *Mastigocladus* HTF (high-temperature form)] are found in hot springs worldwide. The taxonomy of cyanobacteria from most geothermal springs is uncertain. These thermophilic cyanobacteria show distinct morphologies depending on environmental factors such as the chemical composition of the water, temperature, or irradiance (2). Within a taxon such as *Cyanothece*, there appears to be many different strains with ordered distributions along thermal and vertical gradients, suggesting an ongoing process of "speciation" (resulting from adaptive radiation of specialized ecotypes) or, at least, of development of distinct physiological races.

Temperature, pH, nitrogen supplies (especially the combined nitrogen or N_i available, usually as NH_4^+), and free sulfide are major factors controlling cyanobacterial species composition and abundance in geothermal springs (2). Hot springs taxa occur at temperatures ranging from about 50 to 74 °C, and are variable in free sulfide tolerance (range less than 0.05–3 mM). They are most common in near-neutral or alkaline conditions; species diversity becomes limited at pH below 6 and, as in other habitats, they have not been found below pH 4. For example, in areas where outflows of neutral to alkaline, nonsulfidic hot springs with combined nitrogen cool to about 74 °C, a mat of *Cyanothece* HTF may first encounter the spring water and remove most of the N_i. The downstream cyanobacteria at a temperature below approximately 58 °C may be dinitrogen fixers [e.g., *Mastigocladus* (*Fischerella*) cf. *laminosus* or HTF "*Chlorogloeopsis*" at temperature below approximately 64 °C, or *Calothrix* at temperature below approximately 50 °C). Or, a hot spring may be sufficiently nitrogen-rich to be dominated by *Cyanothece* without dinitrogen fixers, or so nitrogen-poor that only dinitrogen fixers occur. Thermophilic cyanobacteria that can grow at temperatures above 56 °C cannot tolerate more than about 10-μM sulfide, but spring water usually is depleted in sulfide once the outflow temperature reaches 52 °C. In some hot springs (e.g., Iceland), sulfide-oxidizing photosynthetic bacteria on the mat surface remove sulfide and thus allow underlying cyanobacteria to grow. Filamentous thermophilic taxa can move 5 to 6 μm/sec in response to changing light and temperature, and the mats move to avoid slow changes in stream temperature. Limited movement (0.1–0.3 μm/sec) has also been shown by coccoid unicells in positive phototaxis (2).

Thermophilic cyanobacteria have intensive localized photosynthesis and high photorespiration, with the majority of photosynthate stored as polyglucose rather

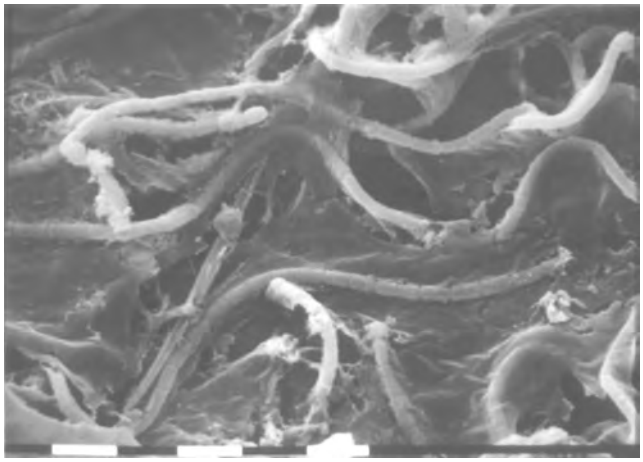

Figure 7. Scanning electron micrograph of the benthic microalgal community from shallow waters (depth 0.25–0.5 m) of a reservoir in the Piedmont region of the southeastern United States, showing abundant Anabaena filaments among a mucilaginous matrix (white bar equals 10 μm). Cyanobacteria dominated the shallow waters of experimental enclosures that had received episodic sediment loading for about 11 weeks over the summer growing season (kaolinite or montmorillonite clay, added at two-day intervals to effect an initial concentration of 25 mg suspended solids/L after additions), alone or with phosphate enrichment (mean $PO_4^{-3}P$ from 45–115 μg/L). From (J. M. Burkholder and B. E. Cuker, *J. Phycol.* **27**, 373–384 (1991).), reprinted with permission from the *Journal of Phycology*.

than as substances needed for growth. Photoexcretion of glycolate (up to 60% of the photoexcreted carbon, and 10% or more photosynthetically fixed carbon) and dark fermentation of polyglucose lead to a diel cross-feeding of most fixed carbon to heterotrophs (2). Under varying light intensities, thermophilic cyanobacteria isolated from hot springs may also excrete fructose, adonitol, oxalate, fumarate, succinate, acetate, formate, propionate, and/or β-hydroxybutryate. Volatile fatty acid products of fermentation accumulate in darkness, and are later taken up by filamentous photoheterotrophs.

Cold, Desiccation, High UV, and Other Extremes. Cyanobacteria are the predominant biota in cold environments such as ice shelves, glaciers, glacial meltwater streams, ice-capped lakes, and recently exposed glacial moraines; and they are also abundant in tundra and polar desert soils, where they are important in nitrogen and carbon cycles (2). In lower portions of polar glaciers and on alpine glaciers in temperate regions, black, mucilage-producing cyanobacteria (e.g., filamentous *Calothrix parietina*, *Phormidium frigiddum, Lyngbya martensiana, Microcoleus paludosus* var. *acuminatus, Nodularia harveyana*, and coccoid *Cyanothece aeruginosa*) can form "cryconite" (cold rock dust) by trapping dust, and the resulting dark patches absorb radiation so that the local heat balance is affected and holes, ponds, and streams are produced. The black coloration is from UVR-screening black carotenoid pigment, scytonemin, found in certain cyanobacteria of polar, high-light, and high-temperature environments. Cyanobacterial colonizers of rocks in Arctic and Antarctic streams and the surfaces of some lakes and ponds are rich in carotenoids (e.g., canthaxanthin, myxoxanthophill that neutralize reactive oxygen species) and other UV-A/B absorbing pigments such as mycosporine-like amino acids with maximal absorption at 320 to 335 nm [e.g., asterina-330, shinorine, phorphya-334, palythene; (2)].

In freshwaters and saline lakes of both polar regions, cyanobacteria can accumulate to benthic mats up to 90-cm thick, with more than 40 μg chlorophyll a/cm^2. Picocyanobacteria often dominate the autotrophic plankton of polar and subpolar freshwater and saline lakes, where they are favored because they are eurythermal (withstanding temperatures down to $-12\,^{\circ}C$ and grow from $5–35\,^{\circ}C$); tolerate desiccation, freezing, and salinity stress (e.g., a brine covering with sixfold higher salinity than seawater); have various adaptive strategies against UV radiation and high solar radiation in exposed habitats; and can shade-acclimate to allow net growth in dim-light environments (2). For example, some Antarctic mat-forming cyanobacteria were completely desiccated within five hours of being exposed to the atmosphere, but photosynthesis and respiration occurred within 10 minutes of rewetting. Thus, in many polar environments they grow slowly but gradually accumulate over many seasons, with only minor losses from biotic and abiotic removal processes (2). In polar oceans, however, cyanobacteria are rare or absent, probably because depressed growth rates at cold temperatures and low light are insufficient to balance losses from grazing, advection, and mixing (2).

Cyanobacteria synthesize compatible solutes to counteract osmotic stresses from freezing and high salinity; and they accumulate trehalose as a water replacement mechanism to maintain the functional integrity of membranes during desiccation. Freshwater cyanobacteria accumulate sucrose in response to osmotic stress; marine taxa accumulate glucosylglycerol, sometimes with trehalose and sucrose; and hypersaline taxa accumulate betaine (and, secondarily, sucrose) (2). Although typically a single, low-molecular-weight organic solute is synthesized in response to osmotic stress, many cyanobacteria produce a secondary compound (e.g., disaccharide), which may assist in rapid response. Cyanobacterial/microbial mats often evolve dimethylsulfide (DMS), produced from DMSP, which can serve as a secondary cryoprotectant.

Endolithic Habitats. Cyanobacteria penetrate porous, translucent rocks to provide the primary-production basis of endolithic communities across an extreme temperature gradient from hot to cold polar deserts. It is hypothesized that the endolithic habit enables survival under extreme osmotic, thermal, and UV or light stress; and, for cold-desert forms, cryoprotection is additionally afforded. In deserts, various translucent rock types contain cyrptoendolithic cyanobacteria (*Gloeocapsa, Chroococcus turgidus, Chroococcidiopsis*) (2). Daily rock temperatures can vary from 22 to $48\,^{\circ}C$; relative humidity above the rock decreases sharply during the day (e.g., from 47 to 24%); and rock moisture content can range from 0.05 to 1.12% (2). The spaces between the outermost rock grains are filled with mineral material ("desert varnish") that is permeable to liquids and gases, but not penetrable by

cells. The cyanobacteria attach to grains beneath this outer layer. Physiological studies on endolithic isolates, *Chroococcidiopsis* sp. and *Nostochopsis lobatus* in a hot desert in South Africa, indicated that light saturation of photosynthetic e^- transport occurred at a similar light intensity (200–350 μmol m^{-2} sec^{-1}) as for the natural community in full sunlight (20–250 μmol m^{-2} sec^{-1} in full sunlight, or 1–10% of I_o). Despite capability for substantial photosynthetic C_i fixation by endolithic cyanobacteria, carbon turnover is probably very slow. Nitrogen is mostly supplied abiotically as nitrate and as ammonia from atmospheric deposition, with little evidence for dinitrogen fixation (2).

LIGHT, PHOTOSYNTHESIS, AND ORGANIC CARBON UPTAKE

Pigments

As mentioned, the green prokaryotes have chlorophyll *b* as their main accessory pigment. Chlorophyll *b* can be formed from a chlorophyll *a* precursor by a single step that involves an oxygen-requiring enzymatic conversion of a methyl to a formyl group (1). Although this has been described as an "easy" step (1), the chlorophylls are among the most taxonomically reliable pigments, and they do not readily interconvert. On the basis of molecular evidence, it has been hypothesized that chlorophyll *b* independently evolved at least four times [represented by three "green prokaryote" or prochlorophyte lineages (see following text), and by the ancestor of green algal and higher plant plastids; 38,39]. Note, in addition, that an accessory chlorophyll *c*-like pigment has been reported in the green prokaryotes, *Prochlorococcus* (40) and *Prochloron* (41). Because these two taxa are not considered closely related on the basis of certain molecular data, it has been further hypothesized that it arose independently in both. Moreover, chlorophyll *d* (found in some red algae) was recently discovered to be the major photosynthetic pigment in the blue-green *Acaryochloris marina*, an organism that has very little chlorophyll *a* and lacks phycobiliprotein pigments (42).

Like eukaryote algae and higher plants, cyanobacteria have a suite of carotenoids such as β-carotene and zeaxanthin, which act as accessory pigments by increasing the harvest blue wavelengths of light that cannot be directly absorbed by chlorophyll *a*, for use in photosynthesis [Fig. 8; (1)]. UVB (280–320 nm) and UVA (320–400 nm) damage molecular targets directly or indirectly via production of reactive oxygen metabolites. The carotenoids partially protect cyanobacteria from UV radiation and harmful photooxidation, as indicated. Their association with chlorophyll also prevents formation of highly reactive oxygen radicals that could otherwise damage the chlorophyll(s), lipids, proteins, DNA, and other molecules (42). Carotenoids and accessory chlorophylls absorb only about one-third of light in the [bluish-]'green window' that cannot be directly absorbed by chlorophyll *a* for use in photosynthesis. That is, they fill a gap between available light energy and the absorbance capability of chlorophylls (25). But the greatest green light-harvesting capability occurs among the blue–green

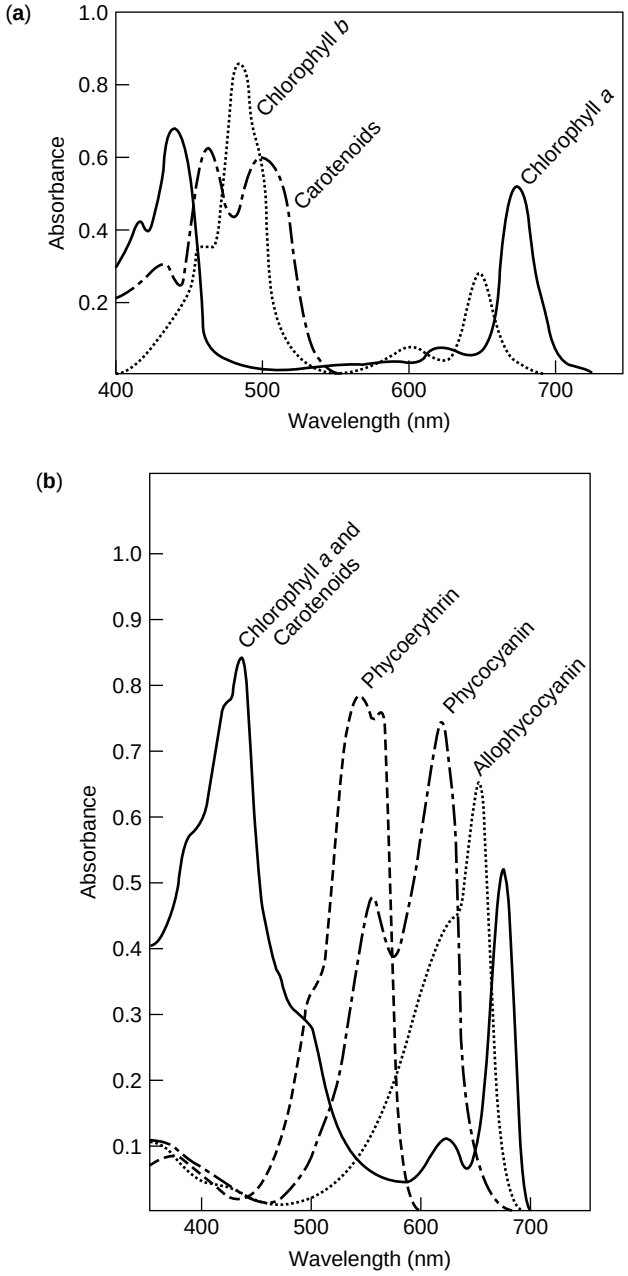

Figure 8. Absorption spectra of light-harvesting pigments in cyanobacterial photosynthesis, including (**a**) the chlorophylls a and b and carotenoids and (**b**) phycobiliproteins. Modified from Gantt (1975) by Graham and Wilcox (1); reprinted from (L. E. Graham and L. W. Wilcox, *Algae*, Prentice-Hall, Upper Saddle River, N.J., 2000) with permission from the authors and Prentice-Hall.

prokaryotes, which are afforded significant ecological advantage over most other aquatic organisms with oxygenic photosynthesis because of their phycobiliprotein pigments (Figs. 8 and 9).

Living and dead organic matter absorb red light, a low-energy photosynthetically active radiation (PAR) that is rapidly removed near the water surface and dissipated or

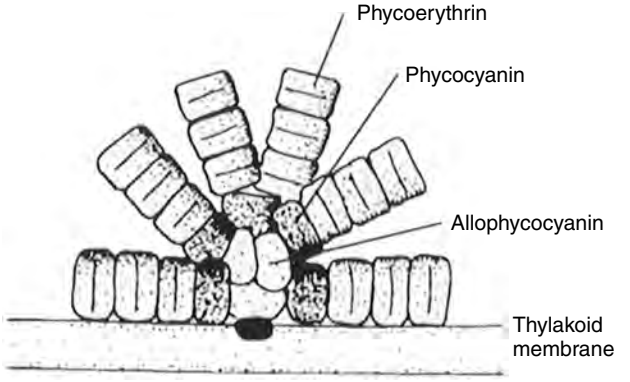

Figure 9. The ultrastructure of a hemispherical phycobilisome in cyanobacteria, showing exterior-most phycoerythrins (absorption and fluorescence maxima at approximately 545 nm and 575 nm, respectively), phycocyanin internal to the phycoerythrins (absorption and fluorescence at approximately 555–618 nm and 636 nm, respectively), allophycocyanin internal to the phycocyanin (absorption and fluorescence maxima at approximately 650 nm and 660–675 nm, respectively), and chlorophyll *a* internal to the allophycocyanin [absorption and fluorescence maxima at approximately 670 nm and 685 nm, respectively; (1)]. Hemidiscoidal phycobilisomes are similarly constructed. Note that not all blue–green prokaryotes with oxygenic photosynthesis have all three types of phycobiliprotein pigments, and that phycoerythrins do not appear to be essential for phycobilisome formation. From C. van den Hoek et al., *Algae—An Introduction to Phycology*, Cambridge University Press, Cambridge, U.K., 1998. Reprinted with permission from Cambridge University Press.

lost as heat (25), and thus effectively compete with chlorophylls. The PAR highest in energy is blue light, which is also absorbed by living and dead organic matter and by water molecules. Within the visible spectrum, especially in waters with moderate to high productivity (and moderate to high organic matter content near the surface), mid-energy wavelengths of light of greenish-yellow color penetrate to greatest depths (25). The phycobiliprotein pigments are capable, through their relatively intricate packaging in phycobilisomes (Fig. 9); of absorbing virtually the entire green window and transmitting the light energy via fluorescence to chlorophyll *a* for use in oxygenic photosynthesis. Thus, they can grow in low-light habitats with insufficient light for most aquatic plants (here, including algae). Phycobilisomes (diameter ca. 40 nm) can form up to 25% of the dry weight and 40% of the total soluble protein of cyanobacterial cells (1). Their structure maximizes light energy transfer to chlorophyll *a*, with up to approximately 90% energy-transfer efficiency (1). In addition to this remarkably efficient pigment complement, some cyanobacteria are capable of chromatic adaptation, wherein they adjust their pigment composition in response to changing light quality. They increase phycoerythrin synthesis in green light (becoming red in color) and increase phycocyanin synthesis in red light (becoming blue in color), which affords adaptive advantage in aquatic systems characterized by a changing light environment (25). The genes that regulate cyanobacterial chromatic adaptation may be controlled by sensor kinases and they encode proteins that are similar to bacterial response regulators, portions of the light-sensing phytochrome pigment of higher plants, and portions of higher plant ethylene receptor proteins (1).

Oxygenic and Anoxygenic Photosynthesis

Cyanobacteria have the typical photosystems I and II (except within heterocysts; see following text) for inorganic carbon (C_i) fixation, but their Rubisco has low affinity for carbon dioxide relative to most other oxygenic photosynthetic organisms, and they are extremely vulnerable to the effects of photorespiration [function of Rubisco as an oxygenase rather than a carboxylase under increasing oxygen; (43,44)]. Cyanobacteria are able to achieve high rates of photosynthesis in oxygen-rich environments because they can use both carbon dioxide and HCO_3^- as sources of C_i and because they have developed a highly efficient, although still poorly understood, C_i-concentrating mechanism. Cyanobacteria take up carbon dioxide, when available, by passive diffusion or active transport (enzyme as yet unknown). Experimental evidence also indicates that they can utilize HCO_3^- as a C_i source, which they take up using a membrane-bound transporter or "pump" (as yet uncharacterized). Bicarbonate is much more readily available than carbon dioxide in neutral to alkaline habitats where cyanobacteria mostly occur (2,44). Although HCO_3^- uptake would require energy, HCO_3^- would be more easily retained than carbon dioxide, which can readily diffuse back out of cells. Cyanobacteria use carbonic anhydrase (CA) to convert HCO_3^- to carbon dioxide, the substrate used by Rubisco. Both CA and Rubisco are colocalized within carboxysomes, which facilitates capture of CA-generated carbon dioxide by Rubisco before the carbon dioxide is lost from the cell by diffusion (45,46).

Although oxygenic photosynthesis predominates in cyanobacteria, some taxa can also conduct anoxygenic photosynthesis (involving only photosystem I) in anaerobic environments with sufficient light and appreciable reduced substrates such as hydrogen sulfide (H_2S), hydrogen gas (H_2), or organic compounds as electron donors. (2) Heterocysts conduct anoxygenic photosynthesis, using substrates from adjacent vegetative cells (see following text). Anoxygenic photosynthesis is also common in microbial mat cyanobacteria, mostly via use of sulfide as the electron donor: $12H_2S + 6CO_2C_6H_{12}O_6 + 12S^o + 6H_2O$. Mats formed by cyanobacteria generally have a surface layer of sand or scytonemin, then a layer of cyanobacteria, an underlying layer of oxidized iron, then a layer of purple sulfur bacteria (rarely underlain by a layer of green sulfur bacteria), and a bottom layer of FeS. The internal mat environment is characterized by steep gradients in light, oxygen, and sulfide. An alternate mode of anoxygenic photosynthesis occurs in the mat former, *Microcoleus chthonoplastes*, which undergoes oxygenic and anoxygenic photosynthesis concurrently. In the latter, it produces thiosulfate from sulfide oxidation, a process that yields twofold more electrons and, thus, appears to be twice as efficient as S^o production by other cyanobacteria (2).

Cyanobacteria have been subdivided into four general groups in degree of sulfide tolerance and potential for sulfide-dependent anoxygenic photosynthesis (2).

Group 1 cyanobacteria (sulfide-sensitive oxygenic photosynthesis only) are extremely sulfide-sensitive. These species mostly inhabit freshwater lakes and terrestrial environments low in sulfide. They cannot conduct anoxygenic photosynthesis and their oxygenic photosynthesis is inhibited at low sulfide levels (less than 0.1 mM). Group 2 cyanobacteria (sulfide-resistant oxygenic photosynthesis only) are much more resistant to sulfide, with oxygenic photosynthesis stimulated at moderate (less than 1 mM) sulfide levels characteristic of marine microbial mats with fluctuating sulfide concentrations. However, these organisms are incapable of anoxygenic photosynthesis. Group 3 cyanobacteria occur in similar habitats as group 2, but conduct sulfide-dependent anoxygenic photosynthesis concurrently with sulfide-insensitive oxygenic photosynthesis. Group 4 cyanobacteria are variably sensitive to sulfide (depending on the taxon, sulfide tolerance ranges from less than 1 to 10 mM) but conduct sulfide-dependent anoxygenic photosynthesis rather than sulfide-sensitive oxygenic photosynthesis. The freshwater bloom former, *Oscillatoria limnetica* from anaerobic H_2S-rich bottom waters of a hypersaline lake, switches off photosystem II when exposed to less than 0.1 mM sulfide, and anoxygenic photosynthesis is induced in a process requiring protein synthesis (2). This organism tolerates up to 9.5 mM sulfide, but anoxygenic photosynthesis is inhibited at more than 4 mM sulfide. The excreted elemental sulfur forms granules on the filament surface, which are believed to be of physiological use (see following text). Cyanobacteria are believed to have been anoxygenic phototrophs before they evolved oxygenic photosynthesis.

Respiration and Heterotrophy

Probably as a remnant from their evolution under anaerobic conditions, some (more likely, many) cyanobacteria use one or more fermentation pathways in which they process cyanophycean starch or other substrates in anaerobic respiration when oxygen is not available. Some fermentation pathways are energetically efficient in utilizing the organisms' accumulated osmoprotectant compounds as substrates. For example, some taxa (e.g., *O. limnetica*, several strains of symbionts, *Anabaena azollae*, *Nostoc* spp.) have homoacetate fermentation, which uses the osmoprotectant, trehalose, as substrate. When oxygen is absent, aerobic respiration apparently is limited or does not occur; many cyanobacteria die, and lysis occurs within two to three hours after transfer to dark anoxic conditions (2,47).

Many cyanobacteria, like many eukaryote algae, are capable of uptake of organic carbon (C_o) substrates and of heterotrophic growth in darkness using C_o substrates or in the light via photoheterotrophy. Substrates taken up by cyanobacteria have included D-glucose, D-fructose, D-ribose, sucrose, acetate, various amino acids, and glycerol, whereas D-galactose, maltose, cellobiose, mannitol, and D-xylose were poorly used (1,2). Where heterotrophic growth in darkness has been documented, rates were significantly lower than that for photoautotrophic growth (1,2).

Although there have been reports that cyanobacteria can contribute to the oxidation and degradation of hydrocarbons, in most cases, the cultures may not have been bacteria-free (2). Cyanobacteria immobilize oil-degrading bacteria and fungi in their outer mucilage, and have probably done so through geologic time (2). Following the largest known oil spill (by the Iraqis, into the Arabian Gulf adjacent to Kuwait, August 1990 to February 1991), visually obvious cyanobacterial mats developed over the oil layers that had drifted to cover approximately 770 km of the Saudi Arabian coast, in areas without sign of other macroscopically visible forms of life (47). Mats with strongly adhering oil layers consisted of associations of two filamentous cyanobacteria, *M. chthonoplastes* and *Phormidium corium*, with up to 10^6 oil-degrading bacteria per gram fresh weight of their sheaths. Apparently, the cyanobacteria afforded the bacteria benefit by preventing them from washing out to sea, providing oxygen, and perhaps providing fixed nitrogen as well, although their role in utilizing the oil as an organic substrate was probably indirect.

Cyanobacteria can degrade and, to varying extents, utilize other potentially toxic organic substrates as well. For example, they can mediate oxidation of naphthalene (common water-soluble pollutant) to 1-naphthol, naphthalene-1,2-oxide, and possibly other substrates, apparently via monooxygenase and dioxygenase systems (2). A monooxygenase system appears to be involved in initial oxidative attack by a cyanobacterium on phenanthrene as well. Some species oxidize 1- and 2-methyl naphthalene at the methyl group, through hydroxylation of the alkyl side chain, and oxidize biphenyl, mostly to 4-hydroxybiphenyl (2). Two autotrophically grown cyanobacteria were shown to metabolize aniline (aromatic amine used in industry for production of dyes, pesticides, and pharmaceuticals) to formanilide, acetanilide, and p-aminophenol. The cyanobacteria, *M. chthonoplastes* and *Phormidium corium*, isolated from oil-rich sediments, were incubated with crude oil or n-alkanes, and growth occurred although the alkanes were oxidized to produce increased proportions of total unsaturated fatty acids with the equivalent chain lengths in their total lipids, an effect analogous to that in hydrocarbon-utilizing bacteria and fungi. Chlorinated cyclic aliphatic hydrocarbons (e.g., lindane) can be oxidized by cyanobacteria (*Anabaena* sp., *Nostoc ellipsosporum*) (2), but the extent to which they utilize such compounds is not known.

Vertical Migration in Benthic Mats

Cyanobacteria use gliding motility to migrate downward into the lower mat or underlying sediment during periods of high light (late morning to late afternoon, summer season) and up to the surface in late afternoon or at sunset. The downward movement is mostly attributed to negative phototaxis, but in soil, may also be in response to higher nutrient concentrations at depth (2). For some species, the cue for daytime vertical migration is the intensity of solar irradiance, especially in the UVR region. The downward movement enables avoidance of high UVR radiation exposure, thereby preventing photoinhibition and photodestruction. Alternatively, some migrating species move to (low) optimum light intensities for photosynthesis. Upward movement may be controlled by chemical factors, for example, movement toward

increasing dissolved oxygen and/or movement away from increasing sulfide (but note that some cyanobacteria are incapable of movement in the dark after a short period, probably after photosynthetic energy reserves are depleted). Light probably does not control upward movement as light would be scattered so that a directional influence would be lost at depth within a microbial mat or in the soil (48).

The geothermal springs taxon, *Oscillatoria terebriformis*, exhibits different behavior. It makes a first migration downward during the high-light period and moves up to the surface in late afternoon, then makes a second migration down into the lower mat or underlying sediment after dusk and returns to the surface in the early morning (2,2). It shows positive phototaxis toward low light and negative phototaxis toward high light, controlling its movement downward during the day. In darkness, it continues random movement until it reaches the sulfide layer. Sulfide (0.7 mM or more) inhibits motility in darkness, and light reverses the inhibition (2,2). During the day, the sulfide layer is displaced downward, relieving inhibition of mobility so that the organism moves up toward the light to the surface of the mat. At high light intensity during midday, it becomes negatively phototactic and moves deeper into the sediment. At night it becomes trapped in the sulfide layer, which is essential for its survival through the dark period. In aerobic conditions, dark respiration would rapidly deplete its carbohydrate reserves, leading to death within several hours (2,2). In the anoxic sulfide layer, *O. terebriformis* undergoes the slow process of fermentation, enabling an extended period to generate sufficient energy to cover its metabolic maintenance needs.

OTHER NUTRITIONAL ECOLOGY

Nitrogen

Nitrogen, used in amino acids, nucleotides, chlorophylls, and phycobiliprotein pigments, and some energy compounds, can form up to approximately 10% of cyanobacteria cells (dry weight basis) (2). The preferred nitrogen form by most cyanobacteria for uptake is NH_3–NH_4^+ (especially at low light intensities) $> NO_3^- \gg N_2$ (49). When NH_4^+ is available (nonlimiting), cyanobacteria do not assimilate alternative sources (50). As in other organisms with oxygenic photosynthesis, nitrogen metabolism is closely connected to inorganic carbon (C_i) fixation because both processes compete for energy and reductant generated by the light reactions of photosynthesis. Assimilation of carbon dioxide to carbohydrate requires four electrons (e^-), whereas synthesis of amino-N from nitrate requires 10 e^-, and at a cellular C/N of approximately 5, up to 50% of the reductant generated by the light reactions is used for nitrogen assimilation (51,52). Nitrogen assimilation can be a carbon "drain" because substantial carbon is required for amino acid synthesis so that nitrogen assimilation influences the rate of carbon dioxide fixation, the partitioning of the fixed carbon, and the production/maintenance of carbohydrate reserves — with major effect, in turn, on cell growth, cell turgor pressure, and cell density/buoyancy (51). Inorganic nitrogen (N_i) as ammonia is taken up by passive diffusion or, as the protonated form NH_4^+, by a specific uptake system; and nitrate is taken up by another specific uptake system (involving the enzyme nitrate reductase, which includes iron and molybdenum as cofactors), and then reduced to ammonia using ferredoxin as an e-donor (thus, the process is closely linked to photosynthesis). Organic nitrogen (N_o) sources such as amino acids arginine, asparagine, and glutamine can be taken up by cyanobacteria (2). Cyanobacteria "luxury-consume" nitrogen, or take up nitrogen greatly in excess of the cell's metabolic needs, for storage as cyanophycin and later use when N_i and labile N_o substrates become depleted (e.g., in eutrophic waters late in the growing season; in many estuarine and marine waters; within the dense, compacted biomass of microbial mats and other biofilm layers, etc.).

Nitrogen gas (N_2) in air and water is much more abundant than N_i or labile N_o, forming approximately 70% of the atmosphere and approximately 95% of the nitrogen in the oceans (1). Cyanobacteria are the only diazotrophs, or N_2-fixing organisms, with oxygenic photosynthesis, affording a major advantage over other algae in usable nitrogen supplies. In nitrogen fixation, dinitrogen is converted or "fixed" into N_i (NH_3) by the following reaction, which is energy-costly and catalyzed by the enzyme, nitrogenase (Nase):

$$N_2 + 8\,e^- + 8H^+ + 16\text{MgATP} \xrightarrow{\text{Nase}} 2NH_3 + H_2(g) + 16\text{MgADP} + 16P_i$$

In cyanobacterial taxa with this capability, N_2 fixation is induced by low levels of N_i, especially NH_4^+, in the external medium. The key enzyme involved, Nase, consists of a molybdenum (Mo)-iron (Fe) protein, several Fe-sulfur clusters, a Mo-Fe-S cofactor (or, in one form of cyanobacterial Nase, vanadium) and an Fe-protein (1). Cyanobacteria actually have two Mo-dependent Nase forms, one that is operative in vegetative cells in anaerobic environments and another that is operative in heterocysts (specialized cells that reduce access of oxygen to Nase) in anaerobic or aerobic external environments.

Nitrogenases are extremely sensitive to oxygen and function only in anoxic microzones (e.g., within colonies insulated from the external aerobic environment by thick mucilage or within benthic mats and other biofilm layers) or anaerobic habitats. Rates of dinitrogen fixation are elevated in some (mostly heterocystous) cyanobacteria during the light period because of increased available (photosynthetic) energy for the process, other taxa fix dinitrogen only at night when oxygen is not evolved from photosynthesis. Other mechanisms have also been found; for example, the unicellular cyanobacterium, *Cyanothece*, downregulates photosystem II during dinitrogen fixation so that little oxygen is produced for several hours (52). The colonial marine plankter, *Trichodesmium*, is unusual among nonheterocystous taxa in its ability to conduct oxygenic photosynthesis concurrently with dinitrogen fixation during the day, which is accomplished by physical separation of dinitrogen fixation and carbon fixation (1,2,29). Similarly, some nonheterocystous taxa colonizing cave walls and rice paddy fields can conduct

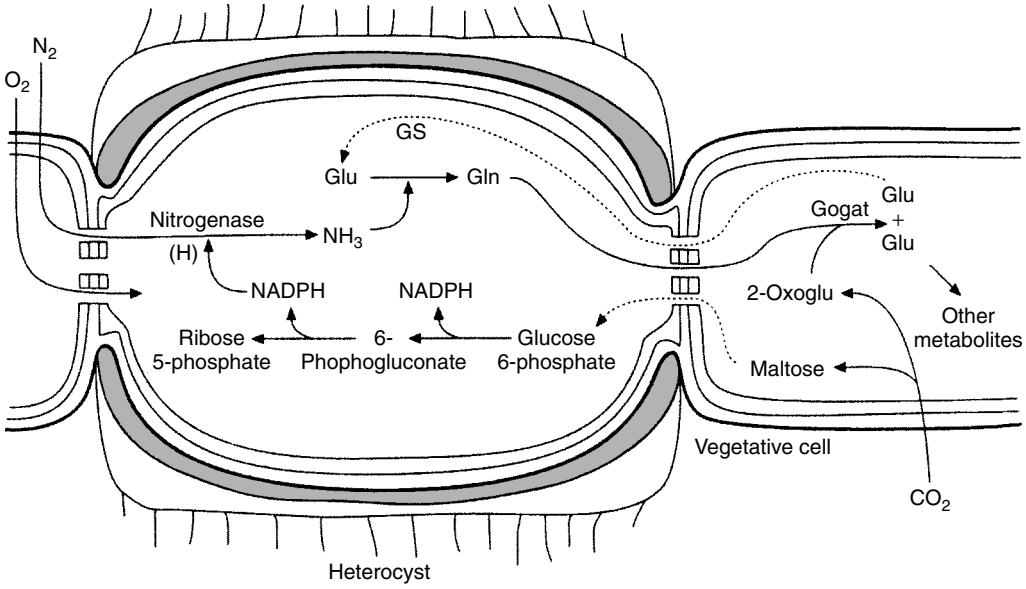

Figure 10. Diagram of a cyanobacterial heterocyst and adjacent vegetative cells, showing the relationship between photosynthetic and N_2-fixation metabolism. The thick walls of heterocysts reduce diffusion of oxygen (and N_2) inward. Thus, entry of these gases occurs via vegetative cells and small pores or channels (micro-plasmodesmata) in the cell walls connecting heterocysts and vegetative cells. These pores also allow movement of fixed nitrogen (Gln = glutamine) from heterocyts into vegetative cells. The GOGAT enzyme system (glutamate synthase (glutamine-oxoglutarate amidotransferase regenerates glutamate, which diffuses into heterocysts. Addition of NH_3 to glutamate is accomplished by glutamine synthase (GS). The NH_3 origi-nates from the activity of nitrogenase, using NADPH (reducing equivalents) generated from carbohydrates such as maltose or glucose-6-phosphate that originated, in turn, from photosynthetic carbon dioxide fixation in the vegetative cells. After Haselkorn, 1978, from (L. E. Graham and L. W. Wilcox, *Algae*, Prentice-Hall, Upper Saddle River, N.J., 2000.) with permission from the authors and Prentice-Hall.

oxygenic photosynthesis concurrently with dinitrogen fixation (2).

Heterocysts, found in certain filamentous cyanobacteria in lakes, estuaries, and the marine high-intertidal zone (but rarely elsewhere in marine habitats), enable enhanced spatial separation of dinitrogen fixation and oxygenic photosynthesis (Fig. 10; 1). These specialized cells are often covered by thick mucilage, helping to create a low-oxygen environment. The microanaerobic condition is enhanced by respiration from aerobic bacterial colonizers, attracted by amino acids that leak from the specialized, N-enriched cells. The thick heterocyst walls provide a diffusion barrier for gases and limit oxygen entry. In addition, heterocysts have photosystem I but not photosystem II; hence, carbon fixation and oxygen production do not occur in these cells. Carbohydrates are imported from adjacent vegetative cells for respiration, needed to generate ATP and reducing equivalents. Microquantities of oxygen are scavenged by intra-heterocyst respiration, and by reaction of H_2 (produced by Nase, which also functions as a hydrogenase) with oxygen to form water.

Diazotrophic cyanobacteria are capable of using dinitrogen as their sole nitrogen source for growth. These organisms contribute most of the planktonic dinitrogen fixation in freshwaters, which represents 6 to approximately 80% of the nitrogen load in some eutrophic lakes) (53); and even when dinitrogen fixation represents a small contribution of the nitrogen loading to a lake as a whole, dinitrogen fixation is of major significance to the success of bloom-forming taxa. Most marine cyanobacterial mats that have been examined also had high dinitrogen fixation (2). Cyanobacterial dinitrogen fixation directly (via leakage of ammonia or amino acid products from cells) or indirectly (after cell death, lysis, or decomposition, and release of labile N_o and N_i) contributes a significant portion of the nitrogen budget for some freshwater rivers and lakes, the high rocky intertidal, major areas of the oceans (e.g., the Sargasso Sea), benthic mat environments, and various other aquatic habitats (1,2,28,53). Through this important metabolic process, cyanobacteria are significant suppliers of nitrogen to N-limited freshwater, estuarine, and marine communities. dinitrogen fixation also is a major factor enabling certain planktonic cyanobacteria to form noxious blooms in freshwater lakes, lower rivers, and certain estuaries (1,2); see following text). Even in the open oceans, cyanobacterial dinitrogen fixation has been increasingly recognized as important to the oceanic nitrogen cycle. For example, although filamentous *Trichodesmium* spp. have been known to be important, widely distributed dinitrogen fixers in the open oceans (29), recent research has shown that unicellular cyanobacterial dinitrogen fixation (e.g., by *Synechocystis* spp. and *Cyanothece* spp.) is widespread in the subtropical North Pacific Ocean (54).

Phosphorus

Phosphate is essential to all life, required for production of genetic information (DNA), "energy currency" molecules, ATP and ADP, and phospholipids used to form membranes. About 0.6% of cyanobacterial cells (dry-mass basis) is P, excluding polyphosphates (2). Phosphate ion PO_4^{-3}, the P form readily taken up by cyanobacteria, can be liberated from insoluble materials (e.g., hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$; strengite, $FePO_4 \cdot 2H_20$) by microbial activity, including production of organic acids and chelators, dissimilatory reduction of ferric iron, and production of sulfide (2). P can occur in other oxidation states (from +5 to −3) but, unlike N and S, it is not important in redox reactions as bacteria rapidly oxidize any reduced P under both anaerobic and aerobic conditions (2). Thus, the microbial P cycle basically consists of P_i-PO_4^{-3} uptake and its release by excretion or autolysis of P_o-phosphate, which is then mineralized by acid and alkaline phosphatases. Once released into the surrounding medium, soluble reactive phosphate (SRP, or dissolved P_i) is recycled or taken up again within seconds (25), and measured concentrations are often negligible in fresh- and marine waters. Pulses of SRP enrichment (e.g., during mixing in lakes) are luxury-consumed for storage as polyphosphate granules and subsequent use.

Many cyanobacteria have high P optima for growth in comparison to [other] algae and, when N_i is limiting, low N:P supply ratios (often considered as N_i:TP in the medium) have been reported to favor their growth in lakes, reservoirs, and lower rivers (25,55; but see 2). Although microbial mats in salt marshes and coastal marine environments are often N-limited (2), mats in those habitats that are formed in part by heterocystous cyanobacteria probably become P-limited. Such mats, when fertilized with phosphate, have significantly increased dinitrogen fixation, indicating that the benthic cyanobacteria were probably P- and N-limited as a direct (because dinitrogen fixation requires phosphate) or indirect effect (by stimulating aerobic bacteria that decreased oxygen in the mat, which would, in turn, be conducive to dinitrogen fixation) (2). Similarly, dinitrogen fixation by the pelagic cyanobacteria, *Trichodesmium* spp. in the central Atlantic Ocean can be P-limited (56).

Sulfur

Sulfur is an essential constituent of amino acids cystine and methionine, nitrogenase, thylakoid lipids, CoA, and DMSP (dimethylsulfonioproprionate, used in osmoregulation or as a cryoprotectant, see following text; 1). Uptake of sulfate is energy- (ATP)-dependent. In freshwaters, sulfate can be transformed to H_2S and, thus reduce limiting levels by anaerobic bacteria. By contrast, seawater contains abundant sulfate (28 mM), and sulfate reduction is usually important in marine coastal microbial mats. Below pH 7, H_2S (g) becomes increasingly important, whereas above pH 9, the predominant form is S^{-2}. At pH 7–9, virtually all sulfide is present as HS^-. Mat cyanobacteria coexist with sulfate-reducing bacteria, which actually occur throughout the mat layers. The cyanobacteria excrete dissolved organic compounds during fermentation and photorespiration (e.g., glycolate), which can serve as substrates for the sulfate-reducing bacteria. Thus, the metabolism of the mat cyanobacteria can directly influence sulfate reduction (2). Some mat-forming cyanobacteria can reduce elemental S_o to sulfide, using electrons produced during glycogen degradation. Sulfate reduction usually does not generate biochemical energy for cyanobacteria, but allows higher acetate production. Thus, sulfur serves as an electron sink during fermentation. An exception is *Oscillatoria limnetica* that appears to be capable of true sulfur respiration as indicated (2).

In contrast to sulfate, free sulfide (H_2S, HS^-, S^{-2}) is common in anaerobic habitats. It is highly toxic to all biological organisms, reacting with iron-containing compounds such as cytochromes and hemoproteins. It can be a potent, irreversible inhibitor of photosystem II, and of anoxygenic photosynthesis as well (2) (but note that sulfide can be used as an e^- donor by some cyanobacteria in anoxygenic photosynthesis as mentioned). H_2S enters cells by passive diffusion. In high-sulfur environments (e.g., benthic mats in some geothermal springs or coastal marine habitats), sulfide can react with S_o to form polysulfides which can be tenfold more toxic than sulfide, but which may also serve as the sulfur that is transported in cells.

Trace Metals

Trace metals are extremely important in the physiology and ecology of cyanobacteria because they are required for many essential metabolic functions (1). For example, zinc is a component of the carbon-concentrating enzyme, carbonic anhydrase, and is also a necessary constituent of alcohol dehydrogenase, glutamic dehydrogenase, and (with trace metal, copper) Cu/Zn superoxide dismutase. Copper is also needed for plastocyanin and cytochrome oxidase. Manganese is required in the oxygen-evolving complex of photosystem II (1). The key enzyme in dinitrogen fixation, nitrogenase, contains molybdenum and iron; and the key enzyme in nitrate uptake, nitrate reductase, has molybdenum and iron as cofactors. Iron is essential, as well, in ferredoxins (which serve as electron donors in dinitrogen fixation, sulfur reduction, and [indirectly] carbon dioxide fixation), cytochromes, nitrite reductase, catalase, and glutamate synthetase. Recent research additionally has shown that a protein encoded by an "iron stress-induced" gene in the open ocean cyanobacterium, *Synechocystis* PCC 6803, encodes a photosystem II-like protein that associates with phototosystem I to form a complex that significantly increases the size of the PSI light-harvesting system. The "extra" antenna formed by this PSII-like protein for PSI apparently helps compensate for depressed phycobilisome and PSI levels in response to iron limitation in open-ocean waters (57).

Given their importance in major metabolic processes, it is not surprising that trace metals sometimes play an important role in controlling phytoplankton production. For example, although iron is among the most abundant elements, its biological availability is restricted by various natural binding and loss processes. In various oligotrophic areas of the oceans (mid-Atlantic, North Pacific gyre, Southern, and Antarctic Oceans), phytoplankton production remains low despite relatively high nitrogen (nitrate), P and silicate availability, apparently because of iron

limitation (58). It has been hypothesized that large surface aggregates of *Trichodesmium* trap incoming iron in dust from atmospheric sources (59). As a more widespread mechanism that actually can control levels of biologically available iron in some aquatic systems, many cyanobacteria commonly produce potent chelators (surface iron-binding substances) called siderophores (siderochromes), which have high affinity for iron and transport iron into the cells (60).

Dissimilatory iron metabolism is important in microanaerobic environments such as cyanobacterial mats in salt marshes and benthic freshwater and marine coastal habitats (2). Within the mats, both ferric (Fe^{+3}) and ferrous iron (Fe^{+2}) can act to immobilize toxic sulfide. In many microbial mats, a layer of oxidized iron often occurs (probably produced by specialized anoxygenic phototrophic purple bacteria) between the cyanobacterial layer and the underlying anoxic layers. The iron layer is believed to form a protective barrier between the aerobic and anaerobic components of the mat: Fe^{+3} would scavenge sulfide and protect cyanobacteria from its toxic effects. Fe^{+2} would react with oxygen to maintain oxygen partial pressure low enough to allow efficient cyanobacterial photosynthesis, although also protecting the underlying purple sulfur bacteria from oxygen (2). Both Fe^{+2} and Fe^{+3} can also act as an effective UV screen because they strongly absorb UV radiation at 220 to 270 nm. Some mat-forming cyanobacteria (e.g., *Microcoleus chthonoplastes*) accumulate iron at the outer sheath. The iron is bound to negatively charged polysaccharides in the sheath, and may act to protect the organisms from UV, sulfide, and high oxygen (2).

Vertical Migration in the Water Column and Nuisance Plankton Blooms

The density of phytoplankton cells (here, including cyanobacteria in an ecological context) is generally 1.01- to 1.03-fold greater than that of water (1,000 kg/m^3); thus, they tend to sink rather than to stay afloat (61). In stratified fresh- and marine waters during periods of active phytoplankton growth, dissolved N_i and P_i often are depleted in surface waters, whereas deeper waters are more nutrient-rich from decomposition of dead organisms as they settle out of the water column. Free carbon dioxide can also increase with depth from increased activity of microbial decomposers. It would be advantageous for phytoplankton to have a mechanism that enabled them to move to the lower water column to gain access to greater nutrient supplies, then to rise back up into light-replete areas for photosynthesis (62). However, in open, deeper waters phytoplankton will not survive if they sink and remain below the euphotic zone (depth in which there is sufficient light for photosynthesis).

Within a pressure-dependable water column, cyanobacteria can regulate their buoyancy in response to environmental conditions using gas vacuoles, which are unique to prokaryotes among the phytoplankton. These structures consist of groups (stacks in hexagonal arrays) of hollow, rigid, pointed cylinders (gas vesicles) with rigid proteinaceous walls that are fully permeable to gases, but with a hydrophobic inner surface that prevents influx of water and heavier cellular constituents (62). They maintain a finite volume of metabolic gases (e.g., N_2) at ambient pressure, and their density (120 kg/m^3) is much less than that of other cellular constituents (2). Gas vacuoles are used by cyanobacteria as an efficient mechanism to provide lift because gases have much lower densities than solids or liquids. For example, Reynolds and Walsby (63) reported that at 15 °C, the volume of gas needed for neutral buoyancy in *A. circinalis* is 1.1% of the total cell volume, and found that the actual volume of gas ranged from 0.7 to 2.3% of the total cell volume. Individual gas vesicles commonly withstand external pressures of 4 to 7 atm (up to 35 atm in marine *Trichodesmium*), enabling cyanobacteria to control buoyancy through a relatively deep water column. Cyanobacteria can control buoyancy in a pressure-dependable water column by regulating the number of gas vesicles, accomplished in part by controlling the internal turgor pressure, that is, the extent to which dense components such as carbohydrates and proteins (density ca. 1600 kg/m^3 and ca. 1300 kg/m^3) accumulate (2). Intracellular osmotic pressure can increase during photosynthesis to 3.5 to 5.0 atm, which is sufficient turgor pressure to eliminate weaker vesicles. Three mechanisms have been described whereby gas-vacuolate cyanobacteria regulate their buoyancy: (*1*) by changing cell density through alterations in cellular composition, mostly by accumulation of carbohydrate reserves through photosynthesis, and their reduction either through respiration or by conversion to less dense protein; (*2*) by collapse of gas vesicles from increased turgor pressure; and (*3*) by collapse of gas vesicles due to depressed gas vesicle synthesis, and dilution of remaining gas vesicles by growth (1).

Gas vesicle production is induced by low light conditions and, therefore, when light is less than optimum, there is an increase in gas vesicles relative to other cellular products. As gas vesicles accumulate, the cell becomes less dense and floats up to a more light-replete area where its photosynthesis increases. The resulting accumulation of osmotically active sugars, with uptake of ions, increases the intracellular turgor pressure which collapses a portion of the gas vesicles, causing the cell to sink. As osmotically active substances are removed by respiration and other cell processes in deeper, darker waters, gas vacuoles reform and the cycle repeats (1,2). Buoyancy tends to increase during the dark period, and to decrease over time during the light period (63). This mechanism interacts with nutrient limitation. Buoyancy tends to decrease when major nutrients such as P_i or N_i limit cell growth because carbohydrates accumulate and turgor pressure increases (2). N_i limitation leads to reduced gas vacuolation and loss of buoyancy because of reduced protein production needed for gas vesicle assembly. Sustained C_i limitation can also lead to decreased cell buoyancy because less energy is available for gas vesicle synthesis. When nutrients are abundant, buoyancy is mostly controlled by light intensity. If light is suboptimum for growth, then the energy supply will be relatively low, carbohydrate reserves are reduced, and cell buoyancy will increase. At higher light, carbohydrate production increases, turgor pressure increases and buoyancy decreases. Marine *Trichodesmium* spp. are exceptional because their extremely strong,

membrane-bound gas vesicles enable them to remain buoyant in highly variable light fields. However, their buoyancy is controlled to some extent by carbohydrate content; thus, they sometimes occur in deep waters below the euphotic zone (64).

Thus, through regulation of gas vesicles, in dependable-pressure water columns cyanobacteria have a mechanism that enables them to sink to deeper, nutrient-replete waters late in the light period and at night, and to rise to reach light-replete (but nutrient-depauperate) waters early in the light period. Additional advantage over other phytoplankton would be afforded for N_2-fixing cyanobacteria, which are favored by low-N_i environments (indicated by low water-column TN_i:TP). The movement to deeper waters would also enable avoidance of damage from photoinhibition and high UV radiation (note that Paerl and coworkers (65) reported that natural populations of *M. aeruginosa* had optimum photosynthetic rates and resistance to photoinhibition at surface irradiances, but Ibelings and Mur (66) used techniques with finer-scale resolution and provided evidence that surface populations of *M. aeruginosa* can in fact be photoinhibited (2)). Gas-vacuolate cyanobacteria are characteristic of periodically stratified eutrophic lakes and certain other locations such as the P-rich Baltic Sea and Caribbean (Fig. 11; 67). Healthy populations are distributed near the surface, then at other locations in the water column depending on the time of day, the physiological condition of the cells, the nutrient regime, and other factors. However, rapid development and persistence of noxious, thick surface blooms and surface scums at the air–water interface is a common aesthetic and economic problem in management of eutrophic lakes. Such "blooms" often include many dying or dead cells, in conditions that are highly unfavorable for growth of cyanobacteria and other aquatic life. Consider, for example, Zohary and Pais Madeiras' (26) description of *Microcystis* surface "hyperscums" several decimeters thick, covered by a crust of photooxidized cells; the bloom had formed during prolonged periods of calm weather in wind-protected sites within a hypereutrophic lake. It extended over 1 to 2 hectares and persisted for 103 days, with concentrations of 1.76×10^9 cells/mL. The environment was anoxic and aphotic with extreme, fluctuating temperatures, and low pH. How do such surface scums occur?

Cyanobacteria buoyancy regulation depends on a dependable external pressure regime that, if variable, changes sufficiently slowly to allow the cells to adjust their internal pressure (63). If the euphotic zone extends deeper than the mixing zone (depth to which wind frequently mixes the surface waters), cyanobacteria may concentrate for part of the day below the mixed layer. If the euphotic zone extends to approximately the same depth as the mixed layer, turbulence will result in distribution of the cyanobacterial cells throughout the mixed layer. Average exposure to light will permit net production little excess photosynthetic carbohydrate reserves; the cells remain neutrally buoyant and are able to adjust buoyancy in response to changing environmental conditions. However, if the euphotic zone is shallower than the mixed layer, decreasing light intensity within the mixed layer promotes increased cyanobacterial buoyancy. Cyanobacterial surface scums often develop under such conditions during calm, warm weather following deep mixing from moderate storms when cells have become overbuoyant as a result of the (previously) low light intensity (63). Because of the sudden change in hydrological conditions, the cells are unable to lose their excess buoyancy and remain at the surface long enough to encounter excessive light intensity that inhibits the photosynthesis needed to increase turgor pressure. High light intensity can also cause photooxidation of pigments and death from UV radiation. Surface tension would help to trap them at the surface, where they would dehydrate at high temperatures. Localized oxygen depletion within the developing layer would depress turgor pressure, and aggregations, or clumping of cells would promote flotation.

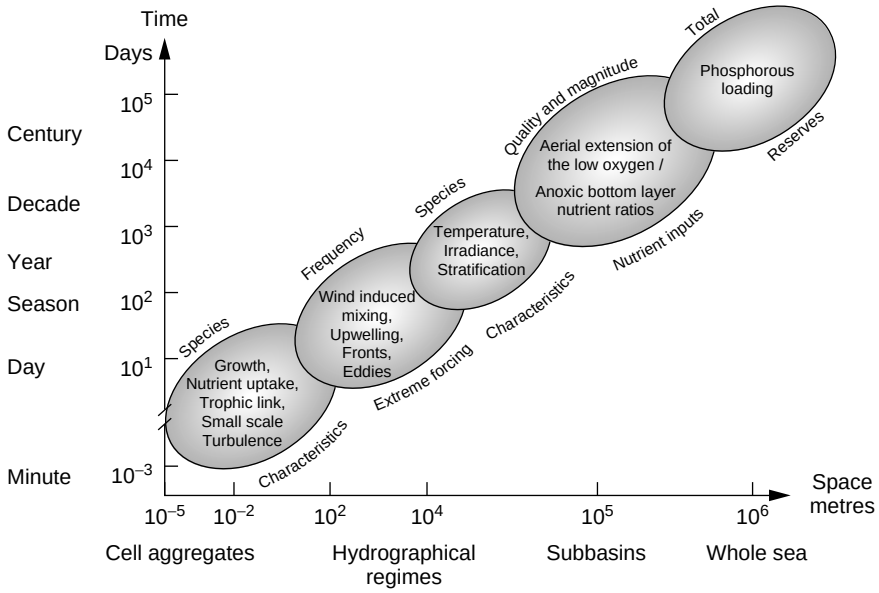

Figure 11. Depiction of the scales and time frames of processes regulating cyanobacterial blooms in the Baltic Sea. From (K. Kononen and J-. M. Leppänen, in M. Kahru and C. Brown, eds., *Monitoring Algal Blooms: New Techniques for Detecting Large-Scale Environmental Change*, Landes Bioscience, 1997, pp. 63–84) with permission from the authors and Landes Bioscience.

These factors in combination would reduce population growth and photosynthesis, and would disable buoyancy regulation. Cells at the surface that lost buoyancy would be physically impeded from sinking by the presence of the underlying, still overbuoyant population. The previously dispersed population would not have to be especially dense because it would be greatly concentrated at the surface. For example, if a population with 2×10^3 cells/mL that was dispersed through 5 m floated up to a 2-cm surface layer, its a surface density would be 5×10^5 cells/mL (2). Thus, cyanobacterial surface scums occur when conditions change too rapidly from low to high light intensity (corresponding to high turbulence, then sudden calm) so that cells cannot correct overbuoyancy; when sensescent or stressed cells cannot increase their turgor pressure; and/or when photosynthesis becomes limited by carbon dioxide diffusion through calm water (68).

BIOLOGICAL INTERACTIONS

Predators and Pathogens

Various mechanisms of grazer avoidance have been invoked in cyanobacteria including "refuge" in small size, large size, or copious mucilage; in habitat (for example, cyanobacteria that closely adhere to sand grains; or colonizers of rocks and ice); and in chemical defense (production of toxins or other bioactive antigrazer substances). All of these appear to be effective with certain grazers under some conditions; yet on a seasonal basis, grazers can significantly influence cyanobacterial populations. Grazing pressure is a major factor restricting the distribution of stromatolites and benthic cyanobacterial mats, and grazing pressure restricts cyanobacterial plankton growth in the polar oceans (2,2).

Although many microfauna and some herbivorous macroinvertebrates and fish avoid cyanobacteria, others (e.g., protozoan ciliates such as *Nassula, Frontia, Ophryoglena*; rhizopodial amoebae such as *Pelomyxa*; many rotifers) thrive in the midst of toxic blooms (e.g., *Anabaena, Aphanizomenon, Microcystis*; Fig. 12; 69) and can significantly reduce even toxic colonial cyanobacteria consisting of cells embedded in thick mucilage (2,69,70). Other zooplankton exhibit physiological and behavioral adaptations to avoid toxic cyanobacteria, including selective feeding and avoidance of depths in which toxic blooms are concentrated (also note that herbivorous carp have been reported to avoid toxic cyanobacteria (2)). Marine herbivorous copepods (e.g., *Acartia*) feed selectively, and can actively discriminate against toxic or low quality algal food. Freshwater copepods selected and consume filaments of cyanobacterium *Oscillatoria tenuis*; however, they rejected the morphologically comparable but toxic species, *Oscillatoria* (*Planktothrix*) *rubescens* (71). In some systems, calanoid copepods avoid cyanobacteria, whereas in other systems, calanoid copepods ingest cyanobacteria with wide variation in assimilation rates (72). If generalizations are possible, given the aforementioned information, reduced grazing on cyanobacteria has been associated with large size, high density, allelopathic compounds, and poor assimilability; and the extent to which grazers can control cyanobacterial blooms often depends on timing of grazing pressure during bloom development (2).

Many effects of grazing on cyanobacteria are indirect and beneficial. For example, grazing by some herbivores (e.g., the snail, *Lymnaea*, grazing benthic microalgae in an arctic lake) adds nutrient enrichment via their excreta and can favor coccoid cyanobacteria at the expense of larger eukaryote algae (73). Some colonial cyanobacteria with thick mucilage exhibit high survival following microfauna gut passage (e.g., cladoceran zooplankton, calanoid and cyclopoid copepods — hence, the cyanobacteria were referred to as "inedible"), and derive benefit from nutrient enrichment during that process. Microfaunal grazers excrete phosphatases that assist algae in phosphate acquisition, and they can also assist in dispersal (2).

Pathogens of cyanobacteria include bacteria, fungi, and viruses (cyanophages). Some aerobic gram-negative bacteria (e.g., Myxobacteriales) lyse cyanobacterial cells (*Anacystis, Coccachloris, Nostoc, Plectonema, Cyanothece*) (74). In laboratory experiments, the cyanobacteria were lysed within 2 to 10 hours (less commonly, within three days) of exposure to the pathogenic bacteria. Although little is known about the extent to which bacterial pathogens affect natural cyanobacterial populations, bacteria tested in artificial ponds were capable of eliminating a bloom of *M. aeruginosa* within two days (75). Fungi that parasitize planktonic cyanobacteria are mostly (uniflagellate) chytrids, with exception of a biflagellate (Blastocladiales) (76), and many taxa are affected including *Anabaena, Aphanizomenon, Gomphosphaeria, Lyngbya, Microcystis, Oscillatoria*, and especially *Scytonema* (2) (Fig. 12). Many of these chytrids appear to have a host range limited to a single cyanobacterial taxon; some attack a specific structure such akinetes or heterocysts (77). For example, the chytrid *Chytridium cornutus* was observed to attack only heterocysts of *Aphanizomenon*; *Blastocladiella anabaena* was observed predominantly on *A. flos-aquae* (76).

Cyanophages have been more intensively examined than other cyanobacterial pathogens because of earlier efforts (1960s–1980s), thus far unrealized, to use them as agents of biological control of noxious bloom-forming cyanobacteria. Cyanophages are lytic infectious agents that belong to three families of double-stranded DNA viruses, the genetically diverse Myoviridae, which commonly infect *Cyanothece* spp. in marine waters; and the Syloviridae and Podoiridae, which are most often isolated from freshwaters and commonly infect filamentous cyanobacteria (e.g., *Anabaena, Nostoc, Phormidium, Plectonema, Anacystis, Cyanothece* [*Synechococcus*]) (2). The myoviridaens are the most abundant cyanophages (occurring at $>10^6$/mL during warmer seasons, and at $>10^5$/gram sediment in coastal areas. For example, in a study in the Gulf of Mexico, at about 50 km from shore and about 50 m-depth there were 9.4×10^4/mL at the sediment–water interface, and 3.0×10^2/mL at 30-cm sediment depth under anaerobic conditions (2). The myoviridaen cyanophages have a turnover time ranging from hours to days in the water column, whereas in sediments they can persist for at least 100 years. In coastal

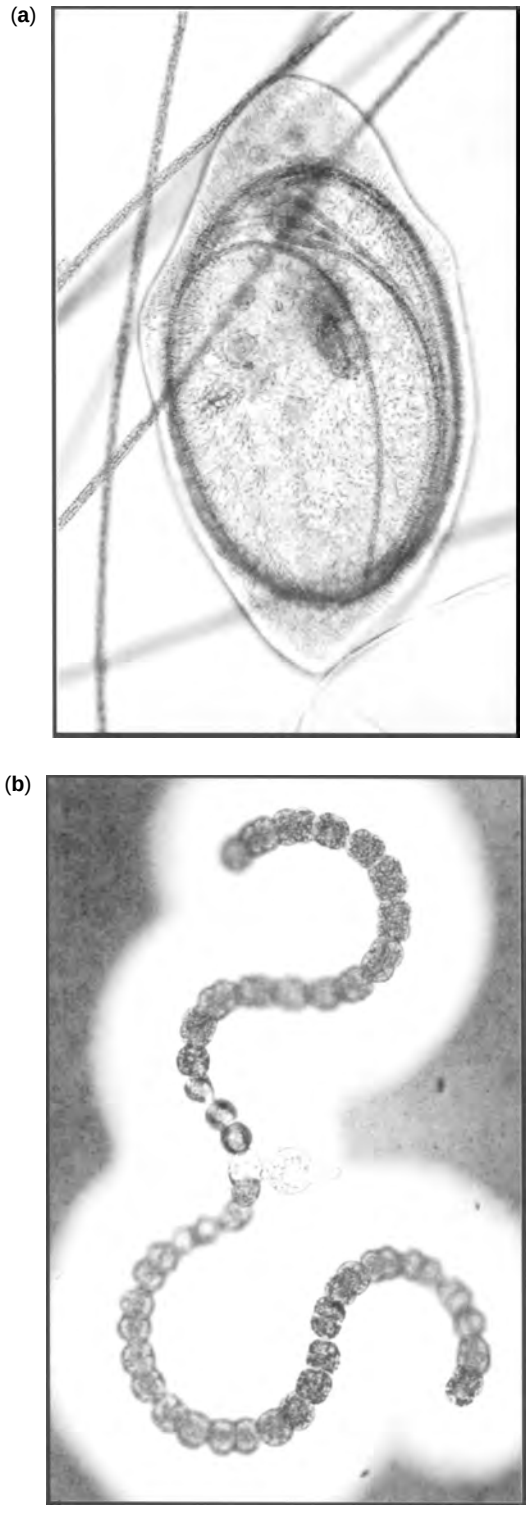

Figure 12. (**a**) The freshwater ciliate, Frontonia (420 × 234 μm), which had ingested several filaments of Oscillatoria (Planktothrix) that are coiled inside; and (**b**) The freshwater chytrid parasite, Rhizosiphon, showing its flask-shaped sporangium (24 × 12 μm) embedded in the mucilage surrounding Anabaena (white, against dark background). From (H. Canter-Lund and J. W. G. Lund, *Freshwater Algae — Their Microscopic World Explored*, Biopress, Bristol, U.K., 1995.), with permission from the authors and Biopress.

waters, high concentrations of cyanophages and *Cyanothece* result in high encounter frequencies and selection for *Cyanothece* strains that are relatively resistant to infection. Virus abundance follows that of its host, with evidence of a threshold in *Cyanothece* of about 10^3 to 10^4/mL, above which cyanophages greatly increase (2). It has been estimated that cyanophages remove approximately 3% of marine *Cyanothece* daily. By contrast, offshore *Cyanothece* populations have lower encounter frequencies and appear to have low resistance to infection. There is only one documented case thus far of a marine filamentous cyanobacterium (*Phormidium persicinum*) infected by a virus, although this phenomenon is probably more common. Freshwater cyanophages are lower in abundance (maxima > 10^3/mL), even in the most eutrophic lakes, than in productive near-shore waters.

UV-B radiation destroys cyanophages and/or depresses their infectivity, selecting for cyanobacterial communities that are more resistant to photodestruction in the summer season. Nevertheless, photoreactivation processes can restore infectivity to a major proportion of the damaged viruses (2). The physiological conditions that influence susceptibility to infection mostly remain to be examined, but there is experimental evidence that nutritional status is one important factor: All cells of P-replete marine *Synechococcus* were lysed when exposed to cyanophages, vs. only 9% lysis of P-limited *Cyanothece*. In addition to lytic infection, lysogenic associations have been shown in both unicellular and filamentous cyanobacteria, but this and other aspects of cyanophage/cyanobacterial interactions (e.g., other environmental controls on cyanophages, and physiological traits enhancing host susceptibility) remain poorly understood.

Symbiosis

Cyanobacteria form symbiotic associations with a range of eukaryote hosts including protists (microalgae, microflagellates, macroalgae), bryophytes, higher plants, fungi, sponges, ascidians (sea squirts), echuroid worms and midge larvae (2). The best understood interactions are mutualistic symbioses with terrestrial and freshwater plant hosts that are easily accessible for study. Nevertheless, cyanobacterial symbioses are widespread across terrestrial, freshwater, and marine habitats. Loose associations between cyanobacteria and other organisms are widespread and both ecologically (e.g., various N_2-fixing cyanobacterial taxa growing in close association with duckweed, *Lemna*) and economically important (e.g., epiphytic and endosymbiotic [*Azolla*-associated] N_2-fixing cyanobacteria enhancing growth and crop yield of rice (2) (Table 3). Many endosymbioses are also known from polar to tropical regions. Of these, most marine cyanobacterial symbioses occur in the plankton and benthos of nutrient-poor tropical waters. Most freshwater cyanobacterial endosymbioses are found in habitats that are enriched in some nutrients but limited by other resources that are augmented by the symbiotic interaction (78). For example, the *Azolla*/*Anabaena* association is widespread among P-rich but N-poor habitats. Similarly, unicellular cyanobionts that appear to be capable of fixing dinitrogen within the cytoplasm of certain freshwater benthic diatoms increase

Table 3. Examples of Cyanobacterial (Cyanobiont) Symbioses

Relationship/Habitat	Cyanobiont(s)	Associate or Host	N_2 Fixation
Loose Association			
Temperate freshwater epiphyte (lower epidermis, reproductive pockets)	*Nostoc, Gloeotrichia, Anabaena, Calothrix, Cylindrospermum*	Duckweed, *Lemna*	+
Temperate freshwater epiphyte	*Nostoc, Hapalosiphon, Tolypothrix*	Moss, *Sphagnum*	+
Temperate (grassland, forest)	*Nostoc*	Mosses, *Ceratodon, Funaria*	+
Tropical freshwater epiphyte (submersed roots, stems)	*Gloeotrichia pisum*	Deepwater rice, *Oryza sativa*	+
Pelagic marine epiphyte Sargasso Sea	*Calothrix*	*Sargassum*	+
Tropical/subtropical marine epizooite (cloacal cavity)	*Prochloron*	Ascidians (sea squirts), e.g., *Lissoclinum punctatum, Didemnum molle*	−
Endosymbiosis			
Temperate freshwater (soft-water lakes, marshes)	coccoid unicells	Diatoms, *Rhopalodia gibba, Denticula, Epithemia turgida*	(+); no heterocysts
Temperate freshwater (softwater, hardwater lakes and subtropical rice cultivation; dorsal leaf cavities)	*A. azollae*	Fern, *Azolla*	+
Tropical/subtropical marine pelagic	*Synochococcus Synechocystis*,	Heterotrophic dinoflagellates, *Ornithocercus magnificus, O. quadratus, Histioneis elongata, H.highleyi;*	−
Temperate marine benthic	*Oscillatoria, Spirulina, Anabaena*	Ascidians, *Pyura cancellata, P. carnea*	+ (*Anabaena*)
Temperate/subtropical marine sponges (intra- and intercellular)	*Aphanocapsa, Phormidium*, rarely *Oscillatoria*	Marine sponges (c. 40 genera)	+ (3 spp.; no heterocysts)
Pelagic north temperate/subarctic	*Richelia intracellularis*	Diatom, *Rhizosolenia*	−
Tropical/subtropical marine (in tunic cells)	*Prochloron*	Ascidian, *Lissoclinium*	
Terrestrial tropical/subtropical (mostly southern hemisphere; in coralloid roots)	*Nostoc (Calothrix)*	Cycads, e.g., *Zamia*	+
Terrestrial subtropical (in stem glands)	*Nostoc*	Angiosperm, *Gunnera*	+
Terrestrial (polar to tropics; Cyanolichens)	*Nostoc, Fischerella Calothrix, Scytonema*, various others	Fungi (usually ascomycetes), phycomycete, *Geosiphon*	+

in number in response to decreasing external N_i, but this increase does not occur under P limitation.

Although it is often unclear how the cyanobacteria in loose associations derive benefit, the other organism(s) involved typically derive nutritional advantage(s). In some loose associations (e.g., *Prochloron* in the cloacal cavity of tunicates), the cyanobacteria clearly derive nutrients from the host (2). In endosymbioses, the host may derive carbon from the cyanobionts (and N, from N_2-fixers), although the cyanobionts gain access to additional free carbon dioxide and are afforded protection from grazers, pathogens, desiccation, and other harmful external factors. The relationships probably enhance survival and growth not only of the symbionts, but of all organisms that directly or indirectly depend on them for habitat or nutrition. For example, in the tropics and subtropics, cycads containing N_2-fixing cyanobacteria in their roots can significantly contribute to the local nitrogen economy (79). The subtropical marine sponge *Chondrilla nucula,* with N_2-fixing cyanobionts, releases sufficient N_i to supply 50 to 120% of the nitrogen needed to sustain local coral reef productivity (80).

Many cyanobacterial endosymbionts are heterocystous filaments, and produce hormogonia that act as the infective agents in the hosts. These symbioses are somewhat analogous to the relationship in free-living cyanobacteria between heterocysts and adjacent vegetative cells (2). The symbionts (like heterocysts) often have negligible photosynthesis, relying on organic compounds excreted by the host for energy and growth, and thus avoiding the potential for the symbionts to inhibit dinitrogen fixation with their own oxygen evolution. All known higher plant/cyanobacterial symbioses involve heterocystous cyanobionts, and in all but one case (*Gunnera*, the only angiosperm genus with cyanobionts, found within all c. 50 spp.), the cyanobionts are extracellular (2). The cyanobionts in higher plant associations mostly are *Nostoc* spp., which especially respond to (largely unidentified)

plant chemical signals that induce hormogonia formation and attract hormogonia (with gliding motility) into the plant tissue (2). Additional signals within the plant host then repress further hormogonia formation although stimulating heterocyst development; the cyanobacteria undergo substantial morphological alterations and usually their growth rate and carbon dioxide fixation are suppressed although their dinitrogen fixation is enhanced, with much of the fixed product lost to the host (often through inhibition of the cyanobiont's glutamine synthetase activity, so that the cyanobacteria are unable to synthesize amino acids with the fixed N_i).

Cyanobionts can supply the entire nitrogen requirement of the higher plant host (2). Even in large *Gunnera* plants (leaf width, 2 m; Table 3), a *Nostoc* cyanobiont mass that is only 1% of the total plant weight can supply all of the host nitrogen needed (81). Less commonly (e.g., *Richelia intracellularis* within the diatom *Rhizosolenia*), the symbiont fixes both carbon dioxide and dinitrogen for the host (82). In symbioses where dinitrogen fixation has not been observed (e.g., in some sponges; unicellular cyanobionts or "phaeosomes" of the dinoflagellates, *Ornithocercus magnificus* and oxygen. *steinii*; *Prochloron* with the tunicate, *Didemnum molle*), the cyanobionts are photosynthetically active and transfer a portion of their fixed carbon to the host (possibly as glucose, maltose, or glycerol); or, (e.g., *Prochloron* in tunic cells of the tunicate, *Lissoclinium voeltzkowi*), the host's entire C_o requirement is met by the symbiont (2,83).

In most cases cyanobionts remain recognizable as cyanobacteria, and they can survive without the host. By contrast, freshwater cyanelles (plastids found in certain photosynthetic, unicellular, or palmelloid eukaryotes, artificial algal class Glaucocystophyceae (1)) apparently represent an extreme in cyanobacterial symbiotic relationships, wherein the symbiont has lost much of its own genetic capability and has become entirely dependent on the host (2). Cyanelles occur in genetically unrelated "Glaucocystophycean" organisms that typically are found in low density as epiphytes on filamentous algae, aquatic mosses, and submersed angiosperms. Although the endosymbionts function as chloroplasts, they still retain a peptidoglycan cell wall that is believed to be a remnant structure of free-living cyanobacterial ancestors. The cyanelles are intermediate between cyanobacteria and eukaryote chloroplasts in most features of gene organization/ sequence (79). They cannot respire because their respiratory chain lacks cytochrome carbon oxidase; they cannot fix N_2; and they contain only approximately 10% of the DNA found in free-living cyanobacteria, so that their genome is similar in size to that of chloroplasts and they have very limited genetic autonomy.

Although the cyanobacteria act as the symbionts in most of the associations, in at least one case the colonial cyanobacteria, *Nostoc parmelioides*, functions as the host and the eukaryote, the chironomid midge, *Cricotopus nostocicola*, is the endosymbiont. This mutualistic association occurs in temperate, moderately fast-flowing streams (22). The larvae inside the colony eat the *Nostoc* and are protected from predation, and *Nostoc* colonies with larvae have higher productivity than unoccupied colonies. Enhanced productivity may occur because occupied colonies grow further into the water flow, enhancing outward oxygen diffusion that would otherwise inhibit dinitrogen fixation, and promoting inward carbon dioxide diffusion for cyanobacterial growth. The larvae apparently trigger hormogonia formation, thereby promoting expansion of the colony and potentially providing habitat for later larval generations.

Toxins and Other Bioactive Substances

Toxic cyanobacterial blooms cause major economic impacts in many countries, and their lethal effects on wildlife and livestock have been reported at least since the 1870s and see the article by Falconer in this Encyclopedia. More than 40 taxa produce an array of cyanotoxins, mostly as cyclic peptides, alkaloids, and lipopolysaccharides (5) –and many other cyanobacteria probably have toxin producing (toxigenic) capability (2). Although most focus historically has been on several toxic planktonic freshwater (*A. flos-aquae*, *A. flos-aquae*, *M. aeruginosa*) and brackish (*N. spumigena*) bloom-forming taxa, recent research has shown that (*1*) many benthic and planktonic "non-bloom-forming" cyanobacteria are capable of toxin production (Table 4); (*2*) many cyanotoxin variants can be produced; and (*3*) cyanotoxins, despite their aquatic origin, generally are less toxic to aquatic biota than to terrestrial organisms including humans (2). For example, microcystin, the most potent liver carcinogen known, shows low toxicity to mussels and crayfish (2).

Most cyanotoxins appear to be secondary metabolites (2) used in defense against predation, but they may also serve other cellular functions such as nitrogen storage (1). Although little information exists on the frequency of cyanobacterial toxicity in environmental samples, the available data are compelling: for example, 44% of the cyanobacterial blooms sampled in Finnish fresh and coastal waters were potentially lethally toxic (88); and approximately 67% of the cyanobacterial blooms collected from approximately 100 freshwater locations in the United Kingdom were toxic (89). Some strains produce three or more toxins, with relative proportions influenced by environmental factors and, as true for many toxic eukaryotic algae, the factors that regulate expression of toxicity are poorly understood (90). To err on the side of caution, some specialists have advised that all cyanobacterial blooms should be regarded as potentially toxic unless shown otherwise by rigorous examination (91). Such counsel would be supported by changes in toxicity that have been documented in cyanobacteria: Toxic strains have become nontoxic (atoxigenic, apparently incapable of toxin production) but, importantly, the reverse has also occurred (2). Toxicity not only varies among strains collected from the same sample in the same bloom, but also among clones of the same isolate (2,92).

Cyanotoxins can be lethal neurotoxins or hepatotoxins, or nonlethal cytotoxins (causing damage to various types of active cells) with selective bioactivity (Table 4; 2; and see the article by Falconer in this Encyclopedia). Direct cyanotoxin poisoning of animals can occur via ingestion of cyanobacterial cells in drinking water, or indirectly via consumption of prey that had accumulated

cyanotoxins (5). Cyanotoxins can bioaccumulate in aquatic vertebrates (fish, especially the liver) and invertebrates (shellfish, especially the hepatopancreas). Cyanotoxins vary in the time required for degradation. Although some toxins degrade rapidly, microcystin and nodularin degrade slowly in living cyanobacterial cells; thus, scums that dry on lake or estuarine shores can contain high toxin concentrations for weeks to months before they are microbially degraded (5). Cyanotoxins and other bioactive substances from cyanobacterra adversely affect some

Table 4. Cyanobacteria, Their toxin(s), and Brief Description of Toxin Effects on Mammals (modified from [2-DS,5,85–88]; and see CYANOBACTERIA-TOXINS IN DRINKING WATER, this Encyclopedia)

Toxin	Taxon (Taxa)	Structure	Effects
Acutiphycin, 20,21-didehydroacutiphycin	*Oscillatoria acutissima*	Macrolides	Cytotoxic to tissue cells; but also has antitumor properties (lung carcinoma)
Anatoxin-A	*Anabaena flos-aquae, A. lemmermanni, A. planktonica, Anabaena* spp., *Cylindrospermum* sp.	Secondary amine alkaloid (MW 165) (nicotinic [cholinergic] agonist; structural analog to cocaine and neurotransmitter acetylcholamine)	Neurotoxin — neuromuscular blocking agent; binds to neuronal nicotinic acetylcholine receptors; causes an influx of Na^+, with sufficient local depolarization to open voltage-sensitive Ca^{+2}, Na^+ channels, blocking further electrical transmission; can lead to convulsions, paralysis, asphyxiation, and death by respiratory failure in mammals (e.g., livestock, wildlife, dogs). Chronic reproductive impacts shown in mice (fetus malformation).
Anatoxin-A(S)	*Anabaena flos-aquae, A. lemmermanni,*	N-hydroxy guanidine methylphosphate ester (naturally occurring organophosphate)	Neurotoxin-acetylcholinesterase inhibitor; causes similar symptoms as anatoxin-A, additionally with ataxia, diarrhea, hypersalivation, tremors.
Aphantoxin AphantoxinII	*Aphanizomenon flos-aquae*[a] *Aphanizomenon flos-aquae*[a]	Alkaloid (MW 315; neosaxitoxin) Alkaloid (MW299 — closely resembles saxitoxin)	Neurotoxins–interfere with neurotransmission (block neurone Na^+ channels across axon membrane); cause irregular breathing, twitching, loss of coordination, death by respiratory failure.
Aplysiatoxins, Debromoaplysiatoxin	*Lyngbya majuscula*,[b] *Schizothrix calcicola, Oscillatoria nigroveridis*	Alkaloids, phenols	Neurotoxins if ingested; dermatotoxins if contacted by skin; potent animal skin tumor promoters; potent tumor promoter if ingested (induces differentiation of promyelocytic leukemia cells, aggregation of lymphoblastoid cells, and stimulation of prostaglandin production and choline turnover); activate Ca^{+2}-activated, phospholipid-dependent protein kinase C to cause contraction of smooth muscle; also cause swimmer's itch (skin irritation, erythema, blisters, deep desquamation).
Ciguateratoxinc[c]	*Trichodesmium erythraeum*	Polyethers	Neurotoxins–open Na^+ channels at resting potential; prevent open channels from being inactivated during subsequent depolarization. Replace Ca^{+2} ions at sites on neuroreceptors that control sodium permeability. Can cause Ca^{+2}-dependent contraction in smooth and skeletal muscle tissues; can promote release of norepinephrine, dopamine from pheochromocytoma cells. Immunogenic after coupling to serum protein.
Cyanobacterin	*Scytonema hofmanni*	Chlorinated diaryl-lactone	Cytotoxin-cyanobacterial inhibitor
Cyanoginosins	*Microcystis aeruginosa*	Heptapeptides (MW 909-1044)	Cytotoxic hepatotoxins

Table 4. (*Continued*)

Toxin	Taxon (Taxa)	Structure	Effects
Cyanoviridin	*Microcystis* taxa of uncertain status (*M. botrys, M. viridis*)	Hepatopeptide (MW 1039)	Cytotoxic hepatotoxin.
Cylindrospermopsin	*Aphanizomenon ovalisporum, Cylindrospermopsis raciborskii, Umezakia natans*	Cyclic guanidine alkaloid (MW 415)	Cytotoxic renal and hepatotoxin; inhibits glutathion synthesis and protein synthesis; causes widespread and progressive (sometimes partially delayed) tissue injury, with cell necrosis in liver, kidneys, adrenals, lung, heart, spleen and thymus (mice). Cause of acute hepatoenteritis and renal damage among an Aboriginal population (Australia).
Demethoxy-cylindrospermopsin	*Cylindrospermopsis raciborskii*	Cyclic guanidine alkaloid	Cytotoxic renal and hepatotoxin.
Endotoxins	*Anacystis nidulans Cyanothece [Synechococcus] nägelli*	Lipopolysaccharides Galactoparanosyllipid	Cytotoxin–pyrogenic (fever-causing) agent; contact irritant, allergen and gastrointestinal irritant in humans (can be lethal to mice).
Hapalindole A	*Hapalosiphon fontinalis*	Substituted indole alkaloid	Lipophilic cytotoxin, inhibitory to algae, fungi.
Homoanatoxins	*Oscillatoria acutissima, O. formosa (Phormidium formosum)*	Secondary amine alkaloids (methylene-anatoxin-A)	Neuromuscular blocking agent, similar to anatoxin-A.
Hormothamnin A	*Hormothamnion enteromorphoides*	Cyclic undecapeptide	Cytotoxic hepatotoxin.
Laxatoxin	*Anabaena laxa*	Cyclic peptides (A, MW 1350-1400; B, MW 1150-1290)	Cytotoxic hepatotoxins.
Lyngbyatoxin	*Lyngbya majuscula*	Alkaloids	Similar activity as aplysiatoxins (e.g., Lyngbyatoxin-A).
Microcystins[d]	*Anabaena flos-aquae, A. circinalis, A. lemmermanii*, other *Anabaena* spp., *Anabaenopsis milleri, Hapalosiphon hibernicus*,[e] *Microcystis aeruginosa, Microcystis* spp. of uncertain affinity *(M. botryis, M. viridis), Nostoc rivulare, Nostoc* sp., *Oscillatoria limosa, O. aghardii/rubescens* group[e]	Heptapeptides (MW 994-1044)	Hepatotoxins (lipophilic); irreversible inhibitors of types 1 and 2A serine protein phosphatases in the liver; potent tumor promoters; cause diarrhea, pallor mucus membranes, vomiting, weakness; death from intrahepatic hemorrhage (microcystin-LR = most potent liver carcinogen known; also affects kidneys, lungs). Chronic reproductive impacts indicated (10% of young mice tested with hippocampal injury and reduced brain size); cause dose-related increase in chromosomal breakage (human lymphocytes).
Nodularin	*Nodularia spumigena*	Pentapeptide (MW 824)	Neurotoxin, hepatotoxin — promotes perchronic neurotoxicoese, gastrointestinal disturbances, cutaneous or respiratory irritation; active liver injury. Potent tumor promotor (liver, bronchogenic, abdominal carcinomas; uterine adenocarcinomas; thoracic lymphosarcomas); strong inhibitor of 1,2A protein phosphatases. Similar to microcystin in both acute and chronic effects; can be as potent as microcystins in causing liver pathology.
Saxitoxins[f]	*Anabaena circinalis, Cylindrospermum raciborskii, Lyngbya wollei, Oscillatoria* sp.	Purine alkaloids	Neurotoxins — bind specifically to the voltage-sensitive Na^+ channel; block Na^+ ion influx in neurons and action potential of cardiac muscle.

(*continued overleaf*)

Table 4. (*Continued*)

Toxin	Taxon (Taxa)	Structure	Effects
			No reports of human health effects from ingestion of drinking water containing cyanobacteria with saxitoxins. Sheep died after ingesting water laden with a bloom of saxitoxin-containing *Anabaena circinalis*.
Scytophycin	*Scytonema pseudohofmanni*	Methylformamide A (MW 821)	Lipophilic cytotoxin (e.g., against human epidermoid carcinoma, mouse fibroblasts); active against intraperitoneally implanted lymphocytic leukemia, lung carcinoma
Tubercidin	*Tolypothrix byssoidea*	Pyrrolopyrimidine	Cytotoxin.
Unidentified, volatile sulfur compounds	*Microcystis aeruginosa, M. wesenbergii*	—	Cytotoxins.
Uncharacterized neurotoxin	*Pseudanabaena catenata*	—	Causes violent convulsions when injected intraperitoneally in mice.
Polybrominated secondary metabolites (2-A)	*Oscillatoria spongelia* (in marine sponage *Dysidea herbacea*)	—	Inhibitory to a range of gram-positive and gram-negative bacteria; deter feeding by generalist fishes.
Uncharacterized cytotoxins	**Anabaena hassalii,* **A. spiroides*. var. *contracta,* **A. variabilis,* **Coelosphaerium kuetzingianum, F. muscicola* ('Fischerellin'), *Gloeotrichia echinulata,* **Gomphosphaeria lacustris,* **G. nägeliana, Nostoc linckia,* **N. paludosum, N. zetterstedtii, Scytonema mirabile*	—	Some with anti-microbial properties (e.g. lethal to protozoans, ostracods, and other potential grazers). Taxa with an asterisk (*) indicate field cases of intoxications.

[a] *Aphanizomenon flos-aquae* toxicity recently has been questioned by Carmichael (87). AphantoxinII closely resembles saxitoxin.

[b] *Lyngbya majuscula* sometimes grows epiphytically on edible algae in Indonesia and the Philippines.

[c] The information on effects of ciguatoxins is mostly from research on the ciguatoxins of dinoflagellates. Ciguatoxins have also been experimentally shown to cause peripheral nervous system damage; stimulate hormone and neurotransmitter release; activate protein kinases; and cause joint pain, miosis, erethism, cyansis, prostration, nausea, vomiting, diarrhea, low blood pressure, bradycardia (85).

[d] Also known as *Planktothrix agardhii, P. mougeotii, P. rubescens*.

[e] More than 60 variants (analogs) of microcystin have been characterized, differing mostly in the type of L-amino acid present; and in the presence/absence of a methyl group on one of the D-amino acids, or on a dehydroamino acid, or both. The basic difference between hepatotoxic and nontoxic *M. aeruginosa* (PCC7806) is the presence of one or more genes encoding for microcystin synthetases. Microcystins act similarly as another group of cyclic peptides, the hepatotoxic heptapeptides called phallotoxins (e.g., phalloidin) of the mushroom *Amanita phalloides*, the green death cap. Microcystin-LR, the best known analog, does not readily cross cell membranes and, therefore, does not enter most tissues. After oral uptake, it is transported across the ileum into the bloodstream through a bile acid-type transporter, and becomes rapidly localized in the liver via active uptake by hepatocytes. Resulting severe liver damage is characterized by disruption of liver cell structure, a loss of sinusoidal structure, increased liver weight from intrahepatic hemorrhage, hemodynamic shock, heart failure, and death. Intranasal installation of microcystin-LR in mice resulted in extensive necrosis of the epithelium of the nasal mucosa of both the olfactory and respiratory zones, progressing to destruction of large areas of tissue down to levels of deep blood vessels. Cumulative liver damage was demonstrated with repeated sublethal dosing. Microcystins and nodularin are regarded as tumor promoters because of their potent inhibition of protein phosphatase, and act similarly (and with similar potency) to other tumor promoting toxins such as okadaic acid, tautomycin, and calyculin (2-DS,85).

[f] Saxitoxins from dinoflagellates that accumulate in shellfish seafood have caused irregular breathing, twitching, and loss of coordination in humans, and death by respiratory failure. These toxins can cause peripheral and central nervous sysstem dysfunction. Eighteen saxitoxins are represented in the cyanobacteria, with neosaxitoxin considered separately as Aphantoxin (5).

microorganisms (e.g., some zooplankton), but not others. In the open oceans, *Trichodesmium* blooms have been linked to death of fish, oysters, and crabs, and tuna have shown bloom avoidance behavior (2).

Fish that are injected or force-fed cyanotoxins develop similar symptoms as laboratory mammals (Table 4), but natural routes of exposure should be considered to evaluate the potential for impacts. Immersion into toxic cyanobacterial blooms adversely affected some fish in experimental tests, but with high variability among fish species in sensitivity. Impacts have included damage to liver, heart, kidney, gills, skin, and spleen (5). Dead fish collected from senescing/dying cyanobacterial blooms had significant damage of the gills (perhaps from the high pH caused by cyanobacterial photosynthesis, and because of high ammonia from cyanobacterial decomposition), digestive tract, and liver (93). Gill damage would enhance microcystin uptake and subsequent

liver necrosis. European carp (*Cyprinus carpio*) that were exposed to microcystins under natural conditions developed atrophy of hepatocytes, gills with pinpoint necrosis, epithelial ballooning, folded lamellar tips, exfoliation of lamellar epithelium, and elevated aspartate aminotransferase activity and serum bilirubin levels –all consistent with impaired hepatocyte function (94). In coastal British Columbia and Washington state (U.S.A.), net-pen-reared Atlantic salmon smolts (*Salmo salar*) that were exposed to microcystin (probably as a feed contaminant) developed liver degeneration ("Net Pen Liver Disease"), which caused major economic loss to mariculture (5,87). Recent research has also confirmed that *M. aeruginosa* microcystin-LR can cause mass mortality of cultured catfish, the largest component of pond-based aquaculture in the United States, through feeding on planktonic diets or passive assimilation through the gills (95).

Human exposure to cyanotoxins has occurred via consumption of finfish, shellfish, or other animals that had bioaccumulated the toxins (e.g., shellfish–nodularin, saxitoxins) (5). Because the cyclic peptide and alkaloid toxins of most potential concern mostly accumulate in animal viscera, to err on the side of caution, viscera should not be consumed. More frequently, humans are exposed to toxic blooms via direct contact, ingestion, or aerosol inhalation has promoted acute, noncumulative health effects including eye and ear irritation, mouth ulcers, nausea, vomiting, diarrhea, fever, cold or flu symptoms and fever (96). These impacts, although causing discomfort, have not been associated with serious health outcomes to date. In lakes affected by cyanobacterial blooms, water-contact sports involving submersion of the head (e.g., diving) or aerosol inhalation (e.g., water skiing), inhalation and resorption through nasal and pharyngeal mucous membranes can present a high risk of exposure. A density of 20,000 *Microcystis* cells/mL (corresponding to 10 μg chlorophyll *a*/L) can contain 2 to 4 (<10) μg microcystins/L (5). This level is close to the WHO provisional drinking water guideline value of 1 μg microcystin-LR/L, intended to be safe for life-long consumption (97). Thus, serious outcomes from such exposure during water sports would be unlikely.

However, to err on the side of caution, recreationists should avoid waters with obvious discoloration potentially indicating high cyanobacterial concentrations. Cyanobacterial blooms can reach maximal densities of millions and, in extreme cases, billions of cells/mL (26). A density of 100,000 toxic *Microcystis* cells/mL (c. 50 μg chlorophyll *a*/L) was recommended (5) as a guideline for a moderate health alert in recreational waters would be expected to contain up to 50 μg microcystin/L. Twice that amount or more (up to 200–400 μg microcystin/L) would be probable if toxic *Oscillatoria agardhii* was present rather than *Microcystis* (5) (Table 4). A 15-kg child who consumed 250 mL of water during extensive play could be exposed to 10-fold more toxin than the recommended tolerable daily intake for human health protection (94). Moreover, *Microcystis* and certain other planktonic, toxic cyanobacteria commonly form thick surface deposits or scums, where densities can be up to a million-fold higher than in water-column suspensions — significantly increasing the risk of high toxin exposure. A large body of evidence exists for potentially severe health hazards from human exposure to toxic cyanobacterial scums, which can contain up to 24 mg microcystin/L (5). Given that the oral LD_{50} (dose at which half of the test mice die) of microcystin-LR in mice is 5,000–11,600 μg toxin/kg body weight, ingestion of ≤2 mg of microcystin by a 10-kg child could cause liver injury (5). Thus, ingestion of only a small amount of scum during recreational activities would be required. Fortunately, no human fatalities have been unequivocally associated with (low-volume) oral ingestion of scum, although many animals have been killed by drinking (larger quantity of) scum-laden water. Moving from lakes to marine shores, some marine beaches have been associated with incidents of severe human dermatitis from benthic-mat cyanobacteria (*L. majuscula*, also *Schizothrix, Oscillatoria* spp.) following storms that dislodged clumps of the mats into the water (2,5).

Information is generally lacking in most countries (including the United States) to evaluate the extent to which chronic human illness may occur from cyanotoxin exposure, because microcystins are not measured or considered in most guidelines for potable drinking water (see CYANOBACTERIA-TOXINS IN DRINKING WATER, in this Encyclopedia). Thus, most nations have not set limits or guidelines for cyanotoxin exposure (exceptions–Australia; in the United States, Oregon (5)). The World Health Organization [WHO] has recommended a limit of 1 μg microcystin-LR/L drinking water (as total cell-bound + extracellular microcystins) to protect public health (97). Supporting animal and human toxicity data are incomplete for most cyanotoxins with exception of microcystin-LR; thus, the WHO limit was based on information available for that toxin, as a provisional guideline to be adjusted as additional data may become available.

Recorded cases of human gastrointestinal and hepatic illness linked to cyanobacterial toxin exposure via potable water supplies have occurred during natural or copper sulfide treatment–induced dissipation of a bloom with extensive cell lysis that released cyanotoxins (e.g., United States, towns along the Ohio River, 1931; Zimbabwe, city that used a cyanobacteria-laden reservoir for potable supplies, 1966). In Australia (1979) after exposure to toxin from *Cylindrospermum raciborskii* in a water supply reservoir, 140 aboriginal children and 10 adults suffered from diarrhea, severe kidney damage and liver damage; approximately 70% of the patients required intravenous therapy and more severe cases went into hypovolaemic/acidotic shock, but all recovered with treatment (5). In China (mid-1990s), chronic liver disease in certain villages (including cancer, related to liver tumor–promoting microcystins; Table 4) was related to chronic exposure to toxic cyanobacteria (5). Epidemiological evidence suggested (but without definitive proof) that in those villages, microcystins from poor drinking water supplies acted with hepatitis B virus to promote liver cancer (see CYANOBACTERIA-TOXINS IN DRINKING WATER, in this Encyclopedia for additional information). Cyanobacterial toxins, like other toxins, most severely impact people who are innately more susceptible

such as children, the elderly, and immunocompromised people of all ages. A total of 88 deaths, mostly children, occurred during a severe gastroenteritis epidemic (Brazil, late 1980s), related to microcystin exposure in drinking water from a reservoir with a dense *Microcystis*/*Anabaena* bloom. Also, in Brazil (mid-1990s), "Caruaru syndrome" was the name given to the symptoms of severe hepatitis that were sustained by 117 patients on hemodialysis treatment, which would have represented "worst-case" or extreme toxin exposure. Of these, 100 patients developed acute liver failure and 49 died. The patients had received microcystin, concentrated through the treatment process, from a water supply containing a dense *M. aeruginosa* bloom (5).

Thus, various studies of human populations have yielded epidemiological evidence relating adverse health impacts to the presence of cyanotoxins in recreational or drinking waters. However, with rare exceptions, these studies have been retrospective and lack complete epidemiological data, especially regarding exposure (cyanobacterial taxa, densities, duration/frequency of exposure, etc. (2)). Although acute exposure can cause death from liver hemorrhage or liver failure, such incidents fortunately can be minimized by avoiding use of water with noticeable cyanobacterial blooms as potable supplies (see CYANOBACTERIA-TOXINS IN DRINKING WATER, in this Encyclopedia). In contrast, risk of long-term exposure to relatively low concentrations of cyanotoxins (especially cyclic peptides, which can promote malignant tumors) in drinking water is more difficult to avoid, because treatment procedures in many water supply plants do not remove these toxins, and also because there would be no noticeable discoloration.

Other bioactive substances produced by cyanobacteria (*Anabaena, Aphannizomenon, Lyngbya, Microcystis, Nostoc, Oscillatoria, Phormidium, Schizothrix, Symploca*) cause serious taste-and-odor problems for water supply plants (5). These compounds emit "earthy" or "musty" odors, especially geosmin (*trans*-1,10-dimethyl-*trans*-2-decalol) and 2-methyl isoborneol, which sensitive people can detect at levels as low as 10 ng/L (5).

Much has been published on adverse effects of cyanotoxins, but considerably less on their value. Cyanobacteria produce many bioactive substances with potential anticarcinogen activity and other medicinal value (85). This aspect of cyanobacterial research has, as yet, received relatively little attention but is gaining in general interest. Certain cyanobacteria (e.g., *Spirulina platensis , S. maxima*) consistently have not been found to be toxic and are mass-cultured for their high-protein content. Thus, they have been economically important to the aquaculture industry in some countries (92). *Spirulina* contains 60 to 70% protein and 50% nucleic acid (dry weight basis). In addition to its high nutritional quality; it has also been used as a diet pill; a few grams taken 30 to 60 minutes before meals causes marked reduction in appetite.

FUTURE DIRECTIONS

With many bacteria-like features, but with the universal plant pigment and higher plant photosynthetic biochemistry, these "primitive," complex organisms provide an excellent illustration of the adage, "Nature mocks at human categories." Their taxonomy has been in disarray for the past approximately 30 years, with various revisions of the historic botanically named species co-occurring with bacterial designations throughout the botanical, bacteriological, general microbiological, and medical literature. Because pure cultures and strain numbers are not yet available for many of the [former] botanically designated species (in part because of culturing difficulties), this confusing mix of taxonomic schemes will continue to characterize the field for some time. Bacteriological naming procedures depend upon such pure cultures, but from ecological, physiological, biochemical, genetic (e.g., polyploidy, gene loss), and even morphological perspectives, extreme caution is warranted because many microorganisms, including the cyanobacteria, have been shown to significantly change when cultured long-term (months to years). Long-term reference cultures frequently become highly aberrant over time in culture (9). It is recommended that cyanobacterial researchers take the necessary steps to determine whether "reference" cultures have significantly changed over time in traits of interest. Otherwise, findings and conclusions about these organisms in many important research areas will probably drift increasingly far from the realities exhibited by natural populations.

Although intensive research has been conducted on the physiology and ecology of benthic mat- and bloom-forming cyanobacteria, major questions remain to be resolved about these and other cyanobacterial communities. As examples, cyanobacteria produce many anticarcinogenic and other potentially beneficial compounds, and research is needed to improve techniques for isolating these substances and harnessing their medicinal value. In summarizing his excellent review on cyanobacterial symbioses, Adams (2) expressed that many symbiotic associations probably remain to be discovered. The identity of many host chemical signals and of the genes they regulate in cyanobionts are presently unknown, but molecular techniques are rapidly advancing insights that could yield substantial benefit — for instance, an understanding of the regulatory systems involved in establishment and maintenance of plant/cyanobacterial symbioses may enable enhancement of existing symbioses, or of establishing novel associations with agriculturally important plants to increase yield (2). Given increased recognition of the importance of cyanobacteria in the world's oceans and lakes, the significance of lysogeny in cyanophages merits additional research (2). Although the movement of cyanobacterial DNA by viruses (transduction) has not yet been demonstrated, there is evidence that lysogenic cyanophages integrate into the host genome. Lysogenic cyanophages may be important as vectors of genetic information within cyanobacterial communities.

Noxious, bloom-forming cyanobacteria in lakes and certain brackish waters produce among the most potent toxins known, adversely affect a range of aquatic organisms and terrestrial mammals including humans. Their ecological impacts will probably increase via stimulation of toxic cyanobacterial taxa by nutrient pollution,

which is increasing in many countries (84). Examples of successful management of noxious cyanobacterial blooms that have already formed are rare, and historic strategies (e.g., application of copper sulfate or other killing agents) does not eliminate the organisms because some are able to form resistant structures, representing an inoculum for the next bloom. At the same time, application of copper sulfate or other pesticides can cause lysis of the biomass, leading to higher risk for health impacts to humans and other affected organisms from the toxins that are released (5). Major questions remain as well about the toxins themselves, including synthesis pathways, environmental factors controlling toxicity, and the full range of chronic and acute effects.

Cyanobacteria have been among the most successful organisms on earth over geologic time, and present-day species are both widespread and of major ecological and economic importance. Strengthened understanding of genetic and environmental controls on their growth, survival, and bioactive substance production will continue to yield information of benefit to humans with applications ranging from environmental management, to crop yield, to improved medical treatment and protection of public health.

CYANOBACTERIA-TOXINS IN DRINKING WATER

IAN R. FALCONER
University of Adelaide
Adelaide, Australia

The safety of drinking water is of paramount concern to the community. The presence of any known toxic compound in water for human consumption has to be regarded as a potential hazard to health. Although deaths of farm livestock caused by consuming toxic cyanobacteria in their drinking water were well described in 1878 (1), the implications of these organisms for the health of the human population are still being evaluated (2). Outbreaks of gastroenteritis among consumers of particular water supplies have been attributed to cyanobacterial toxins in the supply in the United States, South America, Europe, and Australia (3). The most severe cases of poisoning by cyanobacterial toxins in water occurred in dialysis patients in Brazil, who were exposed to the toxins in the dialysis fluid, as a result of which more than 50 people died (4,5).

The chemistry and toxicology of the active compounds from cyanobacteria have been investigated and the toxins include neurotoxins, hepatotoxins and widely cytotoxic compounds. As cyanobacteria are gram-negative organisms they also produce lipopolysaccharide endotoxins, about which relatively little is known. Allergic reactions to cyanobacteria are relatively common, but have only been identified from the colored photosynthetic protein phycocyanin (6). There is increasing evidence to prove that some cyanobacterial toxins can initiate or increase the growth of cancer (2).

The production of toxins occurs in a range of cyanobacterial genera, which are distributed worldwide. Drinking water supply reservoirs in many parts of the world are increasingly affected by water blooms of toxic cyanobacteria as the availability of nutrients to the organisms rises. This has resulted from intensive agriculture, population increase, urban growth, and water reuse, which are characteristic of present-day human society.

As a result of the increasing risk of injury to health from cyanobacterial toxins, the World Health Organization (WHO) has determined a safe Guideline Value (GV) in drinking water for one of the most common toxins (microcystin-LR) and is considering GV for several other toxins. The water supply industry has already evaluated treatment options for removal of these toxins, and more advanced water treatment plants can now reduce the concentrations to below the GV (3). Simple chlorination and flocculation treatment has not been effective in removing cyanobacterial toxins from drinking water (7,8).

Epidemiological studies of the effect of low concentrations of cyanobacterial toxins in drinking water supplies on human health have only recently begun (9). This area of research is vital if the evidence from animal experiments of potential human health risks from cyanobacterial toxins is to be evaluated and the data applied to the provision of safe water supplies.

THE CYANOBACTERIA

Fossil evidence suggests that cyanobacteria were among the earliest life-forms on the planet as the cyanobacterial colonies known as *stromatolites* can be found in rocks from over 3,000 million years ago to the present day (10).

These prokaryotic microorganisms possess chlorophyll-a. They carry out oxygen-liberating photosynthesis with photosystems I and II in a manner similar to eukaryotic plants (11). Their distinctive colors, which range from blue-green through green, yellow, and orange to red, are due to varying amounts of accessory photosynthetic pigments. These carotenoids, phycocyanins, and phycoerythrins assist in light trapping under the low light conditions that occur in deep or turbid water (12).

Cyanobacteria are morphologically a very diverse group, growing as single cells, chains of cells, three-dimensional arrays of cells, and single or stacked filaments, with or without a sheath surrounding the cells. Their tolerance of temperature extends from hot springs to under the Antarctic ice, with habitats from desert rocks to the sea (13). As sources of toxins in drinking water, the planktonic species that float freely in water are the most significant, although benthic species attached to sediments or submerged rocks may be equally toxic.

Cyanobacteria multiply in reservoirs, lakes, and slow-flowing rivers during the summer period of warmer surface water and temperature stratification of the water column. Stratification reduces the vertical movement of water owing to the colder, denser water remaining in the deeper levels of a lake. Due to less oxygenation these levels become anaerobic, with liberation of nutrients from the sediments. The phytoplanktons of a lake include eukaryotic and prokaryotic microorganisms. Their relative abundance will depend on competitive interactions. The toxic cyanobacteria compete most effectively through their regulation of buoyancy, which enables them to move up and down in the water, optimizing energy harvesting in the shallower layers and then sinking into the nutrient-rich deeper water to replenish phosphate reserves (14).

This capability for vertical movement is a consequence of the possession of gas vacuoles by many cyanobacterial species. The balance between sinking and rising is dependant on the carbohydrate status of the cells, counterbalancing the low density of the gas vacuoles. Thus during the day, starch will accumulate to the point that the cells sink, followed by nutrient uptake from the colder higher nutrient layers below during the night. Cell growth and division utilize the carbohydrate reserve, lowering cell density and allowing the cells to rise again (14).

Many species of cyanobacteria have heterocysts, which are specialist nitrogen-fixing cells. This enables them to compete effectively with eukaryotic green algae when water nitrate or ammonia is low (14).

Thus, during the summer when the warm surface layers of water are often depleted of nutrients, cyanobacterial growth can overtake the competing eukaryotic algae to the extent of forming water blooms. These are named from the brightly colored surface scums, which may form during the night in calm weather. Cell concentration in a water body overall may only be 20,000 cells/ml, which is just sufficient to see a greenish or reddish stain in the water. Cells rising to the surface become trapped, and cell concentration may reach greater than 1,000,000 cells/ml. Once formed, these scums accumulate in bays and shallow shorelines and may persist for weeks or months. Cyanobacterial scums are often of toxic species and present a particular risk to both domestic animals and human water users (15). This is discussed later in the article.

The public perception of cyanobacteria — blue-green algae as they are popularly called — is largely a consequence of the increasing frequency of scums in recreational waters and drinking water reservoirs. This increase in scums is a direct consequence of the increase in nutrient availability in freshwater, particularly of phosphorus and nitrate. Use of phosphatic fertilizer in crop production increases the leaching of phosphorus into rivers, and soil erosion in drier countries accentuates this process. Intensive animal production leads to large quantities of fecal material that is returned to the fields from piggeries, feedlots, dairy, and poultry units, which in wet weather increases the nutrient loads entering waterways. Added to this are nutrients from sewage processing plants

that are major components of the eutrophication of waterways. It is estimated that 53% of European lakes and 48% of North American lakes are now eutrophic, often with cyanobacterial dominance (16). In more advanced countries, removal of phosphate from sewage and remediation of lakes are increasingly carried out, coupled (in Canada, for example) with the mandatory domestic sale of phosphate-free detergents. However, reversal of the increased incidence of cyanobacterial scums is not quick because of the continued resolubilization of phosphate from sediments (14).

TOXIC SPECIES AND GENERA

The relationship between toxicity and the classification of the cyanobacteria provides a general guide to the potentially hazardous species, with many fascinating anomalies. For the purpose of water supply authorities, the frequency of toxic water blooms among the total of blooms is sufficient for all blooms to be regarded as potentially poisonous. For example, in Finnish waters, 44% of blooms were lethally toxic under the test conditions and hepatotoxic blooms were twice as common as neurotoxic blooms (17). Subsequent development of sensitive chemical and immunological tests has raised that percentage to 72% of 533 samples from Germany containing hepatotoxins alone (18).

A list of toxic cyanobacteria in fresh water that have been identified so far comprises approximately 20 species from ten genera (19). These were initially classified according to morphological criteria, with considerable success (20). More recently, molecular genetic techniques have largely confirmed the morphological taxonomy (21,22). Toxic cyanobacteria have a worldwide distribution, and the lack of records from a particular country indicates a lack of data, rather than the absence of cyanobacteria. Examples of identified toxic cyanobacteria in different countries, chosen to show diversity of location and toxins, are given in Table 1.

The most abundant toxic species with a worldwide distribution is a colonial spherical-celled organism named *Microcystis aeruginosa*. Figure 1a illustrates this species, from a sample taken from an Australian river (the Hawkesbury), used for water supply and for recreation. There are three related species in the genus that are also toxic, *M. viridis*, *M. wesenbergii*, and *M. botrys*. These cyanobacteria produce a family of cyclic peptide toxins named microcystins, which are discussed in detail later (19). The cells of this genera form approximately spherical aggregates of cells surrounded with mucilage, 2–3 mm in diameter. They can be clearly seen by the naked eye in water samples. The cells contain gas vacuoles and at night they can form floating scums under suitable warm, calm weather conditions, which collect on downwind shores. In water supply dams, scums of this and other species are frequently seen near the main dam wall, close to the off-take, during a bloom. Scums also accumulate in pools upstream of weirs, which are the site of water intakes (Fig. 2).

Table 1. Examples of the Worldwide Distribution of Toxic Cyanobacteria, the Species or Genera Involved, and Their Toxins

Location of Toxic Cyanobacteria	Genera or Species Reported	Toxins	Reference
Australia	*Anabaena circinalis*	Saxitoxins	24
	Microcystis aeruginosa	Microcystins	25
	Cylindrospermopsis raciborskii	Cylindrospermopsin	26,27
	Nodularia spumigena	Nodularin	28
Brazil	*Microcystis aeruginosa*	Microcystins	29
	Aphanocapsa cumulus	Microcystins	30
Canada	*Microcystis aeruginosa*	Microcystins	31
China	*Microcystis aeruginosa*	Microcystins	32
Denmark	*Microcystis aeruginosa*	Microcystins	33
	Planktothrix agardhii	Microcystins	33
Finland	*Nodularia spumigena*	Nodularin	34
	Nostoc spp.	Microcystins	35
Germany	*Anabaena* spp.	Anatoxin-a	36
	Aphanizomenon spp.		
	Planktothrix agardhii	Microcystins	18
	Planktothrix rubescens	Microcystins	18
Israel	*Aphanizomenon ovalisporum*	Cylindrospermopsin	37
Japan	*Microcystis aeruginosa*	Microcystins	38
	Umezakia natans	Cylindrospermopsin	39
UK	*Microcystis aeruginosa*	Microcystins	40
	Oscillatoria spp.	Anatoxin-a	41
USA	*Anabaena flos-aquae*	Anatoxin-a	42
	Anabaena flos-aquae	Anatoxin-a(S)	43
	Aphanizomenon flos-aquae	Saxitoxins	44
	Microcystis aeruginosa	Microcystins	45

The next most abundant toxic genus is *Anabaena*, which has many species producing a range of toxins. The *Anabaena's* form filaments of cells, often coiled, of varying sizes (Fig. 1b). The filaments of vegetative cells also include nitrogen-fixing heterocysts and akinetes, which are large resistant spores. The cells contain gas vacuoles and blooms of *Anabaena* frequently form surface scums near dam walls (Fig. 3). The species of *Anabaena*, which have been shown to be toxic, are listed in Table 2, together with their toxins.

As can be seen from Table 2, samples of *Anabaena* from different sources possess toxins found in the *Microcystis* genus, as well as several different neurotoxins not found in *Microcystis*. This is one of the puzzling features of toxic cyanobacteria, as the same species from different locations can synthesize quite different toxins. The *Microcystis* toxins are synthesized through non-ribosomal peptide synthesis, similar to the production of cyclic peptide antibiotics. The genes have been identified as linked in a peptide synthetase operon, which contains the genetic code for epimerase activity as well as amino acid linkage and a polyketide synthetase gene (21,53). The resulting peptide contains D- and L-amino acids in a seven amino acid ring.

The same species of *Anabaena* can completely lack this peptide toxin synthesizing capacity and produce alkaloidal neurotoxins from separate genetic information. It is not clear whether the transfer of the large genetic elements required for toxin synthesis can take place through plasmid transfer between cyanobacterial species and genera or not. Within a species, strains that lack the genetic information for toxin production, therefore being nontoxic, can be isolated.

The completely different cyanobacterium *Planktothrix* (Oscillatoria) *agardhii* has isolates from different locations that contain Microcystis toxins and others with the neurotoxin anatoxin-a (18,54). This species is abundant in the cool, temperate, and subarctic regions of Europe, and is capable of surviving under ice during the winter. The red form *P. rubescens* is particularly adapted to low light intensities and cold lakes, with high concentration of *Microcystis* toxins. *Planktothrix* grows as smooth filaments that may develop as dense layers deep in clear lakes, at the boundary between the oxygenated and anaerobic layers. In the autumn, it becomes buoyant and can then form surface scum (13).

Another species that forms bands of cells well below the surface is the subtropical filamentous cyanobacterium *Cylindrospermopsis raciborskii* (Fig. 1c). The species became particularly known as a result of a major human poisoning event, which is described later (25,55). The organism has a worldwide distribution but produces different toxins from geographically separated isolates. The isolate responsible for the human poisoning was from Australia and the toxin was identified as a cytotoxic alkaloid. This alkaloid has also been found in the species in Hungary and the United States (Florida) (56,57). By contrast the same species in Brazil produces paralytic

Figure 2. Weir pool with a dense scum of toxic *Anabaena circinalis* showing the drinking water intake. See color insert.

shellfish poisons (58). *Cylindrospermopsis raciborskii* does not have gas vacuoles and does not form scums. As it forms dense layers below the surface in stratified lakes, the first warning that it is present may be the blocking of filters in drinking water treatment plants, which normally draw water from below the surface.

In brackish water estuaries and seas, another filamentous cyanobacterium has caused poisoning of livestock and pets. This is *Nodularia spumigena*, with a worldwide distribution (Fig. 1d). The largest areas of cyanobacterial

Figure 3. Dam wall showing dense scum of *Microcystis aeruginosa*. See color insert.

bloom ever observed are in the Baltic Sea, and are a result of proliferation of this organism. Ships tracking through the Baltic in summer may leave a clear wake in the scum, which can be seen from the air at 10,000 meters altitude, and the extent of the scum can be seen by satellite monitoring from space (59). Because estuarine waters are frequently used for recreation, this species has a major negative economic impact on areas where it occurs. In Western Australia, the State Government funded the cutting of a canal at a cost of approximately $40 million to successfully reduce *Nodularia* blooms in a favorite recreational area south of the State capital (60).

A range of other toxic cyanobacteria exist, and it is likely that new species will be identified as toxic in the future. A comprehensive list is provided by Sivonen and Jones (19).

CYANOBACTERIAL TOXINS

From early veterinary observations on the deaths of farm animals from the consumption of scums of toxic cyanobacteria, it was apparent that two totally different types of toxicity were being observed. In one type, typical of the consumption of scums of *Microcystis*, animals died over several hours or a few days, with postmortem evidence of massive liver damage (61). In the other type, resulting from the consumption of scums of *Anabaena flos-aquae* and many other species, the animals died rapidly, showing neurological symptoms with little postmortem evidence of injury (41).

Cyanobacterial toxins have therefore been classed as hepatotoxins (liver poisons) or neurotoxins (nerve poisons).

Table 2. Species of Anabaena That Have Been Shown to Be Toxic and Their Toxins

Toxic Species	Toxin	Location	Reference
Anabaena circinalis	Paralytic shellfish poison (saxitoxins) (neurotoxins)	Australia	24
Anabaena circinalis	Microcystins (hepatotoxins)	Finland, France	17,46,47
Anabaena flos-aquae	Microcystins (hepatotoxins)	Norway	48,49
Anabaena flos-aquae	Anatoxin-a (neurotoxin)	United States, Germany, Ireland	36,50,51
Anabaena flos-aquae	Anatoxin-a(s) (neurotoxin)	United States	52
Anabaena lemmermannii	Anatoxin-a(s) (neurotoxin)	Denmark	53

Table 3. Comparative Toxicities of Cyanobacterial Toxins From (2)

Cyanobacterial Toxin	Lethal Dose (LD_{50}) per Kg Bodyweight	Time to Death at Minimum Dose	Type of Toxicity
Microcystin-LR	60 μg/Kg	12–24 hours	Hepatotoxicity
Nodularin	70 μg/Kg	12–24 hours	Hepatotoxicity
Anatoxin-a	200 μg/Kg	10–30 min	Neurotoxicity
Anatoxin-a(s) 20 μg/Kg		10–30 min	Neurotoxicity
Paralytic Shellfish 10 μg/Kg saxitoxin		20–60 min	Neurotoxicity
Poisons	Others Higher Doses		
Cylindrospermopsin	200 μg/Kg	4–7 days	Widespread organ damage, incl. Hepatotoxicity

With increasing understanding of both the chemistry and the toxicology, the detailed mechanisms of poisoning are becoming clearer. The result is that the hepatotoxins can be separated into poisons specifically targeting the liver and those that are general cytotoxins, damaging all types of active cells. The neurotoxins can be classed as nerve channel blocking compounds, such as paralytic shellfish poisons, neuromuscular synaptic blocking or activating poisons, and anticholinesterases, similar to organophosphorus insecticides.

The cyanobacterial toxins are highly potent poisons, lethal at doses of micrograms per kg of bodyweight (Table 3). The majorities are stable chemical compounds, resistant to boiling and not removed by conventional water treatment. Consequently, there have been outbreaks of human poisoning from cyanobacterial toxins through the consumption of drinking water from chlorinated supply systems.

Microcystis toxins are predominantly hepatotoxic and form a family of related molecules called microcystins (62). The structure is a peptide ring of seven member amino acids, with only two of the normal L-form. These two vary, and within any particular isolate there may be several variants. The most common are leucine/arginine, arginine/arginine, tyrosine/arginine. About 60 different forms have so far been identified (19). The total amino acids of the cyclic peptide are D-alanine-(L-acid)-D-methyl aspartic-(L-acid)-ADDA-D-glutamate-methyl dehydroalanine, where ADDA is 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid (Fig. 4a). The amino acid ADDA has only been found in related compounds and is essential to the toxicity of the whole structure. The explanation for selective toxicity of microcystins to the liver is that they do not readily enter mammalian cells and are concentrated in the liver hepatocytes by a mechanism similar to the bile acid transporter (63–64). Within the hepatocytes, microcystins selectively inhibit the enzymes protein phosphatase I and IIA, with the possibility of forming a covalent complex that permanently inactivates the enzyme molecule (65–67). One consequence of inhibition of these enzymes is the gross deformation of the cell structure caused by the disaggregation of cytokeratin fibers within the cell cytoskeleton (68). This leads to the cell injury observed in acute toxicity studies of experimental animals, which is followed by death of the animal from blood loss into the liver (24). Continued or chronic consumption of microcystin in drinking water leads to active liver injury and serum enzyme changes, showing liver damage (49,50,69,70). Human liver injury by microcystins in a drinking water supply was observed following a major bloom of *Microcystis* on a reservoir that was treated with copper sulphate as an algicide (7). In these circumstances the cyanobacterial cells lyse and the toxins are liberated into the bulk water, from which they are not removed by conventional filtration techniques (discussed later). A major outbreak of gastroenteritis in the area of the Itaparica Dam in Recife, Brazil, was traced back to the drinking water supply. Of the 2,000 cases reported, 88 died. No pathogens could be found, and families which used boiled water were also affected. Toxic metals or other pollutants could not be found, but a heavy bloom of mixed cyanobacteria occurred on the dam at the time. The outbreak was attributed to the cyanobacterial toxins present in the bloom (71).

More recently in Brazil, there were at least 50 deaths of dialysis patients from liver damage that could be traced to the presence of microcystins in the dialysis fluid. The carbon filters in the dialysis unit and the patient's blood and liver tissue showed microcystins at concentrations similar to those found in experimental lethal poisoning (4,5). Poisoning during renal dialysis is, however, an extreme case, as it is equivalent to giving an intravenous injection of toxin to patients who are already ill.

There is increasing experimental evidence of tumor-promoting activity of microcystins in cell culture systems and in rat carcinogenicity studies. In cell culture, low microcystin concentrations cause hepatocyte hyperplasia, with selective cell death and an inhibition of normal apoptosis (72). In rats and mice a series of studies have shown tumor promoting activity of microcystins, with one study showing evidence of direct carcinogenicity (73–75).

In China, some regions have a frequency of primary hepatocellular carcinoma, which is among the highest in the world that is associated with the consumption of surface water from ponds and ditches. Epidemiological evidence showed a correlation of this hepatocellular carcinoma with hepatitis B virus infection and the consumption of aflatoxin B_1 from mouldy corn and other grains, both of which causes of liver cancer are widespread in these areas of China. Adjacent villages,

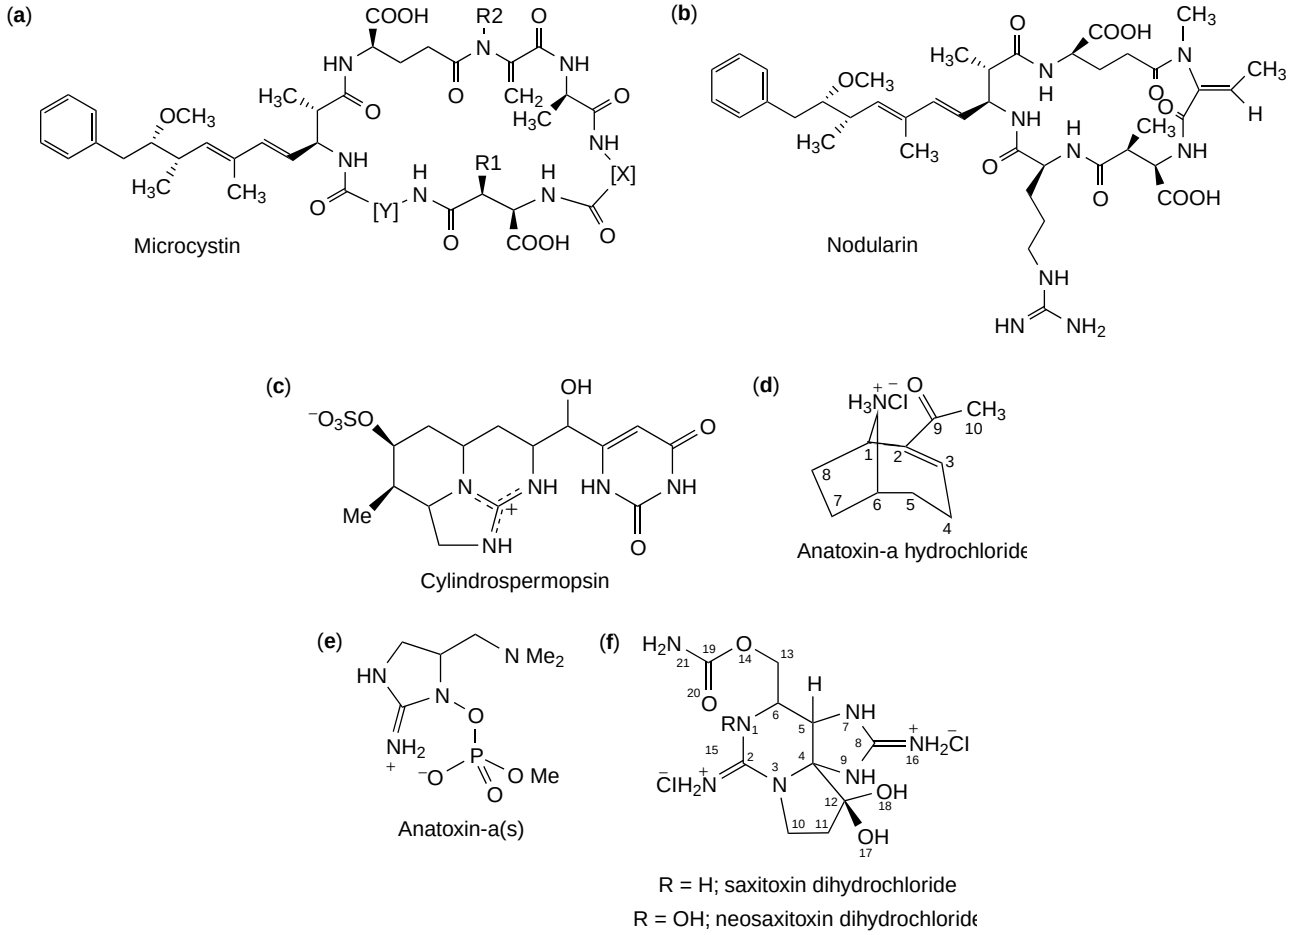

Figure 4. (**a**) Microcystin. Locations X,Y are occupied by L-amino acids. R_1, R_2 are either hydrogen or a methyl group, (**b**) Nodularin, (**c**) Cylindrospermopsin, (**d**) Anatoxin-a, (**e**) Anatoxin-a(s), (**f**) Saxitoxin.

however, had very different cancer rates, with lower rates in villages using deep well water and high rates in villages using surface water. Ponds and ditches in these areas are heavily contaminated with *Microcystis* sp. and microcystins (76,77). Although this evidence does not prove that microcystins are either carcinogens or tumor promoters in man, it is indicative that further epidemiological research is required on this issue and that a potential risk exists.

Another cyclic peptide toxin, in this case having a ring structure containing five amino acids, is produced by *N. spumigena*. The amino acids are D-methyl aspartate-L-arginine-ADDA-D-glutamate-2-(methylamino)-2-dehydrobutyric acid, giving a composition and structure very close to the microcystins (Fig. 4b). The toxin is named nodularin and has the same mechanism of action as microcystin. Human toxicity has not been reported, probably because the brackish water in which this species grows is not suitable for human consumption. Farm livestock was poisoned by drinking from a Nodularia scum in the first reported case of cyanobacterial poisoning in 1878, in Australia (1). Dogs have also been poisoned by *Nodularia* on the shores of the Baltic Sea, as a consequence of their habit of licking their coat clean after swimming (79).

The alkaloid toxin from *C. raciborskii*, named cylindrospermopsin, also damages the liver but has much wider cell toxicity (25,79). The structure is a sulfated cyclic guanidine alkaloid with a hydroxymethyl uracil group attached (Fig. 4c). The alkaloid has also been found in other cyanobacteria, to date *Aphanizomenon ovalisporum* and *Umezekia natans* (36,38). As this toxin was only recently characterized, it is likely to be found in yet more species. The mechanism of toxicity includes the inhibition of protein synthesis, which causes widespread cell injury (80). The liver shows progressive damage from a single injected dose, with mortality over five to seven days in mice. Proximal tubule damage in the kidney and death of white cells in the spleen, as well as injury in a range of other organs (25,26,81,82), have been described. The cyanobacterial species *C. raciborskii* came to attention as a consequence of a major human poisoning outbreak among Aboriginal children on Palm Island, off the tropical Queensland coast of Australia. As a result of local complaints of taste and odor in drinking water, because of the presence of a cyanobacterial bloom in the reservoir, the authorities treated the reservoir with copper sulfate. Within a week, a number of children were admitted to the local hospital with hepatoenteritis, characterized by

initial constipation, sore enlarged livers, vomiting, and headache, followed by bloody diarrhea with severe dehydration. Serum and urine analysis showed electrolyte loss, protein loss, and some cases with ketones and glucose in the urine (55). A total of 140 children and ten adults were treated, the more severe cases by relocation into a major hospital and intensive care. None died. Subsequently, the cause was identified to be the toxic cyanobacterium *C. raciborskii*, which had been lysed by copper sulfate treatment of the reservoir, liberating toxin into the drinking water.

The neurotoxins are found independent of each other, although they may be in the same species from different locations. Anatoxin-a is the most commonly observed neurotoxin in the northern hemisphere, recorded from North America and from Europe (35,83). It has a simple alkaloid structure (Fig. 4d). Cyanobacterial species containing anatoxin-a include *Anabaena flos-aquae, Aphanizomenon flos-aquae*, and *Limnothrix* (benthic Oscillatoria) (19). The toxic action has been well characterized as a depolarizing agent at the neuromuscular junction, similar in action to acetylcholine. It depolarizes both nicotinic and muscarinic receptors with a persistent action leading to a sustained blockade of impulse transmission to muscle. Death of an animal is due to respiratory failure and can occur within 10 minutes of an intraperitoneal injection of a cyanobacterial extract in the mouse (41,84). Poisoning of cattle, dogs, and bats has been attributed to this toxin in North America and Europe (40,83,85). There is no evidence of human injury through drinking water supplies, and it is unlikely that the concentrations of anatoxin-a would reach toxic levels without major prior action by the supplying authority. The predominant toxic cyanobacterial genus producing this toxin is *Anabaena*, which causes off-flavors and odors in water at cell concentrations well below those required to provide a toxicity hazard (86,87).

A further neurotoxin produced by *Anabaena flos-aquae* is the anticholinesterase toxin anatoxin-a(s). The toxin is named after the source organism, and the (s) is derived from the salivation characteristically seen with anticholinesterase neurotoxicity (51). The molecule is an *N*-hydroxyguanidine methyl phosphate ester (88) (Fig. 4e). The molecule closely resembles a synthetic organophosphorus insecticide and has a similar mode of action producing an irreversible inhibition of synaptic acetylcholine esterase. Death is due to respiratory failure resulting from hyperactivity of postsynaptic neurons as seen by salivation, lacrymation, urination, defecation, and convulsions before death (89). This toxin has caused cattle and dog deaths (90) but is unlikely to be present in drinking water at lethal concentrations. It is unstable at alkaline pH and to boiling, and is likely to be destroyed by chlorination during water treatment (89).

Paralytic shellfish poisons are the third type of neurotoxins found in cyanobacteria. These are well known hazards to human health as this type of neurotoxicity has afflicted coastal dwellers and seafarers throughout history (91). The sources of the toxins in shellfish are marine dinoflagellates. Many countries now have monitoring programs aimed at eliminating this risk from consuming shellfish (92). Paralytic shellfish poisons form a group of related molecules based on saxitoxin, and are tricyclic guanidinium alkaloids (Fig. 4f). They were first identified as cyanobacterial toxins in *Aphanizomenon flos-aquae* in New Hampshire, U.S.A. (93), when a bloom of that organism was treated with copper sulfate and resulted in a major fish kill. At that time the chemistry of the toxins was unknown, but was clarified from electrophysiological and structural studies over the next decade (94,95).

In Australia, neurotoxic *A. circinalis* blooms result in sheep deaths during most dry years (96). The chemical structure of the neurotoxin was resolved after the 1991 Darling River bloom in which more than 1,000 km of river contained a highly neurotoxic bloom associated with more than 10,000 deaths of sheep and cattle using the river as a drinking water source (97).

Studies on the physiological response of mice to the toxin indicated that paralytic shellfish poisons were likely, which was confirmed by electrophysiological experiments and structural chemical analysis (23). Since then a separate poisoning of sheep was carefully investigated and a range of paralytic shellfish poisons was identified, including neosaxitoxin, gonyautoxins, and sulfated C toxins in the intestinal contents of the animals (98). The number and diversity of paralytic shellfish poisons lead to complexity in their identification by high performance liquid chromatography (HPLC), and mouse testing is still widely used (99,100). The neuropharmacology of these toxins has been thoroughly investigated and the toxins are sodium channel blocking agents in axonal membranes, leading to interruption of nerve impulse transmission (101). This leads to relaxation of smooth and voluntary muscle and progressive inhibition of respiration, leading ultimately to death (91).

The paralytic shellfish poisons are resistant to boiling and to chlorination. The neurotoxicity attributable to them has been detected in treated drinking water during the Darling River bloom (97).

TOXIC WATER BLOOMS AND CONTROL MEASURES

Monitoring of cyanobacterial concentrations in water bodies is commonly carried out by taking water samples representative of the upper 1 to 5 meters of water, away from the shoreline. Microscopic examination of the water is used to establish the species of the cyanobacterium, and cell counting is used to obtain cell density. This is straightforward with filamentous organisms but extremely difficult with colonial spherical species such as *Microcystis*. An alternative technique used widely in Europe is the measurement of chlorophyll-a, which assesses the total of photosynthetic phytoplankton, including eukaryotic algae (102,103). When cyanobacteria are the predominant organisms, chlorophyll-a measurement provides a quick simple assessment of cell density.

The population of cyanobacteria in a water body varies greatly with the time of year, water temperature, nutrient status, thermal stratification, turbidity and turbulence, and local hydrology. As a result, each water body differs and prediction of cyanobacterial blooms requires repeated monitoring over several years to build up a pattern of cell numbers. The overall potential for

cyanobacterial bloom formation can be assessed from the total phosphorus content of the water. For example, *Microcystis* and *Anabaena* are unlikely to bloom if total phosphorus concentration can be maintained below 50 μg/liter of water (104). Adding to the complexity of bloom prediction are the effects of storms, which bring high concentrations of phosphate into rivers and lakes over a short time period and the thermal stratification of lakes, which allows solubilization of phosphate from anoxic sediments. Cell density is not uniform down the water column, and the depths at which the highest densities occur depend on the cyanobacterial species and on the mixing occurring in the lake. This has particular implications for drinking water supply as water intakes often have variable depths of water entry, which can be used to minimize cyanobacterial cell count in raw water before treatment. Scum-forming and surface-growing species of cyanobacteria, such as *Microcystis aeruginosa* and *Anabaena circinalis*, will be more obvious to plant operators through water discoloration than species such as *P. agardhii* and *C. raciborskii*, which form dense bands of cells, meters down in the water (102).

Control of cyanobacterial blooms in water supplies is becoming increasingly necessary as the number of affected lakes and rivers is increasing. In eutrophic water reservoirs in North America and in Australia, which are operated by water utilities, the use of copper sulfate as an algicide is widespread. The practice is to monitor the water body for cyanobacteria, and when cell numbers begin to increase rapidly, the lake is dosed with copper sulfate to a concentration of one to two parts per million in the upper two meters of water. This is done from aircraft, helicopters, or boats, depending on the area to be treated (105). Within hours of dosage the cyanobacterial cells lyse and any toxin present is liberated into the water. At low cell concentrations the toxin content of the water will be negligible; however, if the treatment is applied at high cell concentrations or when scums exist near the water intake, there is the possibility for human poisoning, as discussed earlier. In Australia, this practice is not permitted in rivers because of the detrimental effects of copper on the overall ecology. Notwithstanding this regulation, about 1 km of the Darling River adjacent to a township was treated with a copper complex during the 1991 *Anabaena* bloom.

More effective long-term control of cyanobacterial blooms is obtained by nutrient reduction to inflowing water sources. Phosphate stripping in sewage treatment can reduce phosphate loads to 1% of the original concentrations, removing a major source of nutrients. Use of polyphosphate-free domestic detergents not only reduces phosphate in sewage but also in septic tank output. In areas where agricultural use of superphosphate is widespread, avoiding distribution adjacent to watercourses reduces phosphate runoff during heavy rain.

In lakes with phosphate-rich sediments, remediation is difficult and costly as it involves capping the sediment to prevent solubilization of phosphorus, dredging to remove the sediment, or preventing thermal stratification. Destratification equipment has been installed in many water supply reservoirs using plumes of air bubbles to mix and oxygenate the water or propellers to mix the water layers. This technique has not been uniformly successful in preventing cyanobacterial blooms (104). In lakes and rivers used for recreation, the seasonal water blooms commonly coincide with the summer holiday period. Another strategy has been used because of the economic impact and the health hazard imposed by the presence of blooms. This is to release sufficient water from an upstream water storage to flush the bloom out of the recreational area. During January 2000, this method was used to remove a toxic *Microcystis* bloom from the Torrens Lake in the center of Adelaide, South Australia. Although this does not provide a permanent solution, this is an environmentally safe and effective method of removing a local water bloom.

SAFETY, HEALTH, AND GUIDELINE VALUES

The WHO have assessed the evidence for adverse human health impacts of cyanobacterial toxins and derived a GV for the best described and understood for these toxins. The GV is based on the determination of a tolerable daily intake (TDI) for the toxin, which is defined as the daily intake that can be consumed over a human lifetime, without detectable injury. The GV can be derived from human epidemiological data, when a dose/response curve to poisoning can be drawn from accidental human exposure. This is currently not possible for cyanobacterial toxins as measures of the amount of toxin consumed are not available in those cases in which human poisoning has occurred. The alternative method for calculation is to use animal data in which the animals have been exposed to a range of nonlethal oral doses of toxin over an extended period. This data is at present only available for microcystins, for which experiments of this type have been performed on mice (106) and pigs (70), using oral microcystin dosing. The oral toxicity of cylindrospermopsin is currently under investigation with the objective of providing data for GV determination.

To convert data from animal experimentation into safe GV for human consumption, a series of safety (uncertainty) factors are applied to the calculation. These are factors of ten for the range of sensitivity within the human population (children to aged), ten for conversion of rodent to human sensitivity and less for pig to human sensitivity as the physiology is closer between pigs and people, and ten for conversion of shorter times of exposure (subchronic) to lifetime exposure. A further modifying factor for excessive toxicity symptoms, possible tumor promotion or uncertainties in the toxicology can also be applied.

The critical experimental information is the maximum daily intake of toxin that does not cause any detectable adverse effects on the animals (No Observable Adverse Effect Level, NOAEL) and the minimum daily intake of toxin that causes an adverse effect (Lowest Observable Adverse Effect Level, LOAEL).

The TDI is thus equal to $NOAEL/10 \times 10 \times 10$ for a standard mouse experiment.

In an experiment conducted on mice for over 13 weeks, a NOAEL of 40 μg/Kg/day of microcystin-LR was found. Applying this to the formula above gives a TDI of 0.04 μg/Kg/day (106).

In an experiment using pigs, a LOAEL was found to be 280 μg/Kg/day of mixed microcystin (70), equivalent to 100 μg of microcystin-LR. In this case a safety factor of 1,500 was applied, 10×10 as before for human variability and subchronic dosage, three for differences between species and five for extrapolating a LOAEL to a NOAEL. This gave a TDI of 0.067 μg/Kg/day, close to the value from mice.

To determine the GV for drinking water, data on average human bodyweight (bw), proportion of toxin intake from drinking water (P), and average daily water consumption in liters (L) are applied to the TDI.

$$\text{Guideline Value} = \frac{\text{TDI} \times \text{bw} \times \text{P}}{L} = \frac{0.04 \times 60\ \text{Kg} \times 0.8}{2} = 0.96\ \mu\text{g/L}(1.0\ \mu\text{g/L}).$$

This GV has been provisionally adopted by the WHO (15) and is being considered by individual countries. It applies to drinking water and water used for normal domestic purposes. For particular "at risk" categories, such as use in renal dialysis or intravenous therapy, special provisions for higher quality water are required (15).

Although the GV is defined in terms of microcystin-LR, its adoption implies that other microcystins are included in the Value. Some toxic Microcystis blooms do not contain microcystin-LR at all, others only a small proportion. Mouse bioassay, using microcystin-LR as a standard, provides total toxicity equivalents that are the biologically effective measure of total toxin content. Biotests using crustaceans have also shown applicability to measure microcystin and other cyanobacterial toxins (107).

Measurement by HPLC is the standard chemical method, which gives separate peaks for each microcystin variant that has a characteristic ultraviolet (UV) spectrum with a peak or shoulder at 238 nm (108). Summation of these peak areas provides a measure of total microcystins, which does not compensate for the differences in toxicity of the variants. Enzyme-linked immunosorbent assays for microcystins are available commercially, and assays based on inhibition of protein phosphatase are under commercial development. Both these techniques have been applied with success in research laboratories (91–94,109–112). Although the operators of water treatment plants now have a standard for the microcystin content of water supply, effective monitoring of raw water sources can usefully include measurement of toxin content when species known to contain microcystins are present in cell concentrations likely to approach the GV in bulk water. The WHO has drawn up a set of Alert levels for cyanobacterial cell concentrations in drinking water reservoirs together with a flowchart for action (113). A similar approach has been taken to preserve the safety of recreational waters containing cyanobacterial blooms, with recommendations for actions at a series of cyanobacterial cell densities (15).

WATER TREATMENT

Although the prevention of cyanobacterial blooms from occurring in water storages is far better than concentrating on water treatment, the practicality of the situation is that many reservoirs and holding lakes are contaminated with cyanobacterial toxins. In a survey carried out on drinking water supplies in southwestern Manitoba in 1995 and 1996, rural municipal supplies showed microcystins in 93% of the water supplied to consumers. Seven supplies were intensively monitored in 1996, and microcystin-LR was found throughout the sampling period of June to December, sometimes at concentrations above 0.5 μg/liter (113,114). From this and similar data elsewhere it is apparent that conventional water treatment with chlorination does not remove microcystins, a conclusion that can also be reached from reports of liver injury or hepatoenteritis from chlorinated supplies drawn from reservoirs with *Microcystis* blooms.

The management of water storage reservoirs can minimize the entry of cyanobacteria into the treatment system. Water can be drawn from levels of the reservoir that carry a minimum of cyanobacteria, and alternative storages or groundwater can be used when available. If algicides such as copper are employed it is essential to withdraw the affected reservoir from supply until cyanobacterial toxin concentrations have dropped to below GV.

Cyanobacterial toxins under normal growth conditions largely remain within the cells and the toxin that leaks out will be degraded by bacteria occurring naturally in freshwater (115). The concentrations of free toxin in water are therefore low compared with the total concentration of toxin, unless algicide use or natural lysis of the bloom occurs. In water treatment it is therefore a considerable advantage if intact, live cyanobacterial cells can be removed before treatment. This may not be possible if the water drops considerably in height through pressure reduction valves or travels long distances in pipelines, between the reservoir and the treatment works (116). The common practice at water treatment plants of injecting chlorine at the flash mixer, where raw water enters the treatment plant, causes cyanobacterial cell lysis, thus immediately freeing the toxins into solution. Subsequent flocculation and sedimentation or dissolved air flotation are then largely ineffective at microcystin removal (117). When intact cyanobacterial cells are present, optimization of flocculation conditions effectively removes the cells and the toxins (118).

Alum or ferric chloride flocculation of suspended organic material does not remove appreciable amounts of soluble cyanobacterial toxins from water (117). In the case of removal of paralytic shellfish poisons from raw water in a pilot plant experiment, reduction of 20% was observed with alum flocculation (8).

Three methods are used to remove alum or ferric chloride flocculated organic matter from the water stream. The most common is sedimentation in a settling tank,

which allows heavy flocculated material to settle out. An effective technique that is particularly useful in smaller plants is the sludge blanket, in which the water with flocculant passes up through a layer of previously formed floc. This has been demonstrated to remove 95–99% of cyanobacterial cells (118). Another highly effective method is clarification by dissolved air flotation in which compressed air bubbles are injected into the bottom of the tank containing the flocculated material. The bubbles carry the floc and entrapped organic material up to the surface, where they are skimmed off. More than 80% removal of cyanobacteria was shown in eight operating dissolved air flotation plants (119).

Toxic cyanobacteria removed during flocculation and floc removal have been shown to lyse rapidly and release trapped toxins, with effectively all the toxin released within two days (120,121). It is therefore important to remove the floc prior to cell lysis, which requires frequent cleaning of sedimentation tanks and removal of sludge from blanket units during a cyanobacterial bloom. The final removal of suspended material is through rapid sand or mixed bed filtration, so that cell lysis also has implications for the frequency of filter backwashing. Backwash water is normally clarified and added into raw water intake, which can lead to recycling of toxins during a bloom.

From measurements of microcystins in treated water it is apparent that simple treatment plants do not remove the toxins (113), and considerable investigation has been undertaken to develop techniques that are effective. Use of activated carbon, either in powdered form or as granules in a filter, has been shown to be effective. The operational requirements for powdered carbon are more complex, but have been shown to remove up to 90% of microcystins (122). In practice, lower removal rates are common and are affected by the presence of alum (123). Paralytic shellfish poisons can also be removed by activated carbon (8). Granular activated carbon is installed in advanced treatment plants that recurrently have taste and odor problems with raw water or organic toxicants. It is highly effective in removing cyanobacterial toxins (8,124) as long as the adsorptive capacity has not been exceeded.

Cyanobacterial toxins can be destroyed by oxidation, which has relevance in water treatment as disinfection is carried out by oxidants. Both chlorine and ozone are in use in treatment plants and have the capacity to oxidize microcystins (122,125). The effectiveness of chlorine in water plant operation as a method of microcystin removal is reduced by the presence of other organic material (122,123) which may be particularly high when a cyanobacterial bloom occurs in the raw water supply. As noted previously, all the cases of human poisoning from cyanobacteria in drinking water occurred in chlorinated water supplies. Ozone offers more promise as an oxidant (117,126), with the ability to completely destroy microcystins, nodularin, and anatoxin-a (127). It appears likely that cylindrospermopsin and paralytic shellfish poisons can also be oxidized by ozone (127).

In advanced water treatment, ozone is used in conjunction with activated carbon filtration to remove any undesirable oxidation products. For example, at the Thames Water plant in Feltham, England, the sequence is initial low dose ozonation; flocculation followed by dissolved air flotation, rapid sand filtration, the main ozonation process, granular activated carbon filtration, and finally slow sand filtration. At the end of the treatment, chlorine is added as a pipeline disinfectant.

Recent developments in membrane filtration and reverse osmosis have demonstrated their potential for microcystin removal in fresh and salt water (128,129). Nothing is known at present about the removal of neurotoxins by membrane filtration.

CONCLUSION

Cyanobacteria are present as a normal component of ecosystems, including freshwater. Their abundance is limited by nutrients; in particular, the availability of phosphate in the water or solubilized from anoxic sediments. The majority of species that form waterblooms in drinking water sources are toxic and hence present a potential risk to consumers of that water. As eutrophication of surface waters increases the chance of cyanobacterial blooms also rises, to the extent that a majority of lakes and slow-flowing rivers have intermittent blooms in the higher populated regions of the world.

The toxins from cyanobacteria, especially microcystins and cylindrospermopsin, can reach injurious concentrations in drinking water, and have caused outbreaks of poisoning in domestic animals and people. Monitoring of surface water sources for toxic cyanobacteria is essential, especially during summer and autumn when lakes thermally stratify and the higher temperatures assist cyanobacterial growth. Water treatment technology has the capacity to remove cyanobacterial toxins but in practice may be inadequate or overloaded when a bloom occurs in a water storage, especially if the bloom is lysed with copper, liberating the toxins from the cells into the water.

The WHO GV provides a concentration of 1.0 μg microcystin-LR/liter of drinking water for safe lifetime consumption; if total microcystin toxicity can be maintained at or below this concentration, there is negligible risk to the human population. As more data are available, GV for other cyanobacterial toxins can be derived for safe drinking water. Recent research has implicated microcystin and cylindrospermopsin in experimental carcinogenesis, which may require reconsideration of GV derived from toxicity data (130,131,132).

VITALIANO A. CAMA
A. B. PRISMA
Lima, Peru

Cyclospora cayetanensis is a coccidian parasite that affects humans causing a gastrointestinal disease known as *cyclosporiasis*. Because of its biological characteristics that are somehow different from other coccidians infecting humans, its true identity took longer to unravel and it was not fully identified until 1993. *Cyclospora* has received increased attention in the past years because of reports of water or food related outbreaks in the developed world (1,2). In the United States, the first waterborne outbreak occurred in Chicago and was associated with consumption of water potentially contaminated with *Cyclospora* oocysts. The mechanisms of transmission are not completely understood; however, most of the cases of cyclosporiasis have been associated to food-borne or waterborne transmission with a case-fatality rate of 0.05% (3). Since 1995, additional outbreaks have been documented in Canada and the United States and were linked to potentially contaminated imported produce or fruits (4). These events have lead to increased awareness, improvements in the detection methods, and development of research initiatives for understanding the dynamics of cyclosporiasis better.

TAXONOMY

The genera *Cyclospora* was first observed by Eimer in 1870 and subsequently named in 1871 by Schneider (5) when *Cyclospora glomerica* was isolated from a myriapod. *Cyclospora* belongs to the *Subphylum Apicomplexa*, *family Eimeriidae*. The species name *cayetanensis* was derived from the Peruvian University where preliminary identification studies were initiated (Universidad Peruana Cayetano Heredia). The morphological characteristics relevant to this classification are anterior polar complex with apical rings, micronemes, and subpellicular microtubules. These features are common to all apicomplexan. *Cyclospora* has a complex life cycle that includes asexual multiplication (merogony), sexual multiplication (gametogony), and formation of sporozoites (sporogony). Merogony occurring within a vertebrate host is characteristic of the order Eucoccidiorida, followed by independent development of male and female gametes (suborder Eimeriorina). Upon gamete fertilization, immature oocysts are formed and excreted into the environment. The oocysts differentiate and mature having two sporocysts, each with two sporozoites, which are characteristics of the genus *Cyclospora* (Fig. 1).

To date there are fourteen additional species of *Cyclospora* that infect insectivores, rodents, and snakes. All of them are morphologically different from *C. cayetanensis*. Molecular phylogenetic studies using the 18S rDNA demonstrated that *C. cayetanensis* is more closely related to *Eimeria* species (6). Three new species of *Cyclospora* that are morphologically similar to *C. cayetanensis* have been said to infect nonhuman primates, and on the basis of phylogenetic analysis of the 18S rDNA, they are dissimilar to *C. cayetanensis* (7,8).

BASIC BIOLOGY

The first documented report attributable to *Cyclospora* infections in humans probably occurred in 1979 from patients with diarrhea in Papua, New Guinea. The

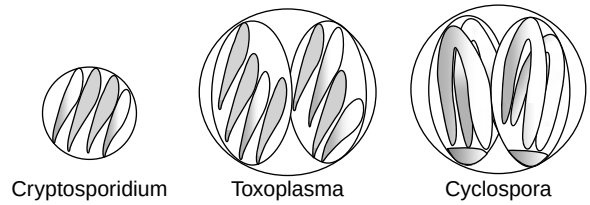

Figure 1. Fully sporulated oocysts of coccidian that cause diarrhea in humans. *Cryptosporidium* measures 4 to 6 μm in diameter, *Toxoplasma* 10 to 12 μm, and *Cyclospora* 8 to 10 μm. *Cryptosporidium* has four sporozoites and no sporocyst and is shed to the environment fully sporulated and infectious. *Toxoplasma* has two sporocysts, each with four sporozoites. *Cyclospora* also has two sporocysts, each with two sporozoites. *Toxoplasma* and *Cyclospora* are excreted unsporulated.

authors described oocysts suggesting it was a new species of *Isospora* affecting humans (9). Before this report, the genus *Cyclospora* had been associated with moles, myriapods, insectivores, and snakes, but never with humans. Previously reported in the literature as Cyanobacter-like bodies, Coccidian-like bodies (CLB), *C. cayetanensis* was recognized and described as a human coccidian parasite in the early 1990s (10). It has since been reported in multiple countries around the world, showing an endemic pattern in the developing world with isolated outbreaks or travel-linked episodes in the industrialized world.

The oocysts are spheroidal with 8.6 ± 0.6 μm diameter, a bilayered cell wall about 113 nm thick, ovoidal sporocysts 4.0 μm wide and 6.34 μm long, with sporozoites 1.2 μm wide and 9.0 μm long. Oocysts autofluoresce under UV epifluorescent microscopy (11) (Fig. 2a) and immature oocysts have internal structures with a morula type appearance (Fig. 2b). The oocysts stain variably with modified acid-fast staining. The formation of sporocyst-like structures occurs by 5 days and appearance of sporozoites within sporocysts within 7 to 13 days. Under ideal laboratory conditions, more than 40% of the oocysts collected sporulate within 7 to 13 days and become infective. In humans, which to date seems to be the only host, the proposed mechanisms of transmission is the ingestion of food or water contaminated with mature (sporulated) oocysts.

The life cycle of *C. cayetanensis* has not been fully understood. Other species of *Cyclospora*, such as *C. caryolytica* of moles, showed asexual and sexual development within the nucleus of the enterocytes (12). *Cyclospora talpae*, which also infects moles, develops asexually within the nucleus of monocytic cells in the liver, whereas sexual development was confined to the nucleus of bile duct epithelial cells (13).

Cyclospora cayetanensis has a different intracellular localization, with parasitic vacuoles containing asexual and sexual stages within the cytoplasm of jejunal enterocytes (Fig. 3); however, the exogenous sporulation closely follows that of *C. talpae* (Fig. 4).

Epidemiological studies including domestic animals in the households of individuals with cyclosporiasis did not report animals infected with *Cyclospora*. In endemic areas such as Nepal, in 1995, 196 different species of animals (14) including pigs, monkeys, dogs, cats, cows,

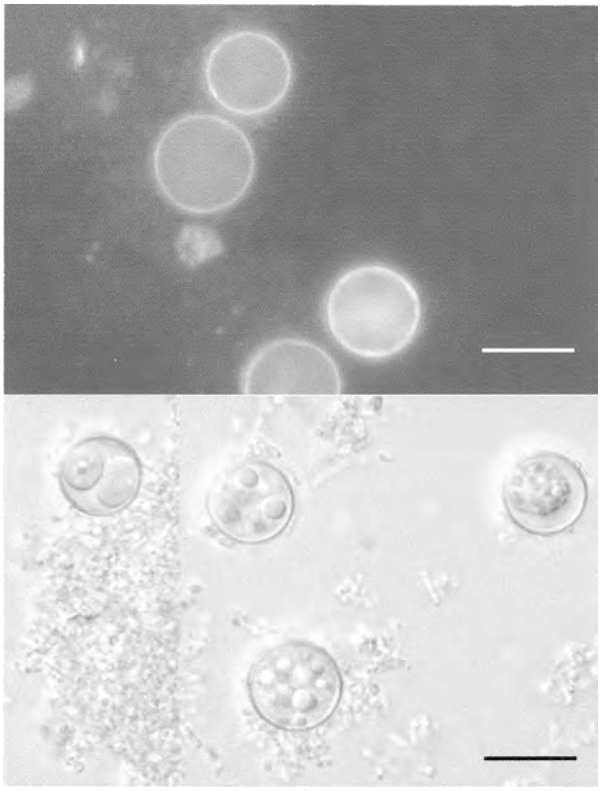

Figure 2. *Cyclospora* oocysts. (**a**) Autofluorescence. (**b**) Unsporulated and sporulated oocysts. Bar = 10 μm.

Figure 3. Merozoite in intracellular parasitic vacuole. Roptries and micronemes are characteristic to coccidians.

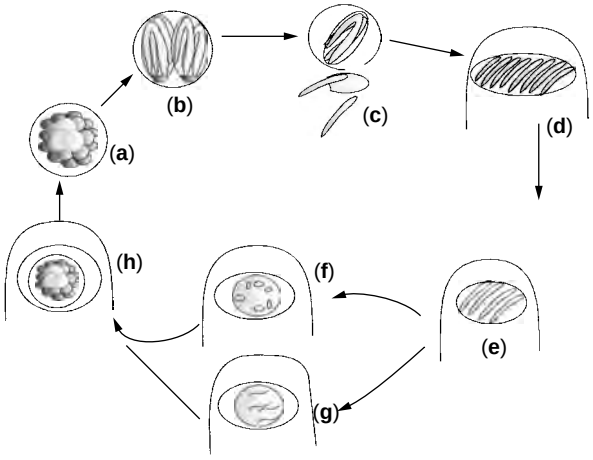

Figure 4. Life cycle of *Cyclospora*. Oocysts are excreted unsporulated (**a**). After 7 to 15 days in the environment, they sporulate and become infectious (**b**). When ingested by a susceptible host, sporozoites are released and infect epithelial cells of the small intestine (**c**). Parasites go through asexual multiplication (**d,e**) and sexual differentiation as macrogametocyte (**f**) and microgametocyte (**g**). Fecundation occurs and zygote is formed and differentiates to an immature oocyst that is excreted into the environment (**h**).

buffalo, goats, rats were surveyed and demonstrated negative to the presence of *Cyclospora*. Surveys of domestic animals in Peru also gave negative results. These surveys included commercial and home raised chickens and companion and farm animals. In 1999, 327 domestic animals from a Haitian study were surveyed and 100% found to be negative to *Cyclospora* (15).

In addition to sampling animals for natural infections, multiple controlled studies have attempted without success to study cyclosporiasis from infections of animal models such as several strains of mice including adult, neonatal immunocompetent and immunodeficient, inbred and outbred strains, and other animal species including rats, sand-rats, chickens, ducks, rabbits, gerbils, hamsters, ferrets, pigs, dogs, owl monkeys, rhesus monkeys, and cynomologus monkeys (16). These results contradict some isolated reports of *Cyclospora* in fecal samples or intestinal contents of ducks, chickens, and dogs. These communications reported parasites in fecal matter, which could be explained as being transient parasites from accidental ingestion of *Cyclospora*-infected human feces. No evidence of parasitized tissues that would demonstrate them as definite hosts for this infection was presented (17–19).

Clinical and Pathological Findings

Infection in susceptible individuals can exist as asymptomatic to severe and persistent diarrhea, mild nausea, anorexia, abdominal cramping, watery diarrhea, and weight loss (20). Vomiting is less common (21). Diarrhea alternating with constipation has been commonly reported. Infections in AIDS patients have similar symptoms but tend to last longer with reported episodes lasting up to four months (22). Onset of abrupt illness caused by *Cyclospora* has been reported in 68% of adult patients, with watery diarrhea and lasting an average of four to seven weeks. Other clinical features associated with cyclosporiasis include an impaired D-xylose and reduced vitamin B-12 absorption, and elevated-fat fecal excretion (21,23).

Cyclospora has been shown to infect epithelial cells of the duodenum and jejunum. Histopathological exam reveals a moderate to marked erythema of the distal duodenum. The lamina propria shows with mild to moderate acute inflammation. Varying degrees of jejunal villous blunting, atrophy, and crypt hyperplasia have been observed in the duodenal and jejunal portions. The intense inflammatory reaction does not correlate to the small number of parasitic vacuoles present. Gastric and colonic biopsies did not show histopathologic changes, nor the presence of parasitic vacuoles (20,24).

A description of *Cyclospora*'s life cycle has been inferred from the intracellular parasitic vacuoles observed in the cytoplasm of epithelial cells of the duodenum or jejunum (20,25). Sexual stages and two types of asexual (merogony) stages of the parasite were observed (24).

The drug of choice for treating cyclosporiasis is Trimethropim-sulfamethoxazole (TMP-SMX). The cessation of symptoms and oocyst excretion usually occurs one to three days after treatment (26). In Nepal, 94% of immunocompetent individuals with cyclosporiasis cleared the infection within seven days of treatment. In a HIV population, recurrence was about 44% in patients with cyclosporasis receiving one week therapy with TMP-SMX (27) and additional seven days of drug administration may be needed in some cases (28). Seven days of treatment using Ciprofloxacin (500 mg BID) produced a 90% cessation of diarrhea, and 64% stopped secreting oocysts in their stools (29). Although Ciprofloxacin is not as effective as TMP-SMX, it is an alternative for those patients who cannot take or are allergic to sulfa compounds. Anecdotal use of tetracycline plus folic acid showed some success (21). Norfloxacin, tinidazole, quinacrine, nalidixic acid, and diloxanide furoate were not effective to treat cyclosporiasis (30).

Diagnosis

Cyclospora can be identified by finding unsporulated oocysts in freshly collected stool samples; sporulated or nonsporulated parasites could be found in fresh vegetables or environmental samples. *Cyclospora cayetanensis* oocysts are 8 to 10 μm in diameter and bigger than those of *Cryptosporidium parvum* (4 to 6 μm), which is also infectious to humans. *Cyclospora* oocysts stain variably using a modified acid-fast technique. They stain best using the modified carbolfuchsin technique. Oocysts also can be stained using the Kinyoun, Ziel-Neelsen, and safranin methods, but do not stain well with iron hematoxylin, Grocott-Gomorri methenamine-silver nitrate, iodine, or periodic acid-schiff stains (31). Safranin uniformly stains *Cyclospora* oocysts when preheated in a microwave oven (32). Oocysts autofluoresce blue under UV epifluorescent illumination using a 365/10 DM exciter filter. To enhance the detection process, *Cyclospora* oocysts can be concentrated by sequential differential centrifugation steps or formalin ethyl acetate purification, followed by sucrose flotation in Sheather's solution.

Molecular assays have also been developed for detection of *Cyclospora*. A nested PCR amplifies 294 bp of the 18S rDNA (33). PCR inhibitors commonly found in diagnostic samples can be removed by pretreatment of the lysed preparation with a resin matrix (Instagene; Biorad, Hercules, CA) and nonfat milk.

The samples to be tested for oocysts are lysed by freeze-thaw cycles in dry ice-ethanol. Primers are those described by Yoder and coworkers. Amplification products of *Eimeria* and *Cyclospora* are of the same size. These can be differentiated by RFLP with the restriction enzyme Mnl I, and the predicted restriction fragment sizes for Cyclospora are 140, 106 and 48 bp. The detection limit of this PCR test was estimated to be 10 oocysts (34).

Other agents causing diarrhea must be considered when processing diagnostic samples. *Cyclospora* may be found in conjunction with one or more additional pathogens such as *Giardia lambia*, *Entamoeba hystolitica*, *C. parvum*, and the microsporidia (35), which also have similar transmission profiles. The confirmation process include the verification of the laboratory findings and, whenever applicable, the concordance between the reported clinical symptoms and the laboratory results. Differential diagnosis of *Cryptosporidium* is particularly

important because it also acid-fast stains, and coinfections with *Cyclospora* have been reported (36). Current immunofluorescent assays for *Cryptosporidium* rely on the use of fluoresceine isothiocyanate, and the resulting fluorescent organisms could be confused with autofluorescent *Cyclospora*. The careful measurement of the parasite and use of positive controls will demonstrate significant differences in size (*C. cayetanenesis* is 8 to 10 μm diameter versus 4 to 6 μm diameter for *Cryptosporidium*) and the intensity of the green fluorescence observed at 450 nm (very bright for FITC, weak for *Cyclospora*).

When investigating outbreaks, bacterial pathogens such as *Escherichia coli*, *Salmonella*, *Shigella*, *Campylobacter*, or viral entities such as Norwalk, adenovirus, and cytomegalovirus shall also be considered as potential causative agents. In the case of immune-compromised patients, *Mycobacterium-avium intracellulare* may also be considered as a potential etiology of diarrhea.

Epidemiology

Cyclospora has been associated to protracted diarrheal illness in humans in North, Central, and South America, the Caribbean, Africa, Bangladesh, Southeast Asia, Australia, England, and Eastern Europe. It has been reported to be endemic in the developing world, in areas of moderate to warm climate. In industrialized countries, *Cyclospora* has been detected in tourists or expatriates returning from countries where diarrheal illnesses are highly prevalent, however, there are additional reports from people with no travel history (37–39). Cyclosporiasis has also been reported in immunocompromised AIDS patients (40–45).

The first reported case in the United States in an HIV patient occurred in 1986 from a traveler returning from Mexico (40). In those days, most of the reported cases of cyclosporiasis were from travelers and expatriates returning from endemic areas (40,46,47). where *Cyclospora* is found predominantly during the warm and humid months (23). This was observed in longitudinal studies in endemic areas of Peru (10); there was an increase in the number of episodes from January to May (summer to early fall) (10,29,48,49).

Age seems to be an important factor in populations in which *Cyclospora* is endemic, with significantly greater prevalence in children older than 18 months of age and younger than 8 years (10). In Nepal, children with diarrhea under 18 months of age were not found positive to *Cyclospora*. However, children 18 months to 5 years old showed a 12% prevalence of cyclosporiasis, and 2% of children without diarrhea had *Cyclospora* (48). This age susceptibility is not fully understood and may be attributed to increased exposure to infectious *Cyclospora* after weaning. In the same area, the consumption of untreated water or unpasteurized milk diluted with water were considered risk factors for contracting cyclosporiasis for travelers and expatriates.

In a two-year prospective cohort in Peru (50), the overall prevalence of *Cyclospora* was 1.6% in children younger than eight years of age, increasing to 3 to 4% during the summer months (January to March), and 0.3% in children older than eight years. Of the infected children, 32% were symptomatic with diarrhea and some of them had concurrent infections with other pathogens. All adults that were surveyed in this studies were found negative to *Cyclospora*.

Seasonality and patterns of age susceptibility in Guatemala are very similar to those described for Peru and Nepal. June is the month with higher incidence, with rates as high as 10%. During the months of May and June, 19% of all pediatric gastroenteritis were due to *Cyclospora*, and children experienced prolonged diarrhea if untreated. Epidemiological analysis demonstrated an increased odds ratio associating cyclosporiasis with water consumption. Among the very young children, direct contact with soil seemed to be a potential source of contamination. Although not clearly understood, the presence of chickens or other fowls in the houses was also considered a risk factor.

WATERBORNE OUTBREAKS

In the industrialized countries, the epidemiology of *Cyclospora* is mainly associated to outbreaks, and in some cases *Cyclospora* has been epidemiologically linked to water consumption. The first documented outbreak attributable to *Cyclospora* occurred in 1990 and affected 20 members of the hospital staff of a Chicago hospital, where tap water was presumed to be the source of infection (37). In Utah, a man was diagnosed with cyclosporiasis after cleaning his flooded basement following heavy rains (39). In another incident, a child became ill and was diagnosed to CLBs in his feces one week after swimming in Lake Michigan. Water samples taken from the inlet of the Chicago municipal water supply system at this lake showed the presence of organisms resembling CLBs, although at that time the organism was not confirmed as *Cyclospora* (38). In Nepal, British soldiers and dependents experienced diarrhea caused by waterborne *Cyclospora*. The drinking water was a combination of river water and municipal water. Despite chlorination, oocysts were isolated from the water, suggesting that *Cyclospora* is resistant to chlorination levels recommended for water treatment (51). When assessing potential sources of infection, all factors shall be considered, including travelers or natives infected with *Cyclospora*, contaminated food, and insects as transport hosts. Further epidemiological studies will help in the assessment of these factors and in the development of control and treatment strategies for *Cyclospora*.

FOOD-BORNE OUTBREAKS

The first reported food-borne outbreak in the United States occurred in 1995 when 45 cases of cyclosporiasis were diagnosed in Florida in people without travel history. In 1996, a total of 1,465 cases from 20 states, Washington D.C., and 2 Canadian provinces were reported. Epidemiological analysis of these cases, using retrospective case-control studies of 180 people from Florida, showed that consumption of raspberries was strongly associated with cyclosporiasis (O.R. = 31.95, 95% CI 7.41–38.2). People who ate raspberries were 17.6 times

more likely to develop cyclosporiasis (RR = 17.6, 95% CI = 19.1–88.8) (52).

In the United States, these cases were related to 55 events between May 3 to June 14, 1996. Raspberries were identified as the potential source of *Cyclospora* infection and definitely served in 50 of the 55 events. In 27 of these events, there was significant association between raspberries and cyclosporiasis, p less than 0.05. The attack rate was estimated to be 56.3% for the 53 events in which information was available. Only one event had blackberries from the same country, and not raspberries. The median event-specific attack rates among people eating raspberries was 93.3% for the 29 events, with sufficient data to trace the source of the berries; all raspberries came from the same country. In sporadic cases, the consumption was 79.4% for strawberries, 57.8% for raspberries, 32.2% for blueberries, and 19.3% for blackberries (53).

The exact mode of contamination of the berries remains unclear. Studies of water used for irrigation of the raspberries showed intermittent contamination with fecal coliforms and *E. coli*, but no *Cyclospora* was detected. River water analysis showed heavy fecal contamination with *E. coli*; *Cyclospora* was found in 2 out of 30 samples with concentrations estimated to be greater than 15,000 oocysts per 10 L specimen (54). A dripping system was used to irrigate the raspberries and was intended to avoid contamination of the berries with irrigation water; however, the same water was used for spraying pesticides and fungicides on the berries themselves, and thus again was the potential vehicle for contamination. Because *Cyclospora* requires 7 to 14 days to fully sporulate and become infectious, it was considered unlikely that infectious *Cyclospora* could have been introduced into the berries during the spraying or during the preparation of dishes served on the events.

In 1997, basil was implicated with an outbreak in the Virginia/Maryland area (55). Clusters of *Cyclospora* positive patients were reported, identified, and associated with luncheons during the months of June and July. Forty eight of 54 people attending the luncheons had illness compatible with the clinical definition of cyclosporiasis. The relative risk associated to the pesto salad was determined to be 5.9, p less than 0.001. The basil used in the luncheons was traced back to a specific distribution company in which the basil (imported) was repacked and sold to the restaurant industry. Twenty five additional clusters were identified and linked to the consumption of fresh basil from the specific company in the area, and at least 20 additional possible clusters were linked to this product. The implicated company was asked to stop selling its basil products and the health departments of Virginia and Maryland issued press releases to inform the public to stop consuming fresh basil, either alone, or in products that could contain this fresh product.

Another outbreak in the Missouri area was reported and studied by retrospective questionnaires. This cohort study was conducted around during two social events and the epidemiological analysis demonstrated that in this *Cyclospora* outbreak, the most likely source of infection was basil. Chicken pasta salad and tomato basil were more strongly associated with *Cyclospora* infections. Rapid intervention allowed the analysis of specific meals linked to the presentation of cyclosporiasis. Leftover pasta salad was found positive by PCR, and one *Cyclospora* oocyst was detected by microscopy (56). Sporulated *C. cayetanensis* oocysts were isolated from the salad. It was postulated that the contamination occurred either way back at the distribution chain or at the original production site.

In a study conducted in an endemic area, *Cyclospora* was isolated from vegetables purchased from local markets (57). One hundred and ten samples were purchased from 13 markets of Pampas de San Juan, a periurban town in Lima, and analyzed for the presence of *Cyclospora*. Results indicated a 1.8% prevalence of *Cyclospora*. In a second collection from the same area, laboratory results showed that 1.6% of the samples were positive for *Cyclospora*, indicating the potential of food-borne transmission via fresh produce. *Cyclospora* oocysts have also been isolated from sewage water and water collected after washing leafy green vegetables such as cabbage, lettuce, and mustard from other endemic areas (14).

Viability can be determined by incubating the organism in potassium dichromate and looking for sporulated oocysts. An alternative method has been recently described. An electrorotation (58) method has been proposed to determine the sporulation of *Cyclospora* from water and vegetables. The lack of an in vivo or in vitro culture methodologies as a gold standard makes it difficult to evaluate the viability of *Cyclospora*.

ENVIRONMENTAL SAMPLING

Drinking water samples can be screened for the presence of *Cyclospora* oocysts. Oocysts can be isolated by filtration by using collection of 10 L water samples, using cartridges, or by flocculation methods developed for removing *C. parvum* in water (59). Oocysts were identified by examination using bright field microscopy and UV epifluorescent microscopy.

Irrigation water and wastewater samples were analyzed by collection of 1 to 5 L using the Envirocheck capsule (Gelman Sciences, Ann Arbor, Michigan). Particulate material was removed from the filter with an eluting solution consisting of phosphate buffer, SDS, Tween 80, and Antifoam A (Sigma Chemical Co, St. Louis, Missouri). The suspended particulate matter was then transferred to 250-mL centrifuge bottles and centrifuged at $1,050 \times g$ for 10 minutes. The centrifuged particulate matter was condensed as the final pellet (60).

Hannifin polypropylene cartridge filter (commercial Filters Parker Hannifin Corp. Lebanon, Indiana) was also used to recover Cyclospora oocysts. Larger volumes of water samples were filtered using these cartridges. The woven filters were then sliced to the core, and fibers washed in elution solution. The eluted suspensions were condensed and centrifuged in 100 mL aliquots at $1,050 \times g$. Oocysts were then purified by either zinc sulfate flotation or discontinuous sucrose separation.

Cyclospora was also isolated from produce. Several strategies have been examined to determine the most

efficient procedure for recoveries, such as washing of produce, sonication, and separation using lectin-coated (wheat germ agglutinin) paramagnetic beads, with recovery efficiencies in the range of 12% (57,61).

FTA filters (Fitzco, Inc., Maple Plain, Minnesota) that are impregnated with denaturants, chelating agents, and free-radical traps lyses most cells on contact, although retaining DNA within its matrix (62) has also been used to improve isolation of oocysts from produce. This methodology would circumvent the presence of inhibitors in food matrices and seems to detect as low as 30 *C. cayetanensis* oocysts per 100 g of fresh raspberries, with the potential to adapt to other food, clinical, and environmental samples.

CONTROL MEASURES

Direct and immediate person to person transmission seems to be unlikely in *Cyclospora* transmission because oocyst require 10 to 15 days from the time of excretion until they sporulate and become infective. The use of drinking water filters suitable for *C. parvum* removal could be effectively used to remove *Cyclospora* oocysts from drinking water. No significant information on effectiveness of disinfectants, temperature, or other physical inactivation or removal methods is currently available.

Washing does not completely remove pathogens from fresh produce. People can prevent infections from *Cyclospora* by limiting the opportunity of ingestion of fecally contaminated materials. Careful hand washing is useful in preventing the spread from food handlers. Travelers should follow routine recommendations and avoid drinking tap water, unpasteurized or nonboiled drinks and foods when traveling to endemic areas. Boiling or adequate filtering of water for human consumption also aid the prevention of this and other pathogens.

Internet resources such as the emerging infections program sites of FoodNet have effectively enhanced the monitoring and early detection of food-borne outbreaks. This system involves the states of California, Georgia, Minnesota, Oregon, and Connecticut.

CONCLUSION

Cyclospora is a fairly new parasite and in the last eight years, significant progress has been made in efforts to understand its biology and transmission dynamics. Important aspects of its basic biology are not yet fully understood such as its life cycle, host susceptibility, survival in environmental conditions, and ideal disinfection methodologies. The lack of laboratory methods or animal systems to propagate the parasite has proven to be the limiting factor for these research initiatives.

DATA ANALYSIS AND MODELING

JONAS S. ALMEIDA
Medical University South Carolina
Charleston, South Carolina

Almost any attempt to monitor the presence and activity of microorganisms in the environment will be met by an abundance of data. Microorganisms are ubiquitous and so is their activity. Many mineral cycles depend on the microbiota for completion, such as nitrogen fixation or sulfate reduction, and all of them can be fully implemented by microorganisms. Another characteristic adding to their ubiquity is the metabolic plasticity that characterizes microbial communities, a response to irregular substrate availability. As a consequence, microbial communities implementing a specific process are expected to emerge whenever that process confers a selective advantage. In many cases, individual isolates will be recovered with the new functionality (such as the recent isolation of denitrifying nitrifiers), but this generalization is mostly valid at the population level, for example, no microorganism was ever isolated capable of converting glucose to methane. The combination of plasticity and ubiquity of microbes is particularly evident in the design of wastewater treatment plants where no inoculation is required. The right microbial community will emerge to make the most of the opportunities for growth provided by the design and operation of the station. In conclusion, monitoring the presence and activity of microorganisms in the environment represents a challenge in choosing and calibrating the relevant analytical technique (Fig. 1). This section focuses on data analysis and how it is ultimately dependent, first, on the choice of environmental signal and, second, on the data available describing the context of the transduced signal.

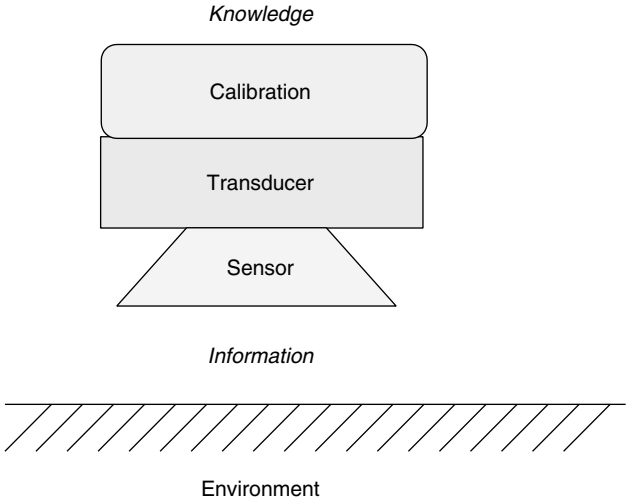

Figure 1. Analysis of environmental information as depending on the choice of the right signal, for example, microbial lipid composition; the use of the appropriate transducer, for example, gas chromatography of the hydrophobic extract; and interpretation of the results by identifying its contextuality, for example, calibration of transduced signal by comparison with database of results from other sites and other microbial communities.

DATA ANALYSIS SCHEME

The data analysis procedure depends on the objectives of the study and the type of data available. Nevertheless, the general layout invariably requires the objectives of the study to be translated in the parallel identification of objective parameters and suitable environmental signals, which are the dependent and independent variables, respectively. It is particularly important that the experimental design or field survey is closely matched by the data analysis layout to explore the possibilities for statistical analysis to the fullest. Accordingly, the scheme outlined in Figure 2 begins with the definition of objectives and proceeds to the point where a mathematical model is developed. However, in many cases, the objective of the study is purely exploratory, in which case, only the left branch of the scheme in Figure 2 applies. In some instances, data analysis is considered only after completion of data collection, and in that case, only the lower half of the scheme applies.

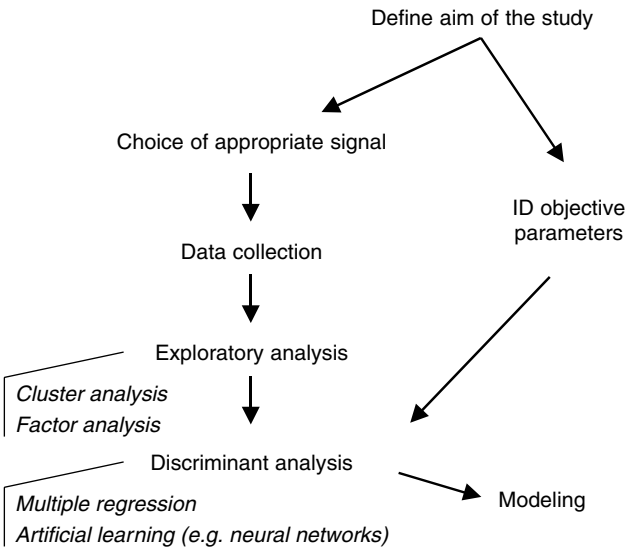

Figure 2. Data analysis scheme, from stating the objectives of the study to developing a mathematical model.

THE RIGHT KIND OF DATA

The other methodological sections overviewed a variety of techniques targeting different components of the microbial

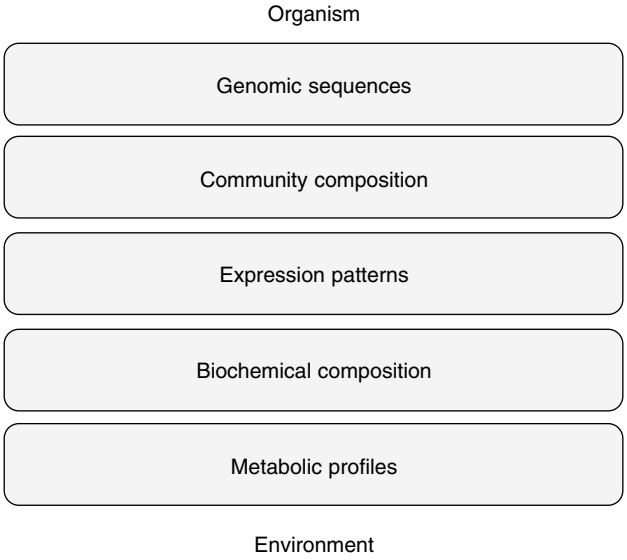

Figure 3. Microbiological signals that can be used to monitor the presence and activity of microorganisms.

community. These components range from the biochemical composition to the genetic makeup and also include expression and metabolic activity patterns (Fig. 3). The usefulness of this information is generally proportional to the mechanistic distance of the target component. For example, the physiological status of a microbial community is more apparent in the lipid composition of cell membranes than on the Restriction fragment length polymorphism (RFLP) pattern of extracted DNA. The diagram in Figure 3 purposefully ignores methods that require isolation and cultivation of microorganisms. That approach, although valid in clinical microbiology or food biotechnology, faces the insurmountable obstacle that the overwhelming majority of microorganisms in the environment would not be detected, that is, less than 1% of soil bacteria detected by direct count are culturable (1,2). Previously well-established environment safety standards based on univariate indicators, such as coliform counts, are now being downplayed in environmental protection regulations as a stand-alone indicator. Therefore, even when convenience is the only concern, multivariate biological indicators offer a better chance for the development of stable standards of environmental quality.

The data produced by these biological signals may take several formats. It may be a vector of concentrations or abundance, it can take a binary format coding for the presence or absence of indicator traits, or finally, it may be reducible to a sequence of categories. One example of each type is presented in Figure 4.

Information Content

In principle, the higher the number of variables in the multivariate signal, the better the chances of finding a predictive association with the objective parameters. However, the individual variables may be correlated and so the added measuring effort will result in an increased redundancy of the signal. The information content can be evaluated by making use of information theory tools, particularly the Shannon information index (3) (Eq. 1):

$$Sh = -\sum_{i=1}^{N} p_i \ln(p_i)$$
$$N : \text{number of components} \quad (1)$$
$$p_i : \text{likelyhood of } i\text{th component}$$

The algorithm to determine the values of p_i is detailed in Table 1, a recent example of this procedure applied to microalgae pigment profiles water samples can also be found in the work by Hofle and coworkers (4).

To compare the information content of profiles with different number of components, Sh can be normalized as an evenness index(5), E, by dividing it by the maximum Sh, which would occur if all components were equally likely ($p_i = 1/N$):

$$E = \frac{Sh}{\ln(N)} \quad (2)$$

Information content indexes are important to determine the ideal conditions to obtain a signal. Figure 5 illustrates this application, where the optimal incubation time for carbon usage tests of solid waste compost samples was found to be approximately 40 hours.

EXPLORATORY ANALYSIS

The variety of techniques available to explore multivariate data is often confusing for the beginning practitioner. The basic statistical techniques for cluster analysis, principal component analysis, correspondence analysis

Table 1. Algorithm to Calculate the Information Content of a Concentration Profile

$C_{i,j}$ = concentration of profile component j sample i. $i = 1, \ldots, n$ and $j = 1, \ldots, m$ i.e., there are m components and n samples.

1. The abundance, A_i, of a component concentration, C_i, is defined as the value relative to the maximum observed concentration. This is a simplistic approach that there may be baseline values and not all concentrations are equally likely. For increased accuracy A_i should be defined as the cumulative frequency of C_i instead.	$C_{\max_j} = \max(C_{ij}, i = 1, \ldots n)$ $A_{i,j} = \frac{C_{i,j}}{C_{\max_j}}$ or (see text) $A_{i,j} = f_{C_{i,j}}$
2. The probability value for each abundance is defined as the relative abundance with regard to the sum of abundances in the sample profile.	$p_{i,j} = \frac{A_{i,j}}{\sum_{k=1}^{m} A_{i,k}}$
3. The Shannon index, Sh, can now be calculated as described in Equation 1	

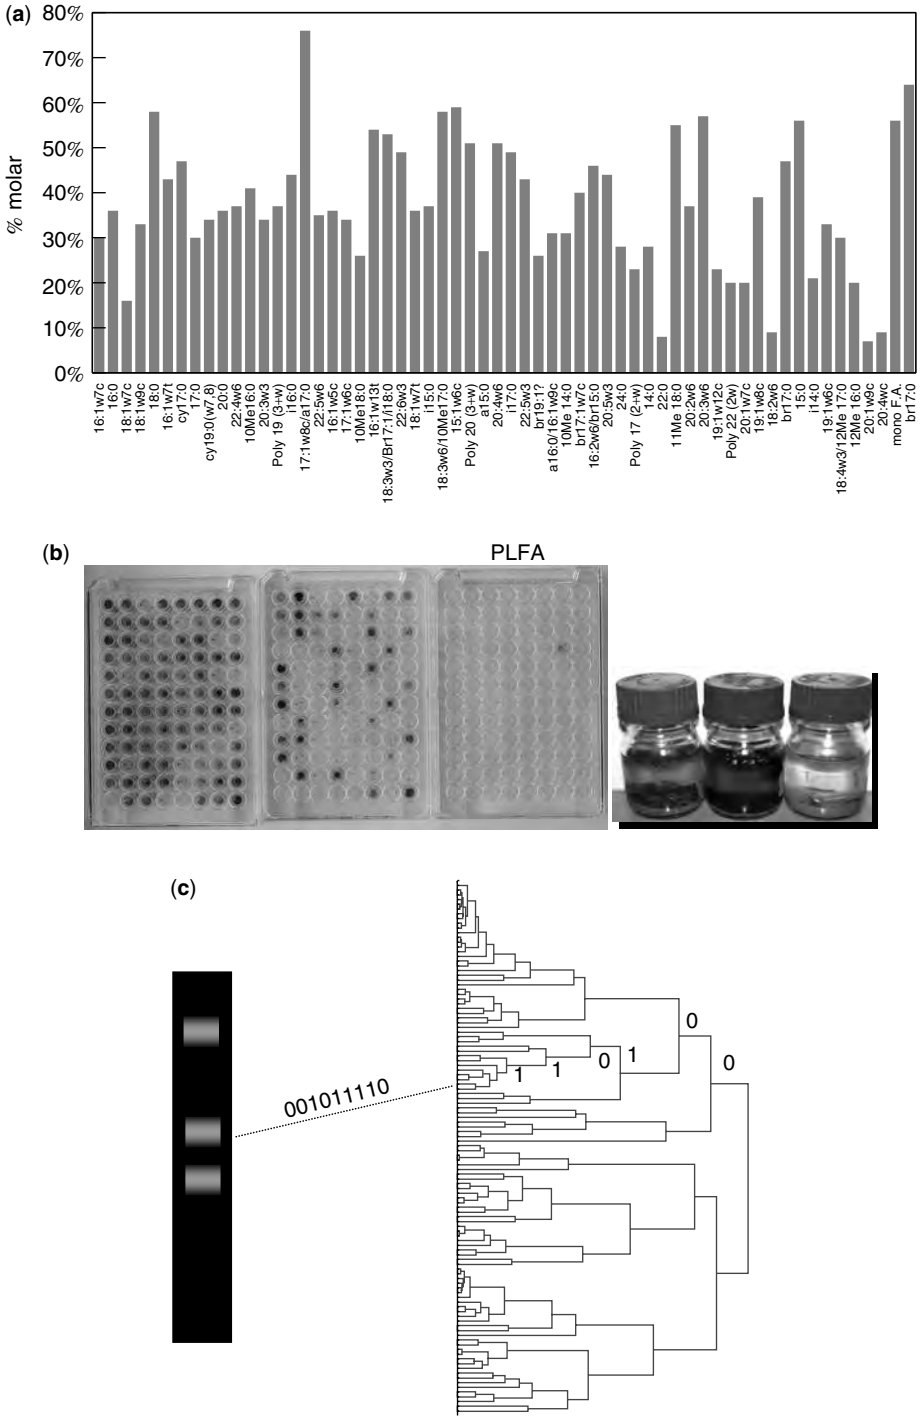

Figure 4. (**a**) Example of a phospholipid fatty acid (PLFA) signature profile. The corresponding numerical format is a vector of molar fractions. (**b**) Carbon utilization pattern obtained with BIOLOG^{TM} galleries inoculated with aqueous extracts of three different soils (flasks). (**c**) PCR amplification of rDNA fragments obtained from soil samples, followed by denaturating gel gradient electrophoresis. The fragments can be sequenced and compared with reference sequences. Its position, with regard to similarity to reference sequences (the position of the band in the gel per se is of little use), can then be translated as sequential binary code as described in the figure. See color insert.

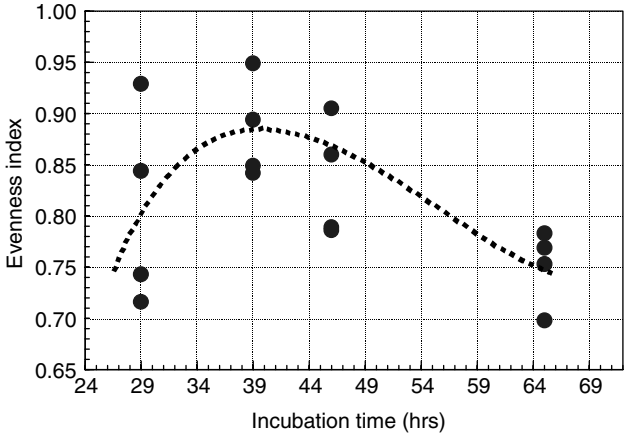

Figure 5. Evenness index (Eq. 2) applied to BIOLOG^{TM} GN carbon source usage galleries to determine the optimal incubation time.

and multidimensional scaling are introduced in this section (Fig. 6). For a more in-depth applied introduction, the reading of Everitt and Dunn Applied Multivariate Data Analysis (6) is recommended. Nonhierarchical clustering by the K-nearest means procedure and the more advanced unsupervised mapping approaches such as Kohonen Maps are also mentioned. It is important to keep in mind that all these techniques are of exploratory nature. They do not test hypotheses regarding their association with the objective parameters (Fig. 2). Instead, they analyze the relationship between the environmental signals and the contribution of their component variables.

The exploratory analysis of acquired data is based on some measure of distance (or dissimilarity) between the sampled signals that is appropriate for the system being studied. As an example, for the binary patterns generated by carbon utilization tests (Fig. 4b) or by bands in RFLP gels (Fig. 4c), it is reasonable to quantify the differences by the number of traits that differ. This is sometimes called the absolute distance or the city-block distance: $d_{i,j} = \sum_k |x_{k,i} - x_{k,j}|$. However, the comparison of concentration profiles using this measure of distance would be biased toward the furthest distances and it is more usual to adopt an euclidean distance: $d_{i,j} = (\sum_k (x_{k,i} - x_{k,j})^2)^{1/2}$. There is a wide variety of similarity indexes and a correspondingly prolific literature (7). The choice of metric is conditioned not only by the nature of the system but also by the objectives of the study. Accordingly, the measure of distance may be of statistical nature, as is usually the case in factor analysis, of geometric nature as in the two examples above, or of any metric that is deemed proportional to the perceived dissimilarity.

Bottom-Up and Top-Down Exploratory Analysis

The descriptive analysis of the multivariate signal is a very extensive field in statistics and the reader is referred to a comprehensive introductory (8) to the advanced (9) literature sources. The choice of analytical approach falls in two complementary sets of techniques, bottom-up and top-down. They both aim at representing the matrix of distances between all the sample signals, with an emphasis on the similarity between individual samples or on the overall similarity structure, respectively.

Cluster Analysis

Cluster analysis designates a technique that iteratively groups (amalgamates) the individual sample profiles by similarity. The importance of this technique for the analysis of biological field data has driven its development from the very beginning, being a statistical methodology largely developed by and for biologists (10). To use this technique, the user needs to define what measures of similarity (or the inverse, distance), and what amalgamation schemes are appropriated for the objectives and nature of the study. Just as the measures of similarity discussed in the preceding text, there is a wide variety of possibilities for amalgamation schemes,

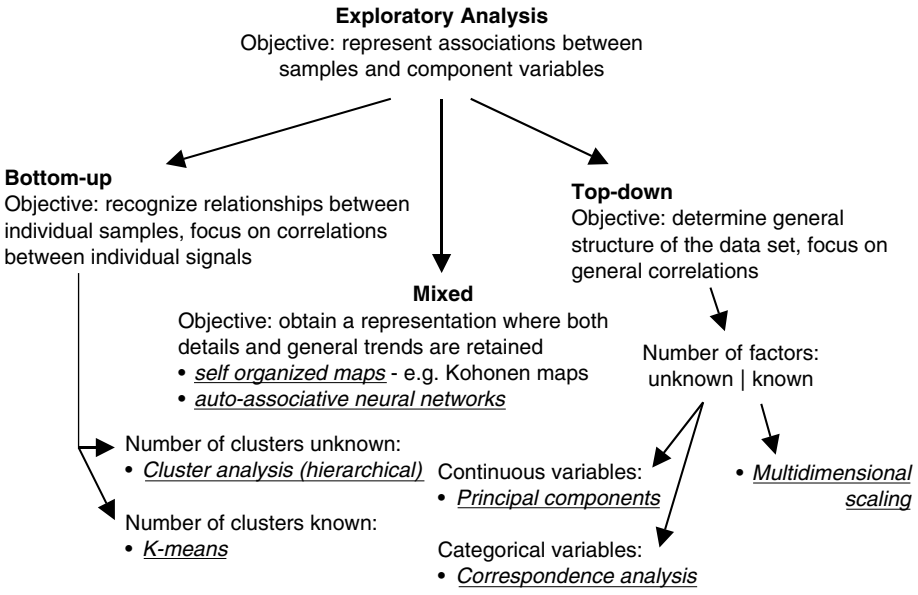

Figure 6. Decision tree to choose the appropriate exploratory data analysis technique.

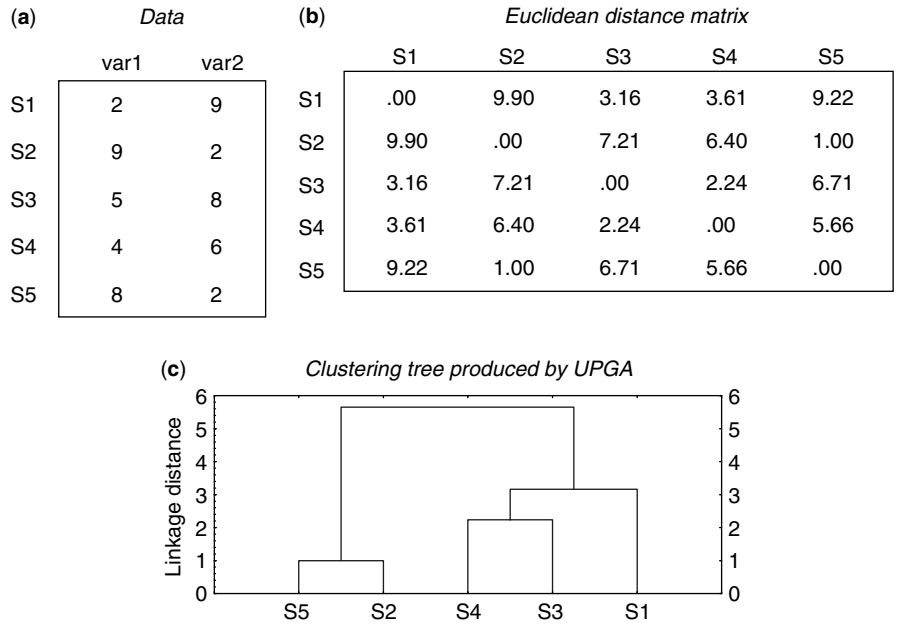

Figure 7. (**a**) Illustration of cluster analysis applied to a data set consisting of five samples characterized for two experimental measures. (**b**) The first step is to determine the distance matrix (dissimilarities, see earlier section) for all possible pairing of samples. (**c**) Then, a tree diagram is generated by following the amalgamation scheme, in this case UPGA, see text.

briefly mentioned in the following text. The linkage between a candidate member of a group can be single or complete. In the first case, the distance is measured with reference to the closest or the average group member, depending on the algorithm. Another variation consists of weighting by the size of the cluster, a useful technique when uneven cluster sizes are expected. Still another possibility is to use the analysis of variance to evaluate distance between clusters (Wards method). With regard to validation, the alternative representations obtained may be evaluated by a number of techniques. The simplest one is to compare the original distance matrix with the distance matrix built from the cluster tree (Fig. 7). The correlation coefficient between the original distance matrix and the matrix of linkage distances in the cluster tree (Figs. 7b,c) is designated as the cophenetic coefficient. More advanced validation techniques involve testing the stability of grouping by removing and reintroducing candidate sample profiles (11), which leads to branching schemes by likelihood of group membership (12). The most frequent choice of amalgamation rule is arguably the unweighted pair-group average, often referred to by the initials UPGA. In Figure 7, this amalgamation scheme is illustrated for five samples in which two variables were measured.

The example in Figure 7 illustrates a hierarchical cluster analysis procedure. As one looks deeper in a cluster, the less reliable it is to use linkage distance to predict similarity between individual samples. If the number of clusters in set beforehand, than a nonhierarchical k means that a clustering technique can also be used. This procedure will distribute the samples between k groups to minimize the profile variance within groups and maximize it between groups.

Factor Analysis

Multivariate factor analysis is the most widely used technique for top-down exploratory analysis. The purpose of factor analysis is to reduce the number of variables or axes required to represent the data set by identifying the contributions of each component of the sample profile, characterizing the data structure. The factors are identified by the linearization that represents most of the residual variance from the previous factor identification. The simple example described in Figure 8 uses the data of Figure 7 to illustrate the extraction of one principal factor from a two-dimensional data set. Factor analysis can be applied to higher dimensional sets where, for practical reasons of visualization, only two or three factors are typically identified. This approach can be applied to both continuous and categorical data. In the former case, principal component extraction is the method of choice, whereas the latter requires correspondence analysis. The resulting representations of sample profiles can be evaluated by determining how much of the total variance is explained by each of the factors extracted.

If the final number of dimensions is known beforehand, and to avoid an uneven distribution of variance by the reduced orthogonal coordinate axis, multidimensional scaling can also be used. This technique aims at representing the multivariate data in a predefined reduced dimension space such that most of the variance is represented, and is so in either reduced coordinate axis.

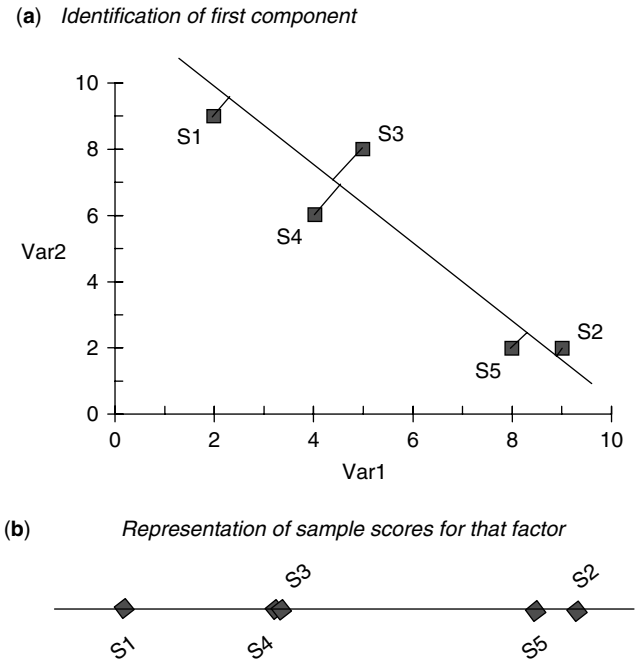

Figure 8. Illustration of extraction of first principal component for the two-dimensional data set of Figure 7. See color insert.

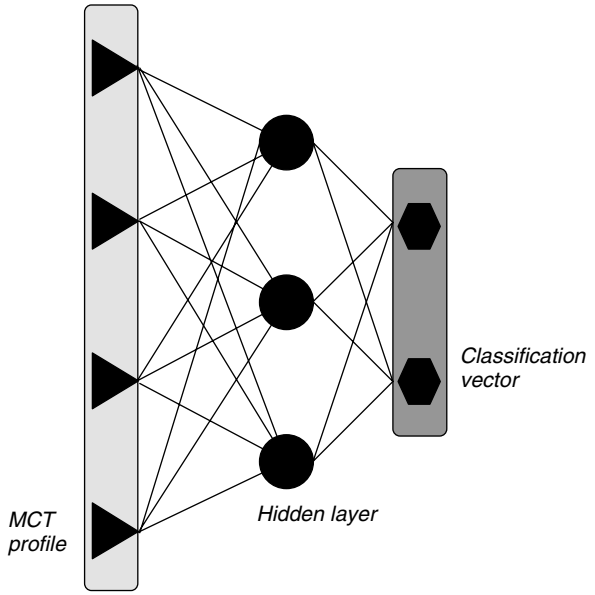

Figure 9. Schematic architecture of a three- layer feed-forward network used to associate microbial community typing (MCT) profiles with classification vectors. Symbols correspond to neuronal nodes (Eq. 8). See color insert.

Self-Organizing Maps

From an applied perspective, self-organizing maps (SOMs) represent a compromise between cluster analysis and factor analysis. The principle consists in organizing the sample in a space such that similar profiles will be close to each other. SOM achieve this by interconnecting all samples and then "straining" its lengths according to similarity between profiles. The resulting maps represent a coordinate system in which the samples can be placed such that their profiles change smoothly with position. This technique reached maturity with the landmark work of Tuevo Kohonen in early 1980s and an updated review of the methodology and application was recently published (13).

Auto-Associative Neural Networks

Feed-forward neural networks (NNs) associate input (independent) multivariate signals with one or more output (dependent) variables. The principles behind its development are discussed below under Discriminant Analysis since NN are primarily a classification technique. However, if the independent variables (Fig. 9, input) are also used as the classification or dependent criteria (Fig. 9, output), then the value obtained for the hidden nodes can be used as coordinates of a space with reduced dimensionality. The resulting map is somewhat similar to the Kohonen SOMs, except that instead of similarity, proximity represents the existence of a similar predictive model. Consequently, dissimilar profiles with component variables similarly related (for example, obeying to fixed rations) will be placed in adjacent regions. The use of auto-associative NNs as an exploratory technique has been applied alongside conventional factor analysis to map changes in soil microbial community composition signaling for bioremediation (14). This approach is sometimes compared with factor extraction by noting that its graphic representation would resemble Figure 8, except that instead of lines, one would find curves becoming a de facto principal curve extraction procedure.

DISCRIMINANT ANALYSIS

Strictly speaking, discriminant analysis is the procedure that identifies which independent variables are distinct between samples recognized as belonging to different classes (for example, subjected to different treatments, coming from different geographic locations, etc.). Out of convenience, this section also includes other modeling techniques such as multilinear regression and neural networks. The rationale is that all these procedures aim at identifying a discriminant function (Eq. 3) that can predict the value of the objective parameters (Fig. 2, right branch), which could be either continuous such as the concentration of a pollutant, or discrete, such as having been subjected to a specific treatment. The discriminant function, f_{DF}, uses the chosen signal components as independent variables (Fig. 2, left branch).

$$\text{Objective parameters} = f_{DF}(\text{signal components}) \qquad (3)$$

Regression of Explicit Functions (Multiple Regression)

The simplest multiregression technique assumes a linear relationship between dependent and independent variables. Therefore, when using multilinear regression, the discriminant function associates each of the n-objective

parameters $OP_{i=1,\ldots,n}$ to a multilinear combination of each of the m-signal components $SC_{j=1,\ldots,m}$ (Eq. 4).

$$OP_i = a_i + \sum_{j=1}^{m} (b_{i,j}\, SC_j) \tag{4}$$

The value of $b_{i,j}$ is more than a proportionality coefficient between OP_i and SC_j, it also quantifies the association between the two. However, when interpreting the associations uncovered, particular attention must be given to the level of intercorrelation between the signal components as mentioned in the section on Information Content. There are several techniques to handle redundancy, such as forward variable addition (15). Another important warning to bear in mind refers to the generality of multilinear models. If the number of components in the input signal is of the same order as the number of signals collected, not enough degrees of freedom will be left to make the model generalizable. The problem of model over-fitting is relevant for all the techniques in this section and it is further explored later in the article while discussing the optimization of artificial neural networks, the ultimate discriminant functions.

The association between environmental parameters is hardly ever linear. Therefore, if there is mechanistic evidence for a particular nonlinear formulation that should be incorporated in the formulation of the f_{DF}. A very common example is the existence of exponential relationships, such as the one that occurs between optical density and concentration. The use of hyperbolic formulations is also a widely used function such as the Michaelis-Menten equation for rate limitation by the availability of substrate (Eq. 5).

$$v = v_{max} \frac{S}{S + Km} \tag{5}$$

The latter example will now be used to demonstrate how a basic nonlinear association can be used to achieve a comprehensive mathematical description. In a waste treatment system most components can be classified as substrates, products, or microbial components. Using the reaction rates as objective parameters implies that the identification of f_{DF} corresponds to defining the dependency on each of these three components. The starting point was Equation 5, for dependency on substrate. The microbial component is the reactive element and as such defines the saturation rate, v_{max} (Eq. 6).

$$v = (X\, v_{max}) \frac{S}{S + Km} \tag{6}$$

Finally, inhibition by-product can also be formulated as a hyperbole by using the difference between the concentration for total inhibition, P_{max}, and the concentration present in the media, P (Eq. 7).

$$v = (X\, v_{max}) \frac{S}{S + Km} \frac{P_{max} - P}{P_{max} - P + Kp} \tag{7}$$

In spite of the apparent over-simplified formulation of the role of the three components in the system, a model built exactly on these principles is currently the gold standard to model microbiological wastewater treatment. Since 1987, the International Association for Water Quality (IAWQ) has been systematically compiling formulations describing the individual effects of an increasing number of microbial and chemical components playing a role in activated sludge systems. The product of this factorization exercise is the widely used ASM, Activated Sludge Model (16).

Neural Networks — A Very Quick Guide

Among the most important tools deriving from bioinformatics research is the artificial neural network (ANN) technique. An ANN is a massively parallel-distributed processor able to store experience-based knowledge and make it available for use. It resembles the human brain in two respects: (*1*) knowledge is acquired by the network through a learning process, (*2*) interneuron connection strengths known as synaptic weights are used to store knowledge (17). The ability of an ANN to identify mathematical models that closely fit data without the need for mechanistic assumptions is ideally suited for the analysis of complex data sets such as ecosystem variables and DNA microarray hybridization patterns. If properly implemented, the resulting mathematical formulation distinguishes signal from noise in the associations among an arbitrary number of parameters. ANNs have a wide range of biological applications, from modeling soil bioremediation (14), to genomic sequence analysis (18). Clustering like samples (19,20) and learning from examples without a priori knowledge of causality (21) are some of the most important uses of ANN. The reader is referred to studies by Hagan and coworkers (22) for applied design and implementation of ANNs, by Haykin (1994) (17 and Bishop (1995) (23) for the theoretical foundations, by Montagne and coworkers (1994) (24) for a review of contributions in biotechnology, and, finally, by Cheng and coworkers (1994) (25) for a discussion from a statistical perspective that approaches ANNs as universal discriminant functions. The steps involved in developing an ANN involve: (*1*) assembling the network of unit processors, (*2*) training them by changing the connection weights to minimize the predictive errors, (*3*) regularizing the solution to ensure its general nature, and finally, (*4*) repeating the previous steps for the domain of ANN topologies to find the optimum extraction of signal versus noise. This four-step procedure is inspired in the process of natural learning and is detailed in the following section for a feed-forward ANN architecture:

1. Assembling parallel processing units in fully connected layers. Each neuronal node is equated to a sigmoidal function, f, of the product of a weight matrix, w, by the input vector x:

$$y = f(wo + w\, x), f(\alpha) = \frac{1}{1 + e^{\alpha}} \tag{8}$$

2. Training ANN with cross-validation as a stop criterion, that is, part of the data are excluded from

training and are used to evaluate the generality of predictions.

3. Bootstrapping each topology evaluated. The validation subset is resampled repetitively and the ANN is retrained with cross-validation each time. The median performer is selected. This procedure avoids the possibility that the validation data set may not be representative of the whole.
4. Optimization of topology. The range of topologies is searched for the one with the best performance. The complexity of the topology selected is proportional to the complexity of the signal extracted (26).

CONCLUSION — MODELING ENVIRONMENTAL COMPLEXITY

"All models are wrong but some are useful" (27) is frequently quoted to highlight the utilitarian purpose of models. Conventionally, models are mathematical formulations of hypothesis. The validity of predictions by models is also the validity of the underlying hypothesis. Although the mathematical formalism varies widely, from simple conditional statements to multiagent systems, the convention calls for the definition of two components state variables, and state equations. The state variables are the parameters chosen to describe the dynamic behavior and the state equations describe their interdependence. The choice of variables and the formulation to describe the underlying mechanism for interaction obeys another frequent quote known as Ocham's razor: "Simplest explanation and theory is right." Ocham's razor applies not only to model formulation but also to the very choice of state parameters "No more things should be presumed to exist than are absolutely necessary" (also quoting W. Ocham). These two principles, usefulness and simplicity, command the formulation and validation of models with the goal of capturing system mechanism and the reproducing system dynamics. Modeling is the ultimate product of data analysis and that is the reason it is discussed last. Like in many other areas, the modern advances in computation are reshaping fundamental aspects of data analysis. Modeling has typically been used as a hypothesis testing tool. However, the advent of machine learning, such as ANNs, is reversing the paradigm. If, in model identification, the mechanistic description is replaced by an artificial learning component, which is allowed to regress to existing evidence, then an implicit, nonmechanistic, formulation emerges. As a consequence, the challenge is moved from model identification to the sensitivity analysis of its predictions. This role reversal turns modeling from a hypothesis testing tool into a hypothesis generating tool. The fundamental question raised by automated modeling identification through machine learning is if that solution may be more than a practical shortcut to an otherwise time-consuming problem. The modern concept of biocomplexity (28) offers some answer by claiming that real open biological systems are not wholly amenable to mechanistic reduction, for example, there is no comprehensive explicit mechanism that describes system dynamics. Accordingly, complexity is defined as a behavior that cannot be reduced to a combination of behaviors of component units. This statement reflects the observation that generation of information in complex systems resides mostly in the interaction between those component units. Since microbial ecology is inherently complex, in the sense described earlier, it is to be expected that artificial intelligence, information theory and statistical mechanics will become more prevalent as tools for data analysis in environmental microbiology.

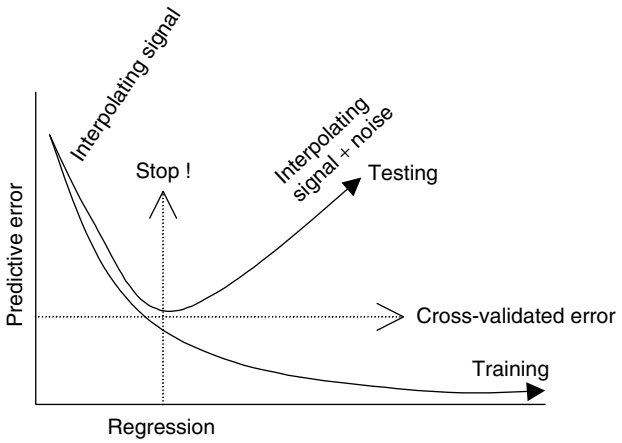

Figure 10. Description of the early stop procedure: regression is applied to the test sub-data set but the error is also calculated for the validation sub–data set. In the course of regression, the divergence between the two signals, the beginning of over-fitting and the regression is stopped.

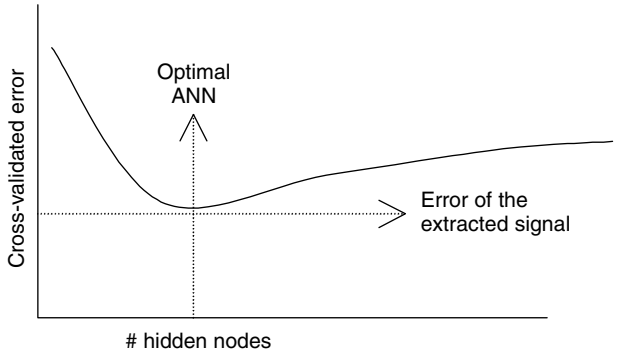

Figure 11. Optimization of topology: the procedure described in 1–3 is repeated for different number of hidden nodes, and the ANN with the smallest cross-validated error is selected.

DENITRIFICATION AND THE MARINE NITROGEN CYCLE

Bioavailable nitrogen, mainly inorganic and some organic species, is one of the essential building blocks of life. In marine systems, which include coastal estuaries and the open ocean, the amount of the bioavailable nitrogen influences the carbon cycle by regulating the accumulation of organic biomass, limiting the rate of primary production, and determining which major nutrient (nitrogen, phosphorus, or silica) limits primary production (1). Simply put, nitrogen cycling in marine systems influences local and global processes. An understanding of nitrogen inputs, recycling, and removal in the marine environment is required for understanding global nitrogen and carbon cycles. Biologically mediated processes govern the transformation of nitrogen among organic, dissolved inorganic, and gaseous forms (Figs. 1 and 2). Three processes serve as cornerstones for nitrogen cycling in the marine environment: nitrogen fixation, nitrification, and denitrification. These processes transform nitrogen between gaseous and dissolved inorganic forms.

The inorganic forms of nitrogen include oxidized (nitrate, NO_3, and nitrite, NO_2) and reduced (ammonium, NH_4) species. Inorganic nitrogen compounds are present at ultralow (nanomolar to low micromolar) concentrations in surface ocean waters, but concentrations increase with depth and accumulations of tens of micromoles per liter are common in deep waters. In addition

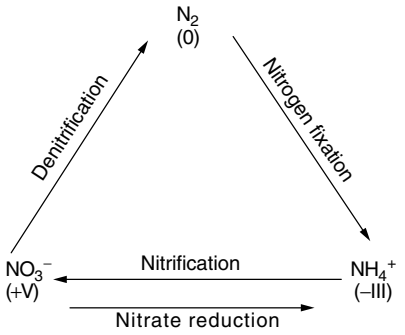

Figure 1. Linkages between the reductive and oxidative processes of nitrogen cycle, focusing on denitrification, nitrogen fixation, and nitrification. Dinitrogen gas, nitrate and ammonium (valence state in parentheses) are the major dissolved inorganic forms of nitrogen. The major reductive processes are nitrogen fixation and denitrification. Nitrogen fixation converts highly inert dinitrogen gases into ammonium, which is assimilated and used to build biological biomass. Nitrification is the oxidative component of the nitrogen cycle and is linked to denitrification, the reduction which closes the nitrogen cycle by regenerating dinitrogen gas. In some cases, nitrate is reduced to ammonium (rather than to dinitrogen) serving assimilatory (providing ammonium for incorporation into biomass) or dissimilatory (using the reduction to generate energy) functions. Conversion of organic nitrogen to ammonium recycles nitrogen to the inorganic pool and connects biological nitrogen fixation to nitrification (Fig. 2).

to dissolved inorganic forms, nitrogen is present in dissolved organic, particulate (organic and inorganic), and other gaseous forms (Fig. 2). Organic nitrogen includes particulate organic nitrogen (e.g., living organisms and detritus) and dissolved organic nitrogen (e.g., amino acids and proteins). Dissolved organic nitrogen concentrations may exceed dissolved inorganic nitrogen concentrations in marine waters. The most abundant nitrogen compound in marine waters is a dissolved gas, dinitrogen (N_2). Dissolved dinitrogen originated either from atmospheric equilibrium or from in situ production via denitrification. Nitrogen trace gases, such as nitrous oxide (N_2O), are present at low (nanomolar) concentrations. Inorganic and organic nitrogen forms are available to biological organisms (i.e., they are "bioavailable") and therefore support the production of new biomass (primary production; Fig. 2). However, dinitrogen (N_2) can serve as a nitrogen-nutrient source only to a limited number of bacteria that possess a special enzyme, nitrogenase, which reduces N_2 to NH_4 and subsequently incorporates NH_4 into the biomass (Figs. 1 and 2) (2). Small deviations in the amount of oceanic denitrification (internal loss of nitrogen) relative to nitrogen fixation (internal gain of nitrogen) can alter the uptake of atmospheric of carbon dioxide by influencing rates of primary production.

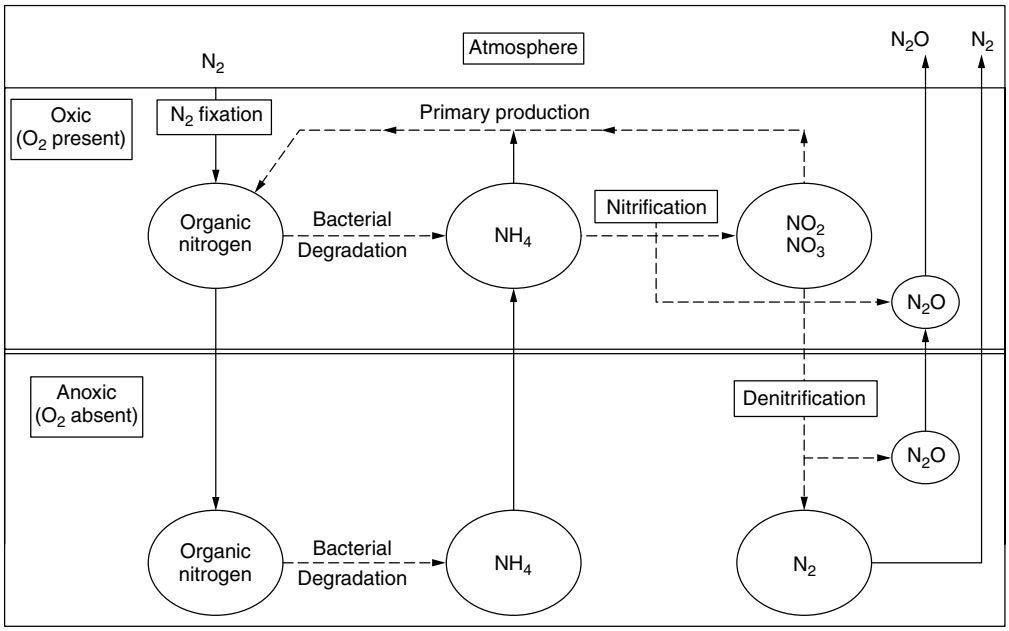

Figure 2. Denitrification in aerobic (O_2-rich) and anaerobic (O_2-poor) marine environment and the connection with the atmosphere. The dominant nitrogen species are shown in large circles, whereas the less abundant species are shown in small circles. The transition from aerobic to anaerobic conditions can occur at the water–sediment interface or within the water column in highly productive areas within a stratified water column. Generally speaking, marine waters are aerobic, whereas sediments are anaerobic. Biologically mediated processes are marked by dashed lines with arrows, whereas physical processes (settling, diffusion) are marked by solid lines with arrows. The three dominant transformations of nitrogen between pools, mainly nitrogen fixation, nitrification, and denitrification, are shown in bold. These three processes are interconnected by the processes of primary production, which produces organic nitrogen and bacterial degradation, which recycles organic nitrogen to the ammonium pool. Whereas primary production and nitrification are largely restrictive to aerobic regions of the water column, denitrification is restricted to anaerobic regions. Bacterial degradation occurs throughout the water column.

Rates of nitrogen inputs, dominant transformations, and removal vary in the different parts of the marine environment. Inputs of nitrogen to marine ecosystems include external (terrestrial or atmospheric sources) and internal (biological nitrogen fixation) terms. Rates of land-derived nitrogen loading from rivers and groundwater to the marine environment are highest near continental margins; the importance of atmospheric inputs depends on the proximity to margins and on atmospheric weather patterns (3,4). As a result, inorganic nitrogen concentrations are highest near the continents and decrease with increasing distance offshore. In stratified environments or in oxygen-limited zones, inorganic nitrogen concentrations are higher in anoxic or suboxic (bottom) waters below the photic zone than in oxic (surface) waters. Rates of biological processes, such as dinitrogen fixation or nitrification, vary as a function of bioavailable nitrogen concentration, oxygen concentration, nitrogen speciation (organic versus inorganic), and the abundance of the necessary microorganisms (5,6) (Fig. 2). Nitrogen input to marine systems is rapidly taken up by biological organisms and a single nitrogen molecule is recycled between organic and inorganic pools many times before being removed from the marine system (7). Of the nitrogen available in marine systems, some fraction is "removed" from the system on an annual basis and is thus no longer available to support biological production. Removal occurs through two mechanisms: burial or denitrification. Burial of nitrogen in sediments removes nitrogen from the active cycle by transferring nitrogen (mainly organic) into a compartment (the sediment) that cycles on timescales exceeding the residence time for nitrogen in the ocean.

The focus of this article is the process of denitrification. Denitrification is the only biological process that culminates in the production of dinitrogen gas (N_2) (8,9). As most primary producers (phytoplankton and plants) cannot use dinitrogen as a source of nutritive nitrogen (2), dinitrogen production serves to effectively regulate the amount of bioavailable nitrogen in an ecosystem. The process of denitrification, the microorganisms that mediate denitrification, and the environmental controls on denitrification will be described briefly. The methods used to quantify denitrification will be summarized, and then the distribution and rates of denitrification in different parts of the marine environment will be overviewed. Finally, important areas of future research on denitrification will he highlighted.

DENITRIFYING BACTERIA

Denitrification is the dissimilatory reduction of nitrate or nitrite to a gaseous end product (e.g., nitric oxide, NO; nitrous oxide, N_2O; or N_2) (10). Denitrification rates are influenced by a variety of microbiological and environmental factors. For denitrification to occur, microorganisms capable of mediating the process must be present. Though more denitrifiers cluster in the alpha and beta subclasses of the proteobacteria, denitrification is distributed in 40 genera of bacteria and is also present in halophilic archaea (10,11). Denitrifying microorganisms obtain energy in a variety of ways, ranging from photoautotrophy (obtaining energy from sunlight), to chemoautotrophy (obtaining energy from the oxidation of inorganic compounds), to strict heterotrophy (obtaining energy from organic matter oxidation). The majority of denitrifying bacteria are facultative anaerobes, meaning that they use NO_3^- as the terminal electron acceptor only when oxygen concentrations fall below a critical threshold concentration, commonly accepted to be around 20 μM (12). Under low oxygen conditions, and when supplied with sufficient nitrate, denitrifying bacteria couple nitrate reduction with the oxidation of organic matter (10,13):

$$4HNO_3 + 5CH_2O \rightarrow 5CO_2 + 7H_2O + 2N_2(\text{gas}) \qquad (1)$$

During this process, nitrate is sequentially reduced to dinitrogen through a series of intermediates (Fig. 3). The reduction of nitrite to nitric oxide is the first step that produces a gaseous intermediate and is thus, technically, the first step of denitrification. Respiratory nitrate reduction to nitrite, followed by nitrite excretion, does not constitute denitrification. Denitrification is catalyzed by enzymes associated with the cytoplasmic membrane, and heterotrophic denitrifying bacteria conserve energy via the generation of an electrochemical proton gradient (11) (Fig. 3). A detailed discussion of denitrification enzymology is available in Zumft (10) and will not be provided here.

At times, the process of denitrification may result in the production of N_2O, rather than N_2, as the primary product. The term "incomplete denitrification" is used to refer to such a short-circuiting in the denitrification pathway. The production of N_2O, instead of N_2, may arise from the fact that the microorganisms carrying out denitrification lack the terminal enzyme, N_2O reductase, and are thus unable to produce N_2. However, under certain environmental conditions (e.g., in the presence

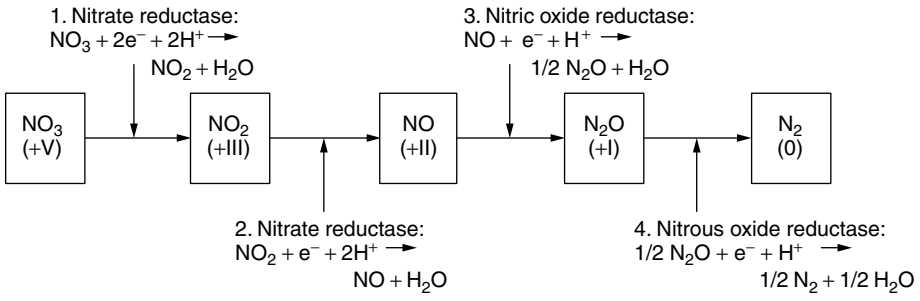

Figure 3. The four steps of denitrification process. Nitrogen species are shown in boxes with the valence state of the species given in parentheses. The enzymes mediating the sequential steps (numbered 1 through 4 on the order of occurrence) of the reaction are also shown.

of hydrogen sulfide or high concentrations of nitrate) microorganisms capable of producing N_2 may produce N_2O instead (Fig. 4; see later). High rates of N_2O production and release into the marine environment may also result from higher-than-optimal oxygen tensions in the denitrification zone. As N_2O is a radiative trace gas that contributes substantially to the greenhouse effect in the Earth's atmosphere, understanding the sources, sinks, and controls on N_2O flux from the environment is important. Denitrification is thought to be a source of N_2O in the marine environment; however, the dynamics of N_2O production and consumption are poorly understood in most marine habitats.

In addition to heterotrophic denitrification, several additional mechanisms of denitrification exist. Some autotrophic microorganisms couple nitrate reduction to the oxidation of inorganic sulfur, hydrogen, ammonia, or nitrite (10). The alternative denitrification pathways referred to as "denitrifying nitrification" (14,15) and the "anamox" reaction (16–19) have been well documented. Of these, the anamox reaction, that is, N_2 formation resulting from NO_3 reduction coupled to anaerobic NH_4 oxidation, could play an important role in the marine nitrogen cycle. However, the importance of this alternative denitrification mechanism on the global nitrogen cycle is largely unknown.

GENERAL CONTROLS ON DENITRIFICATION

The magnitude of the marine denitrification term in the global nitrogen cycle is determined by spatial and temporal variations in denitrification rates, which are influenced by a suite of environmental and physiological factors. Denitrification requires low oxygen concentration and ample supplies of nitrate and dissolved organic carbon (13). Like most enzyme-catalyzed reactions, denitrification rates vary in proportion with temperature. In a given environment, lower temperatures tend to result in lower denitrification rates and vice versa. Other environmental variables, such as salinity and pH, may also impact denitrification in some areas. In most of the marine environment, the salt content (salinity) of the water is high and stable and thus does not impact denitrification rates. However, in coastal regions where the salt content may vary significantly over short (daily, tidal) or seasonal (as a function of freshwater inflow) timescales, increased salinity may result in reduced denitrification rates (20). The pH is probably not a major control for denitrification in marine water columns but may influence denitrification rates in marine sediments. In coastal regions, where lower pH freshwaters mix with marine waters, system-scale variations in pH might affect denitrification rates. The impact of such pH variations on coastal denitrification rates has not been studied in detail. Some denitrifying bacteria use alternative sources of reductants, such as H_2 or H_2S (instead of organic carbon), and the concentrations of these chemical species may influence denitrification, particularly in low oxygen or anoxic water column and sediment environments.

The most frequently used controls for heterotrophic denitrification in the environment are oxygen, nitrate, and

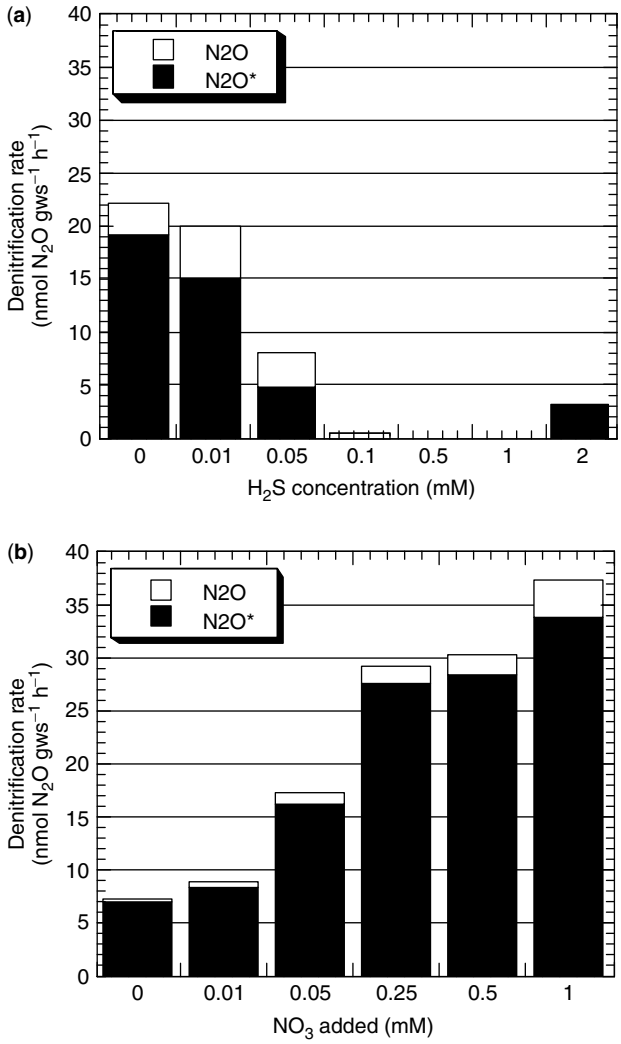

Figure 4. Potential denitrification in estuarine sediment slurries; closed bars reflect nitrous oxide (N_2O) production in the presence of acetylene and open bars reflect N_2O production without acetylene. (**a**) Rates when slurries were amended with varying hydrogen sulfide concentration in the presence of nitrate (1 mM) and glucose (0.5 mM). Denitrification rates are inhibited by low (10 to 50 μM) hydrogen sulfide; no bar infers that the rate was below the detection limit. (**b**) Denitrification rates when sediment slurries were amended with varying amounts of nitrate in the presence of glucose (1 mM) concentration. Both the denitrification rate and the acetylene-free N_2O concentration increase with increasing nitrate concentration. The acetylene-free N_2O production rate increases from less than 1% of the total N_2O production rate to over 10% of the total N_2O production rate at the highest nitrate concentration.

organic carbon concentrations. As denitrifying bacteria are facultative anaerobes, they use nitrate as the terminal electron acceptor only when oxygen concentrations are low; under high oxygen tension, oxygen is respired instead of nitrate. Once oxygen concentrations fall below a certain threshold concentration (20 μM) (12), nitrate respiration begins. However, the ultimate effect of dissolved oxygen (O_2) dynamics on denitrification can

be one of stimulation rather than inhibition. Oxygen availability can increase rates of nitrification (nitrifying bacteria are obligate aerobes). Because nitrification often supplies the nitrate to denitrifying bacteria, higher oxygen tensions could, in effect, stimulate denitrification. When nitrification supplies the nitrate that is denitrified, the process is referred to as "coupled denitrification." Processes that alter the O_2 concentration or the thickness of the oxic zone, such as primary production, aerobic respiration, and aerobic oxidation of reduced metabolites, influence the rates of nitrification and, as a result, denitrification (21).

Whereas photosynthesis may stimulate coupled denitrification by increasing nitrification and indirectly providing an NO_3 source to denitrifiers, photosynthesis may also inhibit denitrification by elevating the O_2 concentration above the critical, inhibitory threshold. High O_2 concentration often leads to a shift from denitrification to aerobic respiration (22). The ultimate effect of photosynthesis on denitrification depends on the absolute oxygen concentration, which results from the balance between respiration and photosynthesis (23). Additionally, the role of benthic photosynthesis as a stimulator or inhibitor of coupled denitrification is influenced by the nitrogen inventory of the system being studied. Stimulation of coupled denitrification by benthic photosynthesis in lake and estuarine sediments has been reported under nitrogen sufficient conditions (23,24). In contrast, inhibition of nitrification and denitrification has been inferred under dissolved inorganic nitrogen limited (i.e., low concentration) conditions (23,25). The interaction between benthic primary production and denitrification is complicated, and seasonal variation in rates of photosynthesis and in the nitrogen-nutrient status of primary producers may lead to alternating impacts (stimulation in summer and limitation in winter) (23,26) on denitrification.

Other environmental factors that alter the distribution of O_2, such as wind-induced mixing of water bodies, bioturbation (i.e., mixing of sediment or pore fluids) by infauna (27,28), or root pumping of O_2 into the sediments by benthic plants may also impact rates of nitrification and/or denitrification (29,30). Nitrification and bioturbation are often positively correlated because bioturbation stimulates nitrification by increasing O_2 availability (31,32). Spatial and temporal variations in temperature, organic carbon supply, and O_2 and H_2S concentration may affect nitrification and, thus indirectly influence denitrification (33,34) or coupling between nitrification and denitrification (35,36).

Nitrate and organic carbon concentrations also strongly influence denitrification rates (22). If either of these substrates is present in limiting amounts, then denitrification rates fall well below maximal potential values. Anoxic fine-grained, organic-rich sediments accumulate significant concentrations of labile organic carbon, such as acetate and other low molecular weight volatile fatty acids. In such environments, ample organic carbon exists to fuel denitrification; nitrate, more frequently than organic carbon, limits denitrification. Nitrate limitation arises from the fact that nitrate must diffuse from oxic environments into the anoxic sites where denitrification occurs. In sandy, organic-poor sediments, organic carbon can limit denitrification rates. Organic carbon limitation of denitrification has been inferred more frequently in tropical systems than in temperate systems. In tropical ecosystems, either nitrate and/or organic carbon may limit denitrification (37,38).

Most denitrification in the environment is dependent on nitrification, the oxidation of ammonium to nitrate (6), for its substrate supply (Fig. 2). Therefore, a close temporal and/or spatial association between nitrification and denitrification is required to deliver nitrified nitrate efficiently to the zone of denitrification. The importance of coupled denitrification in the marine environment cannot be understated. The mechanism of nitrate delivery to denitrifying zones, however, varies. Nitrate may be produced in the water column and subsequently diffuse or advect (via bioturbation) into the anoxic sediments or into an anoxic part of the water column where denitrification occurs (Fig. 2). Alternatively, nitrate may be produced in oxic sediments by nitrification and then diffuse into anoxic microsites or layers where denitrification occurs. Finally, in coastal zones, nitrate may be delivered to, or produced within, an aquifer, and then nitrate-containing groundwater may later be transported through coastal sediments where denitrification intercepts groundwater-derived nitrate (39). The term "direct denitrification" is used to describe the case where nitrate is derived from an external source, that is, a source outside of the system being studied. Though the source of this external nitrate could be nitrification, nitrification and denitrification are not explicitly linked in space and/or time. As the processes are acting independently of each other, they are uncoupled (thus the term "direct" denitrification).

As stated previously, denitrification is restricted to anoxic environments where supplies of both nitrate and organic carbon exist. Most of the marine environment do not fit these criteria; however, certain marine regions do fit the criteria and these areas support extremely high, globally significant rates of denitrification. There are three major regions of denitrification in the marine environment: in bottom sediments, within midwater oxygen minimum zones that occur beneath highly productive surface waters, and within basins where restricted water exchange leads to the development of anoxic conditions. Though denitrification has been documented in particles suspended within oxic waters in coastal environments, the importance of this phenomenon in the global nitrogen cycle is yet to be illustrated. In sediments and water columns, denitrification represents a significant sink for bioavailable nitrogen. Integrated rates of denitrification in these environments are significant compared to other fluxes in the global nitrogen cycle. Thus, denitrification influences the local, regional, and global inventories of bioavailable nitrogen, and thereby impacts patterns of nutrient limitation on short (seasonal) and long (geologic) timescales (7,9,40–42). Because quantifying in situ denitrification rates has represented an experimental challenge, the methods used to quantify denitrification will be presented before summarizing the distribution of denitrification in marine systems.

QUANTIFYING DENITRIFICATION RATES

The product of denitrification, that is, dinitrogen gas, N_2, is the dominant gas in the Earth's atmosphere (78%). Thus, marine waters in equilibrium with the atmosphere contain high dissolved N_2 concentrations ($\geq$300 μmol L^{-1}). This high background concentration makes it difficult to quantify the small changes accurately — usually less than a small percentage of the total pool — arising from in situ denitrification. As a result, many indirect methods, which do not depend on dissolved N_2 quantification, have been developed to estimate denitrification rates. The choice of method for quantifying denitrification depends primarily on whether the goal is to evaluate rates of direct and/or coupled denitrification, and on whether estimates of in situ or potential activity is desired. For simplicity, the various methods will be partitioned into three groups: direct methods, indirect methods, and potential methods. A detailed overview of the methods currently available to estimate denitrification can be found in Cornwell and coworkers (43).

Direct methods quantify the production of N_2 over time, thus providing a direct assessment of the denitrification rate. Dinitrogen concentration can be quantified via thermal conductivity gas chromatography (TCD-GC) or via membrane inlet mass spectrometry (MIMS). The TCD-GC approach is the least sensitive of the two, but this approach is also the more economical approach. Using the TCD-GC approach, samples may be degassed of N_2 and incubated for several days; then the production of N_2 over time can be used to estimate the denitrification rate (44,45). The preincubation period can be eliminated if appropriate anoxic controls are included (45). Several reports of N_2 quantification via TCD-GC without a degassing step are present in the literature (46,47); however, only high denitrification rates can be measured without initial degassing using traditional chromatographic approaches. By employing a different chromatographic column, An and Joye (23,48) were able to determine fairly low denitrification rates in a coastal sediment during an in situ benthic chamber incubation without initial degassing of N_2.

A significant step forward in the quantification of denitrification in the environment was the application of the MIMS technology to the study of denitrification (49,50). The MIMS technique makes it possible to determine denitrification rates quickly and accurately without initial removal (degassing) of dissolved N_2 or preincubation. The MIMS technique has several advantages over traditional GC techniques, including rapid analysis time (2 minutes versus 15 minutes per sample), small sample size (2 mL versus 20 to 100 mL), simultaneous determination of O_2 and argon concentration, and the absence of a gas-stripping step (which is required for the GC methods). This approach has been used to quantify denitrification in coastal sediments (49,50) and will certainly be applied to study denitrification in a variety of marine environments in the future.

There are a number of indirect methods available for estimating denitrification rates. Some indirect techniques measure the accumulation of nitrogen gases (such as N_2O), whereas others use mass balance or stoichiometric modeling approaches to estimate denitrification. The most commonly used method for estimating denitrification is the acetylene block technique (51,52). Acetylene blocks the terminal enzymatic step of denitrification, the reduction of N_2O to N_2, so the accumulation of N_2O in the presence of acetylene is assumed to reflect N_2 production. This technique works well if denitrification is dependent on water column nitrate, if nitrate is not limiting, and if the samples are not sulfidic. Because acetylene also inhibits nitrification, this technique cannot be used to estimate coupled denitrification rates. Spurious rates may be obtained with this technique if samples have low nitrate concentration or if samples are even mildly sulfidic (i.e., tens of micromolar hydrogen sulfide concentrations) (53).

Another common approach for estimating denitrification is to amend samples with ^{15}N (as $^{15}NH_4$ for assessment of coupled denitrification or $^{15}NO_3$ for assessment of direct denitrification) and to follow the production of ^{15}N-labeled intermediates or gases (54,55). An adaptation of this approach, the isotope pairing technique (56), permits the partitioning of N_2 production between direct (water column NO_3) and coupled (to nitrification) denitrification pathways. A drawback of ^{15}N techniques is that sediment nitrogen pools may not be in isotopic equilibrium with the overlying water to which the ^{15}N tracer was added (53,57), which complicates the rate calculations. Quantifying the natural abundance $^{14}N/^{15}N$ isotope ratio in nitrate and/or dinitrogen may also provide a valuable tracer of nitrogen cycling in the marine environment (58).

It is possible to estimate denitrification rates without quantifying the concentrations of nitrogen gases. Benthic flux stoichiometry is a common way to estimate denitrification rates in this manner. Using this approach, measured fluxes of oxygen or dissolved inorganic carbon or phosphorus are used to calculate the expected fluxes of dissolved inorganic nitrogen. This estimated nitrogen flux is then compared to the observed net inorganic nitrogen flux (inorganic nitrogen = ammonium + nitrate + nitrite), and any difference is assumed to reflect the net denitrification rate (59–62). This approach is typically imprecise because of the inherent difficulty in measuring benthic fluxes. Furthermore, any chemical oxygen demand may inflate O_2-based denitrification estimates and temporary storage of reduced metabolites also leads to errors in stoichiometric-obtained estimates. Fluxes of dissolved organic nitrogen that are not accounted for in benthic flux mass balances will also contribute to errors in denitrification estimates. Whole system mass balance models can be used to estimate denitrification rates (63,64), but this method can be imprecise because of the errors associated with other terms of the system nitrogen budget. Diagenetic models can be used to estimate denitrification rates (42), but such models require a great deal of input data that is not always available or easily obtained. Some models are difficult to validate, leading to large errors associated with rate estimates.

Potential denitrification rates are determined under anoxic conditions, with added nitrate and organic carbon

(typically glucose). Potential rates can be determined easily in water column or sediment (slurry) samples by quantifying the rate of nitrate depletion, by amending samples with acetylene and measuring N_2O accumulation (61), or by determining N_2 accumulation (48). Potential rates allow the experimentalist to determine the factors (O_2, NO_3, organic carbon, sulfide, etc.) that influence rates of denitrification (Fig. 4). To ensure the quality of data obtained using this adaptation of the acetylene block method, acetylene-free controls should be run to account for short-term changes in background N_2O production. Nitrous oxide production in the absence of acetylene is usually negligible at low nitrate concentration; however, background N_2O production can constitute 10% or more of acetylene-inhibited N_2O production rates at high nitrate concentration or in the presence of low concentrations of sulfide (Fig. 4) (65). We have observed increases in background N_2O production in samples amended with even moderate (100 μM) concentrations of nitrate to relieve nitrate limitation of denitrification. The rate versus concentration curves (Fig. 4b) generated in potential denitrification experiments can be used to obtain the necessary kinetic data (apparent K_m, V_{max}) for back-calculating in situ rates (61).

LOCATIONS AND PATTERNS OF DENITRIFICATION ACTIVITY IN THE MARINE ENVIRONMENT

Denitrification occurs in areas that are free of oxygen, but have sources of nitrate, from coupled nitrification, from the water column, or from groundwater. Denitrification also requires a source of labile organic carbon. Denitrification is common in sediments. The activity of denitrifying bacteria in the water column occurs only in a few select regions where low oxygen concentrations persist. Numerous studies of sediment denitrification have been conducted in a variety of habitats; however, most research has been carried out in near-shore temperate environments. In these areas, human-induced acceleration of nitrogen loading has created a need to understand the ability of these coastal ecosystems to remove excess inorganic nitrogen loading. Since denitrification can counterbalance nitrogen loading (as nitrate) to some extent, a significant research effort is under way to document the rates and patterns of denitrification in the coastal zone. Relative to near-shore coastal habitats, less information is available for continental shelf and slope sediments. Even fewer data are available for deep ocean sediments. Similarly, more data are available for temperate ecosystems, than for polar or tropical ecosystems.

Denitrification rates in temperate coastal sediments are high. Rates between 3 and 19 mmol N m^{-2} day^{-1} are common (66). Denitrification rates in temperate coastal systems tend to be related to the nitrogen loading rate of the ecosystem (63); however, it appears that the relationship between the system-wide denitrification rate and the residence time may not be as clear-cut as originally thought (67). Denitrification rates in tropical systems are markedly lower than those observed in temperate systems. Frequently, denitrification rates are offset by high rates of nitrogen fixation (31,68). Tropical environments receiving high nitrogen loading rates, via sewage discharge, for example, may exhibit substantial rates of direct denitrification (69). However, rates of coupled denitrification in tropical systems are generally low (68), suggesting that nitrifiers may be outcompeted for ammonium or that denitrifiers are outcompeted for nitrate. Chronic nitrogen limitation of other microorganisms and plants may deter denitrification in tropical environments, resulting in coupled denitrification rates that are low and insignificant. Limited supplies of labile organic carbon may also impact denitrification in tropical sediments. Polar near-shore sediments support substantial rates of denitrification (2 mmol N m^{-2} day^{-1}) (70) despite the cold temperatures; nitrate limitation of activity is common. Because the global area occupied by shallow coastal environments is small, these regions contribute only modestly to global integrated rates of denitrification (12 Tg N $year^{-1}$ removed via denitrification; 1 Tg = 10^{12} g) (8). However, denitrification is a very important process in these systems, removing, on average, between 20 and 50% of the nitrogen input to coastal systems (66).

A significant amount of marine sediment denitrification occurs in continental shelf environments (71–73); however, few direct measurements of denitrification are available for shelf regions. Using a modeling approach, the average denitrification rate for shelf sediments in the North Atlantic region was estimated to be 0.7 mmol N m^{-2} day^{-1} (74), a rate that is substantially lower than that observed in near-shore systems. Christensen (72) estimated the global denitrification rate for shelf sediments to be approximately 50 Tg N $year^{-1}$. Denitrification rates in deep ocean sediments are extremely low. Based on a limited number of actual measurements, the globally integrated rate of denitrification in deep ocean sediments was estimated to be 7 Tg N $year^{-1}$ (despite the fact that deep ocean sediments account for the largest area) (72). Since the number of actual denitrification measurements is limited, Middelburg and coworkers (42) used a modeling approach to estimate denitrification rates for marine sediments. The globally averaged sediment denitrification rate they obtained, 230 to 285 Tg N $year^{-1}$, with approximately 100 Tg N $year^{-1}$ occurring in shelf regions (42), is significantly higher than the range reported in the literature for marine sediments (12–89 Tg N $year^{-1}$) (72,75).

In certain parts of the marine environment, water column oxygen consumption rates exceed oxygen supply, thereby rates generating low (or zero) oxygen concentrations. These locations are called *oxygen minimum zones* (OMZs). Microaerophilic conditions favor both nitrification and denitrification and in these regions, rates of coupled denitrification are significant. Today there are three OMZs in the open ocean: the Arabian Sea and the North and South Eastern Tropical Pacific. Sometimes, OMZs develop near the coast. For example, coastal waters along Western continental margins, adjacent to California, Peru, and West Africa, are characterized by high rates of primary production and oxygen consumption and OMZs. Globally averaged water column denitrification rates in OMZs are about 60 to 90 Tg N $year^{-1}$. Denitrification also occurs in the water column of enclosed

or semienclosed saline water bodies, such as the Black, Baltic, and Mediterranean Seas (76–78), as well as in stratified fjords that become anoxic at depth (79). Denitrification rates in the Black Sea are believed to be approximately 1 Tg N year^{-1}. This rate is much lower than the rate in the Arabian Sea (34 Tg N year^{-1}) but is significant nonetheless. Denitrification may also occur occasionally in anoxic particles traveling through coastal water columns (80,81). The global importance of denitrification in particles or in other water column microanoxic zone (e.g., in zooplankton digestive tracts) is unknown.

In terms of the global nitrogen cycle, the available estimates of integrated denitrification rates exceed those of nitrogen inputs (Table 1). Based on the nitrogen budget presented by Middelburg and coworkers (42), the primary nitrogen sink via denitrification in the marine environment is in sediments. Whereas the highest average rates of denitrification occur in coastal sediments (average of 3.6 mmol N m^{-2} day^{-1}) (8), the total global denitrification rate in coastal sediments (12 Tg N year^{-1}) is but a small fraction of the total sediment denitrification rate (285 Tg N year^{-1}). Denitrification occurring in continental shelf sediments amounts to 101 Tg N year^{-1}, and denitrification in deep ocean sediments amounts to 172 Tg N year^{-1} (42). This upward revision in the global sediment denitrification rate, and hence in the global denitrification rate (42), is driven by significant increases in rates of denitrification in shelf and deep ocean sediments. Previous estimates of sediment denitrification in coastal, shelf, and deep ocean sediments (12 to 90 Tg N year^{-1}) (73) were similar to estimates for water column denitrification (60 to 90 Tg N year^{-1}) (75). These new globally integrated denitrification estimates suggest a large imbalance in the global nitrogen cycle. This imbalance has significant implications for nutrient controls (nitrogen versus phosphorus versus silica) on primary production and for glacial-interglacial changes in nitrogen cycling and in global primary production patterns. If these large deficits of bioavailable nitrogen in the ocean are correct, we will be forced to reevaluate the global rates of nitrogen fixation to ask whether more nitrogen fixation might be occurring in poorly studied parts of the marine environment.

Table 1. The Marine Nitrogen Budget (Tg N year^{-1})

Process	Rate
Inputs	
Riverine	25–43
Atmospheric deposition	40–50
Nitrogen fixation, accepted range	25–30
Nitrogen fixation, probable range	40–200
Total Inputs	90–293
Outputs	
Burial and export	23–43
Denitrification	
Water column	60–90
Sediments	230–285
Total outputs	313–418

Note: Adapted from Middelburg and coworkers (42).

Special Considerations and Future Research Needs

The availability and form of fixed nitrogen is a strong determinant of denitrification rates. As a result, there is a strong positive correlation between nitrogen loading rate and the integrated system denitrification rate (8,63). The relationship between nitrogen loading and denitrification is complicated, however, and is influenced additionally by physical and biological factors (see later). As discussed previously, biological processes, such as photosynthesis, can drive patterns and rates of coupled denitrification. An and Joye (23) found that photosynthesis significantly stimulated coupled denitrification in coastal sediments and that rates of photosynthetically stimulated coupled denitrification exceeded the denitrification estimated derived from the residence time in the ecosystem (based on the calculations of Ref. 63). Furthermore, the rates of denitrification that they documented were much higher than previous estimates in the same system, which also happened to agree with the residence time–based denitrification rates. They concluded that estimates of denitrification obtained during dark, rather than natural day (light) and night (dark), incubations could lead to erroneously low denitrification rates. If the pattern they observed holds for other coastal systems, then the available estimates of denitrification for near-shore environments could indeed be low. Both water column stratification (oxygen availability) and the amount of time water resides in a coastal system (i.e., the residence time) also influence the denitrification rate and the relative efficiency of nitrogen (nitrate) removal via denitrification (63,82–84). Future studies of denitrification in coastal systems need to consider the impacts of benthic photosynthesis and salinity (20) on the rates and patterns of denitrification.

Major gaps in our understanding of denitrification in the marine environment stem from the array of different methods that are used to quantify denitrification rates and from the lack of long-term data sets that include variability in both denitrification and in important environmental variables. Rigorous intercalibration experiments, including some of the old (acetylene block) and newer (MIMS) techniques, would provide us the ability to gauge the accuracy and precision of the existing data. Additional studies are needed in shelf and deep ocean ecosystems to validate global denitrification rates generated in model studies (for example, the rates put forth by Middelburg and coworkers (42)). In particular, more data are needed from polar and tropical ecosystems. Though a fair number of data sets describe denitrification in OMZ environments, the limited spatial and temporal coverage of the data, both within and between ecosystems, makes extrapolation to global scale difficult. More work is needed in these dynamic environments.

CONCLUSION

Denitrification represents a major sink for bioavailable nitrogen in the marine environment. Denitrification is

regulated by the availability of substrates (nitrate, organic carbon), oxygen concentrations, and the concentrations of inhibitors (hydrogen sulfide, salinity). Understanding the impact of photosynthesis and ecosystem residence time on denitrification warrants in depth future studies. Recent advances in the methods available to quantify denitrification, particularly the application of MIMS to study denitrification in marine habitats, promise to lead to significant advances in our understanding of the patterns and controls on denitrification in nature. Whereas denitrification rates are highest in near-shore sediments, offshore sediments dominate the global denitrification in sediments, accounting for about 96% of the total. Denitrification in the water column is approximately one-third of that present in the sediments. Understanding how global patterns of denitrification have changed over time and documenting the impact of denitrification on nitrogen recycling efficiencies in the marine environment, nitrogen to phosphorus ratios, and oceanic primary production are important research avenues that should be pursued in a variety of marine environments.

DESERT ENVIRONMENTS: BIOLOGICAL SOIL CRUSTS

FERRAN GARCIA-PICHEL
Arizona State University
Tempe, Arizona

Biological soil crusts are surface-bound assemblages of microorganisms that consolidate the soil into mm to cm thick crusts. They develop on a variety of environments but reach prominence in cold and hot arid lands wherever the lack of water restricts the settlement and development of higher plant cover. These largely microbial communities, variously known as cryptogamic, cryptobiotic, cyanobacterial, or simply, biological soil crusts (BSC), are initially dependent on the primary production of cyanobacteria and eukaryotic microalgae, either free-living or within lichen symbioses. In arid environments more benign with respect to water availability (such as the Northern Great Basin or the Columbia Plateau), mosses and lichens typically become dominant in mature crusts. Under regimes of strong aridity (such as in the Sonoran and Chihuahuan deserts), cyanobacteria and lichens tend to dominate mature crust communities. BSC's are typically slow growing, since periods of biological activity are restricted to events of liquid water availability linked to precipitation. Only the virtual surface and a very thin layer (1 to several mm) within these topsoil formations can be photosynthetically active. However, when wet, this layer can display very high areal instantaneous photosynthetic activity. High rates of aerobic respiration are typically found reaching down to several mm from the surface, which, if sustained, can result in local depletions of oxygen and the formation of anoxic microniches below the surface. In mature crusts, buried extracellular polysaccharide sheaths from cyanobacteria and lichen rhizoids may further extend the physically cohesive bounds of BSCs downward to about 1 cm from the soil surface. BSCs have been described from aridlands in all continents, including Antartica. In North America, for example, soil crusts cover large portions of undisturbed soils in the Colorado Plateau, the Chihuahuan, Sonoran, Vizcaino and Mojave deserts, in the Great Basin, in the Oregon, Washington, and Idaho high desert, as well as in the rangelands of Wyoming and Montana (1). The mere presence of soil crusts dramatically decreases soil erodibility by consolidating soil surfaces, affecting the hydrology of desert soils by either increasing runoff or infiltration. Their metabolic activities are large enough to contribute a large proportion of the biogeochemical cycles of carbon and nitrogen in aridlands. The ecology and biology of BSC have been recently summarized in an excellent edited volume (2) and the readers are referred to it for a more in-depth presentation.

STRUCTURE, DEVELOPMENT, COMPOSITION, AND DIVERSITY

The colonization of unconsolidated topsoils by cyanobacteria or microscopic algae represents the first step in BSC formation. The first colonizers are usually filamentous microbes that produce copious amounts of extracellular polymeric substances (exopolysaccharide) either of a diffluent nature or in the form of extracellular sheaths (Fig. 1). Filamentous cyanobacteria morphologically pertaining to the form- genera *Phormidium, Oscillatoria, Microcoleus*, and *Schizothrix* are the most commonly reported from young crusts. Little studied but important bacterial, fungal, mold, and flagellate populations may accompany the cyanobacteria at this stage. Unfortunately, very little attention has been given to microbial populations other than cyanobacteria. Because of the microbial nature of BSC's, decomposing, and mycorhizal fungi are probably not very important, but saprophitic forms seem to be able to attain significant populations making use of cyanobacterial and algal exudates. Sexual and sterile forms of saprotrophic fungi are characteristic of soil crust communities. Culturing studies by States and coworkers (3) found the pleosporaceous genera *Embellisia*, *Phoma*, *Bipolaris*, and four sterile dark-pigmented species (*mycelia sterilia*) with abundant chlamydospores most abundant in crust soils of Utah and Wyoming. Recently, culture-independent analysis of cyanobacterial community structure by means of phylogenetic reconstruction based on 16S rRNA gene sequence comparisons (4) have revealed that many of the BDC cyanobacteria form phylogenetically distinct clades, and are not closely related to cyanobacteria from other environments. If this holds true for other bacterial populations, BSC's may harbor a large inventory of untapped bacterial diversity. At the same time, such soil-specific phylogenetic clusters of cyanobacteria are deeply rooted and scattered in the overall cyanobacterial evolutionary tree. This implies that terrestrial cyanobacteria are evolutionarily old and is consistent with the view that soil crustlike communities may have been important terrestrial ecosystems of early Earth before the advent of higher plants (5). Indeed, filamentous, cyanobacteria-like microfossils have been found in terrestrial settings in the mid-to-late Precambriam (6). By far the most important and widespread cyanobacterium of soil crust is *Microcoleus vaginatus*, a filamentous type that forms bundles of filaments enclosed in a common extracellular sheath. Belnap (7) has called attention to the importance of this species in crusts of the U.S. Southwest. Morphologically and genetically indistinguishable populations of *M. vaginatus* occur in desert soils from North America, the Middle East, and Europe (4). All of these filamentous cyanobacteria seem to prefer the immediate subsurface, some 0.5 to 2 mm deep into the soil, where they encounter moderate light intensities and a refuge from UV radiation and erosional abrasion. They are motile by gliding and can make use of photosensory mechanisms to migrate up to the surface whenever incident light intensities are low (i.e., under overcast conditions). This can result in a sudden greening of desert soils under rainy, overcast conditions, making soil crusts under such conditions conspicuous to the naked eye. They return to the subsurface using hydrotactic mechanisms (8). In general, simple crusts containing only subsurface cyanobacterial populations are truly cryptic when dry and can only be distinguished by close, intentional inspection. Motility and cyanobacterial vertical migration within the crusts seems to be an important aspect in the initial stages of soil stabilization and crusting. The trails of extracellular mucopolysaccharide that filamentous cyanobacteria leave behind as they glide, glue the sedimentary particles in the soil surface together, even when the cyanobacteria are no longer present. Trapping and binding of allochtonous aeolian particles by the extracellular investments (particularly clays) may add to the initial stages of crust formation.

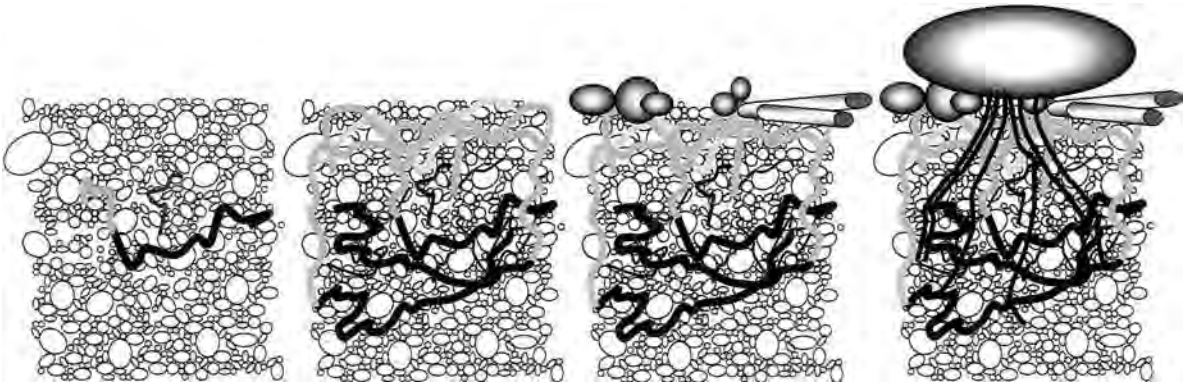

Figure 1. Abstracted view of sequential colonization steps leading to the formation of mature biological soil crusts. Left panel: initial colonization of unconsolidated soils by subsurface populations of filamentous, gliding cyanobacteria (dark lines) producing sediment-binding extracellular sheaths (gray lines). Middle left panel: vertical migrations of filamentous cyanobacteria, which leave trails of extracellular material that consolidate the soil surface. Middle right panel: sedentary, colonial cyanobacteria producing dark-pigmented envelopes colonize the crust surface imparting dark appearance to crusts. Right panel: cyanobacterial and green algal lichen colonization contributes to added physical stability.

A later stage in the formation of soil crust is the colonization of the crust's surface (Fig 1). The process of surface colonization is slow and can only occur when the substrate has been physically stabilized. But even a stable surface represents a very harsh environment for microbes, being directly exposed to full solar radiation, to the temperature extremes typical of desert environments and to the rigors of erosional forces. Only a few cyanobacteria are able to colonize the soil surface, and the process is slow. These are typically dark-pigmented, heavily ensheathed cyanobacteria of the genera *Nostoc* and *Scytonema*. Both of these genera are heterocystous (nitrogen-fixing) and, while they can differentiate specialized, motile forms for the purpose of dispersal, their vegetative cells are nonmotile. They produce copious amounts of sunscreen pigments, especially the extracellular alkaloid scytonemin, which gives their colonies a dark color and, in turn, is largely responsible for the typical black appearance of well-developed soil crusts (Fig. 2). Finally, in well consolidated crusts, given sufficient time, a large variety of soil lichens may develop, including both cyanobacterial and green algal photobionts (9). Shading of the crust by lichen cover may reduce the number of cyanobacteria in the soils, and induce shifts in the decomposer communities from bacteria and actinomycete dominated communities to those dominated by lichenicolous fungi.

FUNCTIONAL ASPECTS AND BIOGEOCHEMISTRY

The functional aspects of soil crust communities are governed by the episodic nature of water availability and by the small-scale distribution of physicochemical microenvironments. Most of the time, crust organisms are in a dehydrated state, during which only losses to the community (both in biomass and viability) occur. Eolian erosional abrasion, accumulation of photodamage, membrane and DNA damage by freeze-thaw cycles, and exposure to high temperatures contribute to this. During the short periods in which water is available, the organism hydrate, become active, and must carry out the metabolic processes for damage repair and growth that will ensure survival of the populations at least through the next drought. Indeed, microbial metabolism responds rapidly to the presence of water, and rates measured in wet crust are high. In cyanobacterial crusts, respiration starts just seconds after rewetting and initiation of photosynthesis occurs just after several minutes (10). Areal rates of photosynthesis attained in such crusts are comparable to those of mesotrophic lakes, and come close to those measured for higher plant leaves (11). Available estimates of annual carbon input in BSCs range from some 30 to 350 $kg\,C\,ha^{-1}\,y^{-1}$ (12,13). For comparison, available estimates for deserts at large, excluding BSC contributions, are about 800 $kg\,C\,ha^{-1}\,yr^{-1}$. Dinitrogen fixation by bacteria, cyanobacteria and cyanobacterial lichens seems to be the main source of nitrogen inputs to BSC's (14). Estimates for gross rates of dinitrogen fixation in BSCs range from as little as 1 to as much as 100 $kg\,N\,ha^{-1}\,yr^{-1}$ (9). The highest areal rates found in these BSCs easily surpass those measured in other terrestrial ecosystems.

Figure 2. Aspects of gypsum dune fields stabilized by biological soil crusts (Cuatro Ciénegas Valley, Coahuila, Mexico). In the foreground is an old gypsum dune field stabilized by mature crusts. The typical dark appearance is imparted by the sunscreen pigment, scytonemin, present in large amounts in surface-bound cyanobacteria and cyanobacterial lichens. The leading edge of wandering dunes of the same substrate is in the background. Note the impact of trampling on biological soil crusts visually evidenced in a seldom-used trail (arrow).

Like in other microbial habitats with high biomass accumulations within very small distances, the ecology and role of BSCs can only be completely understood by analyzing microbial activity, describing physicochemical environments, and assessing biogeochemical transformations at the microscale (μm to mm). Vertical gradients of solar radiation are caused by absorption and scattering of incident light. Vertical gradients in light intensity play an important role in defining the vertical distribution of phototrophs. Other microenvironments are the result of the metabolic activities of microorganisms and they involve localized gradients of chemical species. The formation of vertical microenvironments in the soil solution of BSC with respect to oxygen partial pressure (10,15) pH, light intensity, and light spectral composition (10) have been demonstrated (Fig. 3). When water-logged, the respiratory and photosynthetic activities of microorganisms in cyanobacterial crusts can be sufficiently high to overwhelm diffusive transport of oxygen and thus create spatially localized environments where oxygen might be depleted or supersaturated (10,15). The photosynthetically active zones (ca. the top 1 mm) reach steady states in which molecular oxygen is supersaturated. By contrast, the photosynthetically inactive, deeper zones (from 1 to 3–4 mm deep) are dominated by respiratory processes, and molecular oxygen is partially or completely depleted. In the absence of photosynthesis (wet crusts in the dark) anoxic zones can be much shallower (0.7–2 mm). The presence of internal anoxic zones has obvious implications for the mineralization of organic matter (both allochtonous and, probably primarily, autochtonous) in BSC's. Fermentation or anaerobic respiratory metabolisms may play a significant role in the mineralization of organic matter.

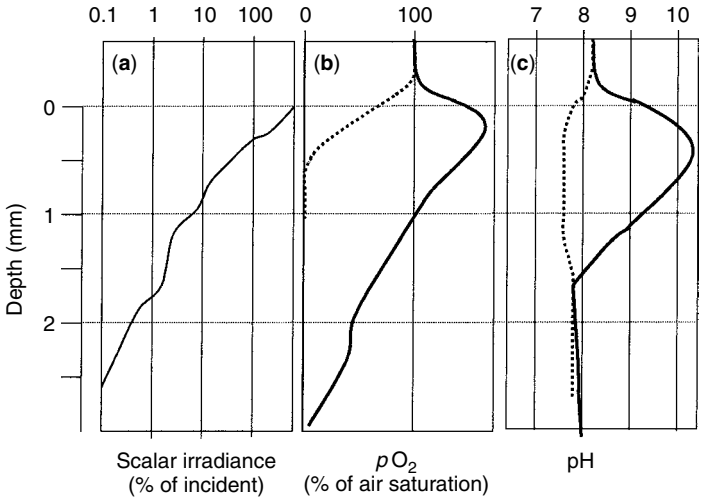

Figure 3. Some physical-chemical microenvironments present within a wet, active biological soil crust. A: extinction of incident light. B: Vertical profile of oxygen partial pressure (percent of atmospheric saturation) in illuminated (solid line) and dark (dotted line) crusts. C: vertical profile of soil solution pH in the light (dark line) and in the dark (dotted line). Redrawn from data in reference 9.

The availability of final electron acceptors other than oxygen in the crusts is likely to determine which processes may dominate. Thus, denitrification may take place in the soil crusts, largely powered by the formation of anoxic microzones. Some indirect estimates (16) point to the fact that perhaps as much as 80 % of the nitrogen assimilated by soil crusts is subsequently lost to the atmosphere during nitrification, denitrification, and volatilization, but direct evidence is still lacking. As a result of carbon dioxide uptake in photosynthesis, and its release in respiration, microscale changes in soil pH are likely to occur whenever oxygen microgradients are formed if the natural buffering capacity of the soils is low. Alkalinization of the top 1 mm of soils crusts by as much as 2 to 3 pH units in the light has been measured (Fig 3). Such depletion of protons may affect the solubilization and mobilization of silica, the establishment and germination of higher plant seeds, and/or the volatilization of ammonia (9). In the dark, acidification by 0.5 to 1 pH units in the dark, has also been measured in sandy soils, but data are lacking for other soil types.

ENVIRONMENTAL IMPACT AND CONSERVATION EFFORTS

The simple fact that aridlands cover some 35% of the total Earth's continental surface speaks for the potential significance of BSCs for global ecology. While BSC's may exert an influence on the overall fertility of soil ecosystems, research on the environmental impact of the presence, and the loss, of crust soil cover has centered on their physical influence on erosion and hydrology.

Studies on the impact of BSC cover on hydrology and water erosion has been very controversial. In some occasions, increases in runoff due to the presence of BSC have been determined (17) while, in other cases, results pointed to increases in water infiltration (18). In all probability, diametrically opposed effects are attained due to the diverse architecture of BSC's themselves. For crusts that do not present a high level of microtopography, Warren (19) has interpreted this variability in the light of known mechanistic hydrological properties of soils at large: "Where the sand content of a soil exceeds 80% and soils are not frost-heaved, the effect of biological crusts on infiltration is generally negative ... where the sand content of the soil is less than 80%, the effect of biological crusts on infiltration tends to reverse." In addition to this, when the crusts are frost-heaved (presenting a large amount of microtopography at the cm scale), BSC's tend to decrease runoff and increase infiltration by creating a multitude of microscale impoundments.

A wealth of studies has demonstrated that BSC's crusts can be a critical factor in reducing soil erosion by wind (reviewed in reference 20). Polysaccharides extruded by cyanobacteria and fungi bind soil particles together, creating soil aggregates, which, in turn, are glued together by live filaments and exudates. These larger, linked aggregates require greater wind work to displace than single grains (21). Cyanobacteria, being generally longer and larger than green algae and most bacteria, seem to impart more stability than other microorganisms (22). The passive nature of this effect is evidenced by the fact that chemically killed crusts (with intact polysaccharide glue) still protect the soil surface from erosion, at least temporarily. But BSC are highly susceptible to disturbance, as most crust organisms are brittle when dry and can be easily destroyed by mechanical forces (trampling, vehicular traffic; see arrow in Fig 2). Resistance to erosion can be significantly reduced after moderate disturbance (23,24). Sediment produced from such disturbances can "sandblast" adjacent crusts and abrade then at increased rates, thus amplifying the effects of disturbance. Because of the slow net growth rates of soil crust communities, recovery from mechanical disruption can take decades. Concerns on the environmental impact of crust degradation through cattle and human trampling on local soil erosion and suspended solid pollution in arid lands has already resulted in implementation of measures for crust protection in many rangeland management plans (25).

CONCLUSION

Because of the large global area covered by aridlands (both hot and cold) and the ubiquitous presence of soil

crusts within them, there should be no question that BSC's represent a major microbial ecosystem on Earth. Their global biomass must be gauged in the thousand millions metric tons. Their impact on global and local biogeochemical cycles has just begun to be explored, but it is likely to gain attention of the scientific community in the near future. Most of the research carried out on BSC, however, has been done at the floristic and ecological level, while virtually nothing is known about the role of bacteria (except for cyanobacteria) and associated microbial processes. The study of the microbial ecology of BSC 's represents one of the research areas where large strides will probably be made in the near future.

DESERT ENVIRONMENTS — SOIL MICROBIAL COMMUNITIES IN COLD DESERTS

HELEN S. VISHNIAC
Oklahoma State University
Stillwater, Oklahoma

The cold deserts of the world are characterized by relatively simple ecosystems and by physical features that approach, as nearly as is possible on this earth, the conditions of other parts of the solar system on which life may have existed. Their biota have therefore been of interest to ecologists hoping to study community structure in its least complicated form, to biochemists hoping to elucidate the molecular aspects of adaptation to cold and arid conditions, and to exobiologists as models (1) and a testing ground for the machinery of exploration (2). Cold deserts exist in polar regions (although little of the so-called Arctic polar desert is ice-free) and at high altitudes where the land lies in the precipitation shadow of mountains (for e.g., in the Atacama of Chile and Peru, which is reputed to be the driest desert on the planet, and the Xizang Plateau of Tibet). Only in the Antarctic, however, has the microbiology of a true cold desert been extensively studied.

PHYSICAL CHARACTERISTICS OF THE ANTARCTIC DESERT

The Antarctic is generally assumed to be covered with snow and ice — a view that is almost justified — as only some 280,000 km^2 that is less than 2% of the continent is ice-free. Although the terms "desert" and "cold desert" are frequently used, the ice-free areas of the Antarctic satisfy the most restrictive definition: precipitation equivalents of 100 mm or less yearly, a mean temperature of the warmest month of 2 °C or less, and a yearly radiation balance of approximately 10 $kcal/cm^2$ (3) (This definition is based on high latitude desert conditions; the radiation balance is naturally higher in nonpolar high altitude deserts). These areas generally have a mean annual air temperature of −20 °C or less and 45 mm or less of water-equivalent precipitation (4). The largest ice-free areas occur in the shadows of the Trans-Antarctic Mountains, the area known as the McMurdo Dry Valleys — because of their lack of ice cover — or the Ross Desert (Fig. 1).

While the climate varies spatially and temporally, the records from Linnaeus Terrace (Wright Valley, 1,600-m altitude) can exemplify temperature and solar radiation in the Ross Desert (5,6). The daily mean air temperature reached −5 °C in January (midsummer), the diurnal

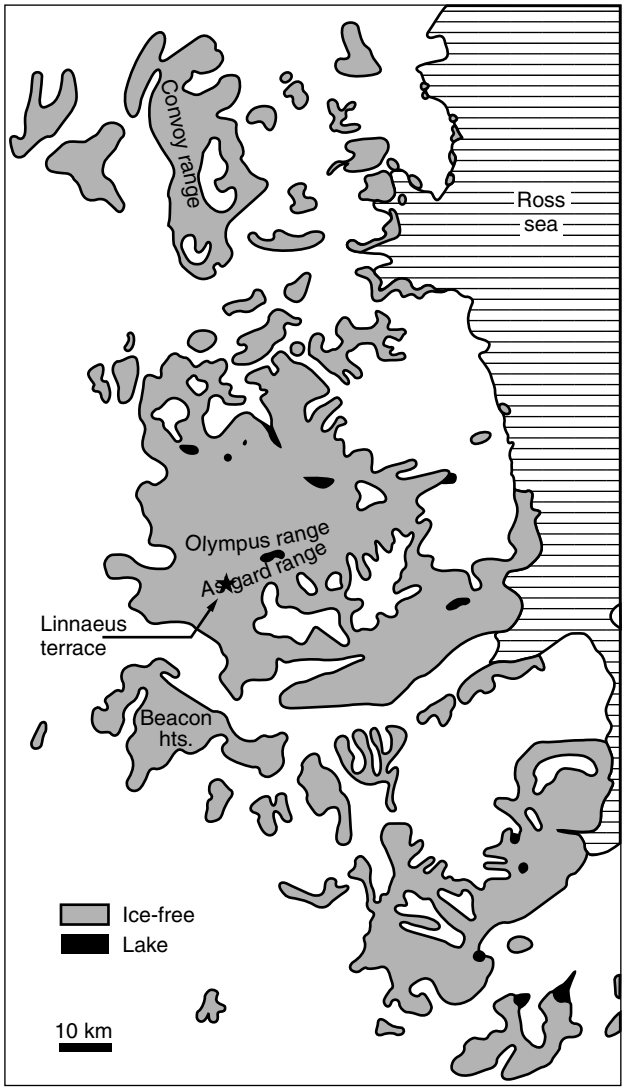

Figure 1. Ice-free areas of the McMurdo Dry Valleys (Ross Desert), southern Victoria Land, Antarctica. Reprinted with modification from J. A. Nienow and E. I. Friedmann, "Terrestrial Lithophytic (Rock) Communities" in E. I. Friedmann, ed., *Antarctic Microbiology*, Wiley & Sons, New York, 1993 by permission of Wiley-Liss, Inc., a division of John Wiley & Sons, Inc., copyright holders.

maximum in solar radiation reached 2,990–4,252 μ moles photons m^{-2} sec^{-1} (reported as 650–1,063 watts m^{-2}). The snow sensor did indicate the occurrence of snowfall but most of such snow sublimes rarely providing soil moisture. Ross Desert soils are dry and water content in the upper layers reportedly range from 0.26 to 5.1% (7).

The valleys are headed by glaciers. Temporal variation in the Antarctic climate provides additional summer moisture to sites immediately below the glaciers through the development of glacial melt streams, and also through the melting of small accumulations of snow in wind-sheltered spots. The insolation of soil and rock surfaces can warm them to temperatures well above air temperature. Heating can be quite rapid; Cameron (8) recorded a rise of 42.5 degrees Celsius (to 27.5 °C) on an insolated rock in three hours. In the Ross Desert, temperatures and the availability of water vary from valley to valley and from site to site, depending largely on exposure factors and the season. Cameron and coworkers, in the course of the first extensive investigations in the Dry Valleys, reported that Wheeler Valley had a more favorable environment than the McKelvey, Victoria, Taylor, and King David Valleys, as evidenced "by the visible presence of soil algal mats and crusts" (9).

The Soils

The soils of the Dry Valleys have been described in part by Campbell and Claridge (10) and more recently by Bockheim (4). They have been characterized as weathered surficial deposits that are barely recognizable as soils, although Bockheim pointed out that they do display horizons and do support "vegetation" (but not of agricultural interest).

Bockheim characterizes them as "skeletal-sandy," "loamy sand or sand with abundant coarse fragments," with clay and silt contents "usually less than 10% each," "unique among world soils in that they contain abundant soluble salts and permafrost." Bockheim points out that the permafrost, in some cases, lacks frost in the usual sense; that is, it is too dry to be cemented by interstitial moisture. The Dry Valley soils, away from the coast, are xerous (below the wilting point of orthodox plants every month in the year, some moisture available but with little leaching of soluble salts (10)) or, particularly in the more remote valleys (Arena Valley, Beacon Valley) and at higher elevations, ultraxerous (liquid water being rarely present). The mineral salts are derived from two sources: weathering of the parent rocks and atmospheric deposition. The parent rocks in the Trans-Antarctic mountains are variously granite and gneiss, dolerite, and sandstones. Weathering takes place largely through wind and salt erosion, coupled with the expansion and contraction resulting from insolation. The typically coarse weathered product receives marine aerosols if nearer the coast, becoming enriched in NaCl, or, if nearer the polar plateau, deposition of $NaNO_3$ through snowfall. Although salt composition varies from site to site, it typically includes chlorides (Cl), nitrates (NO_3), and sulfates (SO_4) of sodium (Na), potassium (K), calcium (Ca), and magnesium (Mg) (Campbell and Claridge, 1987). Salt accumulation, in Bockheim's samples, reached its peak well below the surface, at around 25 cm. As expected, the dominant cations in Bockheim's samples were Na, Mg or Ca, and K (in that order) and the dominant anion was Cl in subxerous soils of the ends of Wright and Taylor valleys nearest the sea ice, SO_4 or NO_3 in the xerous and ultraxerous soils of the more polar Dry Valleys. The heterogeneity of salt content in Linnaeus Terrace (Wright Valley, about 1,600 m alt.) soil samples from surface to 5-cm depths (11) presumably reflects the chance nature of liquid water availability, but should also serve as a warning against applying macroscale characteristics to microscale communities. The total μ Equivalents per gram of the major cations listed above varied from 7.13 to 60.43 in seven samples from this small area (11). The cation contents of the surface to a 7-cm layer in Bockheim's Dry Valley pedons are reported on a millimolar scale greatly

exceeding these values even in the more southerly (and less salty) samples. The organic content of Ross Desert soils is low; 0.05% organic carbon is as much or more than is present in most soils (12,13).

RESOURCES IN ANTARCTIC DESERTS

The energetic basis of community life everywhere is chemosynthesis and photosynthesis. Chemosynthetic organisms have long been sought for in vain in continental Antarctic soils. A description of communities in the Antarctic deserts must cover areas that are not strictly desert because populations at truly desert sites are obliged to import the products of photosynthesis from less arid habitats. Organic matter, although carried for long distances by winds, is very rarely carried from as far away as South America. On Signy Island (maritime Antarctica), Marshall (14) found Nothofagus pollen originating more than 1,500 kms away in South America but with a probable mean annual frequency of no more than 1.5. It has been pointed out that although others have failed to find exotic pollens on continental Antarctica, the growth of exotic "plants" around the volcanoes of continental Antarctica indicates that some immigration occurs, possibly via birds (15,16), although immigration to continental Antarctica is generally considered an unlikely event. As birds have scant motivation for flying over the desert areas of Antarctica, and wind patterns make significant imports from outside the continent improbable, organic matter for heterotrophic growth must come primarily from sources closer at hand.

Photosynthesis in Antarctica is minimized by the relatively low solar radiation and inhibited by the cold. Nevertheless, seasonal photosynthetic activity is relatively high in melt streams and ice-covered lakes and their environs, as is evidenced by cyanobacterial and algal mats visible in soil around the lakes and streams and in the ice of ice-covered waters. Ellis-Evans (17), Vincent and James (18), Simmons coworkers (19), and Vincent and coworkers (20) have written the most recent overviews of freshwater ecosystems in Antarctica. These ecosystems also contain invertebrate herbivores and predators (rotifers, nematodes, tardigrades) and also bacteria and fungi, in aquatic and terrestrial habitats.

In the Dry Valleys, Wright Valley is bisected by the Onyx River and Lake Vanda. Lake Vanda is the deepest and warmest of the Dry Valley lakes and has perhaps the greatest biodiversity; it is the only Dry Valley lake containing a moss (*Bryum algens*) (21). Deep water in Vanda can reach a temperature of 23 °C (18). The Taylor Valley lakes (Bonney, Chad, Fryxell, and Hoare) are shallower and colder, home to photosynthesizing mats in which the dominant organism is *Phormidium frigidum* Fritsch, a cyanobacterium that is "ubiquitous in southern Victoria Land, occurring in soils, lake, glacial melt streams and cryoconite holes, apparently being excluded only by high salt concentrations" (22); although exclusion from soil by aridity should be added. In the summer these lakes are bordered by temporary moats, but photosynthesis also occurs in the dim light beneath the permanent ice cover (4–6-m thick) where the maximum radiation available for photosynthesis is estimated to be on the order of 1 μ mole photons m^{-2} s^{-1}. The resulting oxygen bubbles float mat pieces up to the underside of the ice cover, where 5–10% of the floating mats freeze into the ice. The upper surface of the ice ablates bringing the mixed biota, organic matter, and captured sediments to the surface and makes them available for windborne distribution. The annual escape of organic matter was estimated at 247.4 kg for Lake Hoare and at 8,343 kg for Lake Chad (23).

To the output of these lakes may be added organic matter originating in the glacial melt streams that feed such lakes. This source has only been quantified in terms of the algal biomass represented by chlorophyll a, reported to reach (late in the summer) about 10 μg cm^{-2} for the Fryxell Stream at 0.5 km from its glacial source (24). Single collections of multiple samples from the glacial melt streams of Taylor Valley yielded much higher values at some sites; up to 514.55 μg cm^{-2} chlorophyll a for Bohner stream lower transect in Bonney Basin (25). These streams flow for only 6–10 weeks during the austral summer, then freeze and dry. Although the freeze-dried biota remains viable, as evidenced by recovery during the succeeding summers, it is friable and dispersible. The taxonomic content of these mats varies with flow rate, turbidity, and the nature of the stream bed, but is again dominated by cyanobacteria (*Gloeocapsa*, *Nostoc*, *Oscillatoria*, and *Phormidium*). Chlorophytes (*Binuclearia* and *Prasiola*) and diatoms (*Hantzschia* and *Navicula*) may be included among important genera, and nematodes, tardigrades, and rotifers may be associated with the algal mats (24,25).

At higher altitudes, the bulk of photosynthesis (15) probably occurs within Beacon sandstone, a porous, translucent rock type. The endolithic habitat provides shelter and maximizes moisture, resulting in a warmer and more moist environment (5,26). Nienow and Friedmann (5) have listed five cryptoendolithic communities: the upper zone within the rock is variously occupied by lichens in which the phycobiont is Trebouxia or Pseudotrebouxia, the alga *Hemichloris antarctica*, and various cyanobacteria (characteristically, *Gloeocapsa* spp. or *Chroococcidiopsis*). The lower zone may also contain photosynthetic algae or cyanobacteria, supporting heterotrophic bacteria and at least one yeast (*Cryptococcus friedmannii*). Photosynthesis is optimum between −2 °C and +5 °C; bicarbonate uptake occurs as low as −8 °C. On the basis of the mean annual total time (h y^{-1}) of rocks at temperatures above −10 °C, Friedmann and coworkers (27) estimated that cryptoendolithic communities were possible on Linnaeus Terrace and in the Tyrol Valley (where indeed they occur) but could not exist in some areas of Mt. Fleming or on Horseshoe Mountain. Lichen photosynthesis began at the almost incredibly low matrix water potential of −46.9 MPa (28). Extensive studies (29) of climatic conditions and the positions of rock surfaces affecting a cryptoendolithic lichen community on Linnaeus terrace (with *Trebouxia* as the phycobiont, but also

containing *Hemichloris antarctica*, cyanobacteria, and heterotrophic bacteria) allowed the estimation of the yearly gross productivity of such communities for the entire Ross Desert area at approximately $120–180 \times 10^3$ kg C. Of this only $0.6–0.9 \times 10^3$ kg C was in microbial biomass (about 0.025% of the gross productivity). These communities grow slowly and weather slowly into the surrounding environment, and have a 1,000-y carbon residence time. The great bulk of the photosynthetic product was considered more or less evenly divided between basal respiration and loss to the environment, primarily by leaching into the rock and soil. Amino sugars and amino acids have been found in the substratum of colonized rocks (30–32). Weathering of gross biological materials is visible on rock surfaces; the weathering of at least initially viable lichen biota into the soil is attested to by the isolation of the phycobiont *Trebouxia* from soil (9,33,34) and of other, less defining, inhabitants of the sandstone.

Mineral Resources

The requirements for life include more than the major elements provided by the soluble salts mentioned above, although nitrate, the major nitrogen resource of these desert soils, is thus available. Phosphate, the next highest requirement, and minor elemental requirements do not limit the photosynthetic organisms of streams (25) and rocks (5). Apparently, mineral nutrients do not limit heterotrophic life in soils (7). Indeed, nutrient limitation is not considered characteristic of communities such as these that are under great abiotic stress.

DESERT SOIL COMMUNITIES

Although trophic relationships in Lake Vanda have been diagrammed (35), the soil communities of the McMurdo Dry Valleys have only been described, somewhat incompletely, in piecemeal fashion. Areas of soil in which water is seasonally not limiting may be presumed to have relationships mirroring those in Lake Vanda, with major emphasis on microbial life. The photosynthetic base again consists of cyanobacteria, chlorophytes, and possibly diatoms (in that order) that supply heterotrophic bacteria and fungi as well as nematodes and tardigrades. These replace the rotifers and protozoa of Lake Vanda, rotifers being aquatic and terrestrial protozoa rare, although *Acanthamoeba polyphaga* and *Naegleria gruberi* have been found in lakeshore soil in Taylor Valley (36). Protozoan abundance and diversity are strongly affected by latitude and temperature (37). Tardigrades, as a group, are suctorial feeders on plant cells and other invertebrates (including other tardigrades). They are particularly suited to Antarctic life as they resist dehydration and cold temperatures by accumulating trehalose and forming a "tun" capable of withstanding short exposures to $-196\,^{\circ}C$ (38) and also longer exposures to the higher temperatures of the Antarctic winter. The dominant nematodes in the Dry Valleys are the microbivore (bacteria and yeasts) *Scottnema lindsayae* and the omnivore-predator *Eudorylaimus antarcticus* (39). These nematodes withstand drying and cold so well that they can be used as living experimental material after having been stored frozen for more than two years (40). These elements in moist soil form a simple conventional food web that includes producers, consumers, predators, and biodegraders.

Away from obvious moisture, life in Ross Desert soils is exclusively microbial and probably exclusively heterotrophic, depending on the bounty of the wind and weathering rocks. Such microbial life is concentrated in the uppermost layers of soil. The lower layers sometimes appear sterile. A series of samples representing a profile of soil taken near the junction of Victoria and McKelvey valleys contained 10^2 to 10^3 bacteria/gram in the top 2.5-cm layer but at 15 to 25 cm below the surface produced no bacterial count on a variety of media, and did not evolve significant radioactive carbon dioxide from uniformly labeled glucose (41). The apparent sterility of this and some other soil samples might be laid to the sensitivity of the radioactive assay and to failure in using appropriate culturing techniques: the 5 to 15 media used in these investigations included only the standard microbiological media of the time. Parker and coworkers (33,42) later used a relatively oligotrophic agar containing soil extract (from the site), 0.1% proteose peptone and a 0.02% yeast extract. This technique produced microbial counts up to two orders of magnitude higher than had been found by previous investigators. The varied techniques used by Vishniac and coworkers on soils from 100 to 2,200 m in the Asgard Range produced ubiquitous evidence of life (43–45). Some soils, however, appear to have been genuinely sterile. Three of Cameron's "sterile" samples from the Asgard Range inhibited microbial life when mixed with other soils, an apparent effect of their high (7–16 μg/g) boron content (46). Microbial life in Dry Valley soils is, in any case, sparser than that in more temperate and humid climes and in the Antarctic ornithogenic soils near the coast.

Although lists of the bacteria of Ross Desert soils exist (7), they are minimally useful. The bacteria reported have not often been characterized except as biomass or isolates unidentified or identified only to genus; a characterization that has been deplored as essentially irrelevant in modern taxonomy (47). Franzmann (47) commented that all of the Antarctic strains for which 16S rRNA has been sequenced to date (1996) represent new species from Antarctic lakes. New genera from Antarctic sandstone have subsequently been described with the appropriate sequences included: *Friedmanniella antarctica* (48) and *Hymenobacter roseosalivarius* (49). The identification of Ross Desert soil bacteria has so far indicated — with at least one possible exception (see following section) — that only cosmopolitan taxa had gained entry to these soils (7). Their presence need not indicate colonization as such dry and freezing conditions can prolong viability for many years, given the apparent absence of predators in the more arid soils. The fact that such bacterial taxa — lacking any obvious adaptation to life in Ross Desert soil — could greatly outnumber any indigene raised the question of whether any bacteria were active there. Evidence of activity in the absence of disturbance of environmental conditions

was provided by the presence of microcolonies on soil particles (43) and on buried glass slides (44,45). Some of the bacteria isolated (but not identified) from their soil samples may be true indigenes. The allochthonous bacteria could provide a "seed bank" able to colonize when environmental conditions are mitigated by global warming. (Global warming would not only provide more suitable temperatures for bacteria from the north but might increase the energetic basis for heterotrophic life.) The same is true of the many microfungi (50) that have been isolated from Dry Valley soils. As their mycelia typically do not survive freeze-thaw cycles, the germination of microfungal spores under current conditions would surely be a death sentence for those fungi.

Abundance does not indicate the activity of microbes in Antarctic desert soils, given the preservative effects of cold-drying. Is it possible to define the indigenous microbiota? The available clues include endemism (which may vanish on further investigation) and adaptation to local conditions. The main requisites for microbial activity in arid Dry Valley soils are the ability to survive and recover quickly from desiccation and repeated freeze-thaw cycles, psychrotolerance if not psychrophily, and an oligotrophic mode of nutrition. The rapidity of recovery from desiccation and freezing is crucial as the presence of water and the elevation of temperatures above at least $-10\,^{\circ}C$ is temporary.

The ability to withstand repeated freeze-thaw cycles seems difficult to determine experimentally as some experimental results are at odds with the experience of Wynn-Williams (51), who found that yeast biomass in Signy Island (Maritime Antarctica) peat cores increased both absolutely and in comparison to bacteria and microfungi in early spring in the field and after repeated freeze-thawing in the laboratory. The psychrotolerance required of Antarctic soil microbes is difficult to assess largely because of the absence of data. One may assume that indigenes should at least be able to metabolize and grow at the same temperatures as cryptoendoliths (microbes growing cryptically in rocks) and the photosynthetic microbes of aquatic habitats, while being able to tolerate the highest temperatures produced by surface insolation.

Psychrophily, defined as a maximum growth temperature of less than $20\,^{\circ}C$, is perhaps not to be expected in a habitat with the temperature variations of surface soil. Although some strains of Dry Valley yeast species do conform, the Antarctic microbial species that meet this definition, including both bacteria (47) and yeasts (52), have their primary habitats elsewhere than in soil.

Oligotrophy seems to be dictated by the low organic content of the arid soils and dependence on what are essentially imported substrates. Soil aridity may have a nonobvious effect on organic content: growth depends on the chance availability of liquid water but the sudden wetting of dry soil can release up to 70% of microbial biomass carbon for utilization by the survivors (53). Given the bacterial biomass in surface soils, this represents a substantial increase in available substrates.

Although Ross Desert soils have a high average salt content, halotolerance is not a prerequisite for life there. Why halotolerance is not required is hard to explain as new and apparently indigenous species of Antarctic halobacteria have been described from Antarctic lakes (47), as has a bacterium from the cryptoendolithic community that shares a recent common ancestor with the marine *Vibrio natriegens* (54). The energetic requirements of halotolerance are presumably not met in these depauperate soils.

Quick recovery from desiccation is a property of encapsulated or sheathed microbes, such as cyanobacteria and basidiomycetous yeasts. The bacteria isolated from W. V. Vishniac's collections frequently possessed extensive capsular material. Basidiomycetous yeasts are typically encapsulated. Such yeasts, a minor component of the microbiota in temperate soils, may be typified by *Cryptococcus albidus*, a phenotype commonly encountered in warmer desert soils (55). *Cryptococcus albidus* competed successfully with the natural biota of loamy sand whenever the bacteria were stressed by desiccation, an outcome resulting from the longer lag phase of the bacterial community. Encapsulated bacteria in this soil flourished only at water contents near field capacity; the dominant bacterium at 1% water content was *Nocardioides albus*, an unencapsulated actinomycete (56). Actinomycetes are reputed to include the most desiccation-resistant bacteria, although this reputation seems to be largely the result of their isolation from spores in arid soils. It is, however, possible that the tight growth habit of mycelial actinomycetes has the effect of sheathing or encapsulation. *Nocardioides albus* initially grows as a tight compact colony.

Their desiccation resistance might therefore lead one to expect basidiomycetous yeasts and actinomycetes to dominate in arid soils. This has not been demonstrated for the Ross Desert soils. Yeasts occur in arid Ross Desert soils at about one microcolony per gram of soil (7), far fewer than the recorded numbers of bacteria, although most of the latter may be inactive. Apart from the obvious ability of actinomycetes and their spores to survive in soil through the variable temperatures of temperate winters, nothing is apparent about their ability to survive repeated freeze-thaw cycles. Actinomycetes identified as Nocardia and Streptomyces are recorded only as minor (3%) elements in the bacterial population, although "coryneforms" and "coryneform-related" bacteria constitute a majority of the 568 bacterial isolates in Cameron's collection (7).

The dominant yeast in the most arid Ross Desert soils is *Cryptococcus vishniacii* (commemorating Wolf Vladimir Vishniac, who died while exploring these valleys). *Cryptococcus vishniacii* has been isolated from many sites within the Dry Valleys since the first report (57). It is an oligotrophic yeast, with a low K_s for glucose at $10\,^{\circ}C$ (between 9 and $<26\,\mu M$) (58), with strains capable of growth on a variety of amino acids (59) generated by the proteases characteristic of basidiomycetous yeasts (60) as well as sugars and organic acids, of growth at temperatures down to at least $-3\,^{\circ}C$ and up to $19–24\,^{\circ}C$ (58,61), and at water potentials down to <-4.86 MPa in liquid culture (34). However, in sand microcosms, growth was severely inhibited at -3.56 MPa

and depended on the amount of water with which additions of equal osmolarity were presented (34).

In University Valley (a small hanging valley off Beacon Valley), soil samples taken in the vicinity of a dry glacial melt stream consistently produced another indigenous species, *Cryptococcus antarcticus* (62). *Cryptococcus antarcticus* strains have maximum growth temperatures between <20 °C and 25 °C, have a higher maximum growth rate, and are slightly more halotolerant than *C. vishniacii*, although less so than *C. albidus*, suggesting that substrate availability (higher near an ephemeral melt stream) has directed the adaptation of these yeasts to their respective habitats.

At least one bacterial species possesses some features appropriate for life in these soils. *Hymenobacter roseosalivarius* (49), a taxon within the Cytophaga/Flavobacterium/Bacteroides phylogenetic line that is psychrotolerant (minimum growth temperatures between −0.5 and <5 °C), was isolated from oligotrophic media. It produces "large amounts of extracellular polymer." The 41 isolates of these bacteria were collected not only from a boulder with cryptoendolithic life on Linnaeus Terrace, but also from soil in the vicinity of the boulder, as were other microbes and some black filamentous fungi. It is possible that their presence in soil is passive; the original samples were taken with the idea that their microbial contents would be "comparable to the community in the rock" (63). The *H. roseosalivarius* isolates were not particularly halotolerant, so, if truly colonizing the soil, must live as neighbors of the *Cryptococci*. This species does have the further interesting property of lysing (unspecified) yeast cells, which speaks for its ability to find the substrate in barren soils. The actinomycete from the cryptoendolithic community, *Friedmanniella antarctica*, has not been isolated from soil.

CONCLUSION

The model presented by the McMurdo Dry Valleys leads to the expectation of physically interleaving microbial ecosystems in cold desert soils. In the McMurdo Dry Valleys, this interleaving is seen in the form of temporary glacial melt streams in the heights and more permanent streams and lakes in the valleys. Water, rather than temperature, is the most limiting factor here. Water limits biodiversity both directly and indirectly through its effect on energy production by photosynthesis. These systems are graduated, by the availability of liquid water, from the simple trophic net of lake and streamside to the depauperate population of heterotrophic yeasts and other putative heterotrophic indigenous microbes of the most arid soils. This model, although derived from the most investigated cold desert on the planet, is incompletely known. What is most needed to understand adaptation to the multiple stresses on life in cold deserts is further investigation of microbial life in the most arid soils, an area that is being neglected relative to work on lakes and their environs.

DESICCATION BY EXPOSURE TO SPACE VACUUM OR EXTREMELY DRY DESERTS: EFFECT ON MICROORGANISMS

KLAUS DOSE
Johannes Gutenberg University
Mainz, Germany

Drying probably is the oldest method of preserving food. Drying of food by exposure to dry air, often in combination with sunlight, was already practiced in ancient Egypt 3,000 to 5,000 years ago. Only during the last decades, however, microbiologists, biochemists, and food scientists have begun to understand how metabolic activities including the growth of microorganisms and the decay of food components are affected as their water activity (a_w-value) is decreased. In living cells, the removal of water usually poses a serious hazard to the integrity of proteins, nucleic acids, membranes, and other molecular and supermolecular entities. Some species (including prokaryotic spores and fungal conidia), however, have developed strategies to overcome the threats presented by the loss of cellular water. Although even they cannot maintain essential metabolic activities at low water contents, they have learned to survive in a metabolically inactive ("dormant") state for months and even many years. In an extremely dry environment, however, chemically bound water also is continuously removed. This process ultimately leads to irreversible damages, especially of nucleic acids, and as such limits the survival time of dormant life-forms. The question of longevity of dormant life also has attracted public interest. This interest has focused on the question of whether "germs" arriving on Earth from outer space may have brought life to Earth almost four billion years ago (panspermia thesis).

GENERAL

The presence of liquid water within a cell is a fundamental requirement for almost any form of its biological activity. Liquid water is the solvent for all biochemical processes. The presence of liquid water also is required for maintaining the native structure of proteins, nucleic acids, membranes, and other supermolecular entities especially by means of hydrophobic bonds and/or hydration processes. Only a few biophysical events such as the absorption of radiation energy, the transfer of excited states, and some electron transport reactions do not require the presence of liquid water.

There are essentially two ways to reduce the amount of liquid cell water: by freezing or by removal. The initial phase of freezing especially is traumatic to most cells because growing ice crystals may injure cellular structures and the increasing concentration of solutes in the residual water may create osmotic stress. The process of thawing also may lead to injury of cellular components through physical stress. Liquid water ceases to exist below $-130\,^{\circ}C$. Therefore, no thermally driven reaction that requires the presence of liquid water can occur below $-130\,^{\circ}C$. Storage of biological materials at the temperature of liquid air ($-196\,^{\circ}C$) is therefore a standard method of long-term preservation, provided the damaging effects of freezing and thawing can be minimized (1). The absolute absence of liquid cell water below $-130\,^{\circ}C$ certainly represents an extremely dry environment. Primarily, however, this environment is maintained by extremely low temperatures. For this reason it is not detailed here.

In the laboratory, drying of cells, that is, the removal of cell water is typically achieved by freeze-drying under reduced pressure or by exposure to an environment of reduced water activity. The latter method allows a controlled and stepwise removal of cell water.

The water activity (a_w-value) is defined as the water vapor pressure (p_s) of a solution divided by the water vapor pressure (p) of pure water at the same temperature:

$$a_w = p_s : p \tag{1}$$

The water vapor pressure of pure water (p) is decreased by the addition of a solute. The exact correlation between the vapor pressures and the concentration of n_s moles of a solute in n moles of a solvent was first formulated by F. Raoult in 1886:

$$(p - p_s) : p = n_s : (n_s + n) \tag{2}$$

or

$$(1 - n_s) : (n_s + n) = n : (n_s + n) = p_s : p = a_w \tag{3}$$

Equation (3) shows a direct connection between Raoult's law and the definition of the water activity (a_w) as presented by Equation (1). These relationships, however, are strictly valid only for dilute solutions.

Because the temperature dependence of p_s and p is very similar the quotient p_s/p for all practical purposes shows no significant temperature dependence. It should be recalled, however, that the water vapor partial pressure (at room temperature about 20 mb) is strongly temperature-dependent. The quotient p_s/p, if multiplied by 100%, is practically identical with the relative humidity (RH). However, for certain purposes, the relative humidity is defined in terms of the weight of water vapor in a given volume. The weight of water vapor in a given volume depends on the ambient pressure and temperature. Therefore, minor corrections are required for exact comparisons. Approximate a_w-values are maintained conveniently by placing distinct solutions of inorganic salts in closed vessels at constant temperatures (2). In the presence of larger amounts of wet biological materials, however, the water activity of the solvent systems will eventually increase as the solutions absorb significant amounts of water from the biological materials. An alternative is therefore the preparation of saturated solutions of salts with excessive solid salts at the bottom (3) or the use of solid salts and related materials (e.g., silica gel) with defined hygroscopic properties.

LIMITS OF GROWTH AT LOW WATER ACTIVITIES

Minimum water activities for cell growth at normal temperatures have been reviewed earlier by Mazur (1) and Rose (2). Most eubacteria require an a_w above 0.9 and most fungi an a_w above 0.85. Even a value of 0.9 must be regarded as an extreme physiological value because it requires that the vapor pressure of liquid cell water is in equilibrium with the vapor pressure of a 3 molal sodium chloride solution. Archaea such as halobacteria may even grow at an a_w of 0.76, which is in equilibrium with a saturated (6 molal) sodium chloride solution. The most extreme adaptation to low water activities probably is represented by osmophilic yeasts (e.g., *Saccharomyces rouxii*) and a few molds (*Aspergillus echinulatus*, *Monascus bisporus*). These microorganisms grow at an a_w range of 0.65 to 0.60 (4). An a_w of about 0.6 is in equilibrium with 4.0 M $CaCl_2$. The following section shows that reduction of water activities under 0.6 causes increasing stress especially because of the removal of hydrate water from macromolecules and membranes. Under such extremely dry conditions, no terrestrial microorganism is known to exhibit any growth.

Many organisms do not need the presence of extracellular liquid water for growth. They can take up water from the atmosphere, provided the ambient water activity (relative humidity) is sufficiently high and they can provide a biochemical strategy for the import of water from the gaseous phase. Well-documented studies by Lange and coworkers (5) demonstrated that lichens in the Negev Desert in Israel may become extremely dehydrated during the day, whereas, during the night the lichens can take up some water from the atmosphere at relative humidities above 80%, even in the absence of the condensation of dew. (See the section on Survival Under Extremely Dry Desert Conditions).

According to the laws of diffusion, the uptake of liquid water from the environment is faster and more efficient than its uptake from the gaseous phase because the thermodynamic gradient between intracellular and extracellular water is more favorable for extracellular water in the liquid state.

DORMANT LIFE

The presence of free cellular water generally is thought to be required for the living state. Nevertheless, numerous organisms can survive almost complete dehydration for extended periods. The living state of the dehydrated organisms often is referred to as *anhydrobiosis*. These

organisms typically show no significant sign of metabolic activity. Their state of life is therefore often referred to as dormant. When water again becomes available, they may readily take it up and resume both metabolic activities and growth. According to Keilin (6) this phenomenon was described first in 1702 by Antony van Leeuwenhoek and has been the subject of discussion and experimentation ever since. However, the phenomenon of anhydrobiosis has been part of human experience for thousands of years, as humans have learned to store dry seeds from one year to the next in order to farm new crops of cereals or vegetables. In addition to seeds, many other anhydrobiotic organisms, such as dry yeast cells or fungal conidia, also are familiar in daily life. Less known are certain nematodes, the cysts of some crustaceans such as the brine shrimp *Artemia salina* or the huge variety of microbial spores (7). Coincidently, with the resistance to the unfavorable effects of drying, anhydrobiotic organisms are often more resistant to freezing (1,8) and heating (6,9). Many, though not all, anhydrobiotes have developed the biochemical strategy of accumulating large amounts of nonreducing sugars, especially trehalose or sucrose. The OH groups of these sugars are thought to replace the hydrate water of phospholipids or proteins in some way (10), and thus stabilizes the liquid crystalline structure of phospholipid membranes or the spatial structures of proteins. *Bacillus subtilis* spores, however, protect their integrity, especially of their DNA, by entirely different strategies (11). These include the synthesis of a special class of DNA-binding proteins for DNA protection. All dry-resistant organisms, however, have decreasing survival chances if their DNA is subjected additionally to thermal or radiation-induced lesions while being in the dormant state: in a metabolically inactive state no repair processes can operate. Thus, all damages accumulate and if (after rehydration) the general conditions for growth become favorable again, the damaged organisms fail to recover and to replicate because the number of damage exceeds their repair capacity. The molecular events induced by the removal of water will be outlined and discussed in the following section.

MOLECULAR EVENTS INDUCED BY DESICCATION

Removal of Liquid Cell Water

Fundamentally, the physical and chemical processes are the same if water is removed from any native cell by exposure to an environment of low water activity. A detailed study on the properties of cell water in successively dried *Saccharomyces cerevisiae* has been made by S. Koga and coworkers (12). These authors found that the respiration rate of dried yeast cells approaches zero if the water content was reduced to 20% by exposure to about 95% relative humidity. At this stage of drying, all free cell water that could support an organized metabolism had disappeared and about one half of the remaining cell water had obtained a gel-like structure, whereas the rest was in different states of adsorption to cellular structures. Exposure of the yeast cells to about 65% relative humidity reduced the water content to about 10%. S.Koga and coworkers demonstrated that at this stage no unbound water was left and the remaining water persisted only in various states of adsorption. This conclusion was supported especially by their measurements of the heat of vaporization (H): They observed constant values of about 10 kcal/mol for water contents above 10% and an increase to about 20 kcal/mol if the water content was reduced from 10% to 5%. The relative humidity or water activity at which all free cell water is lost certainly varies from species to species. It should be recalled, however, that so far no growth of microorganisms has been observed at water activities below 0.6. Free cell water is not only the solvent in which most metabolic reactions take place, its presence is also essential for maintaining all hydrophobic bonds (also called hydrophobic interactions) (13). Hydrophobic bonds fundamentally contribute to the stability of the bilayer structure of membranes and the spatial structure of proteins. Some essential features shall be outlined here in a simplified manner: The surface of a hydrophobic residue in contact with liquid water is covered by a netlike layer of relatively highly ordered water molecules. The ordered structure of this layer is maintained by electric dipole–dipole interactions. These interactions are much stronger here than in free water because they are influenced by the low dielectric constant of the hydrophobic residues (usually a side chain of an amino or fatty acid). It may be recalled that the force between two electric charges is reciprocal to the dielectric constant of the medium. Free water has, in contrast to hydrophobic residues, a high dielectric constant. For this reason the dipole–dipole interactions between the molecules of liquid water at room temperature are relatively weak and allow only the transient formation of ordered clusters. Thus, the state of disorder of liquid water is very high in comparison to the layer of bound water covering the hydrophobic residues. If now two or more hydrophobic residues interact with another they will finally "stick" together because they can decrease the surface area that is covered by the net of highly ordered water molecules. (Fig. 1).

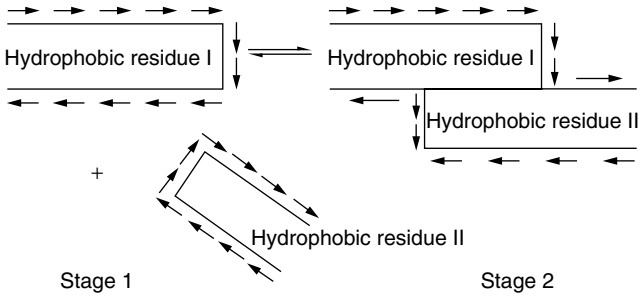

Figure 1. The arrows symbolizes the state of order of water molecules achieved because of their electric dipole properties. The highly disordered water molecules of the medium are not shown. The transition from Stage 1 to Stage 2 is especially favored because the number of ordered water molecules (number of oriented arrows) decrease from left to right and thus the number of disordered (free) water molecules increase, and so increases the entropy (S) of the system. The reaction is driven from left to right because G becomes negative because of the large increase in entropy. For more details, see the text, especially Equation (5).

The transition shown in Figure 1 can also be expressed by the following equations:

$$H = G + TS \tag{4}$$

or

$$G = H - TS \tag{5}$$

H is the change in enthalpy, S is the change in entropy (a term related to the disorder of the system), T is the absolute temperature, and G is the change in free energy. If G is negative, the reaction will be driven from left to right. This is indeed the case here because TS is much larger then H. It is a paradox of hydrophobic systems in biology that the highly ordered structures of membranes or proteins are maintained at the expense of the increasing disorder of the surrounding water molecules.

Removal of liquid water thus causes the breakdown of all structures that depend on hydrophobic interactions. This process is generally not reversible when liquid water becomes available again. Thus, most organisms are killed by dehydration. Those organisms that escape irreversible damage by dehydration have developed special strategies that allow them to regain their original activity after rehydration. Many of these organisms, including conidia of certain fungi and yeast cells, contain large amounts of nonreducing sugars, particularly trehalose (a disaccharide of glucose) (10,14). The OH groups of these sugars interact by hydrogen bonding with the phosphate groups of the lipids. These interactions appear to prevent the fusion of membranes during dehydration and they maintain the lipids in a fluid phase in the absence of water (15). In a related way, the sugars also appear to preserve the structure of some labile proteins (15). Most dry-resistant bacteria, however, do not seem to depend on trehalose, although they may apply related strategies. Many bacteria increase the production of oligo- and polysaccharides during desiccation. Concurrently they accumulate intracellular sugars (10,16), and/or they secrete various types of polysaccharides to form an extracellular coat of slimy or rigid consistency (17). The mechanism of protection by these exopolysaccharides, however, is not known. Even another protection strategy is performed during sporulation of bacilli (11). The liquid cell water of the vegetative cells is actively removed during the sporulation process. The interior of the developing spores becomes densely packed and enclosed by the very rigid sporal cortex, which may have similar protective properties as the rigid exopolysaccharide envelope of some vegetative bacteria. However, in this case also it is not exactly known how the inner membranes and intracellular proteins are protected.

Removal of Hydrate Water

The three major constituents of typical bacterial cells, for an instance of *Escherichia coli* cells, are water (about 70%), proteins (about 15%), and nucleic acids (about 7%). A significant proportion of the cell water is bound to the polar amino acids of proteins and to the bases, phosphates, and sugars of nucleic acids by means of electric interactions and hydrogen bonding. This hydrate water together with the surrounding liquid water is essential for maintaining the native structures of these macromolecules. On an average, each polar amino acid may bind about three water molecules; similarly, each nucleotide binds at least three water molecules. Jaenicke (18) estimated that "monolayer coverage" of a small protein such as lysozyme is reached at about 0.4 g water per gram protein. If these considerations are extended to all cellular proteins of *E. coli*, it can be estimated that a water content of about 6% is required to hydrate all proteins ($\sim 0.4 \cdot 15\% = \sim 6\%$, if a protein content of 15% is assumed). Actually less then 0.4 g water per gram *E. coli* protein will be bound because most *E. coli* proteins are larger than lysozyme (about 10,000 Da); therefore their surface to volume ratio is smaller. If, however, the amount of water required for the hydration of nucleic acids, sugars, metabolites, and inorganic ions is considered in addition, a value of about 10% for bound water in *E. coli* may be reached. These estimates are in agreement with data obtained by freezing of yeast or *E. coli* and related data as reviewed by Mazur (1) and with the data obtained by Koga and coworkers (12), which have been described earlier.

Dehydration is expected to destroy the native conformations of proteins (cause denaturation) because of the drastic decrease of the dielectric constant that occurs if water is removed from the hydrophilic (hydrated) pockets of proteins (18). The significance of the high dielectric constant of water in weakening electrostatic interactions has been discussed earlier. The thermodynamics of denaturation by dehydration is extremely difficult to evaluate because the relatively small change of G governing this transition results from numerous changes of stabilizing and destabilizing interactions (19), as the shielding of polar and hydrophobic groups by water disappears and electrostatic interactions become more predominant. Also, the strategies applied by anhydrobiotic organisms to achieve a renaturation of dehydrated proteins when water becomes available again, is not well understood. Evidently, two factors play a crucial role: The genetically determined design of protein folding by intramolecular bonds (18,19) and the interaction with protective components of the cytoplasm, such as sugars (20).

The structural changes of isolated DNA occurring during dehydration are, in contrast to those of most proteins, relatively well understood (21). Figure 2 illustrates the structures of B-DNA and A-DNA. B-DNA is stable above 92% relative humidity. On partial removal of hydrate water by lowering the relative humidity the B-form becomes converted into the A-form, which prevails below 75% relative humidity. At relative humidities below 44% the C-form becomes stable (not shown). Some essential data of the three DNA conformations are summarized in Table 1.

The significance of these data for cellular DNA is not clear because the conformational states of DNA in active cells are not well known. Interactions with various proteins play a crucial role. Thus, the mechanisms leading to the damages are not only species-dependent, but also dependent on the metabolic state of the cells. Moreover, many damages escape observation because of

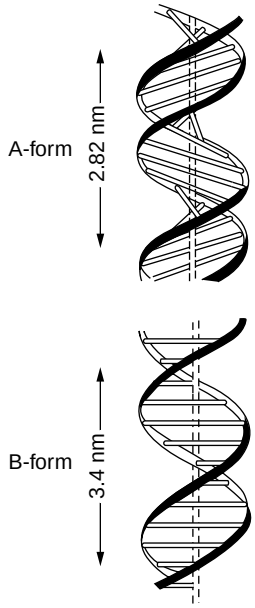

Figure 2. Two conformations of isolated DNA. The B-form is stable at relative humidities above 92%. Loss of hydrate water induces a transition to the A-form. This form becomes stable at about 75% relative humidity. If even more hydrate water is removed, another form, the C-form (not shown), becomes stable at about 44% relative humidity. Because of complexing with proteins and other components, genomal DNA may exhibit other transition states. After Dickerson (21).

Table 1. DNA-Conformations Depending on Hydration Effects

DNA Conformation	Relative Humidity	Nucleotide Pairs per Turn	Angle of Base Pairs Versus Helix Axis
A-DNA	75%	11.0	70°
B-DNA	92%	10.0	90°
C-DNA	44%	9.3	95°

Note: Data largely based on Dickerson, 1982 (21).

repair processes acting during or shortly after rehydration. Typical DNA damages that have been observed in desiccated cells after rehydration are: DNA strand breaks, both single- or double-strand breaks (22–27), formation of DNA-protein cross-links (24–26), and other damages causing mutations (28–31). It is not yet clear to what degree strand breaks are primary effects of desiccation. At least some strand breaks appear to be produced by incomplete repair of primary damages (32), whereas, others may directly result from physical stress induced by structural changes. The latter point has been corroborated by the vacuum-induced conversion of the supercoiled plasmid pBR322 into its relaxed form, which is initiated by a single-strand break (33).

The formation of DNA-protein cross-links are detailed in the next section because this reaction appears to be driven by the removal of reaction water during desiccation.

Additional Damages by Environmental Agents and Secondary Reactions

In addition to the stress caused by the removal of liquid water and hydrate water, desiccated organisms are readily damaged by a number of agents and secondary reactions. These especially include secondary interactions between cellular constituents, such as proteins and DNA, oxidations, and radiation-induced processes.

DNA cross-links with proteins are probably formed by the reaction of a protein-bound OH group with the phosphodiester group of DNA under removal of a water molecule. This reaction appears to be favored by the structural changes occurring after the loss of most hydrate water. The water released in the course of this reaction, however, is to be classified as chemically bound water. The resulting phosphotriester is a labile intermediate that will be readily hydrolyzed upon new contact with water during rehydration. The final reaction yields a DNA single-strand break, the protein being bound to the phosphate group of one of the new terminal nucleotides (25). (See Fig. 3 for more details.) In a related way also, sugars may react with DNA and cause strand breaks in addition to DNA-sugar cross-links.

Depurination reactions may also occur during long-term storage under vacuum. Greer and Zamenhof (34) have studied the heat-induced depurination of dry DNA in vacuum at temperatures between 81 °C and 131 °C. The reaction probably proceeds via the degradation of the desoxyribose. If the extrapolation of their kinetic data to about 25 °C is allowed, significant effects could be expected after several weeks of storage.

The good vacuum tolerance of *Deinococcus radiodurans* probably is related to its efficient DNA repair capacity (24,35). *Deinococcus radiodurans* repairs many of the desiccation-induced DNA damages, especially the DNA-protein cross-links, immediately after rehydration, before the first replication step (36). The same strategy appears to be used by *Bacillus subtilis* spores (11) and related organisms. In contrast to *B. subtilis* spores, however, *D. radiodurans* is inactivated strongly by exposure to relative humidities above 45% (37). The reasons for this unusual response are as yet not known (see also the section Survival under extremely dry desert conditions).

Among the biochemical constituents of cells, reducing sugars can be especially hazardous to proteins and nucleic acids during storage in the desiccated state. In metabolically active organisms, nonenzymic browning caused by the Maillard reaction is an aging process that is initiated by the reaction of the amino groups of proteins with reducing sugars (38). Evidence has been presented indicating that nucleic acids may also become modified by reaction with reducing sugars (39). Mouradian and coworkers (40) have observed that the functional integrity of freeze-dried biological membranes also is affected by glucose during long-term storage. Samples stored at 40% relative humidity showed extensive browning after 28 days of storage. Storage at 11% relative humidity, or even more efficiently in vacuum, strongly reduced the damaging reactions by glucose. Oxygen is a potentially damaging agent for lyophilized bacteria. Long-known examples are the radical production (41,42)

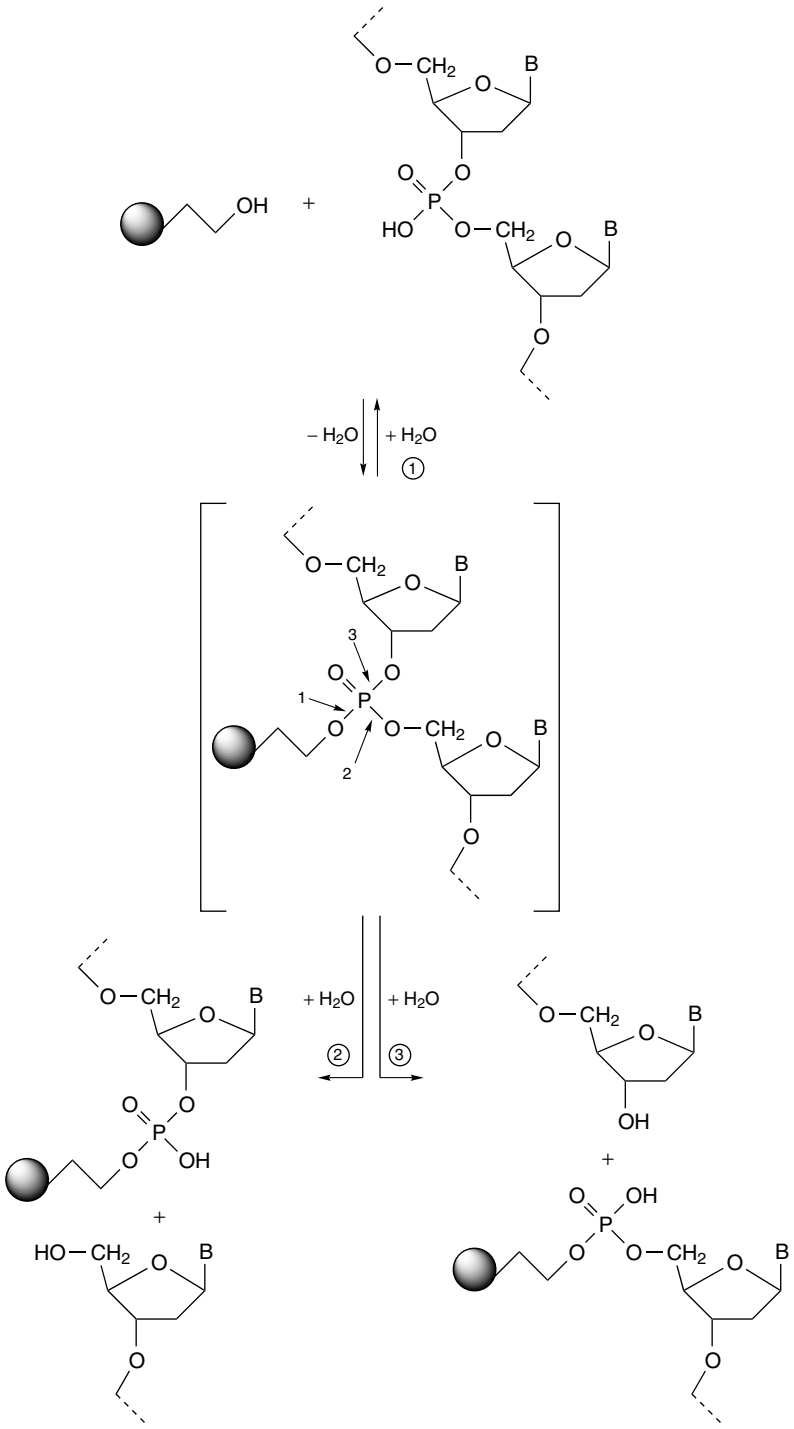

Figure 3. Mechanism for the formation of DNA-protein cross-links during dehydration and rehydration. It is suggested (25) that proteins being associated with DNA undergo a condensation reaction (for example, between a tyrosine-OH group and a phosphodiester group of DNA) yielding a reactive phosphotriester as an intermediate. The strand breaks occur during rehydration as a result of partial hydrolysis of the triester. The suggested pathway is also part of the reaction of type-I topoisomerases with DNA. These enzymes, however, again connect both DNA strands after relaxation of a supercoiled DNA structure. The protein is symbolized by the spherical structure carrying an OH group. After Dose et al., *Adv. Space Res.* **12**(4), 221–229 (1992).

and oxidation of SH groups (43). Molecular oxygen itself is a reactive diradical because its outer electron shell contains two unpaired spin-parallel electrons (a triplet state). Therefore, oxygen reacts readily with other radicals to yield even more reactive species such as superoxides (O_2), hydrogen peroxide (H_2O_2), and hydroxyl radicals (HO·). These species may contribute to DNA damage (44). A physiological source of superoxides is the reaction of oxygen with chelated Fe^{++} involving the transfer of one electron to oxygen according to:

$$Fe^{++}\ (\text{chelated}) + O_2\ Fe^{+++} + O_2 \qquad (6)$$

Therefore, storage in the absence of oxygen, preferably in nitrogen or in vacuum, is advisable (45). Cells can also be affected during long-term storage by ionizing radiation (46). However, the natural radiation environment is not expected to pose a serious hazard

unless geologic exposure times are to be considered. All cells contain a natural source of ionizing radiation: the isotope ^{40}K. Its half-life is 10^9 years. However, a single bacterial cell contains only $4 \cdot 10^3$ atoms of ^{40}K (17). Thus only storage times exceeding millions of years will yield a significant number of decays per cell.

A much more serious hazard is the exposure to solar light. About 1% of the solar light reaching the ground has wavelengths around 300 nm. This UVB fraction (UVB) is absorbed directly especially by the guanine residues of nucleic acids. The photochemistry of the resulting damages is not well known. Even in areas of moderate sunshine (50° N or S), 50% of a population of *B. subtilis* spores were killed during two hours of exposure at noon on a spring day (37).

SURVIVAL AT EXTREMELY LOW WATER ACTIVITY

In the context of this contribution, an extremely dry environment is understood as a dry environment that does not allow active growth of microorganisms. At present, a water activity under 0.6 appears to represent this limit (1–5).

Survival After Freeze-Drying

A discussion of the process of freeze-drying is beyond the scope of this contribution (see FREEZE DRYING: PRESERVATIONS OF MICROORGANISMS BY FREEZE-DRYING). Instead, only the essential damages that limit the survival of freeze-dried microorganisms are summarized here.

Survival of freeze-dried microorganisms is affected strongly by the conditions of freezing, the composition of the suspending fluids applied during freeze-drying, the gas in the storage container, the ultimate water activity, the temperature, and the time of storage. Long-term survival especially is limited by DNA damages. Freezing itself is hazardous primarily to membranes because it implicates the removal of liquid cell water (1,17). Moreover, ice crystals may cause membrane damages (1). However, the subsequent drying process in connection with the ultimate removal of bound water at extremely low relative humidities also will cause DNA damages, including single-strand breaks and mutations (28–30). It should be recalled that the native structure of DNA relies on hydrate water and that at relative humidities between 75% and 44%, the conformation of free DNA changes from the A-form to the C-form. Cells of *E. coli* show a strong increase in the number of mutations if they are desiccated at 55% relative humidity rather than at 75% (28). This effect is caused probably by conformational changes occurring during the dehydration of cellular DNA. Earlier, Clegg (10) has suggested that trehalose and other sugars may replace the water that is removed during desiccation of phospholipid membranes and proteins and thus stabilize the structures of these entities. In a related way, cellular DNA and the cellular DNA-protein complexes, respectively, could be stabilized. Moreover, gases affect the survival of dried bacteria during storage, as discussed earlier. The best survival rates are usually observed for storage in vacuum or nitrogen (45). It has been stated above that oxygen is a particular hazard (30) and that free radicals accumulate during storage in the presence of oxygen (41,42). Their damaging effects show the kinetics of thermal reactions (41): In the case of dry *Serratia marcescens*, the number of radicals increased from $-20\,^{\circ}C$ to $37\,^{\circ}C$ by a factor of 10 during six days, whereas the number of viable cells decreased by a factor of 10^{-5} (41). In view of the potential for damages to DNA occurring during drying and storage, freeze-drying is not the method of choice for preservation of microorganisms. A better way of preservation is the storage of cells at temperatures below $-80\,^{\circ}C$ (1). Not all cells, however, can survive the trauma of freezing, although there appears to exist a close relationship between resistance to freezing and dehydration. Those cells that tolerate dehydration are likely to resist freezing (8). Additionally, however, many other cell types exist, for instance, mammalian cells that are highly sensitive to dehydration although they may survive freezing in the presence of protective compounds (1).

Survival in a Dynamic Vacuum

A dynamic vacuum (pressure about 3×10^{-6} mbar and lower) is defined as an open vacuum that is maintained typically by a continuously running vacuum pump, preferentially by a turbomolecular pump. A dynamic vacuum is represented also by the vacuum of outer space. In fact, most laboratory experiments that have been conducted to study the long-term effects of a dynamic vacuum on biological materials have been designed to simulate the effects of space vacuum. During a space mission, however, the biological samples inevitably are subjected to additional stress factors that may obscure the vacuum effects (see the next section for more details). One essential feature of a dynamic vacuum is that volatile compounds are continuously removed from the sample in a nonequilibrium process. These conditions are in contrast to the storage conditions that may be applied after freeze-drying. In the latter case the sample container is sealed off under vacuum so that finally an equilibrium state is reached regarding the volatile compounds of the solid and the gas phase. Consequently, reactions that are driven by the removal of volatile by-products stop.

The early literature (before 1962) on the survival of bacterial spores or fungal conidia after exposure to a dynamic vacuum is quite controversial. Some relevant data have been reviewed by Morelli and coworkers (47) who also demonstrated that spores of *B. subtilis* var. *niger* show survival of about 50% after 35 days of exposure to an ultrahigh vacuum (10−8 mm mercury). Systematic studies on the correlation between the loss in viability and the increase in the amount of damage during long-term exposure to vacuum conditions has received increasing interest by the space research community since the mid 1980s (48,49) in connection with the planning of the long-term space mission EURECA (European Retrievable Carrier) (see next section). During the 1990s it was firmly established that the survival of microorganisms is especially limited by DNA damages. The extent of these damages increases with the time of exposure to vacuum (24,27). Their deadly impact

therefore differs crucially from that of the small number of mutations (28,30,49), strand breaks (22,50,51), and other damages that are induced during the initial period (minutes to hours) of freezing and/or drying by evacuation (see the section Molecular events induced by the removal of water). The chemistry of the primary DNA damages that are induced directly by long-term exposure to vacuum conditions is not understood fully. The formation of DNA-protein cross-links is well understood (see Fig. 3, in the section on Molecular events induced by the removal of water). This process is probably accompanied by the formation of DNA strand breaks. Additional DNA strand breaks probably are formed by incomplete excision-repair processes. These processes start immediately after rehydration, but they are blocked during the lysis of the sporal cortex or cell walls because of the breakdown of the energy metabolism by the detergents and enzymes of the lysis cocktails. Lysis is an essential step before the analysis of the genomal DNA by pulsed-field gel electrophoresis (26). The latter method allows us to determine the size of DNA fragments up to the size of a complete bacterial genome. Pulsed-field gel electrophoresis therefore is most suitable for the analysis of large genomal fragments resulting from DNA double-strand breaks.

Some typical results on the response to long-term vacuum exposure of some specific microorganisms are summarized briefly: There is a decrease in the viability of *B. subtilis* spores (Fig. 4). Exposure to a dynamic vacuum at 293 K is about twice as effective as exposure at 78 K. Exposure to an inert gas such as argon (293 K and 3% relative humidity) is also less efficient. The temperature dependence of the loss in viability supports the view that chemical reactions are responsible for the damaging effects produced by long-term exposure to vacuum. This point is substantiated by the temperature-dependent increase in the number of DNA double-strand breaks per chromosome observed after lysis of spores (see Fig. 5). About twice as many double- strand breaks are produced at 293 K than at 78 K. For comparison, the exposure to an atmosphere of dry argon (293 K and 3% relative humidity) has about the same effect as the exposure to a vacuum at 78 K. When comparing the loss in viability and the increase of the number of DNA double-strand breaks per chromosome, one has to keep in mind that only those spores that were rehydrated in a growth medium had the opportunity to repair numerous DNA damages before the first replication step. Thus, even after 25 weeks of vacuum exposure at 293 K, only 30% of the spores could repair the DNA damages so efficiently that they were able to replicate again. However, those spores that were rehydrated in a lysis buffer that actually was designed to break up the spores for DNA analysis, could only perform a very incomplete repair so that six DNA double-strand breaks per genome became analyzable. For a better understanding of these and related processes, see Figure 6.

DNA protein cross-links are not efficiently in *B. subtilis* spores during long-term exposure to vacuum (26). This effect may be due to the presence of a special class of DNA-binding proteins in these spores (11). However, in addition to other types of DNA damages a large number of DNA protein cross-links is induced in fungal conidia and even in *D. radiodurans* cells during exposure to vacuum (24,51). Figure 7 demonstrates the relatively good desiccation-resistance of *D. radiodurans* (mutant UVS_{78}). Figure 8 reveals that DNA protein cross-links are readily formed during desiccation of *D. radiodurans* (mutant UVS_{78}), although they can be repaired efficiently under growth conditions after rehydration. The same applies to other types of DNA damages such as strand breaks (24). However, despite its resistance to a huge variety of DNA-damaging agents, *D. radiodurans* has failed to survive under desert conditions (37). (See Survival under extremely dry desert conditions.)

Survival in Space

The Greek philosopher Anaximander, who lived about 610 to 546 B.C., suggested that "germs of life" may originate

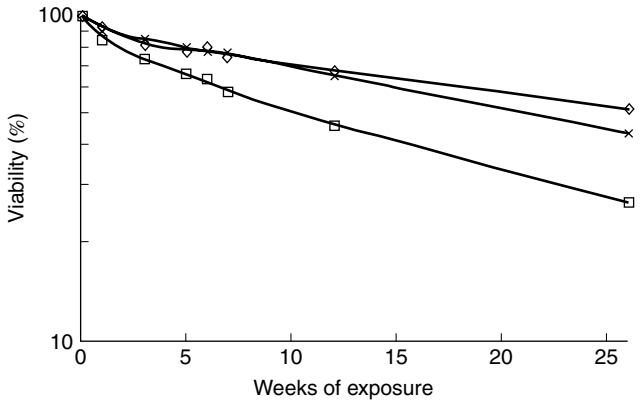

Figure 4. Loss in viability of *B. subtilis* spores (TKJ 3412) during exposure to vacuum for up to 25 weeks at 293 K (–!–) and 78 K (– –). For comparison the corresponding inactivation curve by exposure to dry argon (3% relative humidity) at 293 K is shown (– × –) (27).

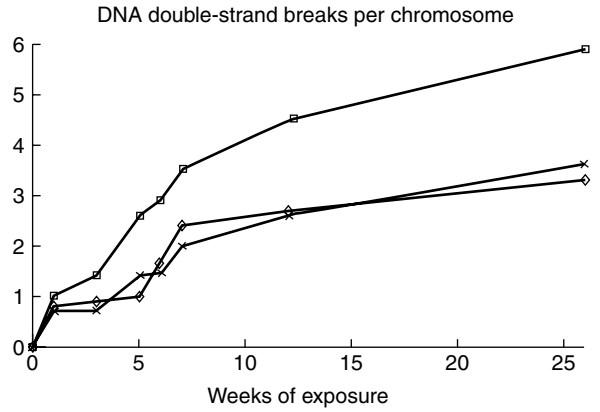

Figure 5. Formation of DNA double-strand breaks induced in *B. subtilis* spores (TKJ 3412) after exposure to vacuum for up to 25 weeks at 293 K (–!–) and 78 K (– –). For comparison the corresponding number of DNA double- strand breaks after exposure to dry argon (3% relative humidity) at 293 K is shown (– × –). It may be noted that most strand breaks occur under lysis conditions as a result of incomplete repair of other DNA damages. [Fig. 6; (27)].

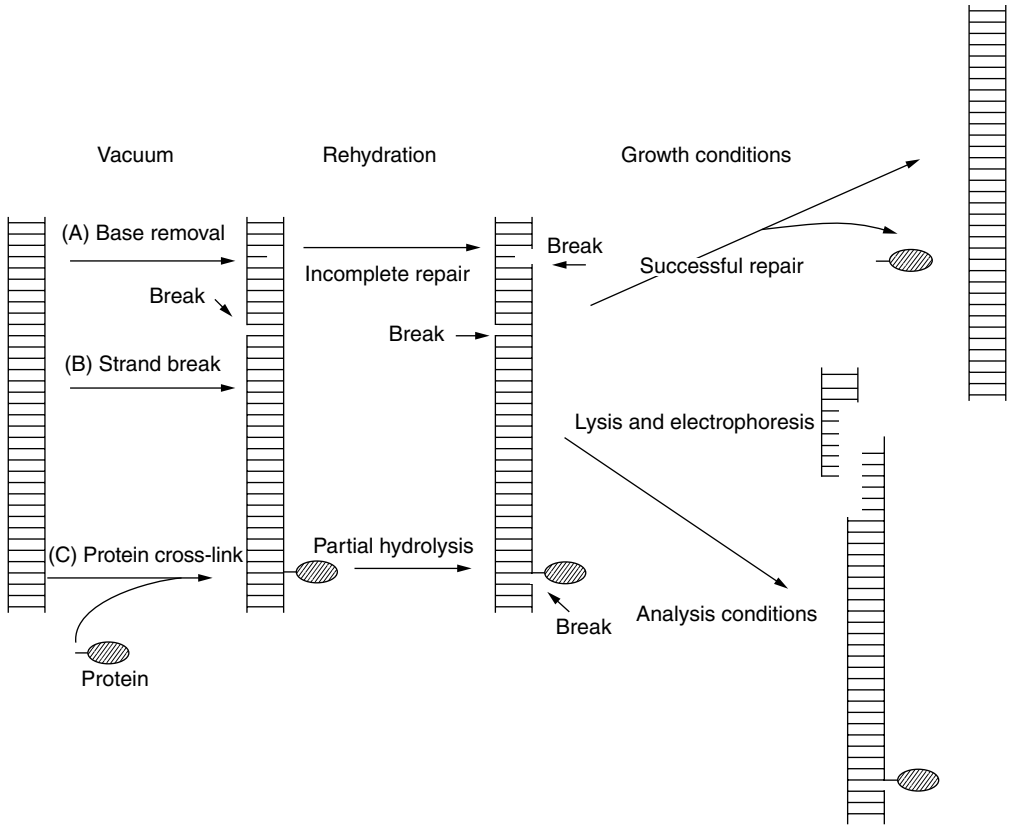

Figure 6. Possible intermediate steps leading to the formation of DNA double-strand breaks by dehydration and subsequent rehydration under lysis conditions. These conditions cause incomplete repair (lower right) especially because of the absence of ATP synthesis. For example, during excision repair the strand connecting ligases cannot function because the necessary energy resources are not available. Under growth conditions, (upper right) at least a fraction of the damaged cells may manage a successful repair. Their success, however, will depend on the number of dryness-induced DNA damages and on the efficiency of their repair systems. Even the most repair efficient strains become failure-prone and die if the number of DNA damages exceeds their repair capacity (26).

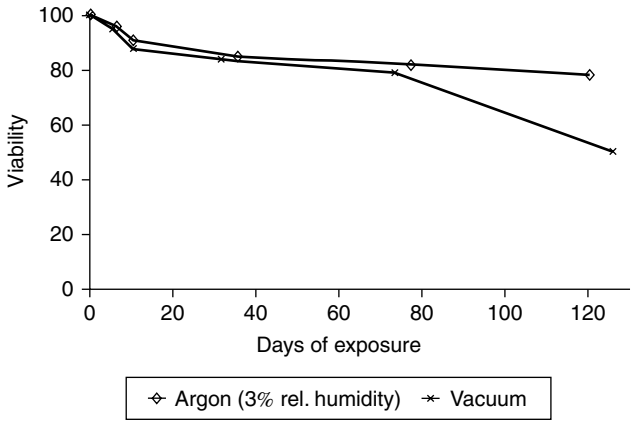

Figure 7. Survival of *D. radiodurans* (mutant UVS_{78}) after long-term exposure to vacuum and dry argon (3% relative humidity) at 293 K. Data from Dose et al., *Origins Life Evolution Biosphere* **21**, 177–187 (1991), and O. Kerz, *Dissertation*, University of Mainz, FB Chemistry and Pharmacy, 55099 Mainz, Germany, (1994).

from the "moisture" that surrounds the Earth and that life could be brought down from the sky with the rain. Related concepts have been held ever since. During the middle of the nineteenth century, it was widely accepted that airborne fungal conidia could be carried across the Alps from the Mediterranean and North Africa and that these organisms therefore could survive at high altitudes. For this reason, the German physician Richter (52) suggested in 1865 that germs of life could be picked up by passing comets or meteorites and thus be transported through space. Richter assumed that after an impact on another planet, one exhibiting favorable conditions for growth, these organisms would multiply and develop according to Darwin's theory. At the beginning of the twentieth century, Arrhenius suggested a similar hypothesis (53), which he popularized as the "panspermia" thesis. In contrast to Richter, however, he suggested that spores could be propelled through the Universe by the pressure of the light radiated from the sun or other stars. However, it was later recognized that naked spores would be inactivated within seconds, if exposed to solar UV. Spores protected by a light-absorbing coat, on the other hand, would be too massive to be transported by the pressure of light. Spores transported by meteorites or comets face numerous additional hazards. These include the heat of friction during the contact of comets or meteorites with planetary

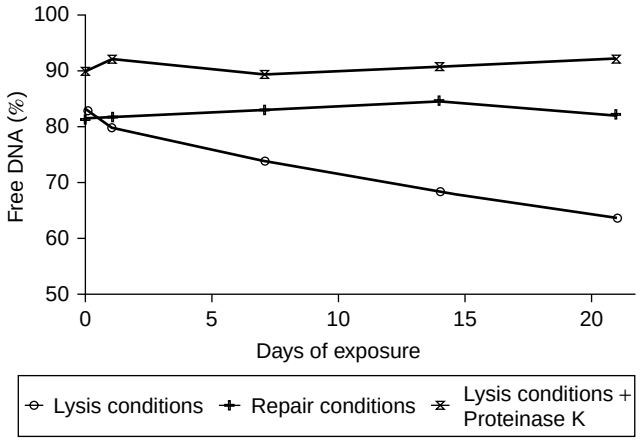

Figure 8. The desiccation-induced cross-linking of DNA to proteins causes a time-dependant decrease in "free" (extractable) DNA in *D. radiodurans* (mutant UVS_{78}) according to Dose and coworkers (24). In untreated cells about 18% of the total DNA is bound to proteins. That means only about 82% of the DNA is "free" or extractable from protoplast after lysis by detergents. The amount of "free" DNA was increased to about 90% by additional treatment with proteinase K (the protein cross-link is degraded). For repair, the cells were incubated in a growth medium for 3 hours at 30 °C.

atmospheres both during pick up and delivery of living spores and high pressures caused by shock waves during collisions (54). Other hazards include cosmic radiations and dehydration by space vacuum during travel times of geologic order (26). For these reasons Crick and Orgel (55) suggested that life may have been brought to Earth through the activity of intelligent extraterrestrial beings, either by manned spaceflight or by a programmed rocket "directed panspermia" from another planet of our Galaxy. It is true that numerous solar systems older than our own may indeed exist at a distance of 100 light-years, and that the formation of Earth-like planets in at least one of these solar systems is a possibility. It is also true that life in the Universe may have come into existence before our Earth was formed. However, space transport systems traveling at about 100 km/s (about 14 times faster than the space shuttle) would require 300,000 years to bridge a distance of 100 light-years. Because of such a long travel time, the idea of "directed panspermia" remains yet in the realm of science fiction.

With respect to the question of the origin of life on Earth, one has also to bear in mind that all hypotheses on an extraterrestrial origin of life move this problem just to another planet. To evaluate the possibility of extraterrestrial life transfer and to test for the possibility of contamination of other planets by space vehicles, especially spores of *B. subtilis*, fungal conidia, and cells of *D. radiodurans* have been exposed to the conditions of free space during various space missions (33,56,57). These missions include Apollo 16, Spacelab 1, LDEF (Long Duration Exposure Facility), the EURECA, and the D2 mission. In typical experiments, suspensions of the microorganisms are applied to small glass disks (about 2 cm in diameter) to achieve statistical monolayers or several milligrams of predried microorganisms (as a powder) are transferred to small cubic aluminum containers (side length 15 mm) that are covered by gas-permeable, but germ-impermeable silver membranes (33). Subsequently the samples are desiccated under vacuum in the laboratory and then transferred to (sealed) containers. These containers are arranged in larger exposure units that often are accommodated at the outside of the space vehicle. During the spaceflight, the exposure units are opened and closed by remote control. The samples were exposed to a space vacuum of 10^{-10}–10^{-6} mbar and at temperatures between −10 °C and 50 °C, depending on carrier and orbit. Exposure to space lasted between 1.3 hours (Apollo 16) and up to 2107 days (LDEF).

So far most space exposure experiments had at least one of the following disadvantages: The samples had to be provided several days or even weeks before the mission and they were returned to the investigator at least several days after the mission. The environmental conditions (such as temperature and relative humidity) during these periods were usually not completely monitored. In addition, the exact temperature control during the missions was often a problem. For example, during the EURECA mission some samples were heated up to 50 °C (57). Moreover, the vacuum on the surface of a space vehicle can be contaminated by gases from the propulsion system. The duplication of an experiment is often not possible because appropriate missions are not offered. For these reasons simulation experiments in the laboratory play a crucial role. The space vacuum around a space vehicle in Earth orbit can be easily be simulated for months with the help of continuously running turbomolecular pumps. Therefore, as expected, it could be confirmed that the laboratory data on the response of microorganisms to vacuum largely agree with the corresponding space data (57), especially if the undesirable effects occurring during the missions are taken into account. Noteworthy with respect to survival are the results of the LDEF mission (56). They show that *B. subtilis* spores can relatively well survive exposure to space vacuum (around 80% survival after five years of exposure), if they are exposed in thick layers with glucose as a protectant. However, if exposed in cellular monolayers and in the absence of protectants survival was reduced to about 1%. These differences are not surprising because removal and diffusion of water from a cellular monolayer proceeds faster than from a thick layer of hydrophilic biomass. Generally, the removal of chemically bound water by vacuum appears to be an extremely slow temperature-controlled reaction (27). Cellular monolayers of spores continue to become inactivated during an exposure to vacuum for more than 10 weeks (26,27).

To monitor the effects of irradiation by sunlight in space, cellular monolayers of the microorganisms are exposed on quartz disks for short periods. The evaluation of the photobiological experiments (56) has confirmed that only 5% of a population of unprotected spores will survive if exposed to the full solar spectrum for only 10 seconds. It should be noted, however, that this value was obtained by extrapolation, not by direct measurement. The UV sensitivity of spores under vacuum is about five times larger than under atmospheric conditions at about 60% relative humidity because of the synergism of dehydration

and UV effects. Action spectra of the solar light show the highest efficiency at 260 nm, the maximum DNA absorption. On the surface of the Earth, the situation is not comparable. Because of the ozone shield practically no solar UV under 300 nm reaches the surface of the Earth. On Earth, spores have to be exposed to solar light for at least 90 minutes (depending on the season and the geographic location; see the next section) to reduce their viability to about 5% (37).

The effects of solar and galactic corpuscular radiations (cosmic radiations) have been investigated during most of the above missions. However, even during the long LEDF mission (almost five years of exposure) the amount of absorbed energy was so low that no general loss in viability could be attributed to these radiations.

The present data on the inactivation of *B. subtilis* spores by long-term exposure to a dynamic vacuum reveal that the exposure time for 50% inactivation at 293 K is about nine weeks and at 80 K presumably still about 20 weeks (26,27). With respect to survival in space, the implication is that unprotected spores would be completely inactivated within a few decades both if exposed to vacuum at 293 (26) or at the extremely low temperatures found at the outskirts of the Solar System (27). The UV-sensitivity of dehydrated spores at 80 K is decreased only by a factor of ~4 in comparison to irradiation at 293 K (27). Solar radiation would therefore continue to be a lethal threat to spores at 80 K. These data seriously restrict the survival chances of unprotected spores while being transported through the Solar System and therefore further limit the validity of the panspermia thesis (53,58). In view of our data, appreciable chances of survival could only be maintained by avoiding any vacuum-induced dehydration or decomposition process. This could be achieved by embedding spores or other cells in huge icy masses at temperatures below 140 K, the critical temperature for freezing out all liquid water. Below this temperature the rate of all diffusion-controlled chemical reactions, for example, hydrolysis is practically zero (1). The size of the germ-transporting icy masses would have to be comparable to the size of the Halley's comet because evaporation processes would lead to huge losses of matter during the long journey from a remote planet. In addition, sufficient shielding from cosmic radiations would be provided by a thick cover of icy matter. The source of such a cosmic "iceberg" could be seen in the glaciers or permafrost areas of another life-bearing planet. It is well known that terrestrial glaciers provide various habitats for life. An example is the cryoconite holes investigated by Wharton and coworkers (59). Viable microorganisms have also been detected in permafrost (60). It is conceivable that a cosmic body (comet or meteorite) could have collided with the life-bearing ice cover of a remote planet several billion years ago and lifted off huge numbers of frozen masses. Some of these icy masses may have finally reached the early Earth and implanted life here. It has been realized, however, that the probability of such a life-transfer process is extremely small. Moreover, there is no significant advantage in moving the origin of life to a remote planet. The age of our Solar System is about 4,500 Myr. Contemporary forms of life may have been present on Earth about 3,700 Myr ago (61). The conditions for prebiotic evolution on Earth may have become favorable about 4,000 Myr ago. This limits the time available for the evolution of microbial life on Earth to less than 300 Myr. The available time for chemical evolution and subsequent development of primitive prokaryotes on an ancient planet could have been much larger. The upper limit for such a timescale is set by the age of the Universe (probably about 15,000 Myr), diminished by the time (probably around 5,000 Myr) required to produce an early planetary system being sufficiently rich in bioelements. Prokaryotes on an ancient planet could therefore have evolved over a period of several 1,000 Myr before appearing on Earth. This advantage, however, is counterbalanced largely by the long time required for transportation of spores through space, by the general risks of such a transport, and by its extremely low probability.

After examining all these imponderables it is realized that the data on the limited survival of spores in an actual or simulated space vacuum put further constraints on the panspermia thesis and therefore encouraged the search for the origin of life on Earth.

SURVIVAL UNDER EXTREMELY DRY DESERT CONDITIONS

The climatic environments of terrestrial deserts differ significantly. Examples are the hot Negev Desert in Israel, the cold deserts of Antarctica, and the extremely dry deserts of northern Chile (Atacama Desert) (see ENDOLITHIC MICROORGANISMS IN ARID REGIONS). Most deserts are at least occasionally subjected to precipitation, periods of high relative humidity (above 80%), and/or dew fall during the early morning hours. During these periods the growth of a variety of desiccation-resistant microorganisms becomes possible. Lange and coworkers (5) have shown that although lichens in the Negev Desert usually become extremely dry during the hot daytime, at night they are capable of absorbing enough water from the atmosphere (at about 90% relative humidity and even in the absence of dew fall) to enable a short period of photosynthetic activity during the morning. Endolithic microorganisms use a different strategy (62–64). Symbiotic colonies of a variety of microorganisms including cyanobacteria live inside rocks, usually sandstones, protected and separated from the outside by a thin translucent rock crust. Although the rock surface is abiotic, the microclimate inside the rock is comparably mild. The endolithic organisms are able to adapt their metabolic activities, including photosynthesis, in response to changes in the environment. This includes the ability to survive periods of extreme dryness in an anhydrobiotic or dormant state. In the Antarctic desert (about 162° E; 77° S) there is no sunshine from May to July, the average air temperatures range from about −30 °C (winter) to about −1 °C (summer), and the annual average of the relative humidity is about 55% (65). During the summer, solar radiation may heat the interior of the endolithic systems up to about 10 °C and some melting snow provides the necessary moisture, whereas, during the winter, the dark, dry, and cold conditions enforce a dormant state. Under these conditions a relatively diverse assemblage of prokaryotes and microeukaryotes

develop. Entirely different is the climatic environment in some areas of the extremely dry and hot Atacama Desert. Only a few areas may receive sporadic rainfall (approximately every four years) because of the recurrent climatic phenomenon called El Niño. Seasonal changes of the relative humidity and of temperature have been monitored at the location "Yungay" (24.1° S; 69.7° W). Some data are summarized in Table 2 (37).

The relative humidity reaches 70 to 80% for a few hours before sunrise on only 15 days in a summer month and about seven days in a winter month. Additional stress is imposed by the strong diurnal changes of the relative humidity. Evidently, these extremely dry conditions will not support any form of active life. Accordingly, the surface of the rocks exhibits no sign of microbial activity. These conditions, including the appearance of the landscape, appear to resemble those of early Mars after the loss of a hydrosphere about 3.5 Gyr ago (37,66).

In this context we have tested the survival chances of *B. subtilis* spores, fungal conidia, and *D. radiodurans* cells (strain R1) under the earlier- mentioned desert conditions by exposing specimens in small containers of the kind used to study survival in space. Some of the data are summarized in Table 3. The survival in the Atacama Desert is affected also by the strong diurnal changes of the relative humidity, which seems to cause additional damages to the membranes rather than to DNA. The survival of *D. radiodurans* cells (strain R1) especially is decreased. This microorganism is resistant to extreme dryness and vacuum at relative humidities under 20%, but it is inactivated readily by exposure to higher relative humidities and therefore is not adapted to survive in a terrestrial desert. Its surprising inactivation is not related to an increase in DNA damages (37). All microorganisms suffer from the daily exposure to solar light, especially UV-B. Some data for an exposure time of 90 minutes are summarized in Table 4.

The data demonstrate that the long-term survival of *B. subtilis* spores is significantly poorer under desert conditions than in a (simulated) space vacuum (26,27,37). Probably also viable spores on the surface of Mars may have soon disappeared after the planet became dry. In the extremely dry areas of the Atacama Desert, chances for microbial life appear to exist only underground. There is a flow of groundwater from the Cordillera in the east. At some places, for example, at the Oasis Pica, the groundwater rises to the surface so that agricultural activities flourish in the otherwise extremely dry and rainless desert. Similarly, on early Mars, microorganisms, if they ever existed, could only survive in an underground habitat.

Table 2. Seasonal Changes of The Relative Humidity and of The Temperature in the Atacama Desert at Yungay (24.1° S; 69.7° W)

	Summer (December)		Winter (June)	
Parameter	Maximum	Minimum	Maximum	Minimum
Temperature (°C)	33 ± 3	10 ± 2	28 ± 3	1 ± 3
Rel. Humidity (%)	60 ± 25	<10	40 ± 35	<10

Note: The data are presented as mean values ± the maximal values measured during the indicated month. Actually the values have been recorded continuously during the whole year (37).

Table 3. Survival of *Aspergillus* conidia, *B. subtilis* Spores, and *D. radiodurans* after Exposure for 13 to 15 months in the Atacama Desert (dark tray)

Sample	Laboratory (silica gel; 15 months) $(N_t/N_o) \times 100\%$	Chacabuco and Yungay (~24° S); 13–15 months $(N_t/N_o) \times 100\%$
A. niger	35 ± 5	28 ± 5
A. versicolor	25 ± 5	17 ± 5
A. ochraceus	20 ± 5	14 ± 5
B. subtilis	17 ± 3	15 ± 3
D. radiodurans	30 ± 10	0.1 ± 0.05

Note: No significant differences could be found between survival after 13 and 15 months of exposure (37).

Table 4. Inactivation of Spores and Conidia by Solar Light in the Atacama Desert

Sample	Dark Control $(N_d/N_o) \times 100\%$	Solar Light $(N_{90}/N_o) \times 100\%$
A. niger	60 ± 5	24 ± 5
A. versicolor	25 ± 5	2 ± 1
B. subtilis	29 ± 3	4 ± 1

Note: The fluence (light energy per surface area) for 90 minutes irradiation time was about 16 kJ/m^2 (wavelength range 280 nm to 320 nm). N_o is the relative number of viable cells in the fresh preparation, N_d is the relative number of viable dried cells (monolayers on glass disks) prior to irradiation in the desert, N_{90} is the relative number of viable dried cells after additional exposure to solar light for 90 minutes (37).

CONCLUSION

It is a long way from learning to store dry seeds for the next season to testing the survival of microorganisms in extremely dry environments such as Mars-like deserts and free space. Although the former is and was essential for the survival of humanity, the latter satisfies just our curiosity: Are we alone in space? Do we really originate from Earth? Neither do we have affirmative answers, nor do we know what the Earth is for and why we are here.

Koyama-Minami, Japan

The growth of industrial civilizations, and, in particular, the use of fossil fuels for energy, have led to the pollution of the environment. The problem with fossil fuels is that the combustion products exert a harmful influence on the worldwide environment. The carbon dioxide emission has caused global warming. The restriction of "greenhouse gas" emission (particularly carbon dioxide) is the subject of worldwide debate in 2001 although the Kyoto Protocol was adopted in 1997. All fossil fuels contain organic

Table 1. Existing and Planned Regulations for Sulfur Level in Fuels for Motor Vehicles

Year	Country	Fuel	Current Sulfur Levels (ppm)	Target Sulfur Levels (ppm)
1993	United States	On-highway diesel	2500	500
1996	Singapore	Diesel	5000	2500
	India	Diesel	8000	5000
	European Union	Diesel	3000	500
1997	Japan	Diesel	2000	500
1998	Taiwan	Diesel	5000	500
2000	South Korea	Diesel	2000	500
	Thailand	Diesel	5000	500
	European Union	Diesel	500	350
	United States	CAAA gasoline	400	50–100
	European Union	Gasoline	500	350
2005	European Union	Diesel	350	50
2006	United States	Diesel	500	15
	United States	Gasoline	300	30
2007	Japan	Diesel	500	50

sulfur compounds, and burning of the fuels releases large quantities of sulfur oxides (SO_x) into the environment, contributing significantly to air pollution and being the principal cause of acid rain. SO_x is believed to contribute a share of the ambient fine particle matter, which can cause disorders of the respiratory system. Moreover, excess amounts of SO_x reduce the ability of catalysts to remove the nitrogen oxides in the engine of motor vehicles. To avoid the production of noxious sulfoxide, sulfur must be removed from fossil fuels before, during, or after combustion.

Hydrodesulfurization (HDS) is the current method for sulfur removal, and is a treatment of the fuel with hydrogen at high temperatures (>300 °C) and high pressures (>100 atm) in the presence of a metal catalyst, mainly molybdenum- or tungsten-based catalyst. Oil refiners depend on HDS process to treat some 20 million barrels of crude oil per day (1). HDS can easily remove inorganic sulfur or simple organic sulfur compounds but not complicated polycyclic sulfur compounds. Although conventional catalysts were alumina-supported bimetallic sulfides of molybdenum or tungsten, new HDS catalysts with improved efficiencies have been investigated. For example, molybdenum phosphide (2) or cobalt molybdenum nitride (3), which differ substantially from other materials, were introduced into the catalysts, and it has been confirmed that they were more active than the conventional catalyst. However, with the depletion of low-sulfur-containing petroleum reserves and increasingly stringent regulations, adequate desulfurization by conventional HDS alone is becoming progressively more difficult to achieve.

Regulations to reduce the sulfur content of fuels for motor vehicles were introduced in the early 1990s and will be increasingly stringent after 2000 (4–6), as shown in Table 1. In the European Union, regulations reducing the sulfur levels to less than 50 ppm in 2005 have been established. The U.S. government has worked out even more stringent regulations of sulfur content in gasoline (below 30 ppm) and diesel oil (below 15 ppm). In Japan, the sulfur level in diesel oil will be decreased from 500 ppm, in 1997 to 50 ppm in 2007. Both governments and petroleum refining companies have recognized that it is difficult to meet the environmental regulations in a cost-effective manner using only conventional HDS technology because the equipment needed for such a high degree of desulfurization is extremely expensive to build and operate.

Another representative fossil fuel, coal, is used as fuel at many power stations, but not in motor vehicles. Although the fuel gas desulfurization is operated for removing SO_x released from coal at the power station, the installation is so expensive that an inexpensive sulfur removal technology has been desired.

Biological desulfurization (BDS) of polycyclic sulfur compounds in fossil fuels was investigated in the late 1970s and early 1980s, but it was not successful because the bacteria isolated at that time were not appropriate for commercial desulfurization. However, with the strict worldwide environmental regulations described earlier, BDS has again attracted attention for its application to the desulfurization of fossil fuels (7–9). BDS is expected to have the potential advantages to complement the HDS technology and to produce less greenhouse gases.

MICROBIAL DEGRADATION AND DESULFURIZATION OF DIBENZOTHIOPHENE

Microbial Degradation of Dibenzothiophene with a Cleavage of Carbon–Carbon Bonds

A variety of sulfur-containing compounds in petroleum have been characterized. Among them, various heterocyclic organic sulfur compounds remain after the current HDS treatment, and the main components are dibenzothiophene (DBT) derivatives. Therefore, for the research of BDS, DBT, which is a commercially available compound,

has generally been used as the model compound of sulfur heterocycles to be desulfurized.

The concept of microbial DBT desulfurization is not new. However, no commercially viable bioprocess for removing organic sulfur from fuels has been developed because the microbial process was not needed urgently. The metabolism of DBT by aerobic microorganisms can be generally classified into three types (Figs. 1 and 2). In type 1 metabolism, the carbon skeleton of DBT is partially oxidized and cleaved, with the carbon-sulfur bond remaining intact. This pattern of metabolism is "DBT degradation" and it should be clearly distinguished from "DBT desulfurization." All bacteria isolated for the purpose of microbial desulfurization previously had this metabolic pathway, DBT degradation. In 1968, *Pseudomonas* strains were reported to have the capacity to degrade DBT (10,11). Afterward, DBT was shown to be metabolized by hydroxylating the benzoid component of the compound to a dihydroxy-dihydro-derivative, cleaving the ring between the diol substituents, and then producing, in sequence, 4-[2-(3-hydroxy)-thionaphthenyl]-2-oxo-3-butenoic acid and 3-hydroxy-2-formylbenzothiophene (HFBT) as shown in Figure 1 (12,13). The occurrence of such a degradative pathway has been ascertained in a number of other bacterial strains (14–16). The genes for that DBT degradative pathway were proposed in *Pseudomonas* sp. C18 (17). This strain grew on naphthalene as a sole source of carbon, and the gene products for the naphthalene degradation were considered to be involved in the degradation of DBT (18). Although biodegradation of HFBT was observed in other *Pseudomonas* strains (19,20), no sulfate release was detected with those microorganisms. In the type 1

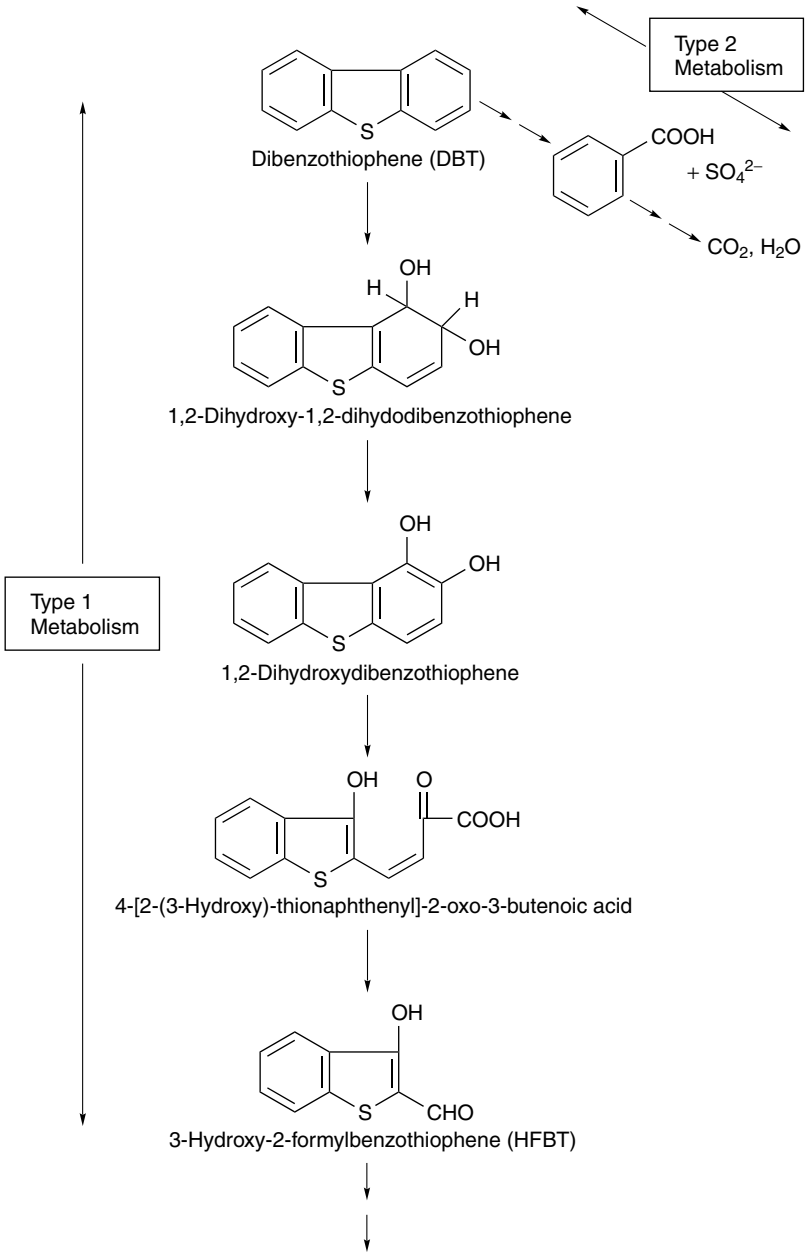

Figure 1. Microbial degradation of DBT with a cleavage of carbon–carbon bonds.

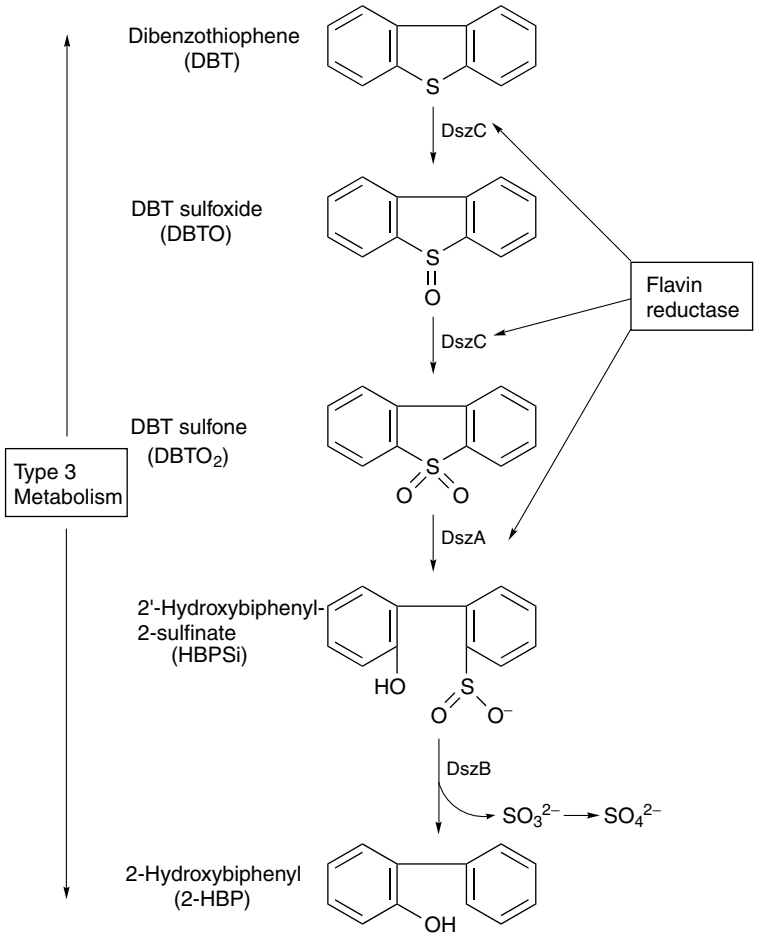

Figure 2. Sulfur specific pathway for microbial DBT desulfurization without a cleavage of carbon–carbon bonds.

metabolism described here, the bacteria assimilated the carbons of hydrocarbon leading to a loss of fuel content, but did not cleave the carbon–sulfur bond in the organic sulfur compound. That is to say, the metabolic pathway used for sulfur removal was in fact a hydrocarbon degradation pathway. The bacteria functioned in a bioremediation mode, degrading DBT to a water-soluble product, not desulfurizing DBT. Moreover, some pigments were formed in the bacterial cultures during DBT degradation, which will lead to trouble with the final oil product.

In type 2 metabolism, DBT is utilized as a sole source of carbon, sulfur, and energy. *Brevibacterium* sp. mineralized DBT, and carbon dioxide, sulfite, and water were formed as the final products (21). *Arthrobacter* DBTS2 was reported to oxidize DBT sulfoxide, but not DBT, forming sulfate and benzoate (22). Only these two microorganisms were known to have a metabolic pathway like that shown in Figure 1. They desulfurize DBT, but also break the carbon skeleton of the hydrocarbon.

It has been demonstrated that DBT is also metabolized by anaerobic microorganisms. *Desulfovibrio desulfuricans* M6, a sulfate-reducing bacterium, degraded DBT anaerobically, and biphenyl was isolated as the major degradation product (23). The degradation ratio was 42%. This bacterium removed sulfur from petroleum using electrochemically supplied electrons (24). It was shown that other sulfate-reducing bacteria also had the ability to convert DBT to biphenyl anaerobically (25,26), but the conversion ratio was very low (0.22 to 1.14%). An anaerobic process for sulfur removal would be attractive because it would not liberate sulfate as a by-product that must be disposed of. However, anaerobic microorganisms effective enough for the practical desulfurization of petroleum have not been found yet.

As described earlier, DBT metabolism, at first, was investigated using microorganisms capable of assimilating DBT as a carbon source. The modes of microbial degradation of DBT are similar to those of three DBT analogs, fluorene, dibenzofuran, and carbazole whose molecules have a carbon, oxygen, and nitrogen atom, respectively, instead of a sulfur atom of DBT molecule (18). These microorganisms seem to have some drawbacks for the microbial desulfurization of petroleum because they consume petroleum and produce unnecessary pigments.

Microbial Desulfurization of DBT with a Cleavage of Carbon-Sulfur Bonds

In type 3 metabolism, DBT serves as a sole source of sulfur, not carbon. DBT is desulfurized by the selective cleavage of the carbon-sulfur bond, resulting in the accumulation of 2-hydroxybiphenyl (2-HBP), as shown in Figure 2. The specific cleavage of the carbon–sulfur bond, rather than degradation/mineralization of the organic

sulfur compounds, is preferred for the microbial desulfurization process because sulfur is removed but the carbon and calorific values remain intact. In the past decade, several effective screening techniques have been developed and have yielded promising strains (27,28). Kilbane and coworkers (29) isolated *Rhodococcus erythropolis* IGTS8 (formerly identified as *Rhodococcus rhodochrous*), which has so far been the most extensively studied DBT-desulfurizing bacterium, and a DBT desulfurization pathway in the microorganism was proposed (30,31). According to the so-called sulfur-specific pathway shown in Figure 2, DBT is metabolized to 2-HBP via DBT 5′-sulfoxide (DBTO), DBT 5′-sulfone ($DBTO_2$), and 2′-hydroxybiphenyl 2-sulfinate (HBPSi). After *R. erythropolis* IGTS8 was found, many other bacterial strains including *Corynebacterium* sp. SY1 (32), *R. erythropolis* D-1 (33), *Nocardia globelula* (34), *Mycobacterium* sp. G3 (35), *Arthrobacter* sp. (36), and *R. erythropolis* KA2-5-1 (37) were reported to desulfurize DBT with a similar metabolic pathway. All these strains were gram-positive bacteria, and no gram-negative bacteria with a sulfur-specific pathway have been reported in the literature. as Apart from the intermediates or final products shown in Figure 2, 2,2′-dihydroxybiphenyl (DHBP) was detected in the culture of *R. erythropolis* IGTS8 (30,38), and DHBP formation was confirmed with growing cells, not with the stationary-growth-phase cells (39).

Kinetic Analyses of Microbial Desulfurization of DBT

Kinetic analyses of the microbial desulfurization of DBT were done using *R. erythropolis* N1-36 in batch, fed-batch, and continuous cultures (40,41). This strain produced more 2-HBP from DBT as a substrate than from $DBTO_2$ (40). In continuous cultures, the maximum specific growth rate was 0.235/h (41). In a fed-batch culture of *R. erythropolis* IGTS8, a high cell concentration of 33 g dry cells was obtained by keeping the concentration of acetic acid and ammonium ion below 3 g/L (42). When the cultivated cells were transferred into the synthetic medium with DBT as a sole source of sulfur, 2-HBP was detected and its production rate gradually increased with incubation time. Incubation for three to four hours was enough for the full induction of DBT-desulfurizing enzymes, and a two-phase cultivation (cell growth phase and induction phase) was proposed to obtain large numbers of cells with high enzymatic activity (42). And in a fed-batch culture of *R. erythropolis* KA2-5-1, ethanol was found to be a preferable carbon source for obtaining a high specific activity of desulfurization compared with glucose or glycerol (43).

Thermophilic Microbial Desulfurization of DBT

In petroleum refining, most of the sulfur compounds are presumed to be desulfurized by the chemical method, and the microbial process is applied to desulfurize the more recalcitrant aromatic organic sulfur compounds. Since petrochemical processing is performed at high temperatures and pressures, cooling a feedstock for bioprocess treatment is not practical. Therefore, thermophilic desulfurization bacteria would be desirable. Although the thermophilic degradation of DBT by *Sulfolobus acidocaldarius*, originally isolated from a hot spring (44), has been reported, this strain "degraded" DBT, that is, "cleaving a carbon–carbon bond." In 1997, the thermophilic desulfurization bacterium *Paenibacillus*, which can cleave carbon–sulfur bonds in DBT at temperatures up to 60 °C, was isolated (45). Maximal desulfurization by *Paenibacillus* sp. A11-2 was observed at 55 °C in the resting cells reaction, whereas that by *R. erythropolis* IGTS8 was observed at 30 °C. In addition, a moderately thermophilic bacterium *Bacillus subtilis* WU-S2B, which could desulfurize DBT at 50 °C in the similar way, was isolated (46). These thermophilic strains have potentials for the microbial desulfurization of petroleum.

GENES FOR DBT DESULFURIZATION

Identification of Genes for Desulfurization of DBT

The genes involved in the sulfur-specific pathway, DBT desulfurization, were identified and cloned with *R. erythropolis* IGTS8 in 1993 (47). Then, the DNA sequence for the genes was analyzed by two groups (48,49). The DBT-desulfurizing phenotype is conferred by a four kb gene locus on a 120-kb linear plasmid (50), organized as one operon with three genes, *dszA*, *dszB*, and *dszC*, transcribed in the same direction, coding for three proteins DszA, DszB, and DszC, respectively, under the control of a single promoter (50). DszC, a 45-kDa protein, is involved in two consecutive monooxygenation reactions, which convert DBT to $DBTO_2$. DszA, a 50-kDa protein, is a second monooxygenase, which forms HBPSi from $DBTO_2$. DszB, a 40-kDa protein, is a desulfinase that catalyzes the formation of the final products, 2-HBP and sulfite. The termination codon for *dszA* and the initiation codon for dszB overlap and there is a 13-bp gap between dszB and dszC. Although they are expressed as an operon, it was reported that there is severalfold less DszB in the cytoplasm than DszA and C (51,52). The reason for this phenomenon is not clear. By using the insertion fragments and *dsz* structural genes as probes, Southern hybridization showed the conserved nature of the *dsz* genotype among several desulfurization strains isolated from different geographic areas (50). Other genes for DBT desulfurization were cloned from the thermophilic desulfurization bacterium *Paenibacillus* sp. A11-2 (53). The DNA sequence contained an operon consisting of three open reading frames that showed an appreciable extent of homology with *dsz* genes of *R. erythropolis* IGTS8.

Regulation of Genes for DBT Desulfurization

The production of enzymes for the desulfurization of DBT is strongly repressed by sulfate or compounds containing sulfur atoms such as methionine and cysteine even in the presence of DBT (54,55). The regulatory region including the promoter was examined. Childs and coworkers cloned a fragment of the 5′ untranslated region of the *dsz* gene cluster and identified the promoter region and the transcription start site (51). The promoter region had sequence similarity with *B. subtilis* promoters (56) that use sigma factor σ^B, but not with the −35

and −10 regions of *Escherichia coli* promoters. Sulfur compounds repressing enzyme production do not inhibit the enzymatic activities (55). In contrast, accumulation of 2-HBP inhibits growth and enzymatic activities (39,55). Therefore, mutants resistant to 2-HBP may be needed for commercial applications.

ENZYMES FOR DBT DESULFURIZATION

Four Enzyme Components for Desulfurization of DBT

The enzymatic study of the microbial desulfurization of DBT was first done using *R. erythropolis* D-1. It was pointed out that NADH was the essential cofactor for the enzymatic desulfurization (57) and flavin coenzyme stimulated the enzyme activity (58) in the cell-free system. These findings have stimulated more enzymatic research. All the four enzymes involved in the desulfurization of DBT, DszA, B, C, and flavin reductase, were purified from *R. erythropolis* IGTS8 (52). The native molecular masses were 180 kDa for DszC, being a tetramer; 100 kDa for DszA, a dimer; and 40 kDa for DszB, a monomer. The subunit molecular mass of flavin reductase was 25 kDa. All proteins were colorless as isolated, indicating that no tightly associated chromophores were present. The DBT monooxygenase, DszC was also purified to homogeneity and characterized from *R. erythropolis* D-1 (59) and a *dszC*-overexpressing *E. coli* strain (60), respectively. DszC is involved in two consecutive steps of the monooxygenase reaction: DBT→DBTO→$DBTO_2$. DszC activity decreased during the purification of enzyme, and the loss in activity was due to the removal of a necessary protein component (59). Then, it was demonstrated that a flavin reductase from *Vibrio harveyi* complemented the activity of purified DszC (60,61). The second oxygenase, DBT sulfone monooxygenase, also required a flavin reductase for the catalytic activity (61). The enzyme was purified to homogeneity and characterized from *R. erythropolis* D-1 (62) and *Paenibacillus* sp. A11-2 (63), respectively. It catalyzed the oxygenolitic cleavage of the carbon–sulfur bond of DBT sulfone and gave HBPSi. Moreover, the enzyme from *R. erythropolis* D-1 also acted on dibenz[*c,e*][1,2]oxathiin 6-oxide (BPSi) and dibenz[*c,e*][1,2]oxathiin 6,6-dioxide (BPSo), and DHBP was formed from these compounds as shown in Figure 3 (38,62). Small amounts of DHBP appeared in the cultivation medium of *R. erythropolis* IGTS8 when DBT was added as a sole source of sulfur (30), and it was thought that DszA was involved in the formation of DHBP. In this case, this enzyme catalyzes the desulfurization reaction, releasing inorganic sulfur. DszA may recognize the sulfone structure moieties within the ring structures of DBT sulfone or BPSo.

HBPSi desulfinase, DszB, catalyzes the desulfination of HBPSi to form 2-HBP. This reaction is unusual because it catalyzes the cleavage of a carbon–sulfur bond of the substrate without any other proteinic component (52). The DszB reaction seems to be a rate-limiting step in the pathway since it is the slowest of the enzymatic reactions. Because of the poor activity of DszB, HBPSi might be accumulated temporarily as the only intermediate on enzymatic desulfurization by the cell-free extract of *R. erythropolis* IGTS8 (52).

Flavin reductase was purified and characterized from *R. erythropolis* D-1, and its gene was overexpressed in *E. coli* (64). The purified enzyme contained no chromogenic cofactors and was found to have a molecular mass of 86 kDa and four identical subunits with 22 kDa. It catalyzed NADH-dependent reduction of flavin mononucleotide (FMN). Flavin adenine dinucleotide was a poor substrate, and NADPH was inert. A flavin reductase was earlier identified as supplying free $FMNH_2$ to the luciferase of the bioluminescent bacterium, which catalyzed the oxidation of a long aliphatic aldehyde, resulting in the emission of light (65,66). In addition, it was reported to activate the chorismate synthetase of *B. subtilis* (67). Thereafter, a flavin reductase has been shown to be required for a number of monooxygenases (68–76).

Properties of the Monooxygenase System for DBT Desulfurization

There are some differences between the *dsz* monooxygenases involved in the microbial DBT desulfurization and the well-described monooxygenases such as methane monooxygenase. First, the known oxygenases are associated with a tightly bound flavin cofactor that can be reduced by NADH or NADPH (77), while the purified DszA and C do not contain any tightly bound flavin because they have no absorption peaks in the range of 300 to 700 nm. Second, all genes for well-known monooxygenase systems including oxygenase, electron transport protein and reductase are often present as a cluster in the plasmid of microorganisms capable of degrading the aromatic compounds. In contrast, the involvement of a flavin reductase had not been predicted by the original cloning of the *dsz* gene cluster, and the gene encoding the flavin reductase was not near the *dsz* gene cluster. Third, the *dsz* oxygenases use a flavin reductase to supply free $FMNH_2$ to them. There was no evidence for a complex between the flavin reductase and dsz oxygenase such as there was for the methane monooxygenase (78). A new class of monooxygenase, which uses a flavin reductase for activity, and includes DszA and C, as well as other enzymes described earlier, is proposed to be referred to as the two-component nonheme flavin-diffusible monooxygenase family (75).

EFFECT OF HYDROCARBON ON MICROBIAL DBT DESULFURIZATION

DBT Degradation in the Presence of Hydrocarbons

Even if the microbial desulfurization reaction proceeds in the buffer solution, it is not a meaningful and practical reaction at all because it should be done in petroleum. Therefore, effects of some hydrocarbons on the DBT degradation have been examined using several microorganisms. It was reported that degradation of DBT by *Pseudomonas* sp. was favored by *n*-dodecane or hexadecanoic acid (79). The reason for the increase in the DBT degradation rate was that the *n*-alkane formed a film around DBT that was easily attacked by the microorganisms and that the fatty acid formed a kind of micelle, which helped the DBT uptake by microorganisms (80). These experiments for DBT degradation were done with growing cells and

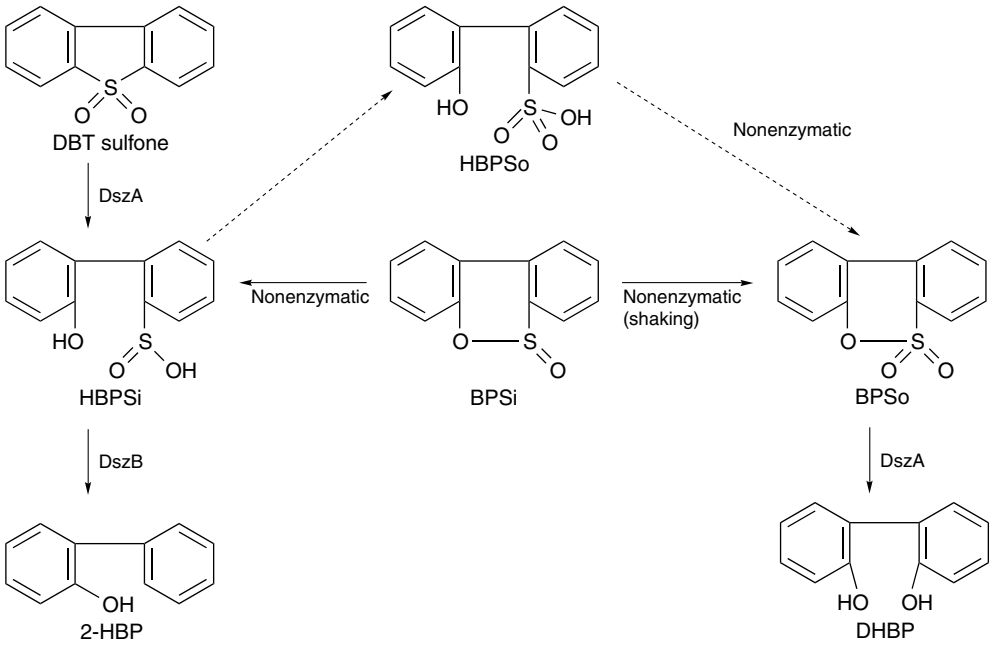

Figure 3. Proposed pathway for conversion of DBT sulfone to DHBP. Solid lines with arrowheads show the reactions verified in Reference 62; dashed lines indicate the reactions hypothesized in Reference 38.

Pseudomonas sp. strain, degraded not only DBT but also the usual aliphatic and aromatic hydrocarbons; it was not a desirable degradation. DBT was reported to be oxidized anaerobically by *D. desulfuricans* in *n*-dodecane (81) and *Desulfomicrobium escambium* in kerosene (82). However, in all the cases described here, DBT was degraded, but probably not desulfurized.

DBT Desulfurization in the Presence of Hydrocarbons

R. erythropolis H-2 with the sulfur-specific DBT desulfurization pathway utilized DBT rapidly in the presence of *n*-tetradecane and assimilated *n*-alkanes with carbon chains longer than C_8 (octane) with or without glucose (83). Because hydrocarbon was also degraded in growing cells of this strain, the reaction in resting cells was examined in the presence of hydrocarbons. Considering the practical scale of the microbial desulfurization process, a bioreactor with immobilized cells will have to be constructed; therefore, it would be essential to investigate the desulfurization by the resting cells. DBT was efficiently converted to 2-HBP by resting cells in a buffer system (33). In this strain, the addition of approximately 40% *n*-tetradecane or kerosene increased the rate of degradation of DBT (83,84). At that time, the formation of 2-HBP was observed. Moreover, the reaction in resting cells proceeded even in the presence of cyclooctane, *n*-hexane, *p*-xylene, and styrene, which at 0.5% completely inhibited the growth of this strain.

Formation of Emulsions in the Microbial Desulfurization of Petroleum

In oil-water systems such as BDS, efficient mass transfer of hydrophobic organic sulfur compounds from the oil to the water is important. Mixing is effective in creating good oil–cell water contact, and the supply of enough oxygen would enhance the reactions catalyzed by the oxygenases. However, this unfortunately leads to the formation of a tight emulsion that must be broken in order to recover the desulfurized oil and to reuse the cells. Microorganisms probably make and excrete the biosurfactant when they react with some hydrocarbon compounds. The emulsion formed by the biosurfactant was observed during desulfurization of DBT in the hydrocarbon by *R. erythropolis* H-2, and this phenomenon was reasonable for the uptake of the water-insoluble materials by the microbe. In fact, adding the surfactants, oleic diethanolamine, and Triton N101 stimulated the desulfurizing activity of *R. erythropolis* IGTS8 (85). One very effective method was the use of hydrocyclones to separate various phases (86). Passage of the emulsion through a hydrocyclone separated the clean oil from the cells and water phase.

DESULFURIZATION OF DBT DERIVATIVES OR PETROLEUM FEEDSTOCKS

Desulfurization of Substituted DBTs and Benzothiophenes

From the standpoint of the practical BDS, what should be desulfurized exists in the oil after the chemical desulfurization. Of the different classes of sulfur compounds found in petroleum, alkylated benzothiophenes, and alkylated DBTs are more resistant to HDS treatment than mercaptans and sulfides. And those with alkyl substitutions at positions four and six on the DBT ring are the most recalcitrant. *Arthrobacter* sp. assimilated 4,6-diethylDBT (4,6-DEDBT) as a sole source of sulfur (87). This strain converted 4,6-DEDBT to the sulfur-free product, 2-hydroxy-3,3′-diethylbiphenyl. This desulfurization pathway was

thought to be identical to the sulfur-specific pathway described earlier. *Rhodococcus erythropolis* H-2 desulfurized the DBT derivatives, 2,8-dimethylDBT (2,8-DMDBT), 4,6-dimethylDBT (4,6-DMDBT), and 3,4-benzoDBT by the resting cells in the presence of hydrocarbon (88). As shown in Figure 4, the initial reaction rates for 2,8-DMDBT, 4,6-DMDBT, and 3,4-benzoDBT were about 120, 60, and 20% that of DBT, and the reaction products from structurally symmetrical 2,8- and 4,6-DMDBTs were the corresponding monohydroxy dimethyl biphenyls. The reaction product from 3,4-benzoDBT was identified as α-hydroxy-β-phenylnaphthalene, indicating that the enzymes involved in the microbial desulfurization could distinguish between the two carbon-sulfur bonds of 3,4-benzoDBT. The steric hindrance caused by the naphthalene ring might lead to this specificity. Aside from *R. erythropolis* H-2, *Mycobacterium* sp. strain G3 and *R. erythropolis* KA2-5-1 were also shown to desulfurize 4,6-DMDBT (35,37).

In 1998, the benzothiophene (BT)-desulfurizing bacterium *Gordona* sp. 213E was isolated (89). This strain grew in a synthetic medium supplemented with BT as a sole source of sulfur, and 2-(2′-hydroxyphenyl)ethane 1-al, the sulfur-free compound was formed as the final product. As shown in Figure 5, the metabolic pathway of BT in this strain was analogous to that of DBT in *R. erythropolis* IGTS8 (Type 3 Metabolism in Fig. 2).

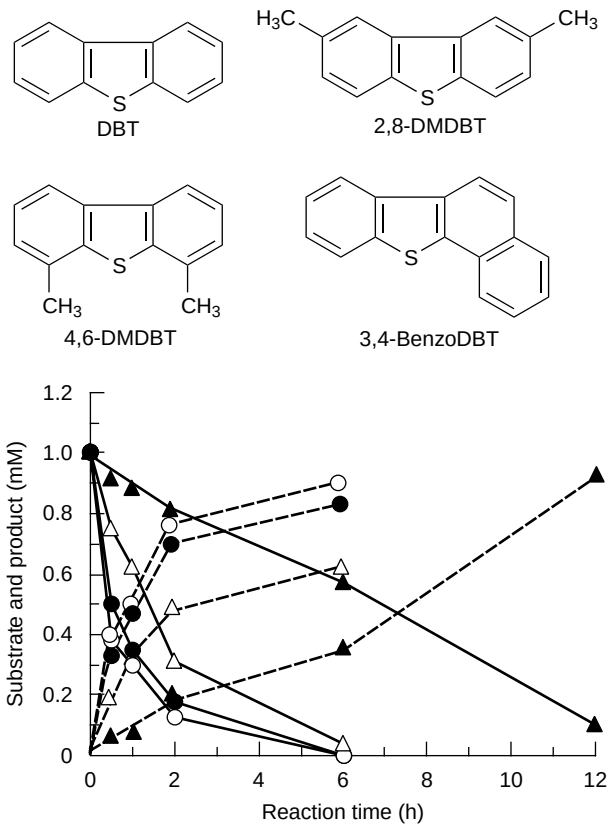

Figure 4. Desulfurization of DBT derivatives in the presence of hydrocarbon by resting cells of *R. erythropolis* H-2. DBT (closed circle), 2,8-DMDBT (open circle), 4,6-DMDBT (closed triangle), and 3,4-benzoDBT (open triangle). Solid and dashed lines indicate remaining substrates and products formed, respectively.

Another BT-desulfurizing bacterium, *Rhodococcus* sp. T09, grew with various alkylated BTs (90). Although these two strains utilized BT but not DBT, *R. erythropolis* KA2-5-1 and *Paenibacillus* sp. A11-2 isolated as DBT-desulfurizing bacteria, were also capable of utilizing BT and its analogs (37,91). However, *R. erythropolis* D-1 isolated as a DBT-desulfurizing bacterium did not utilize BT (33).

Microbial Desulfurization of Diesel Oil or Crude Oil

The possibilities for biocatalytic desulfurization have been demonstrated in diesel oil and crude oil by several researchers. Thermophilic desulfurizing bacteria *Paenibacillus* sp. strains A11-1 and A11-2 grew in the presence of light gas oil (20%) and the content of sulfur in the oil phase decreased from 800 ppm to 720 ppm after the cultivation (45). The resting cells of *Gordona* strain CYKS1 reduced the total amount of sulfur in diesel oil, the middle-distillate unit feed, from 0.15% to 0.06% after 12 hours when the diesel oil was added to the reaction mixture at 10% (92). The analysis of GC sulfur chemiluminescence demonstrated that *Rhodococcus* sp. strain ECRD-1 removed or oxidized more than two-thirds of the sulfur in a middle-distillate fraction of crude oil (93). When the crude oil was treated with *R. erythropolis* IGTS8 cells in a batch-stirred reactor, a negligible decrease in total sulfur was observed (94). However, gas chromatography-mass spectrometry analysis revealed significant desulfurization of DBT and substituted DBTs (94). This result strongly suggests that BDS should be applied to refined products such as gasoline and diesel whose predominant sulfur species are DBTs. BDS of a diesel oil by immobilized DBT-desulfurizing bacterial strains, *Gordona* sp. CYKS1 and *Nocardia* sp. CYKS2 were carried out, and the sulfur content decreased from 3,000 ppm to 2,100 ppm (95). With all the treatments described here, the sulfur content significantly decreased, but the carbon content was the same as before the treatment.

Application of Recombinant Biocatalyst to Diesel Desulfurization

DNA manipulation technology has made it possible to produce large amounts of enzyme in a desirable organism even if the original producer has little activity. Up to now, all the desulfurizing bacteria found were gram-positive. On the other hand, generally, strains belonging to *Pseudomonas* species were known to have high resistance to organic solvents. It was reported that the *dsz* genes of *R. erythropolis* IGTS8 could be expressed efficiently in two *Pseudomonas* strains and they were stably inserted into their chromosomes (96). In comparison with the wild-type *R. erythropolis* IGTS8 strain, the two recombinant biocatalysts possessed improved desulfurization ability. Moreover, the expression of the flavin reductase gene in the *Pseudomonas* strain bearing the *dszABC* gene cluster significantly enhanced the DBT desulfurization efficiency of the recombinant biocatalyst in a resting cell system (97). In addition, in *E. coli*, flavin reductase was shown to enhance the rate of DBT removal when coexpressed with the desulfurizing enzymes (98). *Rhodococcus erythropolis* I-19 containing multiple copies of *dsz* genes desulfurized

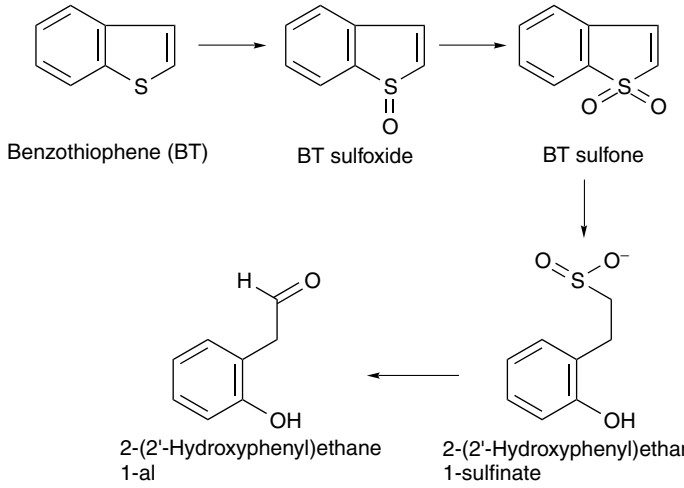

Figure 5. Benzothiophene desulfurization pathway of *Gordona* strain 213E[89].

alkylated DBTs found in a hydrodesulfurized middle-distillate petroleum. The initial desulfurization rate of this petroleum by strain I-19 was 2.5 μmol g dry cells weight^{-1} min^{-1}, more than 25-fold higher than that for wild-type bacteria (99). The recombinant *R. erythropolis* strain carrying the two *dszABC* gene clusters and one *dszD* (flavin reductase gene of the *R. erythropolis* strain with desulfurizing activity) on the vector had a DBT desulfurizing activity that was about fourfold higher than the parent strain (100). This strain also demonstrated improved desulfurizing activity for light gas oil as shown in Figure 6.

COAL DESULFURIZATION

Prior to the extensive study of microbial petroleum desulfurization, the target of fossil fuel desulfurization was coal. However, the bacteria isolated for the desulfurization did not show high levels of activity at this time (the early 1980s). The well-studied *R. erythropolis* IGTS8 was isolated a few years later. The total sulfur content of coal consists of sulfur, which is part of the coal's molecular structure (organic sulfur) and inorganic sulfidic minerals, mainly pyrite (FeS_2). Chemolithotrophic microorganisms have been used for the desulfurization of pyrite. They oxide pyritic sulfur into sulfate and ferrous ions into ferric, using the energy released by the oxidizing process for their own metabolism and growth. It was reported that the adhesion of *Thiobacillus ferrooxidans* to the pyrite surface induced the pyrite floatability by changing the pyrite's surface property from hydrophobic to hydrophilic (101) and that bacterial adhesion to pyrite occurred selectively based on the bacterial recognition of reduced iron in pyrite (102). Although research was carried out into the microbial desulfurization of organically bound sulfur in coal, the efficiency was low (103).

CONCLUSION

As described earlier, increasingly severe sulfur emission standards have forced refiners to make lower sulfur fossil fuels. Compared with the conventional chemical process,

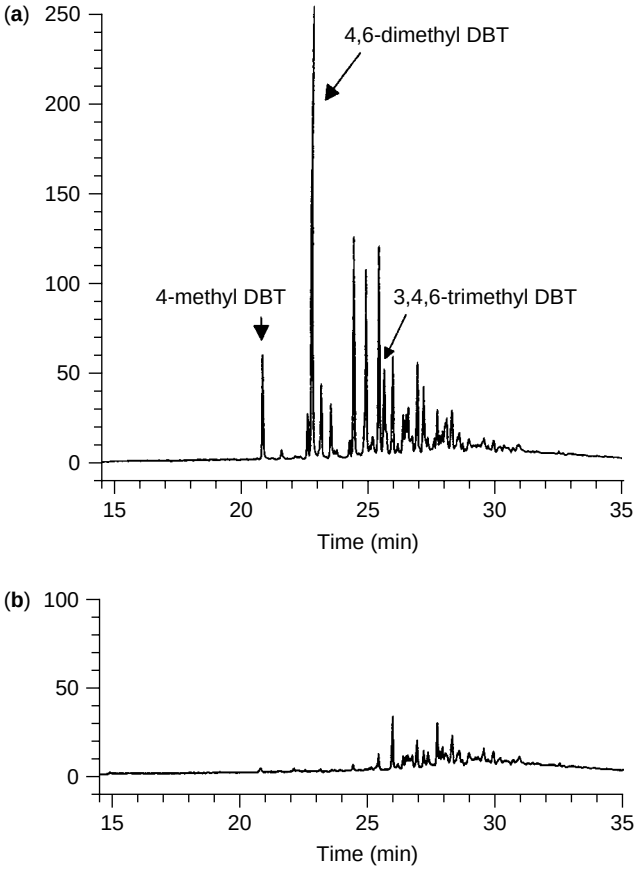

Figure 6. GC-AED sulfur detection chromatograms of light gas oil before (A) and after (B) biodesulfurization using resting cells of *R. erythropolis* KA2-5-1 harboring a plasmid with two *dszABC* clusters and one *dszD* for 23 h[100].

biocatalytic desulfurization is expected to be preferable for the purpose of the desulfurization of the most refractory sulfur-containing polyaromatic compounds because the simplicity of the biotechnology-based approach results in significantly lower capital and operating expenses. In petroleum refining, it has been postulated that BDS should be applied to desulfurize polyaromatic sulfur

compounds that remains even after the HDS treatment. The research of BDS has developed to compensate HDS process, and the promising bacterial strains including the thermophilic bacteria with the sulfur-specific pathway (type 3 metabolism in Fig. 2) were found. It has been demonstrated that these microorganisms desulfurized efficiently alkylated DBTs, which are recalcitrant to HDS. On the contrary, the drawback with biological systems is that the reaction rate is slower than for the chemical reaction. In addition, the emulsion formed during BDS will prevent the separation of oil and water. Since there are such problems to be solved yet, the genetic engineering is expected to enhance the enzymatic activity and stability for the desulfurization, and chemical engineering will bear any satisfactory separation method for the emulsion. These new technologies will make the biological refining process more attractive and cost-effective than the chemical process.

DIATOMS IN BIOFILMS

Keith E Cooksey
Barbara Wigglesworth-Cooksey
Montana State University
Bozeman, Montana

The biofilm literature is dominated by studies on heterotrophic bacterial films. This is understandable in the medical field where biofilmed implants are a serious source of antibiotic-resistant bacterial infections, but in the environmental field, it is less easy to comprehend. Even a casual observer can appreciate that the biofilms on rocks in freshwater streams or on marine sediments in near shore areas are often brown. Further, the primary fouling layer on ships and other fabricated structures in the sea appear similarly colored. Diatoms make up the dominant biomass on all wetted and illuminated surfaces (1–3). The photosynthetic accessory pigments of diatoms are brown, which in turn lends its color to the biofilm as a whole. Figure 1 shows a typical biofilm on a stainless steel surface after exposure for 10 days in a subtropical bay. The predominance of the diatom population is obvious, but bacteria can be seen in close association with the algae. Although the interactions of bacteria and phytoplanktonic algae have been well researched (4), such cell–cell interaction in biofilms is much less well known. Diatoms are of obvious importance as attached primary producers, but they are also involved in such diverse areas as ship fouling, as indicators of chemical and physical perturbations in freshwater streams, and in the stabilization of both marine and freshwater sediments. However, generalizations are difficult to make with

Figure 1. A marine biofilm dominated by diatoms.

certainty because there are no accepted model organisms for diatom research; thus investigators have worked on a multitude of unrelated organisms. There is no organism equivalent to Escherichia coli in diatom research. Other reviews related to this subject, including information on cyanobacteria and green algae in biofilms, can be found in References 3,5–10.

SOME DIATOM MICROBIOLOGY

Cell Structure and Taxonomy

All microbiologists are familiar with the biology of bacteria, but in spite of the ubiquitous distribution of diatoms, few microbiologists are knowledgeable when it comes to this group of organisms. Therefore, some areas of diatom structure and physiology that are pertinent to their involvement in biofilms have been outlined.

Perhaps the most distinguishing feature of a diatom cell is its cell wall, which is constructed of silicon dioxide, and is highly ornate. The diatom cell wall consists of two parts that fit together like the top and bottom of a Petri dish. The two halves, or thecae, are held in place by circumferential girdle bands. In some diatoms, one or both thecae possess a slit or "raphe." This structure allows direct communication between the cell membrane and the extracellular environment. Cells vary in size from a few micrometers to several hundred micrometers. Diatoms contain chlorophylls a and c, as well as brown–yellow photosynthetic accessory pigments, which mask the green chlorophyll coloration, giving these algae their distinctive brown color. They are found in all waters in the planktonic and attached forms. In all but a few cases (e.g., *Nitzschia alba*), diatoms are photoautotrophs, but a significant number of species are facultatively heterotrophic or mixotrophic (11–13).

There are more than 10,000 species of diatoms (14). Diatoms were first noticed in the geological record in the early Jurassic deposits. They are found commonly in the upper Cretaceous period. The geological record also suggests that the radially symmetrical centric organisms gave rise to the bilaterally symmetrical pennate forms. The present classification system for diatoms is based entirely on morphology and recognizes three classes: the radially symmetrical and araphid centric forms, the araphid, bilaterally symmetrical pennate forms and the raphid, pennate organisms. This system of classification is not supported by molecular investigations based on small subunit rRNA (14). Molecular taxonomy recognizes two clades that are not related to the earlier centric–pennate split. More work with a greater selection of organisms is required before the molecular-based taxonomy can replace the traditional scheme. In any event, biofilms rarely contain organisms other than the raphid pennate kind.

Diatom Physiology as It Relates to Life in a Biofilm

Carbon Metabolism. Many phycologists will argue that the ability of diatoms to take up and metabolize small organic molecules such as glucose has little or no ecological significance. That may be true for planktonic organisms where the level of dissolved organic carbon in the water column is small and the fraction of such organisms that are not macromolecular is even smaller; however, for benthic organisms in a biofilm, facultative heterotrophy or mixotrophy may be important physiologies (13). Because the precursors of the mitochondria in eukaryotes were heterotrophic prokaryotes, it is easy to support this contention in evolutionary terms (15). It is not likely that a cell would continue to make the considerable investment in the proteins needed for heterotrophic metabolism (e.g., transporters, chemosensory receptors) if it conferred no survival advantage. Because the biofilm structure limits diffusion and mixing, it is possible that dead and lysing cells of many types within the biofilm could supply significant local concentrations of organic molecules. Self-shading and the presence of other organisms in the biofilm could reduce the available light for photosynthesis thus providing an environment where the ability to utilize already-reduced carbon would be advantageous. There is a paucity of studies on the relative contributions of organic compounds and CO_2 to the overall carbon budget of a diatom cell where both sources are available. However, Tuchman (13) reports that in a mixed species biofilm grown in an outdoor artificial stream system under low (200 μmoles/m^2/sec^1) and high light regimes (200 μmoles/m^2/sec^1), the glucose assimilated by cells at the bottom of the biofilm (under story cells) was threefold higher in relation to the total CO_2 uptake than cells at the top of the biofilm (canopy cells). The light levels impinging on the under story cells was about 85% less than the canopy cells at either light level.

Motility, Adhesion, and Chemosensing. Apart from the generation of energy and anabolic reactions in general, there are three physiological processes that are closely associated with biofilm formation in diatoms. These are adhesion processes, motility, and chemosensing.

Diatoms reach a surface by hydrodynamic means or gravitational forces (16). When they reach a surface, one of two things happens: they either stay or they are removed before they have a chance to become attached. At this point in time, there is no indication that leaving the surface is any more than a stochastic event. However, shortly after their arrival, diatom behavior is active (17), but Wang and his associates (18) believe that the events

immediately after their arrival do not require active synthetic events. The distinctions here could arise from the use of different experimental organisms by the two groups of investigators. As mentioned earlier, this is an example of a situation that makes generalizations difficult. The initial observable event after arrival on a surface is the secretion of an adhesive from the raphe slit. When the diatom falls on that part of its cell surface that bears a raphe, motility ensues immediately. When it does not fall onto a raphe-bearing surface, the diatom can be observed to turn so that a raphe is in contact with the substratum. Wetherbee and associates (3) have proposed that in the diatom Stauroneis decipiens, the strands of the secreted polymer "search" for a substratum, anchor there, and then by some contractile mechanism, move the cell onto its raphe-bearing surface. This is a far more animal-like sensory behavior than has been proposed for diatoms previously, but the fact remains that this process can be seen microscopically. Acceptance of the hypothesis requires that in this organism at least, there is a substratum-sensing mechanism in which the extracellular polymers act as transducers of substratum proximity. After moving over the substratum for some time, eventually, the diatoms secrete further polymers with different properties, and the cell is no longer motile. At this time, the cell becomes enveloped in a layer of a matrix polymer extracellular mucilage(ECM). In some species, this secondary adhesive is secreted in the form of a stalk that elevates the cell above the substratum (18,19).

The initial processes in adhesion and motility are difficult to separate and those leading to the formation of a mature biofilm are complicated. Only recently has some insight been gained at the molecular level; even so, our understanding is far from complete. The polymer responsible for the initial adhesion is synthesized in the Golgi apparatus and packaged into vesicles (20). These vesicles are transported to the raphe area of the cell where they fuse with the plasma membrane, discharging their contents into the raphe canal where they are able to interact with the substratum (for electron micrographs of vesicle fusion, see 21,22). As detected by measurements of the ability of cells to remain adhered after washing of the substratum, the adhesion process can be metabolically disrupted by inhibitors of microtubule assembly, action polymerization, transmembrane Ca^{++} flux, respiratory energy generation, and protein and glycoprotein synthesis but not by photo system-II inhibitors or darkness (3,7,21,23). Furthermore, the Ca^{++} chelator ethyleneglycol-bis-(β-aminoethylether)-*N*,*N*,*N*′,*N*′,-tetraacetic acid (EGTA) removes the diatom *Amphora coffeaeformis* from glass, leaving behind an exact imprint of the raphes, which in this organism, are both on the ventral surface of the cell. These imprints have been referred to as footpads (23). In similar work with bacteria by Neu and Marshall (24), the term *footprints* has been used. In either case, these structures represent a cohesive break in the external polymeric adhesive induced by calcium-complexing agents. This indicates that there is an external role for Ca^{++}, most likely as a bridging agent in the ECM, as well as an internal one (23). It is significant that in the ten species examined, an external concentration of several millimolar Ca^{++} is required for successful adhesion and motility, although cellular growth needs less than 1 mM Ca^{++}. At this lower concentration, cells grow planktonically and apart from being nonmotile or adhesive, appear otherwise quite normal. Wetherbee and associates (3) have stated that diatoms may be able to detach from a surface if environmental conditions deteriorate, that is, bioadhesion in diatoms is reversible, but the mechanism is not known. In support of this, it has been observed that in axenic cultures of many diatoms in media with a high Ca^{++} concentration, cells in the stationary phase of growth are easy to detach from the surface of a glass flask, whereas in the log phase, this is not possible unless mechanical force or ultrasound is used. Detachment of the cells breaks cell-substratum bonds, but cell–cell bonds are disrupted less frequently. Thus, the detachment in this manner results in rafts of cells being produced, not a single cell suspension. The relationship between the two classes of adhesives, that is, the one involved in initial adhesion and subsequent motility and the other that becomes the enveloping ECM is unknown for most diatoms. In general, it is not even known whether these polymers are single molecular entities or collections of similar compounds, or what structural motifs explain their particular biological function(s). Some progress toward these ends has, however, been made.

Extracellular Carbohydrate-Like Polymers. A comprehensive review of the extracellular polymers of both planktonic and sessile diatoms has been prepared by Hoagland and associates (19). The review has particularly fine quality scanning electron micrographs of the extrusion of polymers from the raphe and terminal pores of the diatom frustules. In the light of modern analytical capabilities, however, the large collection of polymer chemical analyses (more than 50) is less useful. Polymers were prepared as extracts of cells or from media from which they were precipitated or lyophilized. Thus, in no case were the polymers shown to be a single molecular entity. Nevertheless, the list of the sugars participating in the potentially mixed polymer structures is rather constant. Most of them contain the sugars glucose, xylose, galactose, mannose, rhamnose, fucose, as well as glucuronic and mannuronic acids. The contentions of Allison, Sutherland, Neu and Marshall (24,25) are well worth reiterating at this juncture. They believe that the effort expended in studying extracellular polymers precipitated from media in which cells have grown may be misplaced. Their idea is that the extracellular polymers important in biofilm structure are not necessarily found in the medium. Neu and Marshall (24) consider that the "footprints" of extracellular polymer that are found underneath cells when they have been removed, either physically or chemically, are more worthy of study in the context of biofilm formation and structure. Although these workers were in fact studying bacteria, the same is probably valid for the diatoms.

The work carried on from the laboratories of Gretz, Hoagland, and Wetherbee (3,18,19,26,28,29) has gone a long way inremedying the insufficiencies mentioned by Allison, Marshall, Neu and Sutherland. Extracellular adhesives from the diatoms *Achnanthes longipes*, *Amphora coffeaformis*, *Cymbella cistula*, and *C. mexicana*

have been characterized by monosaccharide and methylation analysis, as well as lectin binding and cytochemical staining (26). Not surprisingly, polysaccharide was the main component of the adhesives formed during motility of these organisms and basal pad formation in *A. longipipes*. Components of the ECM insoluble in hot water, but soluble in $NaHCO_3$ solution, were anionic polysaccharides. For *Amphora*, these consisted mainly of galactosyl and fucosyl residues with similar sugars and the addition of glucuronyl residues in *Achnanthes*. On the other hand, adhesive polysaccharides from *Cymbella* were soluble in EDTA, contained galactosyl and xylosy residues, but lacked uronosyl residues. Fluorescently labeled sugar-specific lectin binding showed that the fucose was located in the motility polymer of both *Cymbella* and *Achnanthes*, and the adhesive pads of *Achnanthes*. Galactose was located in the capsules [ECM] of *Amphora* and throughout the shafts of the stalks of *Cymbella*. The herbicide 2,6-dichlorobenzonitrile [DCB], similar to the way in which it inhibits cellulose synthesis in higher plants and algae (27), inhibits ECM production in adhesive diatoms (26). *Achnanthes longipes* inhibited by DCB are not motile nor can they adhere, which supports the idea that motility and adhesion are metabolically linked. A similar conclusion was reached by Cooksey and Cooksey (23) from results obtained with the glycoprotein-specific inhibitor tunicamycin and the diatom *Amphora coffeaeformis*. Using yet another organism (*Stauroneis decipiens*), Lind and associates (28) were able to show that two monoclonal antibodies raised to what they named *frustule-associated components* [FACs] were able to label various extracellular parts of the diatom cell. The FACs were shown to contain four proteoglycans by staining after separation on polyacrylamide gels. One antibody bound strongly only to the exterior frustular component but not material in the raphe area, and did not inhibit motility or adhesion. On the other hand, the other antibody that bound to the frustular component, ECM trails and material in the raphe, did inhibit motility and adhesion. This work offers further evidence for the metabolic integration of motility and adhesion.

There is further work from the Gretz–Wetherbee laboratories (26,29) on the extracellular polymers that are morphologically distinct in *Achnanthes longipes*, that is, the adhesive pad, the anchoring stalk, and its collar. Chromatographic analyses of the hot water–insoluble–hot sodium bicarbonate–soluble fractions (WBS fractions) of these structures reveals that they are also chemically unique. They could also be distinguished in terms of their sugar components, amino acid content, and degree of sulfate. From their analyses, Wustman and associates (29) concluded that the outer layers of the diatom anchoring stalk were extruded from the pores in the silica cell wall adjacent to the raphe canal and contained low sulfated components of the WBS, whereas the central core of the shaft was probably secreted from the raphe canal itself. It is significant that there is chemical similarity between the central core material and the cell motility polymer. Both reach the extracellular space via the raphe canal.

McConville and associates (30) recognized another environment where biofilm formation by diatoms was visually obvious. There are extensive diatom blooms along the undersurface of the nearshore Antarctic sea ice during the austral spring. Although this environment has been investigated extensively, the extent to which the bloom is actually attached to the ice crystals as a biofilm is not known. Nevertheless, the diatom film contains a large component of extracellular polysaccharide-like materials. McConville and associates (30) investigated the carbohydrates components of *Stauroneis amphioxys* Gregory — a diatom found in the Antarctic sea ice. The carbohydrates occur as soluble EPS in the culture supernatant, as an ECM and as a part of a distinct organic layer underlying the diatom cell wall (diatotepum). During logarithmic growth, the mucilage EPS rose but fell during the stationary phase. It has often been suggested that the EPS of diatoms may contain some protein, but this has never been shown conclusively. These persons demonstrated chromatographically that the soluble EPS fraction contained about 5% protein. Staats and associates (31) also found protein in diatom EPS.

Although the molecular constituents are only currently beginning to be identified, we can make some partially substantiated efforts to explain how diatom motility operates. Figure 2 shows a schematic of a longitudinal section of a raphid pennate diatom with a series of actin filaments running parallel to the raphe. The sketch is based on work by Webster and associates (21) and Edgar (22,32). The secreted polymer molecules are anchored in the plasma membrane, either by transmembrane proteins or directly. The force generated by contractile events in the actin fibers could be transmitted via the membrane to the extracellular matrix molecules (ECM), which in turn are anchored to the substratum (at * in the figure), thus moving the cell in the opposite direction. The problem with this model is that it explains how the cell could move for only one cell length. For continuous movement, the connection of the ECM to the cell membrane and/or the substratum would have to be broken. Edgar (32) and Edgar and Pickett-Heaps (22) state that diatom trails, that is, the material left behind a cell when it is moving on a surface, are easily soluble in the aqueous milieu, and

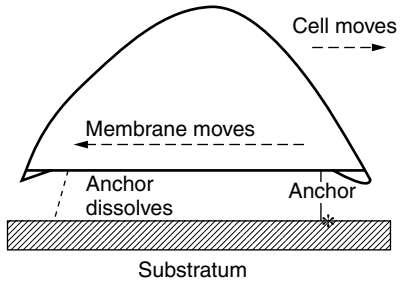

Figure 2. Representation of the interaction of a species of the diatom Amphora with a substratum leading to adhesion and subsequent motility. The cell is seen in longitudinal section. The polymer strand is anchored in the cell membrane and interacts with the surface at the place marked with an *. When, by membrane-associated activity, the strand of polymer reaches the posterior of the cell, the interaction with the membrane dissociates and the cell moves onward. For clarity, only one polymer molecule is drawn [see text for details].

that there are no trail substances evident behind diatom cells, or that the trail substance disperses rapidly. These observations suggest that the trail must detach from the membrane-associated site before it becomes soluble. Such a detachment mechanism at the posterior of the cell would allow continuous movement. However, once again, generalizations are difficult because rarely have two groups of investigators studied the same organism.

A class of Ca^{++}-binding proteins known as *frustulins* have been isolated from the cell walls of several diatoms (33,34). Initially these proteins were thought to be involved in setting the architecture of the silica cell walls. That view is no longer held (35). An alternate suggestion for their role that is in keeping with their distribution within the diatom cell that is cell wall–associated has been proposed (9). Frustulins could be the actin-associated proteins referred to by Wetherbee (3), and these molecules anchor the membrane to the cell wall. If there were no such anchors, the membrane would tend to move within the cell walls instead of transmitting the motive force to the substratum. The precedent for this idea is found in research on the slime mold *Dictyostelium* (36) where a transmembrane protein called ponticulin (for its bridging property) anchors the cytoskeleton to the inside of the cell. If the formation of such anchors is inhibited, it is likely that normal motility would also be prevented. At high concentrations, tunicamycin can inhibit diatom motility completely. At low tunicamycin concentrations, motility becomes aberrant but does not totally cease. Under these conditions, cells can perform only a shunting motion that is more than about one-cell length and are thus unable to make a complete change in position.

There are other aspects of diatom motility that are important in biofilm formation and activity. It has been shown that not only are diatoms motile, but they are capable of chemosensory motile responses. Using a diffusion chamber (37) to allow microscopy of cells in a chemical concentration gradient, Cooksey and Cooksey (38) showed that *Amphora coffeaeformis* and another species of Amphora were positively chemotactic in gradients of D-glucose, 3-*O*-methyl-D-glucose, D-glucoheptose, and D-maltose. They were negatively tactic to D-mannose and did not respond to 2-deoxy-D-glucose. Response to mannose is particularly interesting because at 2 mM, mannose is toxic to species of *Amphora* (12). Thus it seems that diatoms can avoid areas where their metabolism would be impacted negatively. By measuring the response of cells that had been pretreated with sugars and then measuring the reposes of the same cells to the same and other sugars, it was possible to postulate that Amphorae possess separate receptors for glucose and mannose, that 3-*O*-methyl-D-glucose and glucose share the same receptor, and that in this scenario, a sugar is not chemotactically active unless it possesses a hydroxyl group at position 2 of the pyranose ring. In these experiments, diatom cells suspended in minimal medium (39) were allowed to settle out and adhere to a glass surface. The result was a uniform, spatial distribution of cells on the surface. In the absence of an added chemical gradient, cells moved randomly, that is, cell–cell interactions were not detected. When cells were placed on a microscope slide so that high local concentration of cells existed (i.e., clumps), their motility was not random. Species of *Amphora*, *Navicula*, *Nitzschia*, and *Auricula* show dispersal from a clump of cells in a directed fashion (40). Wang and associates (18) have also commented on the ability of cells of *Achnanthes* to distance themselves from one another, but they did not quantify the process. Measurement of this phenomenon requires the use of a dynamic image analyzer to track cells and report the relative direction (i.e., compass bearing) of their progress from the clump. Dispersal takes place only until the cells are about 400 μm from the clump, at which point the cells resume random behavior again. This suggests that the clump is the origin of the putative signal. At this time, there is no substantiated information concerning the identity of the putative dispersal factor, but O_2, which is a photosynthetic product that causes photorespiration, has been suggested (40). Photorespiration does not result in net carbon fixation and is thus not a positive metabolic activity. It could be speculated, therefore, that environments that promote this activity should be avoided.

Both types of chemosensory behavior mentioned earlier are important in understanding how a substratum becomes colonized and a biofilm is formed. Related to this is some work by Paul reported in Reference 41. This group showed that coupons of glass and stainless steel placed in Biscayne Bay FL became colonized rapidly with diatoms. After the initial colonization period, increases in cell number took place only during the day. Because it is known that cells can adhere to surfaces in the absence of light (39), this implies that cell number increase was due to growth rather than to continued colonization from the water column. It seems that directed dispersal and growth are highly influential in the formation of a climax diatom biofilm.

Influence of Surface Energy of the Substratum on Diatom Behavior. The concept that surface energy of a substratum influences the adhesion of microorganisms, especially bacteria, to surfaces has been studied extensively (5,8,39, and 42). However, it is difficult to arrive at generalizations, although a wide variety of organisms and surfaces have been investigated. Problems arise from the fact that the physiological states of the organisms and/or the surface characteristics of the substrata were seldom well controlled. In some cases, surface chemistry was changed to derive differing surface energies on a single substratum such as glass. Although this approach produces informative data, surfaces differing supposedly only in the value of their surface energy actually differ in two ways: the intended variable, that is surface energy and the chemistry that generated it. An example will make this clear. It has been shown that the percentage of a population of the diatom *Amphora coffeaeformis* adhered to chemically modified glass surfaces in a nonlinear manner with respect to surface energy. In fact, the relationship was U-shaped with a minimum value for adhesion at about 20–25 dynes cm^{-1}. In this experiment, the cells were exposed to surfaces bearing the following, quite different, functional groups: methyl, propyl and a (fluorinated isopropoxy) propyl, as well as the physical

chemistry derived from them (5). Thus, a cell could react to either the functional group presented to it, the wettability of the surface (dictated by its physical chemistry) or both of these parameters. To overcome this problem of dual variables, Elwing and associates (43) and more recently Ruardy and group (review, 44) have described the preparation of silicious surfaces bearing spatial gradients of wettability. These gradient surfaces (about 10–40 mm in length) are hydrophilic at one end, hydrophobic at the other, with a nonlinear wettability gradient between the extremes. The use of these gradients allows only one variable at a time to be examined, in this case wettability (measured as water contact angle of the surface). This is because only the concentration of the derivatizing agent is varied, not the type of reagent. Chemical concentration gradients of the derivatizing reagent are prepared and allowed to react with, for instance, a glass plate. The presence of the gradient can be demonstrated with X-ray photoelectron spectroscopy or contact angle measurements. Using this technique, the effects of a methyl-functionalized wettability gradient on the adhesion and motility of *Amphora coffeaeformis* have been investigated (39). Figure 3 shows a steep wettability gradient on glass formed from methyl groups derived from dichlorodimethyl silane. Figure 4, curve 1, shows that response of the organism in terms of percentage motility of the population is dependent on the relative position of the cells along the gradient. By comparing Figures 3 and 4, it can be seen that cells were not motile above a substratum water contact angle of 40°. In fact, at contact angles above this value, cells actively detached. This cellular detachment can be explained in terms of extracellular interaction with the substratum as depicted in Figure 2. If the polymer strands interact weakly with the substratum, motile forces applied to the substratum from the cell membrane–associated system (the cellular "motor") via the polymer bridge will tend to cause the cell to detach from the surface, rather than cause the cell to move. Figure 4 illustrates another potential problem in measuring cellular response to substratum properties. Curves 1 and 2 were made 30 minutes apart. It seems that during the longer incubation time, the cells have made the surface more conducive to cellular motility. In other words, they may have "conditioned" the surface. This requires the secretion by the organisms of an amphipathic molecule(s) that could adsorb to the hydrophobic part of the surface and change its properties so that it becomes more hydrophilic. Furthermore, it is evident that the hydrophilic part of the gradient surface, according to this analysis, was not changed. Studies on diatom adhesion as a function of time are sometimes made in flow cells. If the ability to change the properties of the substratum with time is a general property of diatoms, conclusions derived from such studies warrant further examination. The final properties of the substratum will not be identical to those when the experiment was initiated. Although it is clear that this putative conditioning film was self-generated in situ, it is still not known from where the molecules involved in the formation of marine environmental films originate, nor is there general agreement of their role in the subsequent attachment of diatoms and other marine organisms. Discussion of the formation of conditioning films can be found in Baty and associates (45) and Characklis and Cooksey (5) and references therein, and Schneider and Leis (this volume).

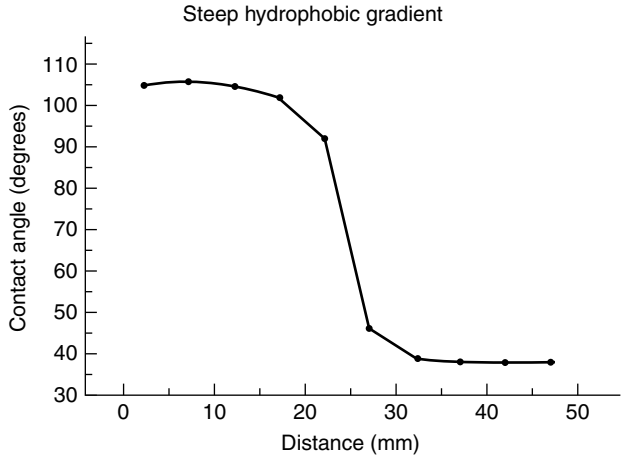

Figure 3. Wettability gradient on a glass surface represented by the advancing water contact angle. The hydrophobic side is at the left.

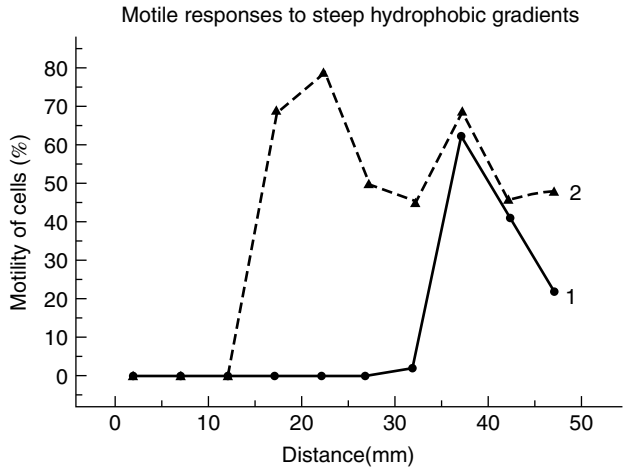

Figure 4. Motility of the diatom *Amphora coffeaeformis* on the surface depicted in Figure 3. Note that motility is not possible at water contact angles greater than 40°. Data for curves 1 and 2 were obtained 30 min apart on identical, but separate surfaces.

Cell-Cell Interactions in Biofilms. It is likely that the interactions of cells in a biofilm are mostly a consequence of their proximity to one another. In a planktonic environment, cells are many micrometers or more apart, whereas in a biofilm they are either in physical contact or only a few micrometers separates them. Furthermore, because biofilm cells are embedded in a polymer matrix, diffusion of potentially allelochemical factors is comparatively restricted. The interactions of diatoms and bacteria in the water column is well researched (e.g., 46), but there is less information on the interactions between these two types of organisms in biofilms. The planktonic environment where these interactions take place is known as the *phycosphere* (4). This term is not usually applied

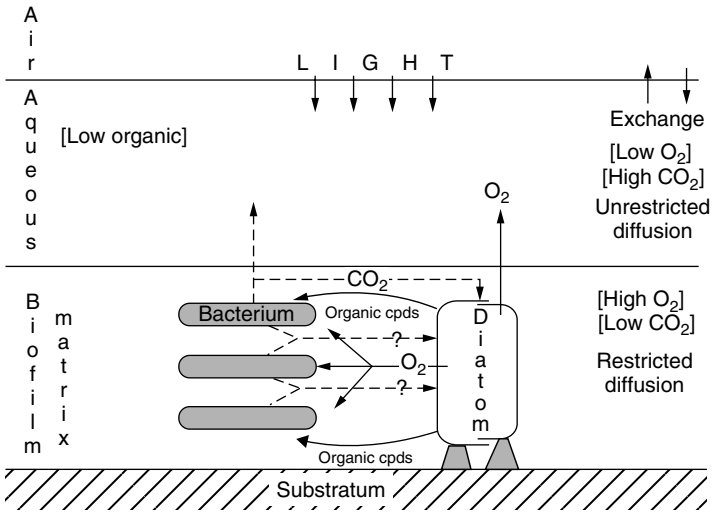

Figure 5. Potential metabolic interactions within a biofilm consisting of phototrophs (diatoms) and heterotrophs (bacteria). The possibilities of interactions at the genetic and signaling levels are not represented.

to the biofilm situation. Interactions can be mutualistic, syntrophic or toxic. Toxic interactions involving bacteria that are algicidal (47) have been described only for the water column so far. In biofilms that are illuminated, the interactions can influence either of the types of cells in the biofilm. Figure 5 shows some possible types of interaction. The secretion of organic molecules by the diatoms and their metabolism by the bacteria is an obvious interaction. An example would be glycolic acid, which is a product of photorespiratory activity of phototrophs. Because diffusion in a biofilm is reduced (48), the photosynthetic product (O_2) that stimulates photorespiration could increase in concentration, thus promoting glycolate production. On the other hand, the presence of heterotrophic bacteria that utilize O_2 as an electron acceptor would counteract this process. There is a possibility that molecules produced by one type of organism influence the metabolism of another by means other than anabolic or metabolic pathways. For instance, cell–cell signaling between bacteria in close association is known as quorum sensing (49, see also Jaeger and Wingender, this volume). Unless the so-called diatom autodispersal factor is counted, there is no such interaction documented between diatoms or between diatoms and bacteria; however, the possibility exists that such interactions can occur, particularly at the genetic level. It is reasonable to speculate that some diatom product could influence the induction of genes in bacteria that are closely associated with diatoms or vice versa. There is some evidence that there is interaction at the metabolic level. Hack and McFeters (50,51) showed that the metabolism of the bacterial component of an alpine stream biofilm that also contained diatoms was closely associated with the metabolic state of the diatoms. The experimental protocol used involved harvesting and homogenization of the attached film. This method was shown by Murray and associates (52) to cause algal cellular disruption and thus the release of intracellular components not normally available to the bacteria. A gentler method favored by Murray and associates (53) was the in situ labeling of the film by ^{3}H-thymidine. A bacterial-diatom film was constructed from *Amphora coffeaeformis* and *Vibrio proteolytica*. The film was incubated with the radioactive substrate and it was shown by autoradiography that the label was present only in the bacteria. Kinetic studies in the absence of an added organic carbon source revealed that the incorporation of ^{3}H-thymidine into the bacteria was light dependent, that is, the metabolism of the bacteria was tied to that of the diatoms. Less easily understood are the observations of Woods and Fletcher (54). On the basis of observations of sloughing from ship hulls, where presumably biofilms would also contain bacteria, axenic films of *Amphora coffeaeformis* var. *perpusilla* sloughed more easily than expected when exposed to a hydrodynamic shear. This observation could be explained in several ways. One possibility is that the axenic culture of diatoms responded to high O_2 levels that were not reduced in the absence of bacteria. The results of Jensen and Revsbech (1989), who found it difficult to form thick diatom films when the bacterial content of the culture was low, would support this idea. It is also possible that a synergistic relationship exists such that bacterial polymers and those from diatoms produce a binary adhesive, the adhesive properties of which are greater than either of the single polymers. Another possibility is that different and more adhesive–cohesive polymers are produced by either member of the consortium in the presence of the other.

Gawne and associates (55) measured the attachment of the fouling diatom *Achnanthes longipes* to various substrata as a function of the presence of several marine bacteria and their extracellular products. The diatom attached best to polystyrene (hydrophobic), but its attachment was inhibited by the presence of bacteria on the surface. Attachment to glass and a silicone elatomer (annealed and unannealed RTV 3140) was either facilitated by the marine bacterium *Pseudoalteromonas atlantica* (glass substratum) or the presence of the bacterium had no effect (RTV 3140). In other experiments, no differences were found in the adhesion of *Achnanthes* when the substrata were covered with either living bacterial cells or the extracellular polymer isolated from them. There were no conclusions to be made concerning the effects of bacteria in general. The authors made the point that the formation of the initial fouling film is highly

complex and species specific. In these experiments, one diatom was used in conjunction with five species of marine bacteria. It is likely that the picture would have been even more complex if further diatom cultures were included. Gawne and coworkers' results can be used to pose an important question concerning diatom adhesion studies: Is it more realistic to work with axenic cultures of diatoms in studies of adhesion, or is it more realistic to use natural consortia of bacteria and diatoms? Reports such as that from Velraeds and associates (56) make a valid assessment of this point even more difficult. Velraeds and coworkers showed that the initial adhesion of one bacterial culture was strongly influenced by a molecule produced by another type of bacterium. The molecule, which was proteinaceous and had the physicochemical properties of a surfactant, adsorbed to (i.e., "conditioned") the test substratum. It is certainly possible that this type of effect could have been operating in the experiments of Gawne and coworkers (55).

Fukami and associates (47) measured the influence of marine bacteria on the growth of various phytoplanktic organisms. Their main interest was in the production of the algae as food for shell fish. The growth of planktonic cultures of *Chaetoceros ceratosporum* as well as biofilms of a *Nitzschia* sp. were stimulated by indigenous marine bacteria, including species of *Alcaligenes*. On the other hand (47), growth of the dinoflagellate *Gymnodinium mikimotoi* was inhibited by a species of Flavobacterium. These differing results show the variation in the effects of bacteria on algal growth.

A potential means to investigate interactions leading to the formation of climax biofilms can be found in publications from the Canadian National Water Research Institute (57–59), where a rotating annular bioreactor was used to produce mixed species biofilms that mimic those found in nature. This type of reactor has an internal cylinder that rotates inside a second outer cylinder. The annular space between the two cylinders (6 mm) is where a biofilm is allowed to develop. The film grows predominantly on the outer wall where removable slides allow samples to be taken aseptically without disturbing the remaining biofilm. The Canadian group has used this system in conjunction with staining by conjugated lectins specific for sugars in the ECM, as well as confocal laser scanning microsopy and the measurement of other cellular parameters, to follow the development of the biofilm. Their results demonstrated that the spatial distributions and biomass of live and dead bacteria, algae and types of ECM in the biofilm were not uniform. They did not differentiate between diatom and bacterially produced ECM, but this should be possible in future work.

Given the importance of cell–cell interaction in biofilms, it is surprising that this area is not better developed; however, the discussion earlier documents the difficulty in separating the various interactions between cells.

Some Practical Considerations of Biofilms Dominated by Diatoms

Fouling. Biofouling is the accumulation of unwanted organisms and their products on surfaces of artificial objects in the aquatic environment (Flemming, this volume). It takes place in both marine and freshwater environments, although marine biofouling is more extensively studied because commercial and naval interests are predominantly marine. Biofouling refers to the accumulation of many types of organisms besides diatoms. There are reviews of the involvement of diatoms in fouling biofilms on shipping (2,5,10,60–65).

The interest in marine biofilms on synthetic surfaces, especially those of ship hulls, is related to the increase in hydrodynamic drag that these films cause compared to clean hulls. For hundreds of years it has been appreciated that fouling layers consisting of macrofoauna (largely barnacles) increase the drag on a vessel as it moves through the water, but it is only in the last 20 years or so that there has been an appreciation of the drag caused by microbes in biofilms. This is because of the fact that the tributyl tin self-polishing copolymer coatings reduced faunal fouling to the point when it was no longer a severe problem, allowing the effects of biofilm fouling — the so-called slime layer — to be more apparent. Lewthwaite and associates (66) quantified the drag caused by slime alone on a ship's hull. They found that a 1-mm thick layer caused an increase in skin friction of 80% and a reduction in speed of 15% when compared to a fouling free hull. Bohlander (64) made similar measurements on the USS Brewton, a U.S. Navy frigate, the hull of which was painted with a copper oxide–tributyl tin ablative coating. The hull showed only minor barnacle encrustation after 22 months in service, but there was a continuous biofilm over the length of the hull. In such circumstances, the biomass in the biofilm will be largely made up of diatoms. Two ship trials were made with the USS Brewton, one before and the other after hull cleaning with an automatic scrubber that removed only the biofilm. The percentage reduction in shaft horsepower for a given ship speed was 8–18% after cleaning. The engine RPM for a given speed was also reduced and the maximum attainable speed was increased by 1 knot. In terms of reduced fuel costs, it took only 20 hrs at 20 knots to repay the cost of cleaning the hull. These two papers, perhaps more than any others, emphasize the need for effective ship hull coatings that are designed to ameliorate the effects of microbial biofilms.

The so-called "fouling release" coatings must take into account the ability of the fouling diatoms to resist removal by hydrodynamic shear stress (54). There are only very few diatoms species that are common on synthetic submerged surfaces. The marine environment, on coatings consisting of self-polishing copolymers, harbor species of *Amphora*, *Amphiprora*, *Stauroneis*, *Achnanthes*, *Navicula*, and *Nitzschia*, with *Amphora* being by far the most common (65). Callow (65) made the important observation that the organisms she found on ship hulls were similar to those found on static test panels placed at various locations around the world. Species of *Amphora* are resistant to copper in antifouling coatings (65,67,68) which probably accounts for their being found frequently on the surfaces of copper-based paints. *Amphora* are able to immobilize copper in cytoplasmic vesicles thus reducing the toxicity of the metal (67), but other mechanisms are also likely (68,69,70 and 71). Some diatoms, notably *Amphora coffeaeformis*, *Achnanthes longipes*, and *Achnanthes subsessilis* are also resistant

to organotins; however, Callow (72) believes that the differences seen in the species composition of diatom slimes on organotin coatings cannot be explained solely in terms of current knowledge of relative resistances to these toxicants.

Current antifouling research and technology have moved toward fouling release coatings and away from toxicant-based materials. The influence of low wettability on the adhesion of diatoms and other organisms to surfaces is now being exploited in the design and manufacture of such antifouling coatings. All major manufacturers of marine bottom paints sell coatings based on this principle. In our opinion, information on the interaction of the adhesives produced by one organism on those fabricated by another in close proximity is needed for the design of these coatings. Because diatoms are major components of marine fouling films, they are used to assess the activity of potential components of antifouling paints (73–77).

Sediment Stabilization by Marine Diatoms. This section deals only with those aspects of the sediment biosphere that inhibit the ability of sediment particles to gain momentum and thus move. The role of microorganisms in the stabilization of sediments is not well defined. However, many of the papers dealing with sediment stabilization (SS) concern the involvement of benthic diatoms in the process. Holland and associates (78) presented the first quantitative information on the involvement of benthic diatoms in SS. They showed that the growth of several species of diatoms, as well as mixed natural populations, inhibited the movement of sediments in stirred flasks and that the effectiveness of the organisms was related to their production of extracellular mucilage. De Jonge (79) found that 13% of sand grains (>55 μm in size) taken from the Eems-Dollard estuary in the Netherlands were colonized by diatoms, but 80% of these were on the mud coating the sand grains, not on the sand grains themselves. Although this finding stresses the importance of fine particles in colonization studies, it offers no explanation why this should be so.

Grant and associates (80) described the microstructure of benthic microbial films and the means by which they influence SS. These workers point out that although there is a large body of literature concerning the means by which the mucus films produced by diatoms can inhibit sediment transport, there is little known about the mechanisms concerned (80 and references therein). Their results showed that field biomass indicators are poorly correlated with SS. SS by diatoms is related to the production of colloidal carbohydrate, which they conclude is an index of the extracellular carbohydrates produced by diatoms. Unfortunately, this view and their analyses not only underestimate diatom polymer production but also include polymers produced by other organisms, especially bacteria. Their results showed that visual estimates of the presence of organisms do not concur with sedimentary analyses. High levels of colloidal carbohydrate appear to be a better indicator of the presence of diatoms than chlorophyll. The lack of a relationship between chlorophyll and a metabolic product such as extracellular carbohydrate is not surprising because although chlorophyll levels are constant in diatoms, the products of metabolism are not. For instance, the amount and type of intracellular storage products are dependent on nutritional status. The SEM studies reported (80) here show that sand grains were colonized by many types of organism, but only the putative role of diatoms was examined. Other studies (81,82) showed the presence of mucoid materials in sediments, but their origin could not be determined microscopically. It should be pointed out that the polymers that are produced by diatoms as a consequence of their motility are soluble in seawater (21,22); so the ability of these polymers to aggregate sand particles is difficult to understand. Threadlike polymer bridges seen in SEMs are almost certainly artifacts of the preparative techniques. Madsen and associates (83) concluded that it is doubtful whether any reasonable specific quantitative information predictions about sediment stability can be made without extensive knowledge about several factors including the physiological status of the organisms. Their conclusions were based on experiments in a linear flume with natural sediments. In contrast to Grant and associates (80), they found that the only parameter which correlated with SS was the presence of epipelic diatoms sampled by exposing lens tissue to the surface of the sediment. The use of this technique has been criticized strongly by Admiraal (84). The presence of extracellular polymers in the sediment did not correlate well with their stability, although there was a qualitative relationship. It is possible indeed that there was a correlation, but it was sufficiently obscured by uncontrolled parameters in the experiment that it became statistically insignificant. Guarini and associates (85) made a multiparameter study in which they followed mud surface temperature (MST) and correlated it with microphytobenthic productivity over tidal, solar, and seasonal cycles. The fact that the populations showed midsummer photoinhibition coupled with the highest MSTs because of low tides occurring near midday indicated that there was little acclimation of this population to environmental conditions. Guarini and associates (85) emphasize that these physiological dynamics will also control sedimentary dynamics. Lack of appreciation of the involvement of variable levels of photoinhibition may explain some of the less-than-perfect correlations between the size of microphytobenthic populations(e.g., chlorophyll a) and SS seen by others. For instance, Madsen and associates (83) noted that weak correlations were obtained when the sediments contained diatoms of the genera *Amphora*, *Navicula*, and *Nitzschia* (20–40 μm).

A laboratory study by Sutherland and associates (86) using a nonaxenic culture of *Nitzschia curvilineata* showed that the bulk carbohydrate of surficial sediments was negatively correlated with erosion rate. Colloidal carbohydrates were barely detectable by the phenol–sulfuric acid method used (87). Possibly the most interesting aspect of this paper is the observation that bulk carbohydrate and erosion rate became decoupled towards the stationary phase of diatom growth. Sediments were more stable than the bulk carbohydrate content suggested. They speculated that the sugar composition (qualitative of quantitative) of carbohydrate polymer changed with time. When diatom

cultures age, the cells become less motile, the extracellular polymer becomes insoluble in the growth medium and thus easily visible with dark-phase microscope optics. There is either a change in extracellular polymer state or a different type of polymer is synthesized. Decho (88) has observed that even subtle changes in composition such as bridging, adsorption of metals and enzymic interactions within the exopolymer matrix can alter its tertiary state. The solubility of microbial extracellular polymers is highly dependent on the cationic environment and the solvent (88). It difficult to understand why polymers that are soluble in seawater (salinity c. 36 ‰) and thus will diffuse can be extracted from a sediment core quantitatively with 30 ‰ NaCl (89). This underscores some of the confusion that is found in the literature on this subject. In support of this notion, De Winder and associates (90) found that a considerable proportion of the colloidal carbohydrate produced by a diatom biofilm on a tidal sandy beach was soluble in water and therefore is likely to disappear when the sediment becomes inundated. Thus it could contribute only to a limited extent to SS.

The herbicide Diuron has been used in several studies to inhibit diatom activity and thus supposedly provide a control situation for the involvement of diatoms in SS. Diuron (DCMU) inhibits diatom photosynthesis at the level of photosystem II; however, it does not prevent motility (90). Thus, if it is postulated that the involvement of motility-derived polymers is important in SS, then DCMU-treated sediments are not a useful negative control. Daborn and coworkers (91) found that DCMU gave inconsistent results. Paterson (92) also used DCMU to manipulate diatom populations in natural sediments. He found that the SS measured was lost during the tidal cycle and concluded that this was due to the presence of diatoms and the ephemeral nature of their motility polymer. Several other points made by Paterson are relevant here. He found that the erodibility of sediments with an established diatom assemblage remained lower after (tidal) immersion than the controls, suggesting a residual effect. Paterson states that it is not possible to say whether this effect is diatom-produced or due to a stimulation of bacterial populations in the presence of diatoms. He states further that biochemical analysis of the quantity and type of mucopolysaccharides present is desirable.

Sediment populations of diatoms have been manipulated by means other than the use of DCMU. For instance, Underwood and Paterson (93) used formaldehyde spraying to reduce diatom (and other living) populations in intertidal sediments with a view to examining the influence of indigenous microflora on SS. Formaldehyde did reduce sediment chlorophyll a, but it recovered to a normal level in six days. However, grazing microfauna did not recover, and because of this, diatom populations eventually became greater in biocide-treated areas than in the untreated areas. This exemplifies very well the problems encountered in uncontrolled field situations. Underwood and Paterson also found that there was an inverse relationship between sediment water content and shear strength. This was attributed to the compaction of the sediments in the biocide-treated areas because of the absence of burrowing fauna. Freshly deposited sediments were not retained by the biocide treated sites. Colloidal carbohydrate (soluble) in sediments was correlated with chlorophyll a and presumably the number of diatoms, but total carbohydrate concentrations in sediments did not correlate with a measure of SS. It is interesting to note van Kooten and coworkers (94) found that glutaraldehyde-fixed human fibroblast cells were much harder to remove from a surface with a liquid flow than were live cells. "Fixing" the sediment and the cells in it with formaldehyde may have had a similar and undetected effect; thus the biocide may have an influence other than that proposed by Underwood and Paterson. These workers in a similar study (95) showed that there was no significant correlation between chlorophyll a concentration in sediments and bacterial density, suggesting that, given their other findings (a correlation between chlorophyll a and critical shear stress), bacteria are not involved in SS. In this study, there were no significant differences in critical shear stress between biocide-treated and untreated areas. Critical shear stress is a measure of the force necessary to erode surface particles. It is increased with an increase in microbiological biomass and a decline in water content of the sediment. As both chlorophyll a and colloidal carbohydrate were lower in very wet sediments than in drier ones, it was difficult to separate the relative importance of these variables (water content and biofilm strength) on determining critical shear strength. However, multiple regression analysis showed that a consideration of carbohydrate and water content together explained the data better. Again, this is an example of the complexities of the natural world and the interpretation thereof. The authors stress the need to use in situ methodology, particularly for measuring sediment erodibility, but also underline the problems of working with natural cohesive sediment systems, including the difficulty of separating biological and physical effects, and the problem of establishing suitable and realistic "control systems." They also suggest that future studies should be conducted in the laboratory with natural sediments. This is not acceptable. Given the varied and variable populations found in marine sediments, model controlled systems should come first.

A study that relates laboratory-based experimentation directly to the sediments is that of Smith and Underwood (96), but it only adds to the difficulty in understanding the processes that take place in natural diatom biofilms. Production of EPS (diatom motility polymer in this case) is closely related to migratory rhythms of the diatom cells. During periods of photosynthesis, assimilated carbon is stored as intracellular glucan and is used to produce EPS for motility. Diatoms are also motile in darkness and in the presence of the photosystem-II inhibitor DCMU. Under these conditions, intracellular glucan is the source of EPS carbon and presumably the energy source needed to drive motility. Smith and Underwood showed that the stimuli required to initiate the flux of carbon from glucan to EPS were dim light, darkness, and migration of the cells downward in the sediment that was linked to an internal clock driven by the tidal cycle. Such influences on sedimentary diatom metabolism complicate benthic carbon budgets as well as the design of models to explain biogenic

stabilization of sediments. Currently, there is no postulated trigger for the reallocation of glucan carbon, but it may be tied into the surface-sensing system (7). Probably a major lesson to be learned from the literature on studies on sediment stabilization by benthic diatom biofilms is that it is impossible to make generalizations. All diatoms do not appear to behave similarly. One reason for this is that the various diatom carbohydrate fractions that are extracted, analyzed and postulated subsequently to have specific roles in the stabilization process, are merely operationally defined. The fractions do not represent specific molecular entities (97). The papers of Smith and Underwood (98) and Staats and associates (99) support this. In a laboratory study with several species of diatoms, Smith and Underwood (98) found by pyrolysis-mass spectrometric analysis that the EPS changed in composition as cells moved from logarithmic to the stationary phase of growth and that EPS production increased in the dark. On the other hand, using one of the organisms (*Cylindrotheca closterrium*) investigated by Smith and Underwood (98), Staats and associates (99), showed no secretion of EPS in the dark. It is possible that the reasons for these apparent anomalies could be explained by the differing extraction techniques used. The dynamics of production of the various types of EPS should be examined further. A potential technique to accomplish this is that of Leriche and coworkers (100) who used sugar-specific lectins in an enzyme-linked lectinsorbent assay (ELLA) to quantify the components of the EPS in bacterial biofilms.

Vandevivere and Kirchman (101) demonstrated that some freshwater bacterial strains exopolymer production was greater by attached cells than their free-living counterparts. Sand-packed columns or free sand in suspension were used in this study. The lesson from this paper is that the genes controlling exopolymer synthesis are turned on by the surface. Davies and coworkers (102) have shown that an alginate gene (Alg C) activity was greater for cells of *Pseudomonas aeruginosa* on a Teflon surface than in cells free in suspension. This regulatory effect of surfaces on gene expression has obvious relevance in the colonization of sediment particles, and thus SS. There is no analogous information on diatoms, but it has been suggested that diatoms could recognize surfaces by a receptor-based process (7).

Most literature has focused on the intertidal zone. A large experimental effort is expended in this area of the ocean because it is accessible and bears the brunt of human activities. This area is also important from the point of view of its overall productivity (103). If bacteria are involved in SS, their influence will be apparent as long as there is supply of organic carbon. This condition will be met as long as there is a productive ocean above the benthos. This is likely, at least across the continental shelf, but what of phototrophs? Diatoms can metabolize autotrophically at light levels down to 0.1% of surface radiation (104). Low levels of DOC uptake by phototrophs have been measured by various workers (105–107) and mixotrophy is considered an important physiology (103,104). Cahoon and coworkers (104 and references therein) maintain that benthic microalgal abilities allow them to sustain some productivity to 0.1% photon flux density. They calculated that this light level was available at 30% of the 17,879 oceanographic stations with a depth of 200 m around the U.S. coast where light measurements were available. Diatom patches have been observed on the sediments at 70 m in the Tongue of the Ocean, Bahamas. In the samples taken by Cahoon and coworkers (104), they found mostly (97%) pennate forms of the genera *Amphora*, *Nitzschia*, and *Navicula*. Thus it seems that the proposed model system will be relevant at least to a depth of 200 m.

It is likely that the concentration of small organics in the sediment pore water is not uniform and in fact concentration gradients exist (97,108). These gradients could be a factor in the establishment of diatom films because these algae move along them toward an area of higher concentration. This has been established for two diatoms of the genus *Amphora* (38). The formation of such areas of diatom concentration in sediments will lead logically to enhanced SS. For the chemosensory perception of gradients by diatoms to fall into the former category, they must be able to derive some nutrition for the effort expended because optimal-foraging theory proposes that evolution will favor those behaviors that maximize net nutritional gains (109).

CONCLUSION

Diatoms are found in all illuminated biofilms, yet they have not been studied in detail. Most research on this subject is related to the fouling of shipping and the stabilization of marine and freshwater sediments. Work in these areas is hindered by the paucity of information available on the physiology and cell biology of the organisms concerned, as well as their interactions with other microorganisms in the biofilm. From what has been mentioned so far, it is evident that diatoms differ in some aspects of their physiology and biochemistry, such that generalizations are not wise. Because the practical and ecological importance of diatoms in biofilms are closely tied to their ability to secrete extracellular polymers, it seems reasonable to suggest that more studies of the mechanisms that control the synthesis and secretion of these molecules are needed, but research in this area is hampered by a lack of information of the molecular genetics of these organisms (110).

The disinfection process in the treatment of water is designed to insure the inactivation of microbial pathogens. These pathogens that serve as the etiological agents of waterborne disease comprise a diverse group of microorganisms, which include bacterial, viral, and protozoan species. Disinfection coupled with physical removal processes, such as clarification and filtration, comprise the basic unit processes used in water treatment. However, under certain circumstances, disinfection may serve as the sole method of treatment. Chlorine, monochloramine, and chlorine dioxide, are commonly used halogenated oxidizing agents used in the disinfection process. These chemical disinfectants are utilized in both the treatment of water and wastewater and for maintaining disinfectant residuals in water distribution systems.

The disinfection process may be effected by a variety of factors, all of which can influence biocidal activity. In terms of physical factors, two of the most important parameters in the microbial inactivation process are water pH and temperature. For halogen disinfectants, inactivation is less effective at lower water temperatures. Numerous studies have shown that disinfection rates generally increase by a factor of 2 to 3 for every 10 °C increase in temperature. Changes in pH effect individual halogen disinfectants in different ways. Water turbidity and oxidant demand are two other physical parameters that influence microbial inactivation. Particles in water and agglomerations of microorganisms themselves can serve as a means of protecting microbes from the effects of a disinfectant. This type of protection is particularly true for organisms associated with biofilms or corrosion products, which may be found in a water distribution system. The oxidant demand of a given water must be evaluated to achieve the desired level of disinfectant. The amount and the manner in which a disinfectant is applied, coupled with the requirement for adequate mixing, are important operational parameters that need to be taken into consideration. Microorganisms themselves differ widely in their resistance to inactivation by chemical disinfectants, with vegetative bacterial cells being more

readily inactivated than viruses, bacterial endospores, or encysted forms of protozoa. Prior growth conditions or metabolic status of bacterial cells may also influence their response to disinfecting agents. Lastly, the methods for determining the viability of a given microorganism after exposure to an oxidizing agent may influence the observed results. This is particularly true in the case of bioassays for determining the viability of encysted protozoans. It has also been noted that the constituents of carbohydrate-based media used for the propagation of bacteria may influence the recovery of oxidant-stressed organisms.

CT CONCEPT

As mentioned earlier, many variables can affect the inactivation process. These variables, along with basic differences in experimental designs, have contributed to the difficulties in comparing various reports on microbial inactivation. In attempts to overcome these problems, researchers have used mathematical principles to describe the inactivation kinetics of microorganisms. One of the most widely used of these mathematical procedures is known as the *CT* concept (1). *CT* values have been used by governmental agencies to provide guidance to water utilities regarding the levels of inactivation required for different microorganisms. The mathematical expression for *CT* is the product of the disinfectant concentration (C) multiplied by the time of exposure (T) required to achieve a given level of inactivation for a particular microorganism. The equation used for determining *CT* values was developed from analysis, which compared the biocidal action of a chemical disinfectant with the kinetics of chemical reactions (1). This concept is known as Chick's law

$$\log_{10} \frac{N}{N_o} = -KT$$

where $\log_{10} N/N_o$ represents the surviving microbial fraction, T represents the exposure time, and K is a proportionality constant. Watson further defined Chick's law as

$$K = C^n T$$

where C stands for the disinfectant concentration, n is a constant known as the coefficient of dilution, and T represents the exposure time required to achieve a given level of inactivation. In an analysis of inactivation studies conducted under oxidant demand-free conditions it was found that most values of n were close to 1.0 (1). The *CT* concept is essentially the Watson equation, with the implicit assumption that n is equal to 1

$$CT = K$$

where C is the disinfectant concentration (mg/L), T is time (minutes), and K is the proportionality constant. Using this equation, simple *CT* values can be calculated for different levels of inactivation for various waterborne microorganisms. Comparative *CT* data for the inactivation of several microorganisms are listed in Tables 1 to 3. Although *CT* values can be useful for comparing microbial inactivation studies and establishing compliance guidelines, it should be noted that the concept has certain

Table 1. CT Values for 99% Inactivation by Chlorine for Various Microorganisms[a]

Organism	Temperature (°C)	pH	Mean *CT* (mg min/L)
Bacteria			
Escherichia coli	5	6.0	<1.0
	5	10.0	<1.0
	15	10.0	<1.0
Virus			
Polio 1	5	6.0	2.0
	5	10.0	10.5
	15	6.0	1.0
	15	10.0	3.9
Encysted Protozoa			
Giardia lamblia	5	7.0	97
	15	7.0	32
Cryptosporidium parvum	25	7.0	7,200

[a] Adapted from Hoff, 1986 and Korich et al., 1990.

Table 2. CT Values for 99% Inactivation by Preformed Monochloramine for Various Microorganisms[a]

Organism	Temperature (°C)	pH	Mean *CT* (mg min/L)
Bacteria			
Escherichia coli	5	9.0	160
	15	9.0	66
Virus			
Polio 1	5	9.0	1,420
	15	9.0	646
Encysted Protozoa			
Cryptosporidium parvum	25	7.0	7,200[b]

[a] adapted from Hoff, 1986 and Korich et al., 1990.
[b] value for 90% inactivation.

Table 3. CT Values for 99% Inactivation by Chlorine Dioxide for Various Microorganisms[a]

Organism	Temperature (°C)	pH	Mean *CT* (mg min/L)
Bacteria			
Escherichia coli	5	6.5	<1
	10	6.5	<1
Virus			
Polio 1	5	7.0	3.6
	15	7.0	1.6
Encysted Protozoa			
Giardia muris	5	7.0	11.2
Cryptosporidium parvum	25	7.0	78[b]

[a] adapted from Hoff, 1986 and Korich et al., 1990.
[b] value for 90% inactivation.

inherent weaknesses. It has long been known that the first-order kinetics described by Chick's law is subject to various deviations that may occur for a variety of reasons, not the least of which is the failure of microorganisms to behave like the reactants in a chemical reaction. Variations in resistance among a portion of the microbial population as well as other factors such as depletion of disinfectant residual may also contribute to the observed deviations.

CHLORINE

Chlorine is the most frequently used disinfectant in water treatment. It has been successfully used in both drinking water and wastewater applications. The inactivation of microorganisms by chlorine is highly pH dependent. Chlorine disassociates in water to form hypochlorous acid and hypochlorite ion. Hypochlorous acid predominates at lower pH values and is a much more potent biocide than hypochlorite ion. Some of the earliest disinfection research centered on chlorine inactivation of enteric bacterial pathogens and sanitary indicator organisms represented by the coliform group of bacteria. More recent studies on chlorine inactivation of coliform bacteria have centered on the recovery of sublethally stressed organisms (2,3) and the protective effect from inactivation afforded from coliforms associated with naturally occurring particulate material (4). These reports have emphasized the role of different types of bacteriological media in the recovery of chlorine-stressed organisms and support the importance of water clarity in the disinfection process. Representative chlorine Ct values for various microorganisms are presented in Table 1. Using the virus polio 1 as a representative organism, it is readily seen that increasing the pH decreases the biocidal efficiency of chlorine. Similarly, when the pH level is held constant, it can be seen that increasing the temperature from 5 °C to 15 °C increases the rate of inactivation, resulting in lower Ct values.

The survival after chlorination of coliform bacteria in association with other organisms has also been reported. *Escherichia coli* and *Enterobacter cloacae* were found to be protected from chlorine inactivation when these organisms were associated with microcrustaceans such as the amphipod *Hyalella azteca* (5). Similarly, bacteria that were ingested by protozoa have been shown to exhibit an increased resistance to inactivation by chlorine. This protective effect has been demonstrated for coliform bacteria and several waterborne pathogens (*Salmonella typhimurium*, *Yersenia enterocolitica*, *Shigella sonnei*, *Legionella gormanii*, and *Campylobacter jejuni*) when ingested by free-living protozoa (6).

There have been numerous studies on the effect of chlorine on bacterial pathogens (7). Most studies have suggested that enteric bacterial pathogens are inactivated by chlorine in a manner similar to that seen for coliform bacteria. For example, studies have shown that the causative organism of hemorrhagic colitis, *E. coli* 0157 : H7, exhibited similar resistance to chlorination as that seen with nonpathogenic *E. coli* strains (8). This finding has also been shown to be true for *Helicobacter pylori* (9) and the two closely related bacterial pathogens, *C. jejuni* and *Arcobacter butzleri* (10,11). Certain nonenteric waterborne microbial pathogens such as the nontuberculosis mycobacteria, however, have been shown to be more resistant to disinfection than coliform bacteria (7).

Animal viruses and bacteriophages (bacterial viruses) are generally considered to be more resistant than bacteria to chlorination. Early chlorine disinfection studies with viruses concentrated on the inactivation of poliovirus under oxidant demand-free conditions (1). Studies have been conducted to study the inactivation of both purified preparations of single virus particles and virus particles associated with tissue culture cells to compare their resistance to chlorination. In all instances the cell-associated virus was more resistant to inactivation than were preparations of single virus particles. In studies on the inactivation of bacteriophages it was concluded that the bacteriophage, like the animal virus, is sensitive to inactivation by chlorine (1,7).

Several research studies have examined the inactivation kinetics of the waterborne protozoan parasite *Giardia* spp. (1,7). Studies using *G. lamblia* cysts derived from an animal model (mongolian gerbils) as opposed to cysts obtained from human donors have shown that the gerbil-derived cysts were somewhat more resistant than cysts obtained from human donors, suggesting that the host source of cysts may affect cyst resistance to disinfection (12). The encysted forms (oocysts) of the waterborne parasite *C. parvum* have been shown to be very resistant to chlorination (Table 1).

CHLORAMINE

The use of chloramination in water treatment has gained increasing popularity as concerns have grown regarding adverse health effects attributed to chlorine disinfection by-products. Monochloramine is considered a weak biocide in comparison with chlorine, requiring longer exposure times to achieve comparable levels of inactivation (Table 2). Chemically, chloramines are a complex group of disinfectants, however, only the monochloramine form is of major interest for drinking water disinfection. When chlorine and ammonia are mixed in equimolar proportions, nearly all free available chlorine is converted to monochloramine. This is an equilibrium reaction and is affected by the chlorine to ammonia ratio. The rate of formation also exhibits a pH dependency. In studies on the efficacy of microbial inactivation by chloramination, pH levels are generally maintained at 8 or higher to insure that monochloramine is the predominant form present. Traditionally, laboratory studies have concentrated on the use of preformed chloramine, and while these results yield conservative values for inactivation they are not representative of the disinfectant's effectiveness under field conditions. The chlorine to ammonia ratio, the pH, and the method of application are crucial parameters to consider in chloramine inactivation and must be clearly delineated to determine biocidal effectiveness under various experimental conditions (1).

As with chlorine, particle protection has also been observed with monochloramine inactivation of coliform

bacteria. Coliforms associated with smaller size particle fractions were inactivated more rapidly than the organisms associated with larger size particle fractions, thus mimicking the results observed with chlorine (4).

There has been relatively little research on the role of chloramination for the inactivation of protozoa. It has been shown that monochloramine was less effective than chlorine or chlorine dioxide for inactivating *C. parvum*. For chloramine, a *CT* of 7,200 produced only a 90% level of inactivation of *C. parvum* oocysts (Table 2).

CHLORINE DIOXIDE

Chlorine dioxide exists as an undissociated gas dissolved in water in the pH range from 6 to 9. Chlorine dioxide is a potent disinfectant and is generally considered to have a biocidal efficiency greater than chlorine or monochloramine (1). Like monochloramine, chlorine dioxide has gained interest among water utilities concerned with disinfection by-products such as trihalomethanes. Trihalomethanes are not formed when chlorine dioxide is used as a disinfectant if the oxidant is produced without excess chlorine.

The effect of prior growth conditions has been examined for the inactivation of *E. coli* and *Legionella pneumophila* by chlorine dioxide (13). Chemostat-grown bacteria were compared to batch culture bacteria in reference to their resistance to chlorine dioxide. A resistant subpopulation of each organism survived in the presence of a constant chlorine dioxide residual. The observed resistance was attributed to a phenotypic trait, which could be manipulated by altering the antecedent growth conditions in the chemostat cultures. However, in most instances chlorine dioxide is considered to be very effective for inactivating bacteria (Table 3).

Studies conducted on chlorine dioxide inactivation of viruses have shown that this oxidant has potent viruicidal properties (Table 3). Chlorine dioxide has been shown to be an effective biocide for *Giardia* (Table 3) and to be more efficacious than chlorine or monochloramine for the inactivation of *C. parvum* oocysts (14).

CONCLUSION

The disinfectants discussed in this section represent three of the most commonly used chemical oxidizing agents used in water treatment. Two important considerations that need to be addressed regarding the choice of disinfectants is biocidal efficiency and stability (15). In terms of biocidal efficiency the disinfectants may be ranked as chlorine dioxide > chlorine > chloramine. It should again be noted that temperature is an important factor to consider, with effectiveness improving with increasing temperatures within the ranges normally encountered for water samples. The effect of pH is most apparent with chlorine, with effectiveness decreasing with increasing pH levels. For chloramines the pH level needs to remain above 8 to insure that monochloramine is present. Increasing pH appears to have a beneficial effect for chlorine dioxide. However, the mechanism is not well defined. In terms of stability monchloramine is more stable than chlorine or chlorine dioxide. The biocidal effectiveness of monochloramine is less than the other two disinfectants; however, the ability to persist over a prolonged period may be beneficial, particularly in cases such as maintaining a disinfectant residual in a distribution system.

DISINFECTION OF PROTOZOAN PARASITES

CHRISTIAN CHAURET
Indiana University
Kokomo, Indiana

One of the challenges facing the water industry is to provide drinking water safe from disinfectant-resistant protozoan parasites and at the same time to minimize the formation of harmful disinfection by-products (DBP) in drinking water. Protozoan pathogens are unicellular

eukaryotic microorganisms that, unlike fungi, lack a cell wall. Protozoa are typically larger than prokaryotic bacteria and are distinguished from algae by their lack of photosynthetic pigments. Many protozoa are motile in aquatic environments; however, members of the group Sporozoa, to which many important human pathogens such as *Cryptosporidium* and *Toxoplasma* belong, are generally nonmotile. In aquatic environments, protozoa are found as cysts, oocysts, or spores, and all of these forms are very resistant to disinfection. Some of the protozoan parasites of concern to the drinking water industry include *Cryptosporidium parvum*, *Giardia lamblia*, *Entamoeba histolytica*, *Cyclospora cayetanensis*, *Toxoplasma gondii*, and the microsporidia. *Giardia lamblia* and *C. parvum* have especially been associated with several outbreaks of waterborne gastroenteritis and are amongst the most important etiological agents of waterborne disease (1,2). For example, *C. parvum*, which causes severe gastroenteritis that is often fatal in immunocompromised individuals, was implicated as the etiological agent in an outbreak in Milwaukee, Wisconsin, where more than 400,000 people were infected (3). More than 400 waterborne disease outbreaks were documented in the United States between 1980 and 1996, of which *Giardia lamblia* accounted for the largest fraction, 20.9%. In contrast, a highly significant 82.5% of cases of illness were attributed to *Cryptosporidium parvum* (the Milwaukee cryptosporidiosis outbreak being responsible for the elevated percentage of cases) (4). Therefore, both *Cryptospordium* and *Giardia* are of great concern to the water industry and are further described below. In addition to these two organisms, *Entamoeba hytolytica* can also be transmitted through water; however, outbreaks of disease caused by this organism appear to be limited to tropical and subtropical areas. The remaining protozoan parasites mentioned earlier are potential waterborne pathogens, but information with respect to their occurrence in water or their sensitivity to disinfection is limited.

DRINKING WATER DISINFECTION

Disinfection is the inactivation of disease-causing microorganisms, such as bacteria, viruses, and protozoa, by the addition of a chemical (a disinfectant such as chlorine) into water. Disinfectants may inhibit growth or kill target organisms. The target sites that may be affected include, depending on the type of microorganism, the bacterial peptidoglycan layer, the bacterial outer membrane, the cellular cytoplasmic membrane, structural proteins and enzymes, nucleic acids, and/or viral envelopes and capsids (5). The ideal water disinfectant should have the following properties: it should inactivate pathogens within a practical time period and over a wide range of water quality, it should be nontoxic to humans and animals at required concentrations, it should be palatable at required concentrations, it should persist in a water distribution system and maintain a residual concentration to prevent bacterial regrowth and contamination by infiltration, and ideally it should be easy and cheap to measure and use.

In a water treatment plant, disinfection is typically the last barrier in water purification, and its main purpose is to achieve a reduction in pathogen numbers (6). Disinfectants are also often used where raw water enters the water purification plant (prechlorination). Although prechlorination does achieve pathogen removal, its main purpose is typically to minimize taste and odor problems. Chlorine was first used in the beginning of the twentieth century and remains the most widespread disinfectant in the water industry (7). Other traditional disinfectants and alternative disinfection strategies include chloramination, ozonation, the use of chlorine dioxide, and the application of ultraviolet irradiation, the later method being a physical means of achieving disinfection. Each technology has some advantages under certain conditions. Because of protozoan resistance to disinfection and the concerns related to waterborne outbreaks of protozoan parasites, recent research has focused on alternative disinfection methods for the water industry; however, several investigators have noted that with the exception of ozone, the use of disinfectants alone may not be sufficient to inactivate enough protozoan parasites in water to prevent waterborne outbreaks (8,9). Disinfection technologies have to be developed along with better physical removal of organisms to ensure adequate protection of drinking water. Sequential use of disinfectants may yield synergistic inactivation and provide additional removal, but additional work is needed to confirm these results. Several of these applications are currently being studied, especially with respect to reducing the risk of *Cryptosporidium* transmission in water.

It is important to note that most studies of water disinfection of protozoan parasites have been conducted in batch-scale systems in disinfectant demand-free buffers that may not correctly simulate the operation of water-treatment plants. Although batch-scale experiments are easy to replicate and have been used to derive inactivation kinetics, they do not simulate water treatment hydraulics and do not account for other factors that are present in water treatment. Ideally, to determine the ability of a water-treatment plant to inactivate microorganisms, models of disinfection should attempt to use natural water and should simulate the flowing water process of contact between disinfectant product and target organism by making use of pilot plants.

Factors Influencing Disinfection

Many factors are known to influence disinfection (7). All microorganisms do not show the same resistance to disinfection. In general, protozoan cysts and bacterial spores are most resistant (7), whereas viruses and vegetative bacteria are much more sensitive to disinfectant action. Chemical kinetics predict that disinfection of protozoa (and other organisms) is more difficult to achieve in colder waters than in warmer waters, and this was empirically demonstrated in several studies (10,11). Other general factors include water hardness and the protection of microorganisms when they form aggregates, clumps, or biofilms in a water distribution system (12,13).

In addition to factors influencing the disinfection process itself, the analytical method for determination

of protozoan viability also affects disinfection results. All protozoan disinfection experiments must involve a measurement of viability or infectivity. Viability of protozoan parasites such as *Cryptosporidium* oocysts and *Giardia* cysts, however, has been assessed in several different ways, making interstudy comparisons very difficult. Different methods yield different results and typically, in vitro methods, such as in vitro excystation have been shown to underestimate inactivation by disinfection (14,15). Excystation of the cysts/oocysts occurs in the intestine of the host. Therefore, in vitro excystation methods simulate this condition and have been taken as an indication of survival (14,16). For *C. parvum*, the oocysts are incubated in an excystation medium made of taurocholic acid and trypsin (16,17). Numbers of oocysts, partially excysted oocysts, empty oocysts, and sporozoites are then counted by using differential interference microscopy. A correlation between in vitro excystation and infection of mice with large inocula (10^5 oocysts per mouse) of *Cryptosporidium* oocysts has been reported (18); however, the correlation with lower numbers of organisms and different susceptible species remains unclear, particularly after increased levels of inactivation (14). Therefore, consideration of some cellular injuries preventing productive infection, without necessarily preventing excystation, must be taken. The major disadvantages of in vitro excystation are the length of time (several hours) for completion of a test and the requirement of large numbers of organisms.

A second method for the measurement of protozoan viability involves the inclusion or exclusion of fluorogenic vital dyes by cysts/oocysts. For example, 4',6-diamidino-2-phenylindole (DAPI) and propidium iodide (PI) have been utilized extensively in the United Kingdom to assess the viability of *Cryptosporidium* oocysts (19). It has been shown that only cells with disrupted or broken membranes can be stained with PI (20). Motile sporozoites never incorporate PI. Correlation between inclusion of DAPI (DAPI+) and excystation yield was shown to be highly statistically significant (19). Oocysts that incorporated neither dye (DAPI- PI-), but that were not empty oocysts, could be converted to viable (DAPI+) oocysts by a trigger mechanism (for example, preincubation in acidified Hank's balanced salt solution). Such oocysts are considered viable. This method provides the advantages of speed, simplicity, and low cost. The DAPI–PI assay has been used to evaluate ozone disinfection and UV inactivation of *Cryptosporidium* oocysts (21,22). Other vital stain methods have been tested, for example, Arrowood and coworkers (23) used a modified fluorescein diacetate (FDA)–ethidium bromide (EB) staining procedure to assess the viability of *Cryptosporidium* oocysts. In this fluorogenic assay, the esterases in viable cysts convert the highly permeable nonfluorescent FDA to fluorescein that fluoresces green (24). However, the assay was not correlated with other viability assays. More recently, Belosevic and coworkers carried out an extensive study of the use of the fluorescent stain SYTO®-9 for testing the viability of *Cryptosporidium* (25). SYTO®-9 is a live or dead stain that stains dead oocysts green or yellow, leaving live oocysts either unstained or displaying a green halo. SYTO®-9 vital staining was shown to correlate with in vitro excystation and animal infectivity in CD-1 mice (26); however, other researchers (15), in a study involving inactivation by ultraviolet light and ozone, found that none of the in vitro assays tested were capable of predicting oocyst inactivation, with animal infectivity better reflecting inactivation levels in all cases. Clearly, the most effective vital stain method would be one that involves an enzyme system that is critical to the initiation of infection. Unfortunately, such an enzyme system is not known at present.

As mentioned several times in the preceding paragraphs, a third viability measurement method is the animal infectivity (8,14,27). The potential to infect neonatal mice can be used to assess the viability of oocysts. Neonatal mice are inoculated, sacrificed after several days, and parasite development stages are detected by microscopy in histological sections of the gut. As previously discussed, recent research (8,15) indicates that in vitro excystation underestimates inactivation when compared with animal infectivity. As inactivation increases, the difference between excystation and infectivity also increases. The animal infection procedure does, however, have some disadvantages, including the cost, the expertise needed, the length of the assay, and the requirement of large numbers of animals to ensure quantitative results, consequently leading to a need to maintain a large colony of mice.

In addition to the methods mentioned earlier, other viability methods for *Cryptosporidium* have recently been developed. Among the most promising ones are molecular methods in combination with cell culture (28) and a cell culture method combined with immunofluorescence and most-probable number determination (MPN-infectivity assay) (29). These methods hold great potential for future work because of their sensitivity, rapidity, and relatively low cost. Molecular methods, notably the polymerase chain reaction (PCR), have the potential to probe for the induction of synthetic processes such as mRNA synthesis that could result from an environmental trigger such as heat treatment (30). Filkorn and coworkers (31) developed a PCR assay for *Cryptosporidium* sporozoites. The assay uses excystation in combination with DNA-digestion, followed by PCR. Rochelle and coworkers (28) developed a detection procedure for *Cryptosporidium* using cell culture combined with PCR. The oocysts were inoculated onto monolayers of Caco-2 cells grown on chamber slides. The infection of the cell culture was assessed by detection of mRNA from the heat-shock protein gene by reverse transcription-polymerase chain reaction (RT-PCR). This method was tested with 10^3 oocysts. The MPN-infectivity assay consists of diluting *C. parvum* oocyst samples, plating them in triplicate onto a suitable cell culture line, incubating them for a certain period of time, and detecting infectious stages in the cell culture by immunofluorescence (29). Calculations are done using MPN tables or computer software.

None of the available viability methods is definitive. Assays based on animal infectivity cannot be extrapolated from one species to another (for example, from mice to humans). In addition, large numbers of animals are

required for statistically accurate determination of the infectious dose.

Disinfectant Concentration and Contact Time

Disinfectant effectiveness is often expressed as a *Ct* value. *C* is the disinfectant final residual concentration and *t* is the time required to kill a certain percent (or $\log_{10}$ inactivation) of the population (32). Critical *Ct* values for achieving a certain level of inactivation have been used for regulatory purposes under the Surface Water Treatment Rule (SWTR) by the U.S. Environmental Protection Agency. Tables listing *Ct* values, which provide the required *Ct* value that must be achieved to reach a certain level of inactivation, have been developed for various disinfectants under different conditions of temperature and pH.

Type of Disinfectant

Chlorine. Chlorine remains the most popular water disinfectant in North America. When chlorine gas (Cl_2) is injected into water, it hydrolyzes to form hypochlorous acid (HOCl), which dissociates in water to form hypochlorite ions (OCl^-). In general, chlorine is more efficient at low pH values (hypochlorous acid formed) than at high pH, which favors the formation of hypochlorite ions (33,34). This association between pH and chlorine has also been shown for disinfection of protozoa such as *Entamoeba hystolytica* (35) and *Giardia lamblia* (Table 1). Most studies on the mechanism of action of chlorine have been performed on bacterial cells. For example, several studies have shown that permeability disruption was the cause of chlorine damage to bacteria (32,36,37). Other studies have demonstrated that chlorine has an effect on bacterial DNA (38) and on bacterial enzymes, such as catalase, resulting in the intracellular accumulation of hydrogen peroxide (39).

Table 1 shows *Ct* values for some protozoa under various conditions. In recent years it has been recognized that the use of chlorine to provide disinfection of drinking water may not adequately inactivate all pathogens, most notably *Cryptosporidium parvum*, which is much more resistant to chlorine than *Giardia lamblia*, *Escherichia coli*, and waterborne viruses (Table 1). Quinn and Betts (40) demonstrated that preaging *Cryptosporidium* oocysts for up to seven days in tap water at room temperature did not have any significant effect on their subsequent inactivation by chlorine. Even oocysts aged in natural waters in situ for up to 26 days did not show increased susceptibility to chlorine (or monochochloramine) (16). As mentioned earlier, studies on disinfection of *Cryptosporidium* oocysts have repeatedly confirmed their relative resistance to disinfection by the levels normally used in drinking water treatment. Therefore, chlorine as a single primary disinfectant is not useful to eliminate the risk of cryptosporidiosis and other protozoan diseases in water.

Chloramines. Monochloramine is an alternative to chlorine. It has been used in some facilities for a long time. For example, in Denver and Ottawa, it was first introduced in 1917 (6). Monochloramine (NH_2Cl) is formed when hypochlorous acid (HOCl) from chlorine reacts with ammonia (NH_3). Dichloramine ($NHCl_2$) and trichloramine (NCl_3) are also formed in the process, but monochloramine is predominant at pH value greater than 8.5 (7). Chloramines are less effective as disinfectants than free chlorine; however, they appear to be very effective at controlling biofilms in distribution systems. Their use is recommended as a secondary disinfectant in systems having extensive biofilm problems (44). Monochloramine on its own is less effective than free chlorine against *Cryptosporidium* (8,10,16) and *Giardia* (45), as shown by the very high *Ct* values (Table 2), and it is not recommended as a single primary disinfectant to prevent waterborne outbreaks of protozoa (46).

Chlorine Dioxide. Another alternative disinfectant to free chlorine is chlorine dioxide (ClO_2), which may be strong enough to control *Cryptosporidium* and does not typically form as many carcinogenic disinfection by-products as chlorine. It does not form trihalomethanes or chloramines but reacts to form chlorite and chlorate, which although not carcinogenic like trihalomethanes or haloacetic acids, can be acutely toxic at high concentrations.

Chlorine dioxide can be produced by combining hydrochloric acid with sodium chlorite according to the following reaction:

$$5NaClO_2 + 4HCl \rightarrow 4ClO_2 + 5NaCl + 2H_2O$$

ClO_2does not hydrolyze in water but remains present as a dissolved gas. The pH of water has an impact on

Table 1. Inactivation of Protozoa and Other Selected Microorganisms by Chlorine

Microorganism	Temperature (°C)	pH	Inactivation ($\log_{10}$)	*Ct* value	Reference
Giardia lamblia	5	6.0	3.0	150	51

Cryptosporidium parvum	22	8.0	>2.0	3,600	10

Table 3. Inactivation of Protozoa by Chlorine Dioxide

Microorganism	Temperature (°C)	pH	Inactivation (log_{10})	*Ct* value	Reference
Giardia muris	5	7.0	2.0	10.7	53
Giardia muris	25	7.0	2.0	5.1	54
Giardia muris	25	5.0	2.0	5.8	53
Cryptosporidium parvum	20	8.0	2.0	150	47
Cryptosporidium parvum	4	8.0	2.0	900	47
Cryptosporidium parvum	1	6.0	0.5	120	52
Cryptosporidium parvum	22	6.0	2.1	120	52
Cryptosporidium parvum	25	7.0	1.0	78	8

the formation of chlorate and chlorite; more of these DBPs being formed as the pH is increased. Inactivation rates are, however, approximately the same at pH 6 as at pH 8 (47).

The mechanism of action of chlorine dioxide on protozoa is poorly understood. In viruses, it is known to penetrate the capsid and react with nucleic acids (48,49). In bacteria, the main site of action appears to be proteins in the cell membrane and causing inhibition of protein synthesis (5,50). Few studies have been published on the chlorine dioxide inactivation of protozoan parasites in water; however, enough data have been collected so far to suggest that chlorine dioxide is a stronger oxidant than free chlorine. Accordingly, chlorine dioxide is more germicidal than free chlorine, as indicated by the much lower *Ct* values under similar conditions for a given organism (Tables 1 and 3). There is a lot of disparity in the chlorine dioxide inactivation data with *Cryptosporidium* (Table 3), and some investigators remain cautious about the possibility of using chlorine dioxide to inactivate protozoal agents (9,51). Other researchers such as Finch and Li (52) have stated that chlorine dioxide is an effective disinfectant for *Cryptosporidium*, even at low temperatures. In part, the disparity is due to different analytical methods for measuring both parasite viability and chlorine dioxide concentrations, which seems to suggest that more research is warranted to better understand the usefulness of chlorine dioxide for inactivating protozoan pathogens.

Ozone. Ozone (O_3) was first used for water disinfection in Europe in 1906 (43). Ozone forms free radicals that inactivate microorganisms. Its main effect seems to be on enzyme activity and DNA (55). Ozone has become more prevalent during the past 20 years in the United States and Canada as an alternative to chlorine for two reasons. (*1*) The recognition in the 1970s that chlorination leads to the formation of DBP and (*2*) the emergence and recognition in the past decade of waterborne cryptosporidiosis as a major health problem and the resistance of its causative agent to chlorine. Ozonation is recognized as one of the most efficient ways to inactivate protozoan parasites such as *C. parvum* during water treatment (8,14,56), as shown by the very low *Ct* values required to achieve certain levels of inactivation (Table 4). As with other disinfectants, *Cryptosporidium* is more resistant to ozone than *Giardia* (Table 4). The use of ozone for *Cryptosporidium parvum* inactivation seems to be more effective at higher temperatures and is better described by a nonlinear model such as the Hom model that accounts for ozone decay (10,14).

Only a few studies have shown that ozone in a pilot plant is efficient against *Cryptosporidium* (57). The overwhelming majority of inactivation studies have been conducted at bench-scale. It has, however, been reported that *Giardia* and *Cryptosporidium* inactivation data obtained at pilot-scale in natural waters were comparable to bench-scale results obtained in laboratory waters (57). Although such comparisons are always difficult to make, these findings seem to indicate the enormous potential of ozone for inactivating *Cryptosporidium parvum* and other protozoan parasites.

Ozonation studies have clearly demonstrated that in vitro excystation consistently underestimated *Cryptosporidium* inactivation when compared to mouse infectivity (14). Therefore, infectivity assays must be used when testing disinfectants as excystation may occur without infectivity. Comparison of past studies is also difficult because of the different viability assays utilized. Finally, comparison of various studies is especially difficult because ozone reactions are typically specific to particular water systems and vary depending on the water characteristics, suggesting that modeling must be done at each individual

Table 4. Inactivation of Protozoa by Ozone

Microorganism	Temperature (°C)	pH	Inactivation (log_{10})	*Ct* value	Reference
Giardia muris	22	5.7–8.3	3.0	0.30	14
Giardia lamblia	22	6–9	3.0	0.31	60
Cryptosporidium parvum	25	7.0	>1.0	5	8
Cryptosporidium parvum	room	—	2.0	4.6	61
Cryptosporidium parvum	7	6.9	2.0	7	14
Cryptosporidium parvum	22	6.9	2.0	3.5	14
Cryptosporidium parvum	22	6–8	2.0	1.7–2.7	62

site for proper optimization of the technology. A drawback of ozonation is that, unlike free chlorine, ozone reacts very rapidly, typically leaving no residual in the water distribution system.

Ultraviolet Light. Recently, ultraviolet light (UV) was shown to be effective at inactivating significant levels of protozoan parasites (22,27). The germicidal effect of UV irradiation involves photochemical damage to DNA within the organisms. DNA absorbs light energy in the wavelength of 240 to 280 nm, and the resulting DNA damage is often in the form of dimerization of thymine molecules, which leads to lethal mutations. Besides its germicidal action, UV has many additional advantages. For examples, it is a noncorrosive technology with no need for storage of toxic chemicals. UV irradiation also produces no known DBPs. Also, the technology is relatively low maintenance, although fouling of the lamps can be a problem. Three types of systems have been designed and evaluated for drinking purification: low-pressure UV (the more traditional technology that is employed in wastewater treatment), medium-pressure UV, and pulsed UV (15). UV is typically measured in mJ/cm^2 (that are equivalent to mW sec/cm^2). Typical UV doses in water are between 16 and 40 mJ/cm^2. One of the problems associated with UV technology is that, unlike with chemical disinfectants, no UV "residual" can be measured in water, making correct evaluation of the applied dose more difficult. Also, as for ozone, this lack of "residual" is not appropriate for biofilm control. Thus, UV technology must be used in combination with other processes such as biological filtration and/or chemical disinfection to control biofilm growth.

Using animal infectivity, bench-scale experiments have demonstrated a greater than 4.0 log_{10} inactivation of *C. parvum* with a dose of 41 mJ/cm^2. A comparable 3.9 log_{10} inactivation was achieved with a dose as low as 19 mJ/cm^2 at "demonstration-scale" at the Mannhein water treatment plant in Waterloo, Canada (15). The 111-L UV reactor tested in the later study consisted of six 1-kW medium-pressure UV lamps with an overall flow rate of 814 L/min. Therefore, the results from these recent studies suggest that UV at very low doses causes significant parasite inactivation and that this technology may become more widely used in the near future for drinking water purification. One issue that remains to be addressed, however, is the possibility of the existence of UV repair mechanisms, such as photoreactivation repair or excision repair, in protozoa similar to those known in bacteria.

Synergistic Effect of Disinfectants

Finch and coworkers demonstrated that sequential disinfection of *Cryptosporidium* with chlorine and monochloramine resulted in a synergistic effect on inactivation (63). In other words, the use of two disinfectants in sequence has an enhanced disinfection effect greater than the sum of the individual disinfectants. For example, individual applications of either chlorine (dose of 5 mg/L for 60 minutes) or monochloramine (dose of 5 mg/L for 480 minutes) resulted in less than 0.5 log_{10} inactivation of *Cryptosporidium*. When both chemicals were used sequentially at lower doses (chlorine at 1 mg/L for 60 minutes and monochloramine at 2 mg/L for 240 minutes), more than 1.5 log_{10} inactivation was measured (63). Similarly, ozone, which itself is a very good disinfectant, followed by monochloramine shows a synergistic effect (10). Synergistic effects also have been shown with chlorine dioxide (62,63). Researchers have postulated that the synergistic effect is produced when the primary oxidant affects the oocyst wall permeability, permitting the secondary disinfectant to better diffuse through the oocyst wall to damage the sporozoites (10,62).

CONCLUSION

Protozoan parasites are recognized as important etiological agents of waterborne illnesses. Historically, *Giardia lamblia* has been the most frequently cited etiology of waterborne gastroenteritis; however, in recent years, *Cryptosporidium parvum* has been implicated in several outbreaks of disease and is now recognized by water utilities as the main direct water-related threat to public health. One of the reasons for the prevalence of protozoan pathogens in drinking water is their resistance to commonly used disinfectants such as chlorine. Cysts/oocysts of these organisms are difficult to inactivate using acceptable doses of disinfectants. In the past few years, and especially in response to the 1993 waterborne outbreak of cryptosporidiosis in Milwaukee, there has been a tremendous amount of research performed to evaluate the efficacy of alternative disinfectants and disinfection procedures against *C. parvum* (and, to a lesser extent, *G. lamblia*). For use as single disinfectants, disinfectant efficacy of chemicals follows this order: ozone > chlorine dioxide > free chlorine > monochloramine; however, some

researchers have demonstrated that sequential disinfection may have a synergistic effect, thereby justifying, under certain conditions, the use of monochloramine or chlorine to inactivate protozoa. Additional research, especially at pilot-scale, is warranted to confirm these results. Some studies have also proposed that mixed oxidants may provide adequate inactivation levels (64). Finally, nonchemical means of disinfection, namely UV technology, have been shown to inactivate significant levels of *Cryptosporidium* in both bench-scale and demonstration-scale experiments and may provide an affordable alternative to chemical inactivation, at least with respect to parasite inactivation during treatment. There is no doubt that new technologies will emerge in the future to build on (or replace) current technologies, especially as concerns over toxic and carcinogenic DBPs will probably remain as long as chemical oxidants are added to drinking water. For example, membrane filtration (not a "disinfection" process) has been shown to be very efficient at removing parasites during treatment (65).

E

ECOLOGICAL SIGNIFICANCE OF SUBSURFACE MICROORGANISMS

JAMES K. FREDRICKSON
Pacific Northwest National Laboratory
Richland, Washington

Terrestrial subsurface environments are inhabited almost exclusively by microorganisms and are in essence "aphotic" ecosystems. Photosynthesis plays only an indirect role in subsurface microbial ecology, providing reduced organic compounds that can be metabolized by aerobic or anaerobic heterotrophic bacteria. Organic compounds are introduced into the subsurface, in general, via burial of detrital organic matter or as solutes that are transported to the subsurface in the form of dissolved organic carbon (DOC) in waters that percolate downward and recharge aquifers. Microbial generation of energy in deep subsurface environments results from biochemical reactions involving the oxidation of reduced compounds and the subsequent transfer of electrons to an adjacent oxidized compound. It is these metabolic processes that have a great impact on microbial ecological interactions in the subsurface and subsequent impacts of microbial metabolism on groundwater geochemistry and geological processes such as diagenesis (1). This article will provide an overview of the sources of energy that drive microbial metabolism in the subsurface and the physical constraints on the presence and function of subsurface microorganisms. The distributions and general characteristics of microorganisms in the subsurface will be examined and critical issues with regards to sampling the subsurface and enumerating associated microorganisms will be discussed. Finally, the extent of the subsurface biosphere on the Earth will be explored along with how this concept has focused the search for life elsewhere in the solar system to the subsurface of other planetary bodies.

ENERGY SOURCES

Microbial processes involving energy generation are constrained mainly to electron transfer reactions involving the following elements: hydrogen, carbon, nitrogen, oxygen, sulfur, manganese, and iron. The scale of redox couples involving these elements and the relative energy yield of each reaction is shown in Figure 1. The electron activity, shown as ε^0 or the negative log of the electron activity in the diagram, is defined as:

$$p = -\log\{\varepsilon\} = p + 1/n \log\{\text{oxidized}\}/\{\text{reduced}\}$$

where {oxidized} and {reduced} are the activities of the oxidants and reductants, respectively. The redox couples are shown in descending order in Figure 1, from the strongest oxidants at the top to the strongest reductants at the bottom. From this diagram it can be seen that, from a thermodynamic standpoint, it is feasible to couple the oxidation of organic carbon to carbon dioxide using O_2, NO_3^-, MnO_2, FeOOH, or SO_4^{2-}. Figure 1 also provides the ΔG values for the oxidation of organic carbon coupled to various microbial electron acceptors: these values indicate that the oxidation of organic carbon should occur sequentially, beginning with the reduction of O_2, the most thermodynamically favored reaction, in descending order through methane fermentation. From microbial and geochemical standpoints, there are a number of factors that can influence the sequence and extent of these reactions, such as the bioavailability of substrates and reaction kinetics. However, at macroscopic scales in systems where microorganisms are active, such as a sediment–water interface or along an aquifer flowpath, the sequential utilization of the oxidants as

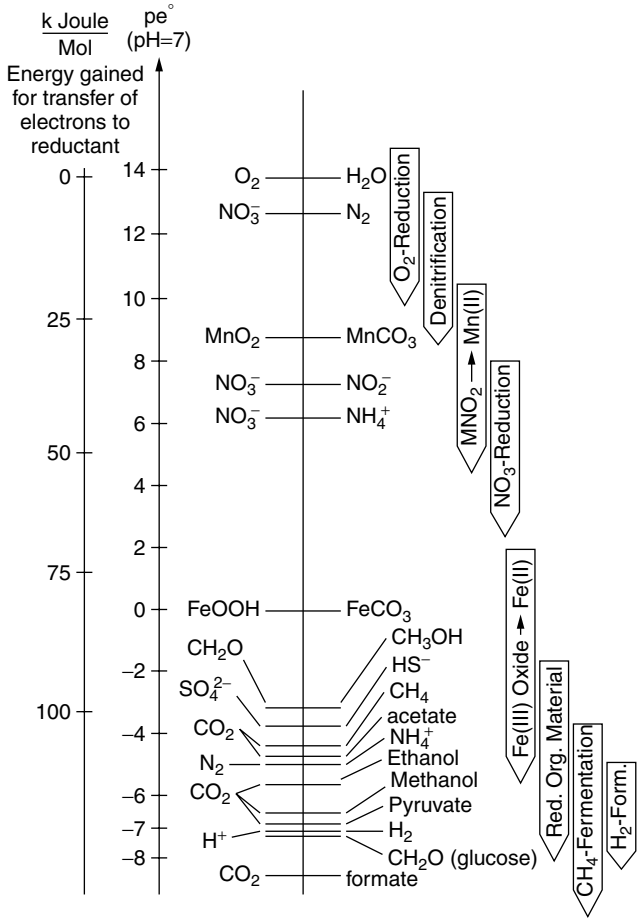

Figure 1. In a closed aqueous system, the oxidation of organic matter is achieved predominantly via microbial metabolism. Oxidation of CH_2O is coupled to the reduction of electron acceptors in order of decreasing $p\varepsilon$ or increasing thermodynamic favorability, From Reference 2, with O_2 being consumed first, followed by nitrate, Mn(IV), and so on.

electron acceptors can be observed readily. The change in relative concentration of redox active aqueous species with increasing distance along an idealized groundwater flowpath is shown in Figure 2.

One of the principal carbon and energy sources in sedimentary depositional environments is organic matter; this also holds true for many terrestrial subsurface environments. Dissolved or colloidal organic matter is likely only a significant source of reductant in shallow (<50 m) aquifers; whereas sediment-associated (detrital) organic matter of terrestrial or marine origin and soluble hydrocarbons are believed to be major sources of carbon and energy for microorganisms in deeply buried sediments and sedimentary rock. Another potentially important source of energy for deep subsurface microorganisms is methane. Although most deep terrestrial groundwaters are anoxic, methane is oxidized in anaerobic sediments (4). More recent evidence suggests that methanogens operating in reverse (oxidizing methane to hydrogen and carbon dixoide) in cooperation with sulfate-reducing bacteria may be key microorganisms in anaerobic methane oxidation in sediments (5). Given the widespread occurrence of methane in the deep subsurface, it is possible that it may be a significant source of energy for microbial metabolism, particularly in environments with significant concentrations of sulfate or Fe(III).

In addition to organic carbon, reduced inorganic elements, for example, Fe^{2+}, Mn^{2+}, S^{2-}, or H_2, can also provide reducing power for microbial metabolism. These reactions are particularly favorable when coupled to a strong oxidant such as O_2 (Fig. 1), but some microorganisms can gain energy from oxidation of some reduced inorganic species coupled to weaker oxidants such as nitrate. Microorganisms that can derive energy from the oxidation of inorganic compounds for metabolism and growth are termed *chemolithotrophs* or *chemolithoautotrophs*. Reduced inorganic species may be the dominant source of energy for microorganisms in some deep terrestrial subsurface environments, particularly those dominated by hard rocks, such as basalt (6,7) or granite (8), where organic carbon is scarce or absent. The extent to which H_2 drives deep subsurface microbial metabolism on a global scale is yet to be determined. There are a number of processes by which H_2 can be generated in deep geological strata (9) but these must be further explored and quantified before the theory of a deep biosphere driven by H_2 can be confirmed.

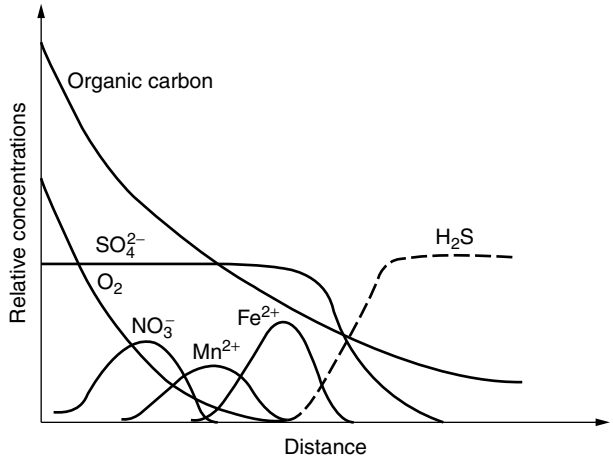

Figure 2. Changes in groundwater concentrations of ions reflecting the influence of microbial metabolism along an aquifer flowpath (3).

PHYSICAL CONSIDERATIONS

It is clear that microorganisms have evolved or adapted to occupy essentially any niche in which energy can be obtained from oxidation/reduction reactions involving organic and inorganic species, as long as those reactions have a favorable *G*. The ability of microorganisms to survive or even thrive in environments in which energy is theoretically available is influenced by a number of biological and abiotic factors. In the deep subsurface, as in other environments, the distribution, community composition, and activity of microorganisms are largely a function of the chemical and physical properties of the environment.

Assuming permissive temperatures and available energy, available pore space and water are two important requirements for microorganisms in the subsurface. Because of their small size, generally 1 mm or less, prokaryotes are more widely distributed in the subsurface than are microeukaryotes (10). Therefore, subsurface environments are microbial ecosystems that, with the exception of shallow, organic-contaminated coarse-grained aquifers (11), are generally free of microeukaryotic predators.

Spaces in rocks and sediments consist of pores of various sizes, fractures or fissures and, more rarely, macroscopic cavities. Pore size and interconnectivity are important factors controlling microbial presence and activity, particularly in sediments and sedimentary rocks. Pore size can have a direct impact on microorganisms. For example, the size of most bacteria, the dominant microbial inhabitants of deep subsurface environments, ranges from several tenths of a micron to approximately 10 μm. Therefore, bacteria are generally absent or inactive in rock or sediments where the pores average less than several tenths of a micron in diameter. For example, in deep core samples collected from a shale-sandstone sequence in northwestern New Mexico, no metabolic activities were detected in samples where pore throats were 0.2 μm or less (12). In contrast, significant activities were detected in cores with most of the porosity associated with pores from 0.2 to 15 μm. Interestingly, in some of the poorly permeable shales with small pore throats, viable sulfate-reducing bacteria were recovered and reduction of $^{35}SO_4^{2-}$ was detected (13). It has been postulated that bacteria in low-permeability subsurface sediments and sedimentary rocks may be remnants of microbial communities associated with sediments during deposition (14,15), but such hypotheses have proved difficult to test. Interestingly, the transition zones between poorly permeable but organic-rich and permeable but organic-poor strata appear to be regions of the subsurface that are relatively productive and contain a diverse microbial community that oxidizes detrital organic matter associated with the poorly permeable material (13,16,17).

Water availability (potential) and water content are also important factors impacting the ability of microorganisms to survive and function in the subsurface. Water availability and content are an important concern to microorganisms residing in the vadose zone. A detailed discussion of water availability is beyond the scope of this article and is discussed in greater detail in the articles in this section by Kieft and Brockman.

MICROBIAL DISTRIBUTIONS IN THE SUBSURFACE

The geological history of the subsurface influences the rate and age of water flowing through the system, the porosity and permeability, and the chemical composition of the rocks or sediments that ultimately influences aqueous geochemistry and nutrient availability. Although not a complete listing, Table 1 provides a number of examples of geological environments representing regional or intermediate flow systems (18) that have been sampled for microbiological analyses. Table 1 is arranged in sections beginning with sediments, followed by consolidated and indurated rock, and finally groundwaters from deep subsurface environments.

Examination of a limited data set comprising broad level measurements, such as microbial biomass and viable bacteria, does not allow the development of specific conclusions regarding ecological relationships between the microorganisms and the subsurface environment. However, there are several striking and important aspects to this summary. With the exception of the Atlantic Coastal Plain (ACP) sediments sampled on the U.S. Department of Energy's Savannah River Site (19,20), the estimates of microbial biomass associated with subsurface sediments and rocks are several, and in some cases many, orders of magnitude below the biomass in near-surface sediments and soils. Although this result might be expected, low biomass is an important feature of deep subsurface environments and impacts how scientists view and study the interactions of subsurface microorganisms with their environments.

Another important implication of the information presented in Table 1 is the relative paucity of microorganisms in consolidated and indurated rock; many of the samples investigated had microbial biomass levels near or below limits of detection. Although evidence for microorganisms being present in these environments is strong, there are equally as many or more instances of samples where microorganisms were not detected. All of these studies used extensive precautions to reduce and measure contamination during sampling. Nevertheless, it is extremely difficult to eliminate all contamination, an issue that will be discussed in greater detail in the following section. In fact, it is a testament to using rigorous procedures that microorganisms were below limits of detection in many samples. The paucity of microorganisms in these environments is expected because the lack of nutrients, water, pore space, and so on, would not be expected to support extensive microbial populations. Not surprisingly, scientists investigating these environments have had a tendency to focus on samples in which cells are observed directly or indirectly via growth in enrichments. Yet, it is also important to note environments where the populations of microorganisms are below detection using standard methods. This information provides important constraints on the types of environments that microorganisms may inhabit in the subsurface and illustrates their common patchy distribution (34).

In some contrast to rock cores, groundwaters sampled from aquifers invariably harbor bacteria at densities between 10^3 and 10^6 mL^{-1}. Valid concerns have been raised as to whether organisms associated with groundwater sampled from wells represent indigenous subsurface microorganisms, allochthonous microorganisms that colonized the well following construction, or both. Sterile solids suspended in groundwater wells were rapidly colonized by bacteria (35); the source of these organisms was believed to be indigenous aquifer bacteria. Also, recently established wells contain higher populations of bacteria than do older established wells (36), indicative of a disturbance-enhanced population. In spite of these concerns, bacteria are invariably observed in waters flowing from fissures in mines and in groundwater from established wells that have been purged to eliminate any organisms associated with stagnant water in the well bore (29), indicating they are indigenous groundwater microorganisms.

The common occurrence of microorganisms in groundwaters, almost regardless of environment, should not be surprising because bacteria are dependent upon diffusion, through water, of substrates to and of products from cells for metabolism and growth. Groundwater from wells or fissures originates from the most transmissive zones of the aquifer, and these are the zones that typically have adequate pore space and higher fluxes of nutrients to support microbial populations. Hence, deep terrestrial environments through which water is readily transmitted are more favorable habitats for microbial populations than are regions where pore spaces or fractures are small or nonconductive (12,37).

SAMPLING AND MICROBIAL ENUMERATION ISSUES

Microbiological investigations of deep subsurface environments present an exceptional challenge to scientists for several reasons. The most difficult obstacle is also the most obvious one, accessibility. Other than access via mines (26,38), caves (39), and tunnels (40), the main approach for obtaining subsurface rock and sediment samples for microbiological and geochemical analysis is via drilling and coring. Considerable effort has been directed toward adapting and modifying drilling and coring approaches for obtaining subsurface samples suitable for microbiological and geochemical analyses and for applying tracers, appropriate controls, and so on, to measure and account for contamination (41–43), and this topic is discussed in greater detail in other articles in this section. In spite of these efforts, it is extremely difficult to eliminate and measure low levels of microbiological or chemical contamination, especially when sampling environments that are deep (>300 m) and require the use

Table 1. Microbial Biomass in the Deep Terrestrial Subsurface Environment

Site Description	Geology/Sample Type	Microbial Biomass	Biomass Method	Notes	References
Atlantic Coastal Plain; Black Creek Formation	Lower delta plain sediments; lignite, Fe sulfides	10^5 to 10^6 CFU g^{-1}	Viable plate counts	Aerobic heterotrophs	19,20
		4×10^6 to 4×10^7 cells g^{-1}	Acridine orange direct counts	Total bacteria	
Atlantic Coastal Plain; Middendorf Formation	Upper delta plain sediments; fine to coarse sands	10^2 to 4×10^7 CFU g^{-1}	Viable plate counts	Aerobic heterotrophs	19,20
		8×10^5 to 7×10^7 cells g^{-1}	Acridine orange direct counts	Total bacteria	
Atlantic Coastal Plain; Magothy and Patapsco Formations	Fluvial sands, gravels, clays	10^4 to 10^5 cells g^{-1}	Acridine orange direct counts		21
		10^2 to 10^4 cells g^{-1}	Direct viable counts[a]		
South Central Washington; Ringold Formation	Lacustrine; compact silty clay	<1 to 10 MPN g^{-1}	Most probable number	Anaerobic (fermenters)	22
		$<4 \times 10^4$ to 10^5 cells mL^{-1}	Acridine orange direct counts	Total bacteria	21
		<0.5 to 45 pmol PLFA g^{-1}	Total phospholipid fatty acids[b]	Total bacterial biomass	14
South Central Washington; Ringold Formation	Paleosol; clay, silt, sand, carbonate nodules	<1 to 10 MPN g^{-1}	Most probable number	Anaerobic (fermenters)	22
		$<4 \times 10^4$ to 2×10^5 cells g^{-1}	Acridine orange direct counts	Total bacteria	22
		<0.5 to 1 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacterial biomass	14
Nevada Test Site; Rainier Mesa	Zeolitized tuff with perched water	7×10^4 CFU g^{-1}	Viable plate counts	Aerobic heterotrophs	23
		6×10^7 cells g^{-1}	Acridine orange direct counts	Total bacteria	
Western Colorado, Piceance Basin, Wasatch Formation	Cemented sandstone; cross-bedded siltstones and shales	Occasional cell growth	Enrichments	Iron-reducers, fermenters	24
		<0.4 to 10.1 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacteria	
Northwestern New Mexico, Cerro Negro site, Clay Mesa Formation	Shale; low permeability, high total organic carbon and total sulfur	Cell growth in one of four samples	Enrichments	Sulfate-reducing bacteria	12
		<0.4 to 4.2 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacteria	
Northwestern New Mexico, Cerro Negro site, Cubero Formation	Sandstone; high permeability, low total organic carbon and total sulfur	No growth in five samples	Enrichments	SRB, fermenters	12
		<0.4 to 1.5 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacteria	
Northern Virginia, Taylorsville Basin	Shale, siltstone, sandstone	Below detect to 10^5 MPN g^{-1}	Most probable number	Dissimilatory iron reducers	25
South Africa, Witwatersrand Basin	Mineralized carbon leader	3×10^7 to 7×10^7 cells g^{-1}	Acridine orange direct counts	Total bacteria	26
		<0.4 to 62 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacterial biomass	

Table 1. (*Continued*)

Site Description	Geology/Sample Type	Microbial Biomass	Biomass Method	Notes	References
Central Sweden, Stripa mine	Groundwater from quartzbanded hematite/granite	1.6×10^3 to 2.3×10^5 cells mL^{-1}	Acridine orange direct counts	Total bacteria	27
	Glass slides contacted with groundwater for 56 to 117 days	2.2 to 5.5×10^6 cells cm^{-2}	Acridine orange direct counts	Total bacteria	
Southeastern Sweden, Äspö rock laboratory	Groundwater associated with granites	7.5×10^4 to 1.8×10^6 cells mL^{-1}	Acridine orange direct counts	Total bacteria	27
		4.1×10^2 to 3.9×10^4 CFU mL^{-1}	Viable plate counts	Anaerobic heterotrophs	
South Africa, Witwatersrand Basin	Groundwater	5×10^4 cells mL^{-1}	Acridine orange direct counts	Total bacteria	26
		<0.4 pmol PLFA g^{-1}	Total phospholipid fatty acids	Total bacterial biomass	
Gabon, Africa, Oklo natural reactors	Groundwater from wells penetrating Oklo uranium deposit	4.5×10^4 to 5.8×10^5 cells mL^{-1}	Acridine orange direct counts	Total bacteria	28
South Central Washington, Columbia River Basalts	Groundwater (artesian) from Priest Rapids aquifer	3.6×10^3 cells mL^{-1}	Acridine orange direct counts	Total bacteria	29
		$\geq 10^4$ organisms mL^{-1}	Enrichments	H_2 acetogens[c]	
South Central Washington, Columbia River Basalts	Groundwater (artesian) from Grande Ronde aquifer	7.6×10^5 cells mL^{-1}	Acridine orange direct counts	Total bacteria	29
		$\geq 10^4$ organisms mL^{-1}	Enrichments	H_2 acetogens, H_2 SRB	
North Central Montana	Groundwater from Madison Formation	0.8 to >240 MPN mL^{-1}	Most probable number	Thermophilic SRB	30
		1.0 to 1.3×10^3 mL^{-1} to 1.3×10^3 mL^{-1}	Acridine orange direct counts	Total bacteria

[a] Direct viable counts as determined using the method developed by Kogure and coworkers (32).
[b] A conversion factor of 5×10^5 cells μmol^{-1} for bacterial biomass in subsurface sediments has been reported (33) although this value is likely to vary by as much as one order of magnitude because of variations in cells size, degree of starvation, and so on. A value of 0.4 μmol PLFA g^{-1} is considered background.
[c] Acetogens that can grow with hydrogen and carbon dioxide.

of rotary drilling and coring equipment. This is particularly important considering that microbial populations in deep subsurface environments are typically sparse (Table 1). It is often difficult to state unequivocally that a specific microorganism or population of organisms came from a specific sample, particularly one that was obtained using rotary mud drilling and coring. The careful use of innovative drilling and coring techniques to minimize penetration of fluids or other contaminating materials into cores combined with aseptic sampling methods and the use of sensitive tracer techniques can greatly improve the quality of such samples and the confidence that they are representative.

Mines, tunnels, and caves can provide excellent opportunities for studying deep subsurface microorganisms and the processes they catalyze. However, there are a number of factors that must be considered when accessing mines for sampling to investigate indigenous microorganisms; these factors have been discussed in detail by Russell (38). A major consideration is that mines often develop microbial communities that appear in response to the development and operation of the mine and, therefore, may not be representative of indigenous endolithic microorganisms. The flow of air associated with ventilation systems can promote the development of aerobic lithoautotrophic biofilms on rock surfaces or is associated with reduced groundwater that seeps into the mine. Ventilation systems and routine mine operation can disperse allochthonous microorganisms throughout the mine. Therefore, it is important to access fresh rock surfaces, well away from any potential impacts from ventilation and wall surface colonization, when sampling for indigenous subsurface microorganisms. Tunnels and mines are particularly well suited for certain types of investigation,

such as establishing the spatial distributions of microorganisms (40,44).

Sampling of groundwater can also provide important insights into the microbial ecology and biogeochemistry of subsurface environments; in some cases it provides the only means for sampling the subsurface. For example, in low-porosity rock, microbial communities will be concentrated along fractures. Because of the size and the capacity for transmitting water, fractures are extremely susceptible to intrusion by drilling fluids that can harbor microbial contaminants (45). Sampling of groundwater may be the only means of obtaining representative microbial communities from such environments. When collecting groundwater samples for microbiological analysis, an important issue is whether the microorganisms associated with the water are representative of the in situ populations. Although it is assumed that most microorganisms in the subsurface are attached to solids, there is little information comparing groundwater-associated, or planktonic, microorganisms with those attached to solids (46). Also, groundwater, depending on the well configuration and screened interval distance, can represent mixed (42) water from several regions within the aquifer, whereas solids are usually considered "point" samples. Hence, mixed waters from different regions may not be characteristic of any particular section but rather constitute a composite sample (47). Vertical mixing of groundwater over a screened interval can result in considerable dilution of solutes and colloids, including suspended microorganisms. Because of these issues, the collection of samples from discreet zones within the subsurface is preferred. There are several approaches for conducting this type of sampling, including the use of a passive multilevel sampler (48) that has been applied to shallow subsurface environments (49).

GENERAL MICROBIOLOGICAL CHARACTERISTICS OF THE SUBSURFACE

It is estimated that more than 99% of the microorganisms existing in nature are not cultivated using standard microbiology techniques (50). Such estimates are based on comparisons of culturable microorganisms detected using dilution plating, or most probable number enumerations of total microbial populations measured by direct microscopic counts of cells, or analyses of biochemical components of microbial cells such as lipid phosphate or adenosine triphosphate (51). Although culturing methods have been used extensively by microbial ecologists, they are of limited application for studying subsurface microbial populations. Because of the requirements for sample dispersion to dislodge cells from particle surfaces, and dilution, the practical detection limit for direct microscopic counting of cells in sediment or rock samples is approximately 10^4 to 10^5 cells g^{-1}. The measurement of total microbial phospholipid fatty acids is one of the most sensitive techniques for estimating microbial biomass and has been applied extensively to subsurface samples (12,14,24,52). Even with this sensitive technique, the detection limits are in the low picomolar range (53) (per gram of sediment or rock), a value that corresponds to between 6×10^4 and 5×10^5 cells g^{-1} based on reported conversion factors (33,52). Microbial lipid measurements have an added advantage in that they can provide information on community composition and physiological state (54,55). One advantage of sampling microorganisms associated with groundwater is that the biomass can be concentrated by filtration (56), in effect improving the limits of detection.

Because of low levels of metabolic activity and the potential for the presence of dormant cells in many subsurface environments, a major challenge in interpreting biomass measurements is in establishing the extent to which cells are viable versus dead or moribund. A number of staining techniques have been developed, which have attempted to distinguish viable from nonviable cells microscopically on the basis of esterase activity as detected by the ability to cleave fluorescein diacetate (57) or membrane integrity using commercially available staining kits (58). These methods may have some utility in subsurface microbiology but they are also limited in that they do not work for all types of microorganisms and may not be sufficiently sensitive to measure low levels of metabolism. Because they are microscopy based, they are also subject to the problems described earlier. Measurements of diglyceride fatty acids (DGFAs) have been used as indicators of dead cells in deep subsurface samples (52) and in microcosm studies investigating bacterial survival (59). Where the ratio of DGFA to phospholipid ester-linked fatty acids (PLFA) has been used as a measure of dead to viable biomass in deep subsurface environments, the ratio often exceeds 1 (12,52,60).

Although phospholipids are rapidly turned over in sediments where bacteria are active (61), the turnover rate in low biomass deep subsurface sediments and rocks is unknown (12). Typically, the PLFA concentrations are higher in the clay-rich layers relative to sandy- or coarse-textured sediments. Establishing concentrations of viable biomass in deep subsurface environments is problematic because of detection limits imposed by currently available methods and because of uncertainties in distinguishing viable cells from dead cells.

The rates of in situ microbial metabolism in the deep subsurface are among the slowest in those environments where microorganisms are known to be active (15). Phelps and coworkers (62) estimated that the average carbon dioxide respired on a per cell basis in deep aquifer sands of the Atlantic coastal plain of the southeastern United States was 0.00002 pmol $year^{-1}$, which translates into an estimated doubling time of cells on the order of several centuries. Numerous other studies using either direct measurements of microbial activities associated with subsurface samples or indirect measures of in situ metabolism based on changes in concentrations of electron acceptors or donors along the groundwater flowpath within a pristine aquifer indicate that the rates of microbial metabolism are very slow compared to other environments. Direct measurements of microbial activity, such as those that utilize isotopically labeled substrates, often overestimate in situ activities based on groundwater analyses by as much as 10^6-fold (62).

In separate studies using chemoheterotrophic bacteria isolated from deep subsurface environments, Kieft and coworkers (52) and Amy and coworkers (63) found that the cells underwent typical starvation-survival responses observed in other bacteria, including reduction in cell volume and decreasing viability, based on the ability to grow on culture media, relative to the total number of cells. Microbial populations in deep subsurface environments are generally characterized as having a high proportion of miniaturized, nonculturable cells (64). The physiological state of microorganisms, termed *starvation-survival* (65,66), is probably common to many deep subsurface environments because of the low flux of nutrients and energy sources. In effect, deep terrestrial subsurface environments contain microbial cells that range from recently divided culturable to nonculturable cells in a state of starvation-survival to dead, moribund cells that are slowly decaying.

CONCLUSION: A PLANETARY PERSPECTIVE

Evidence accumulating over the past decade supports the existence of a global deep subsurface biosphere (67) which may extend to significant depths in the Earths crust. Thermophilic bacteria have been isolated from core samples collected at depths of 2.7 km (68,69). These bacteria have physiological characteristics consistent with the environment from which they were isolated. There have also been reports of thermophilic bacteria isolated from depths greater than 5 km (70) but, in this case, the bacteria were enriched from water samples collected from a borehole rather than from core samples. The current upper limit for microbial growth is 113 °C (71), and the upper temperature for survival under nongrowth conditions may be significantly higher. Onstott and coworkers (72) estimated the depth limits to be from 4 to 6 km for microorganisms, using a conservative 110 °C upper limit for growth and survival and average geothermal gradients of 26 and 19 °C/km for oceanic and continental crust, respectively. The presence of a deep biosphere has significant implications on global ecology, subsurface geological processes, the development and evolution of life on earth, and the search for life elsewhere in our solar system.

There have been several estimates of the total number of prokaryotes (25,73) in the subsurface, using a variety of assumptions and biomass values that represent a relatively small fraction of the subsurface. Although there is considerable uncertainty, the estimates indicate the total number of prokaryotes in the subsurface is immense, ranging from 10^{28} to 10^{30} cells, a value that exceeds the number inhabiting other regions of the biosphere (73). Additional scientific investigations are required to refine our understanding of the deep biosphere, to better define the limits and environmental controls, and to better understand the contributions of the deep biosphere to the overall functioning of our planet.

The subsurface represents a compartment of the biosphere that would have been largely protected from the effects of catastrophic events, such as asteroid collisions or major volcanic eruptions that were probably responsible for the extinction of many multicellular life forms over the history of the Earth. In addition, prokaryotes inhabiting the subsurface would be relatively shielded from the effects of long-term changes in the Earth's climate. Indeed, there is evidence in the form of microfossils (74,75) that prokaryotes have long inhabited the subsurface and that the ancient organisms functioned in a manner similar to modern subsurface microbial communities. The concept of a deep biosphere that functions independent of sunlight and is shielded from atmospheric and climactic changes has focused the search for life elsewhere in our solar system on the subsurface of Mars and Europa (76). Mars is a likely candidate for such a search as it has been suggested that there may remain some volcanic activity deep in the planet that could provide energy in the form of CH_4, H_2, or H_2S for chemolithotrophic microorganisms (77), such as those found in the Columbia River basaltic aquifers (6). Although conditions on the surface of Mars are unlikely to be conducive to microbial life as we know it, liquid water may be present beneath the surface of the red planet, which may provide suitable conditions for microorganisms. Although there appears to be sufficient information to suggest the subsurface of Mars and even Europa are logical targets for the search for life elsewhere in our solar system, the technical challenges of obtaining and analyzing samples while meeting contamination and planetary protection criteria (78) will be great.

ECOLOGY OF MARINE MICROBIAL BIOFILMS

MARION KÖSTER
LUTZ-AREND MEYER-REIL
Institut für Ökologie der
Ernst-Moritz-Arndt-Universität
Greifswald
Kloster/Hiddensee, Germany

Microorganisms attach to virtually any wetted surface submerged in aquatic environment. The cells are mostly immobilized and produce extracellular polymeric organic substances (EPS), grow and divide, thus forming the structure of an assemblage of microorganisms termed biofilm. Besides bacteria, cyanobacteria, microalgae, protozoa, fungi, and invertebrate larvae contribute to the complex structure and function of natural assemblages. The *term* biofilm is equivalent to the German word *aufwuchs* (growth on surfaces) (1). Although the latter term seems to be more appropriate because it relates to a dynamic process, it has not gained

general acceptance. To characterize natural biofilms on surfaces in aquatic environments, the adjectives epiphytic (on plants), epilithic (on rocks), and epixylic (on wood) are commonly used. The corresponding microbial communities are called epiphyton, epilithon, and epixylon, respectively.

The development of microbial biofilms is the net result of transport and exchange processes between the biofilm and the surrounding medium, and modification and decomposition processes of inorganic and organic matter within the biofilm. Biofilms consist of a mono- or multilayer of cells usually some hundred micrometers to some millimeters thick, although stabilized biofilms can grow to a thickness of some centimeters, gaining the character of mats. Biofilms and mats may be differentiated from each other by their dimensions and the stabilization, which characterize the latter. Biofilms reveal pronounced spatial and temporal heterogeneities. Besides the cells and their products, inorganic and organic material adsorb to the biofilms because of the spongy and porous structure of the complex matrix (2,3).

Although there is much information available on the attachment of bacteria to artificial surfaces of different properties as well as on the physical and chemical structure of biofilms based on pure cultures, information on the structure and function of natural microbial biofilms is much more limited. This is certainly dependent on the complex structure of natural assemblages of microorganisms which are much more difficult to analyze as compared to pure cultures. In the following review, we intend to summarize some of the information that is available on the ecology of natural marine microbial biofilms. Because virtually all available surfaces in the marine environment are covered by biofilms, the microbial colonization of sediments, plants, animals, suspended particles, and aggregates as well as of artificial (man-made) structures actually have to be considered. However, most of the information seems to be available on sedimentary biofilms. Additional information about biofilms from other habitats, and on pure culture biofilms that might be relevant for the understanding of the function of microbial biofilms in marine sediments is discussed whenever appropriate. The discussion of sedimentary biofilms, however, bears additional constraints. One is the scale of view. A biofilm already exists as an assemblage of a few cells embedded in their organic matrix on the surface of a particle, visible only by microscopic examination. Conversely, biofilms exist that are visible to the naked eye on sediment surfaces. Furthermore, it appears that almost everything that concerns the biological function of sediments relates to microbial biofilms. Dealing with sedimentary biofilms, therefore can be understood as a general discussion of the roles of microorganisms in marine sediments. This, however, is beyond the scope of the review. Instead, it focuses on the most important aspects that have specific relevance for the understanding of the structure and the function of marine sedimentary microbial biofilms.

MICROBIAL ATTACHMENT TO SURFACES

For the study of the development of microbial biofilms, various microscopic techniques have been applied, such as transmitted or incident light microscopy, and transmission or scanning electron microscopy (4). Recently, confocal laser scanning microscopy in combination with image acquisition and image analysis techniques have been used in comparison to conventional microscopic techniques (5–7). Generally, it can be concluded that confocal laser microscopy represents an invaluable tool for examinations of the spatial structure and growth of biofilms. However, species richness and relative abundance of cyanobacteria in biofilms was best enumerated by scanning electron microscopy (8).

The microbial colonization of surfaces is a matter of discussion. From the earlier work it becomes obvious that the colonization pattern generally can be divided into different phases with overlapping time sequence (9). The first step is the formation of a conditioning film of organic compounds (e.g., polysaccharides and proteins), which rapidly develops if clean surfaces come in contact with water. As a result of the decrease in the energy of the surface by the formation of the organic layer, the total free energy of the system decreases. Differences in the replication cause some doubts on the correct performance of experiments using “clean” surfaces (10). Within less than an hour after the conditioning, organisms attach to surfaces. Earlier investigations point to an obligatory order in the succession. Following bacteria, diatoms, cyanobacteria, microalgae, protozoa, fungi, and invertebrate larvae attach in the time span of hours, days, and months (4,9,11,12). Very small starvation forms of copiotrophic bacteria, adapted to growth under rich nutrient conditions, seem to be the initial colonizers. Because of the elevated nutrient concentrations on surfaces, starved bacteria may grow into rod-shaped forms (13). The subsequent appearance of oligotrophic, prosthecate bacteria, adapted to growth under low-nutrient conditions, was interpreted as a result of the exhaustion of nutrients by the initial growth of copiotrophic bacteria on the surfaces. Using a cultivation-independent genetic approach, the diversity of bacterial colonists was determined on test surfaces differing in their degrees of surface free energy. The results indicated that the succession rate of the early bacterial community may be influenced by surface physicochemical properties (14). In the literature, however, there is some doubt about the obligatory order of the sequence of colonization. Investigations imply that diatoms may colonize surfaces as rapidly as bacteria. Furthermore, problems arise from the difficulties in distinguishing between settlement on one hand, colonization and subsequent growth on the other (10).

The transport of microorganisms to surfaces is mainly governed by physical forces (4,9). Planktonic bacteria can be transported over large distances by water currents and turbulence. Fluid frictional forces slow the bacteria down in close vicinity to surfaces. Chemotactic response to a nutrient gradient around surfaces may be an additional possibility for motile bacteria to approach surfaces. After

penetrating the structured layer of water molecules surrounding all solid surfaces in water, physical forces between the cells and the surface become relevant. The cells are immobilized by antagonistic electrical repulsion and van der Waals attraction forces. During this stage the cells can be easily removed from the surface by gentle shear forces. Bacteria may overcome the electrostatic barrier by the secretion of polymers (polysaccharides, proteins, glycoproteins), which can bind the cells to the surface by various short-range forces. Therefore, the reversible attraction (adsorption) turns into an irreversible attachment (adhesion).

Results of the influence of substratum surface on the microbial attachment differ in the literature, dependent on the type of organisms and their physiological state, as well as on the experimental conditions that were not always reproducible (10). In this context, it is notable that environmental stresses (extremes of pH, high concentrations of oxygen, metals, and xenobiotics) induce formation of biofilms by an anaerobic hyperthermophilic marine bacterium (15). The attachment of bacteria to surfaces stimulates the production of extracellular polysaccharides (16). Evidence is increasing that the synthesis of extracellular polymers is the response of bacteria to (multiple) environmental signals. For a series of organisms, it could be shown that polymers used in the initial adhesive event and matrix polymers are distinct (10,17).

In a dynamic system like a biofilm, attachment and detachment occur. As a result of increased fluid shear forces, grazing, enzymatic degradation of the adhesive structures, and reproductive mechanisms, cells detach from surfaces and enter the planktonic phase (4). The extent of detachment could be derived from experiments following the rapid colonization of pure cellulose particles added to sediment suspended in particle-free interstitial water. Eventually, biofilm material is released in flocs caused by increased fluid shear forces, a process termed *sloughing*.

Equations have been described regarding attachment and growth during surface colonization (18). Growth, detachment, reattachment, attachment of foreign cells, and death of single cells were included in a mathematical model for the growth of bacterial microcolonies on marine sediments (19). By automated analysis of digitized images of acridine orange-stained culture cells, cellular RNA and DNA contents, cell volume, and frequency of dividing cells were determined as four independent growth rate–related parameters. Attached cells showed an almost constant growth rate that was independent of the dilution rate in the chemostat (20). Recently, a fluorimetric method with a high sensitivity based on the in vivo fluorescence of chlorophylls has been described to measure growth of adhering phototrophic microorganisms (21).

BIOFILM ARCHITECTURE AND FUNCTION

Biofilm systems generally consist of various compartments: substratum, base and surface biofilm, bulk liquid, and gas phase (22). The nature of the substratum plays an important role in the early development of biofilms. In the case of the colonization of wood or detritus, for example, the substratum may equally serve as a decomposable substrate. The base biofilm is relatively compact and well structured, and molecular diffusion dominates. The surface biofilm usually shows an irregular topography, and interfacial transfer processes dominate. The bulk liquid influences the transport of cells, material, and energy to the biofilm by its flow dynamics, and also facilitates the removal of end products of the microbial metabolism from the biofilm. The gas phase provides the supply of oxygen and carbon dioxide, and the removal of gaseous microbial metabolites (e.g., nitrogen, methane, hydrogen sulfide). The biofilm architecture is very complex. From confocal laser scanning microscopy (23), it is known that channel-like structures connect the film surface with deeper layers to allow the transport of nutrients and waste products in an otherwise diffusion-limited system. The composition of nutrients has a significant impact on the biofilm architecture. The cultivation of laboratory biofilms with a commercial herbicide and trichlorobenzoic acid, respectively, resulted in highly specific patterns of cellular coaggregation and growth, which did not develop when the biofilms were grown on more labile substrates (24,25).

Biofilms colonize stones in shallow water coastal inlets ("Bodden"), in the brackish water of the southern Baltic Sea (26). The communities grow to a thickness of some millimeters and consist of photoautotrophic and heterotrophic microorganisms (photoheterotrophic biofilms). The surface biofilm represents the photoautotrophic component mainly consisting of filamentous cyanobacteria, diatoms, and green algae. It reveals a loose structure and an irregular topography with filaments of cyanobacteria extending into the water. Bacteria and hyphae of actinomycetes were closely associated with cyanobacteria. With increasing depth, the biofilms became more dense. The compact base biofilm consisted of coccoid cyanobacteria and heterotrophic bacteria, embedded in an extensive slime matrix secreted by the organisms. The carbon content (C) of the photoheterotrophic biofilms varied between 50 and 70% of the dry weight. With increasing biofilm depth, the ratio between C and ATP (adenosine triphosphate, the energy storage of the cells) increased from 100 to 200, indicating less ATP per unit of carbon. This can be explained by changes in biofilm structure. From the surface to the base biofilm, the matrix became more dominating. Besides the cells, the matrix contributed to C, but not to ATP.

Until the early 1980s, the release of copious slime secretions (extracellular polymeric substances, EPS) by microbial cells was largely overlooked (27). Exopolymers are abundant as capsules closely surrounding microbial cells or as a dispersed slime in colloidal and particulate form. Microorganisms spend a large portion of their carbon and energy supply (up to about 60%) for the production of extracellular secretions, which primarily consist of polysaccharides including other components (e.g., amino acids, amino sugars, uronic acids and glycoproteins) of high molecular weight. The porous gel structure and the highly adsorptive nature of EPS are responsible for a number of biological functions, which enhance the survival and the competitive success of microbial cells.

Table 1. Functions of the Extracellular Organic Matrix for Biofilm Microorganisms and Their Environment

Functions of EPS	Literature

Inhibition, facilitation of settlement of larvae	37
Trophic source	36
Stability of detritus, sediments	2,131

The fibrous polymer matrix plays a key role for the organisms and their environment (Table 1). EPS contribute to the attachment of cells, although not all exopolymers secreted are involved in adhesion. Different types of extracellular polymers are secreted by microbial cells for different functions (i.e., attachment, detachment and movement on surfaces). Through the secretion of polymers around the cells, microorganisms create and maintain favorable microenvironments, which allow them to use carbon and energy efficiently. Extracellular enzymes can act in close proximity to the cells, and decomposition products of the hydrolysis of higher molecular weight material can be directly taken up by the cells. Extracellular enzymes liberated through the lysis of organisms bind to the exopolymers, which may protect the enzymes from degradation, in a manner analogous to the enzyme-humic complexes observed in soil (28). If the enzymes retain their activities, they may play a role as biocatalysts of considerable benefit for biofilm cells in their surrounding. In defined bacterial biofilms, high rates of conjugative gene transfer were observed (29). Because of its capacity to retain water, bacterial slime protects the cells against rapid changes of environmental conditions (e.g., pH, desiccation). The biofilm matrix and the deposition of ultraviolet (UV)-absorbing compounds act as a sunscreen to protect the microbial communities against UV radiation damage (30,31). Cyanobacteria apparently are able to sense UV radiation and respond by migration to limit their exposure to UV light (32).

Exopolymers possess high binding affinities for organic material through the cation exchange processes. Organic material can be concentrated and subsequently metabolized, and this is of special importance under poor nutrient conditions (33,34). Biofilm formation represents an effective mechanism by which starved cells can rapidly recover in environments of an intermittent nutrient supply (35). Besides nutrients, exopolymers bind metals and other poisons, thus presenting a general mechanism for detoxification.

The role of bacteria in symbiosis and syntrophic relationships obviously depends on secretions of polymers. Capsular EPS protect symbiotic bacteria from digestion by their host. For the colonization of heterocysts (specialized cyanobacteria cells for nitrogen fixation) by bacteria, specific polysaccharides are responsible. The slime layer reduces the diffusion of oxygen to the heterocysts, thus allowing the oxygen-sensitive process of nitrogen fixation under otherwise aerobic conditions. Although EPS can protect bacteria from grazing, the exopolymers present a potential carbon source for heterotrophic organisms, including perhaps the producers of the specific exopolymer (36). Laboratory experiments have shown inhibitory and facilitatory effects of microbial biofilms on the settlement of marine larvae (37). A glycoprotein from a gliding bacterium isolated from a biofilm inhibited the colony expansion of another bacterial strain (38). Finally, the extracellular matrix of bacteria and diatoms greatly contributes to the stability of marine sediments by increasing critical shear velocity and modifying bioroughness. For evaluating the important functions of microbial exopolymer secretions in ocean environments, the reader is referred to a comprehensive review for further details and references (39).

MARINE MICROBIAL BIOFILMS

In natural habitats, bacteria attach nonspecifically to a variety of nonbiological and biological surfaces. Specific attachment requires complementary receptors of the cell surface and the substratum. Specific polysaccharides in the EPS can bind to specific proteins (lectins) present on the attachment surface. The use of lectin probes offer a potentially useful technique for the investigation of spatial and biochemical heterogeneities of microbial biofilms (40). Information on the microbial colonization of marine surfaces is very limited. From epifluorescence and scanning electron microscopy analyses, it becomes obvious that the overwhelming portion of the microorganisms in marine sediments is attached to particles. However, the cells colonize only a very small part of the surface available on quartz sand between 0.01 and 5%, dependent on the method used (41,43). A direct comparison of these data is further restricted to the fact that cell numbers were determined applying different homogenization and staining techniques (44). Sand and silt particles are preferentially colonized, whereas clay particles are not colonized, or rarely colonized obviously because of their small size. Besides, the type and size, the roundness of the particles is important: with increasing age (roundness), the colonization decreases. Microorganisms are preferentially found in depressions and crevices of sand grains where they are protected against mechanical shear. Deep fissures of the sand grains are rarely colonized (45). The microbial occurrence in the protected areas of the sand grains is a reflection of their survival rather than their preferential colonization (43). The distribution of cyanobacteria and diatoms is the result of competition for grain sizes and temperature (46). Like many other bacteria, Bdellovibrios (bacteria that are parasites of bacteria) preferred to associate with surfaces and the numbers were significantly increased at higher salinities (47). In intertidal sand mats, the irradiance spectra were quantitatively and qualitatively correlated with the distribution of photoautotrophic microorganisms. Through their pigments, the photoautotrophs govern the penetration of light within

the mat (48). Oxygenic phototrophic microorganisms in hypersaline mats revealed a high diversity according to morphotypes, 16S rRNA genes, and carotenoids (49).

Higher organisms (plants, animals) and their biogenic structures in marine sediments are intensively colonized by microbial biofilms. Structure and function of epiphytic communities on eelgrass (50) and seagrass (51,52) reflected the nutrient availability in the water. Particular sites of marine copepods (depressed parts of the body) were colonized by bacteria of a high diversity (53,54). Infaunal burrows and tubes of worms supported elevated levels of microbial biomass and activities as compared to the bulk sediment (55–58). The stimulating effects of higher organisms and their biogenic structures on microbial communities can be understood by direct and indirect effects. Through their metabolism, plants and animals may directly provide the microbial assemblages with nutrients (for nutritional relationships between plants and microorganisms see the following section). On the other hand, through their biogenic structures (burrows, tubes), benthic animals exhibit a strong impact on sediment topography (bioroughness), thus increasing the availability of oxygen and nutrients (59).

IMPORTANCE OF GRADIENTS IN BIOFILM METABOLISM

The complex structure of microbial biofilms exhibits strong impacts on biological processes. Immobilized in their polymeric matrix, organisms metabolize in close vicinity to each other. Products released by some of the organisms can be directly taken up and metabolized by other organisms. Syntrophic interactions between microorganisms are especially pronounced in biofilms. This requires that physiological groups of organisms with complementary metabolic reactions already colonize in the vicinity. If the colonization is random, the chances of organisms with complementary metabolic reactions coming in contact with each other is low. There is no information yet known in the literature addressing this question. However, the fact that syntrophic interactions function in biofilms point to mechanism(s) of accomplishing the interactions.

From the close association of microorganisms, their high biomass, diversity, and metabolism in biofilms, pronounced gradients in biotic and abiotic parameters arise, which are the net result of various metabolic activities. It can be speculated that the gradients are the driving force for the microbial metabolism. Gradients are highly dynamic including variations in both space and time. Besides spatial and temporal fluctuations in the activity of the organisms, spatial and temporal variations in environmental conditions (e.g., light, nutrients, temperature, salinity, and currents) will greatly influence the expression of the gradients. The application of microelectrodes to biofilms turned out to be a powerful tool to follow small-scale variations in chemical parameters with a minimum of disturbance. With microelectrodes, spatial resolutions of 10 μm and less can be achieved, which characterize the direct sphere of influence of even small consortia of microorganisms. Oxygen microelectrodes were used to analyze the diffusive boundary layer as well as oxygen fluxes in sediments (60,61). Photosynthesis and respiration were calculated from the microdistribution of oxygen (62,63). Although microelectrodes are small in size, their impact on the distribution of oxygen in biological systems has to be considered (64,65). Besides electrochemical microelectrodes, fiber-optical microsensors for the measurements of oxygen, temperature, light (photosynthetically available radiation), and surface detection of biological systems have been introduced recently (66–68). Furthermore, microsensors are available for measurements of depth profiles of pH, hydrogen sulfide (69), nitrite (70), and nitrous oxide (71).

Microelectrode measurements have greatly enhanced knowledge of the impact of environmental conditions on the dynamics of biological systems. Using oxygen microsensors, it could be shown that the diffusive boundary layer covering solid surfaces in aquatic environments, is of special importance for the oxygen flux of sediment biofilms. The thickness of the layer is dependent on the flow velocity of the water and the roughness of the surface. The oxygen uptake of sediments is limited by the diffusion of oxygen through the diffusive boundary layer. Because of the restriction of the oxygen flux, sediment biofilms with high rates of oxygen consumption may become anoxic thus requiring the use of alternative electron acceptors for the oxidation of organic carbon.

ROLES OF NITROGEN, PHOSPHORUS, SULFUR, AND IRON

Limited information is available on the role of inorganic compounds (nitrogen, phosphorus, sulfur, iron) in biofilms and mats. In biofilms from nutrient-rich streams, oxygen respiration and, denitrification activity were calculated from depth microprofiles of oxygen and nitrous oxide. Denitrification occurred only in the absence or at low concentrations of oxygen, the process was determined by the penetration depth of nitrate. Most of the labile organic matter added was used by oxygen respiration in the upper layers of the biofilm (72). The availability of nitrogen and phosphorus greatly influenced the structure and nitrogen fixation of an intertidal microbial mat community. Cyanobacteria were able to circumvent the nitrogen limitation by the fixation of nitrogen, whereas diatoms were dependent on nitrogen and phosphorus in the community (73). In contrast, another study showed that the nutrient limitation of photosynthetic carbon dioxide fixation and nitrogen fixation of tidal marine microbial mats were obviously dependent on their growth rates. Mats from more productive areas showed higher frequencies of nutrient limitation, whereas slow growing tidal mats exhibited no nutrient stimulation (74). The access to phosphate supplies from the water in epiphyte communities was determined by the position of the organisms in the matrix. Loosely attached microalgae took up significantly more phosphate than did underlying adnate cells (75). Pure-culture bacterial biofilms revealed specific patterns of alkaline phosphatase expression primarily controlled by the local availability of the carbon source and the electron acceptor. The dimensions of the zone of active protein synthesis was restricted to the availability of oxygen (76,77). Significant activity

of sulfate-reducing bacteria was detected under aerobic conditions in biofilms of a hypersaline pond system. The response of sulfate-reducing bacteria to specific carbon sources in the individual layers of the mat was different, indicating different groups of sulfate-reducers and/or adaptations to different substrates (78). In aerobic trickling-filter biofilms, sulfate reduction accounted for up to 50% of the total mineralization of organic carbon. The resulting hydrogen sulfide was rapidly oxidized. Anaerobic oxidation of hydrogen sulfide with nitrate as an electron acceptor could be induced (79). The enhanced oxygen uptake of artificial cyanobacterial mats in the light reflected to a large extent the reoxidation of reduced endproducts (notably reduced sulfur) accumulated during darkness (80). In an aerobic bacterial biofilm, sulfate-reducers were present in the oxic and anoxic zones. The genetic diversity of the microbial community increased during the development of the biofilm. Sulfate-reducers detected by molecular analysis were not all sulfidogenically active in the biofilm (81). Facultative aerobic respiration, filamentous morphology, motility, diurnal migration, and aggregate formation were the most conspicuous adaptations of sulfate-reducing bacteria to the life in hypersaline cyanobacterial mats of Solar Lake (82).

Biofilms are able to concentrate minerals from extremely diluted environmental conditions (83,84). The binding of iron and manganese by surface-colonizing bacteria in a lake was accompanied by the fixation of carbon dioxide (13). In epilithic biofilms investigated in an underground research laboratory, elements were chemically complexed together to form amorphous or crystalline fine-grained minerals. The elements were thought to be concentrated by passive sorption and by energy metabolism. One of the biofilms showed both, oxidation and reduction of iron (85). The most abundant mineral associated with epilithic river biofilms was a complex iron-aluminum silicate of variable composition. It was concluded that biomineralization was a surface process associated with the anionic nature of the cell wall (86). An iron deposition associated with cyanobacteria mats was observed in hot springs. Iron was totally oxidized at the surface, whereas reduced iron was detected in greater depths of the mat. It was speculated that photoautotrophs could potentially increase the rate of iron oxidation by increasing the pH and the oxygen concentration (87).

In general, these results seem to indicate that the microbial assemblages are dependent on the uptake of nitrogen and phosphorus from the water, in their metabolism, to maintain a certain structure and/or activity. In marine environments, sulfur seems to be an important alternative electron acceptor besides oxygen for the oxidation of organic material carried out by a high diversity of sulfate-reducing bacteria adapted to various substrates. The oxidation of reduced sulfur compounds causes an enhanced oxygen demand of the community. The accumulation of iron occurs by passive sorption or by energy-yielding reactions carried out by chemoautotrophic microorganisms. The participation of both processes, however, needs further investigation.

POOLS AND SOURCES OF ORGANIC CARBON

Organic material plays a key role in aquatic environments. Particulate organic carbon (POC) represents the majority portion of organic matter in sedimentary systems, whereas dissolved organic carbon (DOC) dominates in water. The pools of DOC and POC consist of a broad variety of material, most of which is only poorly chemically identified. Because organisms contribute through the lysis of cells to the pool of organic matter, one can expect to find the whole spectrum of organic material characteristic for organisms in their habitats as well.

The microbial utilization of particulate or polymeric organic material requires processes by which the material is degraded into products that can be taken up by the microorganisms. The enzymatic decomposition of high molecular weight material is the initial and rate-limiting step in organic carbon oxidation (88). The hydrolysis processes are mediated by extracellular enzymes that are produced by the cells. The enzymes act in close vicinity to the cells, bound to the outer membrane or in the periplasm (89), which enables the cells to take up the hydrolysis products efficiently. Investigations have shown that the colonization of particles is a prerequisite for their microbial decomposition. Dead and decaying organisms also contribute to the pool of extracellular enzymes. As shown in soils, the enzymes may escape degradation by binding to humic acids bound to clay particles. They may act as "starter" enzymes for the degradation of substrates (28). For the determinations of enzymatic activities, chromogenic and fluorogenic model substrates are available. The release of the corresponding dyes serves as a measure of enzymatic response (90–92).

The DOC pool can be operationally divided into a refractory and a labile fraction. The former is more resistant to microbial attack (turnover times in the range of months and years), whereas the latter is easily available. The labile portion represents the carbon microorganisms rely on to meet their carbon and energy demands on a short-term scale. This fraction has to be continuously recycled to allow microbial metabolism. Because chemical analyses of DOC permit only a limited assessment of its bioavailability, information on the available organic carbon (ADOC) is of special interest. There have been a few attempts to determine concentrations of ADOC in waters and sediments, mostly relying on the growth of test organisms as a reflection of available carbon in filtered water or extracts of sediments (93). Recently, a biosensor for the fine-scale measurement of ADOC has been developed. This biosensor consists of an oxygen microelectrode with microorganisms attached to the tip. The oxygen consumption of the immobilized cells serves as a measure for ADOC. The response of the biosensor is sensitive and rapid. ADOC is defined with respect to the metabolic activities of the test organism chosen and the carbon source used as standard (94).

The understanding of the carbon dynamics in aquatic ecosystems has been enhanced during recent years. The adsorption of dissolved organic matter to particles (95–100) was a mechanism that supposedly "stored" labile organic carbon temporarily (101). In addition, the

sorptive preservation of labile organic carbon to mineral surfaces was shown for marine sediments (102). The concept of "storage" of labile organic carbon is supported by the observation that the adsorption of low molecular weight compounds to a hydroxyapatite surface decreased their biodegradation rates (103).

Heterotrophic microbial biofilms are ultimately dependent on the uptake of carbon from the surrounding water. On the basis of experiments with boreal river epilithon, it was discussed that slowly metabolized high molecular weight compounds from the water saturate adsorption sites on the epilithon surface. No sooner than these compounds are removed, labile low molecular weight molecules are more readily adsorbed (104). In communities consisting of photoautotrophic and heterotrophic organisms (photoheterotrophic biofilms), the autotrophs may supply the heterotrophs with carbon.

NUTRITIONAL RELATIONSHIPS IN PHOTOHETEROTROPHIC BIOFILMS

The production of photoautotrophic organisms in epilithic biofilms from shallow water coastal inlets of the southern Baltic Sea (Bodden) amounted to approximately 100 mg C/m^2 h (26). The data are close to maximum values reported for epilithic biofilms in rivers (105). Compared to the microphytobenthos and the phytoplankton in the Bodden, epilithic biofilms revealed production rates that were higher by a factor of 2 and 100, respectively. However, the productivity (taking into account chlorophyll a) of the biofilms was by 10 to 100 times lower as compared to the pelagic and benthic production, respectively (106,107).

Nutritional relationships can be expected from the close spatial associations between photoautotrophic and heterotrophic microorganisms. This is supported by a number of investigations carried out in epilithic biofilms in streams (105). It could be shown that there was a direct flux of soluble algal products to the bacterial populations, with little heterotrophic utilization of dissolved organic material from the stream water (108). Bacterial heterotrophic activities significantly decreased as the photoautotrophic community declined (109). The marked lack of response of the epilithon to the external nutrients was attributed to the nutrient supply by the photoautotrophs. Attached microbial communities grown without algae were strongly dependent on riverborne organic material (110). Bacteria associated with algae grew twice as fast in the light as in the dark (111).

Under low-nutrient conditions in the bulk water, diatom-bacteria consortia exhibited higher growth rates as compared to biofilms composed solely of bacteria (112). Marine epiphytic biofilms were closely coupled to exudation products from the primary production of eelgrass (113,114). The significant relationship between bacterial abundance and chlorophyll a in marine sediments was attributed to the release of extracellular material by the microalgae (115). A close association of heterotrophic microorganisms taking up dissolved organic matter with photoautotrophic organisms was observed in intertidal marine microbial mats (116). Photoheterotrophic microbial mats from intertidal and subtidal environments appeared to mediate coupling between autotrophic and heterotrophic processes, thus minimizing losses of fixed carbon and nitrogen from the system (74). In sedimentary biofilms of the Bodden (shallow water inlets of the southern Baltic Sea), concentrations of available organic carbon (determined with a biosensor) of up to 80% of the total dissolved organic carbon were measured. Relationships between ADOC and concentrations of chlorophyll a imply that the labile organic matter was supplied by the photoautotrophs (117). In this context it has been inferred that legionellae grew extracellularly in the absence of amoebae in tap water biofilms, obviously supplied with sufficient nutrients by the bacterial consortium (118).

Although there is no doubt about the trophic relationships between photoautotrophic and heterotrophic components in microbial biofilms, the mechanisms are poorly understood. This applies to the transport and to the chemical nature of the exudates. Microscopic observations confirmed that a number of bacteria in photoheterotrophic biofilms were closely associated with cyanobacteria and algae, thus facilitating the nutrient transfer (26). However, the majority of bacteria within the matrix must be dependent on the transport of substrates to the cells. From the response of sulfate-reducing bacteria in cyanobacterial mats to the addition of specific carbon sources, it may be concluded that glycolate was an important product released by the cyanobacteria (78).

An unknown (probably the largest) part of the organic matter supplied from the surrounding water or by primary production in biofilms is high molecular weight material and has to be decomposed by extracellular enzymes before the uptake by microorganisms. In river biofilms, the accumulation of extracellular enzymes has been demonstrated. The spectrum of hydrolytic enzymes comprised phenol oxidase, peroxidase, α- and β-D-glucosidase, *N*-acetyl-β-D-glucosaminidase, and phosphatase (105,119). In sedimentary biofilms, proteolytic enzymes contributed to the spectrum of hydrolytic enzymes as well (90,91,120,121). Deep-sea sediments are exclusively dependent on the supply of nutrients from the water via sedimentation. The association with particulate matter or with higher organisms seems to be a strategy of microorganisms to come in contact with decomposable organic material (122,123). Laboratory experiments have shown that deep-sea microbial assemblages specifically responded to the addition of nutrients (88,124). Within less than a few days, enzymatic activities increased. It is of interest that the hydrolysis products were primarily respired by the sedimentary microorganisms, yet their biomass production was delayed (121). Extracellular enzymatic activities were used to characterize the accumulation of refractory substances in marine aggregates. With increasing succession from marine snow to gel-like aggregates (increasing age), the ratio of α-D-glucosidase activity to β-D-glucosidase activity declined, which implies the accumulation of more recalcitrant β-1,4-linked polymers (125).

Determinations of enzymatic activities using chromogenic and fluorogenic model substrates contributed to our understanding of substrate decomposition in aquatic environments. However, the interpretations suffer from

a number of limitations. Because artificial (mostly soluble) substrates are applied under laboratory conditions, the data describe potential activities rather than actual degradation rates. As justification, it may be accepted that the activity of naturally occurring enzymes is measured, and that these have been produced by the organisms as a response to preceding variations in the natural food supply. Most of the measurements represent more a reflection of the spectrum of labeled substrates commercially available rather than a reflection of the spectrum of enzymes naturally occurring which is, as well as the spectrum of natural substrates, almost unknown. The "standardization" of enzyme activities based on cell numbers is more than misleading because the number of cells responsible for the enzyme activities is not known. Even if the number of active cells are known, it must be assumed that enzymes of unknown origin (not bound to individual cells) contribute to the activities as well. Further progress can only be expected if the pool of naturally occurring enzymes and their substrates, the microorganisms implicated, and the location of the enzymes are identified.

The development and activities of marine biofilms reflect the gradient of nutrient enrichment (eutrophication) in the water column. Epiphytic biomass on eelgrass increased with increasing concentrations of total nitrogen. The increase was more than tenfold higher than the increase in phytoplankton biomass (50). The effect of nutrient enrichment on epiphyte levels across a nutrient availability gradient was pronounced (52). The gradient of nutrient enrichment in coastal inlets of the southern Baltic Sea (Bodden) was clearly reflected by the contribution of primary production and heterotrophic decomposition processes (respiration, enzymatic activities) in epilithic biofilms. With increasing eutrophication, photosynthesis decreased and respiration processes became more dominant. Respiration accounted for about 20% of the photosynthesis under mesotrophic conditions, whereas under polytrophic conditions about 70% of material produced by primary production was respired (26), thus leading to anaerobic conditions below the biofilm surface. From the spectrum of hydrolytic enzymes analyzed in sedimentary biofilms in the Bodden, it may be concluded that proteolytic enzymes gain more importance with increasing eutrophication (120).

DISTURBANCE OF BIOFILMS

Disturbance of biofilms occurs by grazing and physical forces. Zooplankton and benthic animals have strong impacts on microbial biofilms and mats by grazing and physically destroying the microbial assemblages (126). However, grazing may keep the microorganisms in an active stage of growth (4). Physical disruption of hot spring cyanobacterial mats resulted in substantial structural and physiological changes of the mats (127). High sediment transport rates produced significant abrasion in the abundances of bacteria and diatoms on particles in marine sediments. Only microorganisms colonizing protected areas of the sand grains were protected against abrasion (128). This underlines the conclusion that the microbial occurrence in crevices and depressions of sand grains is more a reflection of survival rather than preferential colonization (44). Water movements caused by storm events initially reduced the diversity and activities of biofilms, however, subsequent enhanced growth led to a recovery within days (105). It is interesting to note that drifting green algae covering diatom mats exhibited no adverse effects on the biomass of benthic communities. This points to mechanisms of the diatoms to adapt to reduced light conditions (129). However, epiphytic biofilms developing on different freshwater and marine macrophytes caused a severe stress to their hosts because of shading and oxygen depletion during intensive respiration (130).

In shallow coastal environments, water movements lead to a resuspension of sediments caused by low wind speeds. The unconsolidated fluffy layer covering sediment surfaces in protected coastal areas, in particular, is easily resuspended. The effects are the release of inorganic and organic nutrients, pollutants, and the accumulation of particles in the water. Microbial biofilms colonizing particles are exposed to conditions that differ from those experienced in the much more densely packed particles in the sediments. Competition effects are reduced, and concentration gradients of nutrients and oxygen are diminished. Microbial assemblages generally respond to resuspension of sediments with enhanced activities. However, the accumulation of particles in the water may restrict the light availability for photoautotrophic microorganisms. During resuspension, planktonic microorganisms may colonize the particles, and inorganic and organic dissolved and particulate material may adsorb, thus changing the biological and chemical milieu and the composition of the particles. After transport and sedimentation of the particles, the attached microbial communities have to adapt to the life in the sedimentary environment again. Because information on the structure and function of microbial assemblages on particle surfaces in the water ("snow") has greatly increased during the recent years, this interesting subject requires separate attention.

CONCLUSION

Biofilms consisting of complex assemblages of immobilized microorganisms and their matrix represent an early evolutionary stage in the organization of organisms. Although the individual members of the biofilm community are to a certain degree independent, there exists a high microbial interspecific coordination in the transfer and use of energy and substrates. This results in pronounced gradients in biological, chemical, and physicochemical parameters, which are no longer the response of individual organisms, but the effects of microbial communities. The organization in biofilms may be regarded as a strategy for survival and competitive success of microorganisms. The high structural dynamics of biofilms is reflected by attachment and detachment occurring next to each other. Through the interactions between photoautotrophic and heterotrophic organisms, microbial biofilms present a self-sustaining miniature ecosystem.

Current knowledge on the function of natural microbial biofilms in marine environments is very limited.

Some information on the structure and the biological components of the biofilms and something about biofilm activities, mostly measured as the net result of different individual processes is known. However, within the biofilms, the interactions between the processes as well as the organisms contributing are not well understood. This becomes especially obvious from considering biofilms consisting of photoautotrophic and heterotrophic organisms. There is clear evidence for the existence of syntrophic nutritional relationships. The phototrophs provide the heterotrophs with organic substrates via exudation of material produced by primary production. The heterotrophs respond by making inorganic nutrients available via remineralisation. However, the chemical composition of the exudates and the routes of their distribution remain unclear. The problem of identification is greatly enhanced by the small scales along which material is exchanged. Adequate methods for the small-scale measurements of activity rates are almost lacking. Concentration gradients of chemical parameters are of limited value, if the processes causing the stratification are not known. It is the within-biofilm dynamics that need urgent attention.

In biofilms, the appropriate scales in time and space have to be considered. Exudates produced by photoautotrophs and the adsorption of dissolved organic material to detritus and sand grain surfaces may provide a pulse of decomposable organic matter to the biofilm, thus stimulating microbial respiration. Within a short period of time, the substrates may be used up, thus leaving the microorganisms in a stage of nutrient limitation until the next pulse occurs. If the appropriate timescale is already a problem, what are the spatial dimensions that have to be looked at in biofilms? Does the spectrum of physiological diversity measured in biofilms on an individual sand grain already reflect the overall diversity of the sedimentary biofilm? How are the activities distributed throughout the individual particles? To increase our understanding of the function of biofilms, we have to adapt our investigations to the scales in time and space relevant to marine microbial biofilms.

Marine biofilms bear a great potential to be used in marine biotechnology. With knowledge of how the biofilms function, they can be manipulated to be used as biosensors to monitor environmental parameters. The analysis of products generated by biofilm organisms as a defense mechanism against other colonizing microorganisms may help to control marine microbial biofouling.

ECOLOGY, PATHOGENICITY, AND SYSTEMATICS OF *AEROMONAS* IN THE ENVIRONMENT

GEERT HUYS
JEAN SWINGS
University of Ghent
Ghent, Belgium

Members of the genus *Aeromonas* are gram-negative rod-shaped bacteria that constitute a part of the natural microflora in virtually all types of freshwater ranging from sewage treatment plants to drinking water. In addition, aeromonads have also been frequently isolated from nonaquatic origins including foods, cold- and warm-blooded animals, and human clinical specimens. Except for the psychrophilic fish pathogen *Aeromonas salmonicida* subsp. salmonicida, none of the known Aeromonas taxa are considered to be primarily pathogenic in animals or humans. However, because of their emerging presence in human extraintestinal and gastrointestinal infections and their ability to produce a wide range of putative virulence factors, a number of mesophilic species are now increasingly recognized as presumptive opportunistic pathogens for humans. At present, the global research on the pathogenesis and the epidemiology of Aeromonas-associated diseases is strongly hampered by the rather complex and straightforward taxonomic structure of this genus, often leading to misinterpretation of identification results in routine analysis. The possible link between the incidence of aeromonads in aquatic environments, especially in drinking water, and the spread of waterborne diarrheal disease imply that a better understanding of the taxonomy and ecology of *Aeromonas* would benefit gastrointestinal disease control.

PATHOGENICITY ASPECTS

Aeromonas, An Emerging Human Pathogen

The first evidence for the pathogenicity of aeromonads was observed within a number of cold- and warm-blooded animals that suffered from *Aeromonas*-associated septicemic diseases. Many of these infections often had fatal consequences for the infected host (1). In fact, a group of nonmotile psychrophilic aeromonads originally known as *Bacterium salmonicida* (now known as *Aeromonas salmonicida*) was soon identified as the primary cause of fish furunculosis, a disease leading to severe economical losses in fish farming. Although the first human infection

with an Aeromonas strain was already reported in 1954, it is only during the mid-1980s that aeromonads have been increasingly recognized as opportunistic pathogens in humans. During this relatively short period, various *Aeromonas* species were recovered from a wide range of extraintestinal infection sites (1) and it could be shown that many of these isolates indeed produced a variety of putative virulence factors.

Hence, many clinical microbiologists are interested in *Aeromonas* for its role as a potential gastrointestinal pathogen for humans. Hundreds of reports, varying from single-case studies to long-term outbreak monitoring surveys, have revealed a relationship between high Aeromonas densities in drinking water or food and diarrhea in humans (2). Despite the large collection of clinical and microbiological data available, however, not a single study has so far been successful in presenting unequivocal proof for the causality of aeromonads in human intestinal disease. In this context, the developments of appropriate animal models as well as further molecular biological research on the role of disease-inducing factors are currently ongoing. Well-documented outbreaks and field studies of *Aeromonas*-associated gastroenteritis in Europe and the United States have changed the original belief that epidemic cases of this disease mainly occur in countries such as Africa, South America, and Southeast Asia. In a publication of the Institute of Medicine, National Academy of Sciences (3), members of the genus *Aeromonas* were cited as one of the emerging microbial threats to public health in the United States.

Aeromonas Infections in Animals

The pathogenicity of aeromonads was first established with cold-blooded animals that are continuously exposed to high Aeromonas densities through their natural aquatic environments (1). Among the amphibians, red-leg disease in frogs is the most frequently reported *Aeromonas* infection. This disease is mostly associated with members of the *Aeromonas hydrophila* group and typically causes hemorrhages in the leg muscles. Members of the *A. hydrophila* group have also been recovered from a wide range of freshwater fish and, to a lesser extent, from marine fish, primarily causing red-sore disease. Undoubtedly, the best-known fish pathogen in the genus *Aeromonas* is the nonmotile psychrophilic species *Aeromonas salmonicida*, which has been recognized as the etiological agent of furunculosis in salmonids. Because of its epidemic nature, furunculosis has mainly caused enormous economical losses in commercial salmon and trout farms during the past few decades (4). Although contact with diseased fish is assumed to be the main route for *A. salmonicida* to spread itself throughout the aquatic environment, survival studies have indicated that this bacterium is able to persist in fresh, brackish, and sea water as well as in natural and fish pond sediments for prolonged periods (4). Currently, two fundamental problems are encountered with the diagnosis of *Aeromonas*-associated furunculosis. First, the frequent isolation of atypical *A. salmonicida* isolates from various fish and from diverse geographical locations is leading to contradictions in identification and typing studies (5). Secondly, there is evidence that *A. salmonicida* cells can enter into a viable nonculturable (VNC) state under certain conditions of environmental stress (6). As a result, conventional medium-dependent techniques are no longer reliable for routine monitoring of furunculosis outbreaks. The majority of the studies devoted to the detection and characterization of VNC bacteria in the environment involve DNA-based enumeration techniques in combination with fluorimetric applications. The administration of antibiotics is one of the main methods to control furunculosis in fish farms next to good hygiene management including maintenance of good water quality and efficient disinfection policies. However, the generation of plasmid-mediated resistance to frequently broad-spectrum antibiotics such as oxytetracycline (OTC) in *A. salmonicida* strains as well as in the bacterial communities indigenous to salmon culture sites has seriously hampered the efficiency of the latter approach (7). Second-generation fluoroquinolones are used to overcome the problem of OTC resistance, but other methods for disease control including vaccination with genetically modified *A. salmonicida* strains and the use of probiotic Vibrio strains seem promising alternatives (4).

In warm-blooded animals, strains belonging to mesophilic *Aeromonas* species have been shown to be pathogenic for a wide range of mammals (including cats, dogs, horses, rabbits, guinea-pigs, monkeys, and mice) and avians (including chickens, turkeys, and companion birds). However, most of the reported infections occur only sporadically and are localized at the most diverse sites within the host.

Aeromonas Infections in Humans

Extraintestinal infections can be caused by a broad spectrum of Aeromonas taxa and often have severe or fatal consequences for adult individuals. Septicemia is generally considered the most life-threatening form of all systemic Aeromonas infections described so far. Although several categories of septicemic diseases are known to exist (8), 90% of all cases are typically associated with immunologically impaired adults that suffer from one or more underlying diseases. In addition to classical signs such as fever and chills, this specific form is often followed by other clinical implications such as cellulitis and liver disease, with estimated mortality rates ranging from 30 to 50% (8). Six Aeromonas taxa are known to cause septicemia in humans, that is, *Aeromonas hydrophila, Aeromonas caviae, Aeromonas veronii* biovars sobria and veronii, *Aeromonas jandaei*, and *Aeromonas schubertii*.

The second most frequently encountered site for human Aeromonas infections are the wounds next to the gastrointestinal tract. Three major types of *Aeromonas*-associated wound infections have been described so far. They are cellulitis, myonecrosis, and ecthyma gangrenosum (8), of which the latter two categories often have fatal consequences for the host. Most wound infections are probably community-acquired, involved male adults, were preceded by an injury, and resulted from environmental (i.e., freshwater or soil) contamination. The etiological agents of Aeromonas wound infections

are mostly situated in the species *A. hydrophila* and *A. veronii* (8).

Aeromonas-associated gastroenteritis seems to have a relatively narrow species spectrum and mainly occurs in infants less than five years old or adults older than 60 years old (8). No single study has been able to identify *Aeromonas* as the true causal agent of gastroenteritis (2). Single-case studies of Aeromonas diarrhea are relatively rare and mainly describe gastrointestinal infections that occurred in individuals who had traveled to developing countries or in workers who accidentally ingested aeromonads in laboratories or hospitals. In contrast, surveillance studies are believed to be far more useful in assessing the role of *Aeromonas* as an emerging enteropathogen because these reports usually contain long-time investigations on a large number of patients (2). As such, *Aeromonas*-implicated outbreaks of diarrhea have been reported in Sweden, Scotland, United States, and Australia. In these cases, drinking water and food are considered as the major sources of gastrointestinal contamination with *Aeromonas*. An overall comparison of major field studies clearly reveals that the epidemic form of *Aeromonas*-related diarrhea is most massively encountered in developing countries (2). In some of these investigations, *Aeromonas* was found as the sole bacterial enteropathogen, whereas other studies mentioned the presence of copathogens such as *Escherichia coli, Campylobacter, Shigella*, and *Salmonella*. In the majority of the cases, *A. caviae* was shown to be the major species isolated followed by *A. hydropohila* and *A. veronii* biovars sobria and veronii. In this context, it has been suggested that a pH shift in the intestine of young children may actually favor the survival and cytotoxicity of *A. caviae*, which further supports the role of this organism as a pediatric enteric pathogen (9).

Putative Virulence Factors

In recent years, intensive clinical and molecular research has resulted in the description of various structural, enzymatic, and cell-associated virulence factors. Among the structural determinants, including pili, S-layers, lipopolysaccharides, and outer membrane proteins, only the S-layer of *A. salmonicida* harboring a 49-kDa cell surface protein has been unambiguously associated with the development of a specific disease (i.e., fish furunculosis) (10). It is assumed that the highly hydrophobic S-layer may protect the bacterial cell from complement-mediated lysis and that the loss of this layer can result in autoaggregation deficiency and a reduction of virulence. The presence of S-layers has also been observed among pathogenic strains of *A. hydrophila* and *A. veronii* biovar sobria. It has been suggested that these S-layers may not be very crucial factors in the pathogenicity of these species (11).

Apart from various proteases, lipolytic enzymes, and polysaccharide-degrading enzymes, hemolysins and enterotoxins belong to the main enzymatic virulence factors described in *Aeromonas* so far (12). Hemolysins typically act as channel-forming bacterial cytolysins toward a broad range of erythrocytes and are usually produced by members of *A. hydrophila, A. caviae*, and *A. veronii*. Two major classes of hemolysins have been recognized so far. The aerolysins or β-hemolysins that produce clear hemolytic zones on blood agar and are heat-labile (56 °C, 5 min), and the α-hemolysins that exhibit incomplete hemolysis on blood agar and are not expressed at growth temperatures exceeding 30 °C. In addition to their cytotoxic activity, aerolysins also display enterotoxic effects indicating that aerolysins may have multifunctional properties and can act as cytolytic enterotoxins in human gastroenteritis (13). The cytotonic enterotoxin, on the other hand, is clearly distinct from α- and β-hemolysins and acts according to a cholera toxin-like mechanism. This toxin has been observed among environmental and clinical isolates of *A. hydrophila, A. caviae*, and *A. veronii* (14).

Recently, a number of possibly new virulence factors, either associated with the bacterial cell surface or located in the cytosol, have been described for some *Aeromonas* sp. These factors include invasins, adhesins, and plasmids. However, most of the arguments brought forward to define the precise role of these determinants in *Aeromonas* pathogenesis are often speculative and additional research in this field is necessary (13).

ISOLATION AND ENUMERATION OF *AEROMONAS*

Because of their physiological diversity and their distribution in the most diverse environmental and clinical habitats, aeromonads cannot be readily isolated using one universal medium and methodology. As such, the isolation of psychrophilic *A. salmonicida* from fish will require a very different approach compared to the recovery of mesophilic aeromonads from a human stool sample. Apart from a number of physicochemical parameters, bacteriological factors such as the density of competing microflora or the presence of injured cells are likely to vary from sample to sample and should be taken into account when choosing the most appropriate medium for isolation. In food or clinical samples, the actual isolation procedure may be preceded by an enrichment step leading to qualitative or presence–absence analysis of *Aeromonas*. The recovery of aeromonads from environmental samples, on the other hand, usually does not require preenrichment and thus allows quantitative enumeration. A concise overview will be given below of the techniques widely used for isolation and enumeration of psychrophilic and mesophilic aeromonads from diverse environments. For a full review on these methods and for literature on the isolation of aeromonads from clinical specimens, the reader is referred to reference (15).

Environmental Samples

For the isolation of mesophilic aeromonads from the environment, the standardized collection of representative samples from the aquatic or terrestrial sites of interest is a first requirement. Water samples are usually collected in sterile, screw-capped glass or plastic bottles or tubes, whereas soil and sludge samples may be collected in sterile screw-capped containers or Whirl-Pak bags. In the case of sampling raw or processed drinking water, it is

recommended that the sample recipients contain 24-mg/l sodium thiosulfate to inactivate free residual chlorine. In addition, at least 50 mg/l ethylenediamineacetic acid (EDTA) can be added for chelating free metals such as copper that are know to cause death of many bacteria in drinking water samples. In the past, the formation of biofilms has often been overlooked in bacteriological analyses of drinking water distribution systems. Regrowth of aeromonads can be determined by taking surface swab samples at technical control points in the distribution network. In general, environmental samples should be stored at 2–8 °C and processed within three to five hours after collection to minimalize the "bottle effect" on quantitative assessment of aeromonads. For routine analysis of water samples, appropriate dilutions are usually concentrated using membrane filtration before inoculation of the selection medium of choice (16).

As aeromonads are usually found together with *Enterobacteriaceae* and *Pseudomonas* spp. amongst other autochthonous bacteria in environmental samples, selective media should be used for the specific recovery of *Aeromonas* from the naturally occurring background flora. Within the range of media developed for selective isolation of *Aeromonas* spp., ampicillin-dextrin agar (ADA) (17) is most frequently used. Combining the positive aspects of mA agar and dextrin-fuchsin-sulfite agar, the ADA medium suppresses background flora and stimulates growth of *Aeromonas* by making use of the high specificity of dextrin fermentation and the addition of 10 ppm ampicillin. Except for the species *Aeromonas trota* (18), the majority of the aeromonads is believed to be ampicillin-resistant and appear as typical yellow colonies with a dark center on the blue ADA medium. For enumeration purposes, colony counting should be performed after 24 hours incubation at 28 °C as longer incubation will result in the gradual overgrowth by background flora. The addition of the vibriostatic agent 0/129 and ethanol is sometimes recommended to inhibit proliferation of vibrios (17) and *Klebsiella* spp. (16), respectively.

Fish

Fish may be analyzed for the presence of both *A. salmonicida*, the primary agent of causing furunculosis, and members of the *A. hydrophila* complex leading to septicemia. For isolation of aeromonads from fish and other cold-blooded animals, swab samples are usually taken from gills, organs, external lesions, and directly collected into an enrichment medium like tryptone soy broth. Bacteria are enriched by incubating sample suspensions at 25–26 °C for 24–48 hours. Broth cultures are then streaked on tryptic soy agar (TSA) and may be incubated at different temperatures (range 20–30 °C) to allow recovery of both mesophilic and psychrophilic aeromonads. Traditionally, *A. salmonicida* colonies can be immediately recognized on isolation on TSA by the production of a brown water-soluble pigment and through a positive oxidase spray test, result although nonpigment producing and oxidase-negative strains have been described (4).

Food

Because of the suspected association between specific cases of foodborne *Aeromonas* infections and the generation of gastrointestinal disease in humans, many attempts have been made to optimize the isolation of aeromonads from raw and processed foods. In most standard procedures, 25 g samples are collected in sterile stomacher bags to which 225 ml of 0.1% alkaline peptone water (APW) is added. The suspension is homogenized using a blender or stomacher, and appropriate dilutions are prepared for plating. Food samples need to be refrigerated during transport to the lab as some mesophilic *Aeromonas* strains are known to survive and grow at 5 °C in specific food matrices. For quantitative recovery, appropriate dilutions of the APW suspension are directly plated on the recommended isolation medium. When enrichment is desired in qualitative assessments, APW suspensions should be incubated overnight at 28 °C before direct plating and incubation at 35 °C for 18–24 hours. Currently, Bile salts irgasan brilliant green (BIBG) medium is highly preferred as the medium of choice for selective spread plate isolation of aeromonads from food products. BIBG agar provides a high selectivity for aeromonads by suppressing growth of most enterobacteria and indicates presumptive Aeromonas colonies by a positive oxidase spray test. As BIBG agar does not contain antibiotics, the medium will not inhibit recovery of ampicillin-sensitive *Aeromonas* strains as may be the case with ADA medium. Recently, modified BIBG agar (mBIBG) was evaluated to reduce the occasional inhibition of brilliant green sensitive *Aeromonas* strains on the original BIBG medium (19).

SYSTEMATICS

Identification to the Genus Level

Conventional microscopy identifies aeromonads as rods that exist singly, in pairs, or in short chains, and ranging in size from 0.3 to 1.0 μm in diameter and from 1.0 to 3.5 μm in length. Most species, except *A. salmonicida* and *A. media*, are motile by a single polar flagellum. Most aeromonads grow well and relatively fast (i.e., overnight incubation) on standard media like TSA or nutrient agar and do not require special culture conditions. To obtain optimal growth, however, it is clear that the incubation temperature should be adjusted depending on whether mesophilic (range 28–30 °C) or psychrophilic (range 22–25 °C) *Aeromonas* strains are cultivated. In general, strains can grow at a temperature range as wide as 0 to 45 °C and between pH 4.5 and 9.0. As a group, aeromonads can be easily distinguished from other gram-negative, facultatively anaerobic rod-shaped bacteria (i.e., *vibrios*, the *Enterobacteriaceae*, and *Plesiomonas*) by a few simple phenotypic tests (Table 1). In this regard, it has been noted previously that fermentation of lactose at 37 °C is an unreliable test to differentiate aeromonads from enterobacteria, and showed that the routine use of this particular test had caused false-positive counts in the determination of total coliforms in drinking water analysis. Aeromonads do not require Na^+ (sodium ion) for growth and are

Table 1. Phenotypic Differentiation of *Aeromonas* from Other Gram-Negative Rods

Feature	Reaction For			
	Aeromonas	*Vibrio*[a]	*Plesiomonas*	Enterobacteriaceae
Oxidase test	+	+	+	−
Resistance to:				
0/129 (150 mg)	+	−	−	nd
Ampicillin (10 mg)	+[b]	v	v	−

[a] Halophilic *Vibrio* spp. can be further differentiated by their inability to grow in the absence of NaCl
[b] *A. trota* is the sole ampicillin-sensitive member of the genus *Aeromonas* (8).

resistant to the vibriostatic agent 0/129 (2,4-diamino-6,7-diiso-propylpteridine) and to most penicillin.

Taxonomy

Essentially, modern Aeromonas taxonomy has expanded from the so-called "four-species concept" of Popoff as described in the first edition of Bergey's Manual of Systematic Bacteriology (20). In the latter classification, the genus *Aeromonas* consisted of three mesophilic motile species, that is, *A. hydrophila, A. caviae*, and *A. sobria*, and one psychrophilic nonmotile species that is, *A. salmonicida*. Because the taxonomy of this genus has changed a great deal owing to the addition of newly described species and the reclassification or amended description of existing taxa. In addition, the combined use of the terms *phenospecies* (i.e., a taxon delineated on the basis of phenotypic characteristics) and *genomospecies* (i.e., a DNA hybridization group [HG] determined on the basis of DNA homology values) in the current Aeromonas taxonomy seems highly confusing to many taxonomists outside the field. At least 14 *Aeromonas* species have been validated so far, some of which are either grouped together in one single HG (e.g., *A. salmonicida* and *A. hydrophila* in HG3), are dispersed among different HGs (e.g., *A. caviae* in HG4, HG5A, and HG5B), or are further subdivided into genetically similar biovars (i.e., *A. veronii*). In addition to the detailed taxonomic review (21), Table 2 shows a list of the *Aeromonas* taxa recognized on March 2001.

Identification to the Species and DNA Hybridization Group Level

To a certain extent, the introduction of chemotaxonomic and molecular methods in bacterial systematics has addressed some of the classical problems of resolution and reproducibility typically associated with phenotypic methods. As modern *Aeromonas* taxonomy strongly relies on genotypic data, the latter methods often give inaccurate or unreliable results in the classification of unknown *Aeromonas* isolates. As a result, speciation of *Aeromonas* sp. is now increasingly becoming the responsibility of a few research units harboring specialized equipment coupled with a strong reliance on in-house expertise and up-to-date libraries. The major phenotypic, chemotaxonomic, and genotypic methods are described later that have proven to be suitable for the identification and classification of aeromonads.

At a first identification level, aeromonads can be classified in two major physiological groups including the motile, mesophilic and the nonmotile, psychrophilic aeromonads (i.e., *A. salmonicida*). However, this phenotypic division is not well defined because some nonmotile *A. media* strains are able to grow in the temperature range of 22 to 37 °C and atypical (motile, growth at 37 °C) *A. salmonicida* isolates are known to exist. Similarly, the production of a brown soluble pigment on TSA alone should not be considered typical for all psychrophilic aeromonads because only one of the four subspecies in *A. salmonicida* (i.e., subsp. salmonicida) displays this characteristic. For many years, the routine phenotypic identification of mesophilic Aeromonas isolates to the species level was based on a limited set of biochemical tests allowing discrimination among the taxa constituting the four-species concept (20). However, as increasingly new *Aeromonas* taxa were described, the classical identification scheme of Popoff (20) soon became inefficient. For this reason, Carnahan and coworkers (22) and Abbott and coworkers (23) recommended the use of 20 to 25 selected phenotypic features for the correct allocation of mesophilic *Aeromonas* strains to one of the seven major clinical species or to one of the 14 HGs (see Table 2), respectively. However, the authors conceded that it was very difficult to define reliable phenotypic markers for rare taxa such as *A. sobria* HG7 and also indicated that additional strains from diverse origins should continuously be included as a matter of postevaluation of their phenotypic schemes. To facilitate routine identification, a number of small-scale test kits have been brought on the market for the rapid speciation of unknown *Aeromonas* isolates. So far, at least 15 commercial systems including API 20E/NE, BIOLOG GN2, Vitek, B-D Crystal, and MicroScan currently have representatives of the major *Aeromonas* species included in their databases. However, the general experience is that the resolving power of these systems is often too low to deal with the high phenotypic relatedness that exists between some of the Aeromonas taxa. For instance, evaluation of the API 20E system revealed that only 52% of the *Aeromonas* strains tested were correctly identified to the genus level (24). Here, additional tests were mandatory to obtain taxonomic information beyond the genus level.

For the past 15 years, almost every chemotaxonomic technique applied in the field of bacterial

Table 2. Species and DNA Hybridization Groups Situated in the Genus *Aeromonas*

HG (= Genomospecies)[a]	Species Name (= Phenospecies)[a]	Main Source of Isolation
1	*A. hydrophila*	Humans, animals, freshwater

[a]Genomospecies and phenospecies represent taxa that are delineated on the basis of DNA hybridization data and phenotypic characterization, respectively (9). HG, DNA hybridization group.
[b]HG3 contains motile, mesophilic strains (*A. hydrophila*) and nonmotile, psychrophilic strains (*A. salmonicida*).
[c]HG8 and HG10 are genetically similar, but constitute two biochemically diverse groups in *A. veronii*.
[d]Not defined yet.

systematics has been evaluated for its taxonomic potential in the genus *Aeromonas*. Some of these methods were described as promising alternatives for the rather laborious methods used in phenotypic identification, whereas other techniques have not been fully evaluated (e.g., pyrolysis mass spectrometry) but seemed valuable in the characterization of aeromonads to the strain level (e.g., serotyping, phagetyping, and whole-cell protein fingerprinting). Essentially, only multilocus enzyme electrophoresis (MLEE) and gas-liquid chromatographic (GLC) analysis of cellular fatty acid methyl esters (FAMEs) have been successfully applied for the identification of *Aeromonas* isolates. In general, MLEE data show a good correlation with the DNA hybridization groups established in *Aeromonas* results, whereas a further automation of the method is required toward routine applications (25). Modern equipment for FAME analysis, on the other hand, provides many possibilities for automated strain identification and has proven to be discriminative at the phenospecies level or even at the HG level in *Aeromonas* (26). In this regard, it should be mentioned that standardization of culture media, time, and temperature of incubation are crucial to obtain reproducible and taxonomically resolving FAME patterns.

During the 1990s, a wide range of techniques based on restriction fragment length polymorphism analysis and/or on the polymerase chain reaction (PCR) was applied to identify *Aeromonas* strains. The taxonomic value of some of these DNA-based fingerprinting methods, including randomly amplified polymorphic DNA analysis, pulsed-field gel electrophoresis, and restriction endonuclease analysis (REA), is believed to be limited within the genus *Aeromonas*. For this reason, the latter techniques are more valuable when used in typing studies for individual strain differentiation. In contrast, the use of rRNA gene restriction patterns (i.e., ribotyping) and whole-genome fingerprinting using the amplified fragment length polymorphism (AFLP) technique as taxonomic tools in *Aeromonas* have been relatively successful. Visual comparison of ribotyping patterns allows discrimination among most *Aeromonas* HGs (27) and has been applied for the identification to the HG level of aeromonads from aquatic, food, and human clinical origin. Essentially, the AFLP concept combines the specificity of double REA analysis with the selective amplification of modified restriction fragments yielding a highly informative autoradiographic or fluorescent fingerprint (28). Numerical analysis of AFLP patterns show a perfect correlation with *Aeromonas* HGs and allow the construction of genotypic databases for identification of unknown or poorly characterized aeromonads. Other important developments in the molecular identification of aeromonads concern the application of the fluorometric DNA–DNA hybridizations in micro dilution wells (29) and the use of PCR assays using species-specific

PCR primers designed on the basis of 16S-rRNA sequences (30).

OCCURRENCE OF *AEROMONAS* IN THE ENVIRONMENT

Aquatic Environments

Numerous ecological investigations and microbial population studies have demonstrated that aeromonads occur in virtually all types of aquatic environments throughout the world. From the data compiled in Table 3, it is clear that every type of water displays its own specific range of *Aeromonas* counts, confirming the long-time belief that the occurrence of *Aeromonas* in specific water habitats is largely determined by physicochemical and microbial factors inherent to the site (31). The possible link between the incidence of aeromonads in drinking water and waterborne diarrheal disease implies that a better understanding of these aspects is also beneficial to workers in the field of *Aeromonas* epidemiology and gastrointestinal disease control.

In general, a limited amount of data is available on the isolation of aeromonads from naturally occurring, nonpolluted groundwater sources. In deep aerobic and anaerobic ground waters, *Aeromonas* numbers of up to 35 CFU/100 ml have been determined indicating a pronounced dominance of *A. hydrophila* over *A. caviae*. The same two species have also been found in underground waters where it was observed that the overall structure of *Aeromonas* populations autochthonous to this type of water could remain constant for long periods. Interestingly, a Belgian study indicated that free radicals spontaneously generated in oxidizing (Iron) Fe_{2+}-containing ground waters on aeration caused inactivation of *A. hydrophila* amongst other aquatic species (32).

In the past 20 years, a great deal of scientific and economical attention has been paid to the microbial quality of surface freshwaters, and this is mainly because of their importance as sources of drinking water and as habitats for aquaculture. During a two-year survey, Hazen (33) determined densities of *A. hydrophila* in a South Carolina cooling reservoir, receiving heated effluent from a nuclear reactor. The author concluded that the *A. hydrophila* densities were significantly higher in the thermally altered parts of the reservoir, and found that the mean monthly counts of this species were positively correlated with the incidence of red-sore disease in largemouth bass. If one compares studies that were devised to identify factors possibly affecting the *Aeromonas* population in surface water, different relational patterns can be observed (31). As such, high correlations are known to exist between *Aeromonas* numbers in estuaries with heterotrophic plate counts (HPC) at 35 °C and fecal coliform (FC) densities, whereas studies performed in raw surface waters used for the production of drinking water revealed that *Aeromonas* densities were positively correlated to HPC at 37 °C but negatively correlated with FC counts. Seasonal influence and the related changes in freshwater temperature, on the other hand, usually showed a highly stable correlation with *Aeromonas* densities. In temperate areas, highest *Aeromonas* counts are generally determined during summer, whereas the reverse effect is seen with surface waters located in (sub) tropical regions. Similarly, the influence of the tropic state of the water also seems to vary between studies. Schubert (34) determined that the incidence of anaerogenic aeromonads (now *A. caviae*) versus the incidence of aerogenic aeromonads (now *A. hydrophila* and *A. veronii* biovar sobria) in rivers and brooks depended upon the saprobicity of the water. In Schubert's study (34), anaerogenic *Aeromonas* strains were predominant in polysaprobic streams, but their levels declined in favor of aerogenic aeromonads when oligosaprobic sources were examined. In concordance with these data, workers have reported that *A. caviae* predominated in rivers with a high degree of organic pollution, whereas levels of *A. hydrophila* and *A. sobria* increased in less polluted waters.

Although aeromonads are not exactly typical marine organisms, the major mesophilic *Aeromonas* species autochthonous to aquatic environments have been recognized as halo-tolerant (31). In this context, most enumeration studies concentrated on coastal waters where freshwater possibly interferes with the natural marine system. As was the case for surface freshwaters, a positive correlation between *Aeromonas* densities and water temperature has been reported for marine waters. In coastal bay water, *A. hydrophila* and *A. sobria* have been shown to be predominant during summer months, whereas *A. caviae* numbers reached their peak in winter season.

Aeromonads are not only widespread in nonpolluted freshwaters and marine waters, but have also been frequently isolated from domestic and industrial wastewaters. High concentrations of fats, proteins, and polysaccharides are known to favor the selective mass growth of *Aeromonas* strains in these environments. Similarly to nonpolluted waters, studies in sewage treatment ponds have indicated that the total aeromonad densities follow a seasonal cycle, with highest numbers reported in summer (35). On the other hand, FC was dominant during winter periods. Furthermore, this study (35) also showed

Table 3. Typical Mesophilic *Aeromonas* Counts in Different Types of Water

Aquatic Environment	Typical Count (CFU/100 ml)
Sewage treatment plants	
— Influents	$10^7 - > 10^9$
— Effluents	$10^3 - 10^8$
Lagoon receiving sewage effluent	$10^4 - 10^6$
Unpolluted rivers, fresh water lakes	$10^3 - 10^4$
Marine estuary	$10^3 - 10^4$
Private unchlorinated drinking water well	$10 - 10^4$
Drinking water production/treatment plants	
— Raw groundwaters	$< 1 - 10^2$
— Raw surface waters	$10^3 - 10^5$
— Treated waters (postchlorinated)	$< 1 - 10$
— Distribution systems (unchlorinated)	$< 1 - 10$
— Distribution systems (chlorinated)	$< 1 - 10^2$
— Tap water	$< 1 - 10^2$
Bottled mineral waters	$< 1 - > 1$

Data compiled from (15).

that *A. caviae* was the dominating organism in the sewage inflow through out the year through, indicating that this species was autochthonous to the raw sewage. Conversely, the relative abundance of *A. hydrophila* and *A. sobria* is dependent highly on seasonal influence. In Italian urban wastewater purification plants, extremely high levels of *A. veronii* biovar veronii have been reported. This opportunistic human pathogen is normally associated with wounds and stool, which clearly indicates the importance of reliable *Aeromonas* speciation in cases where waste processing outflows are being used for irrigation in agriculture (31). In general, removal efficiencies of *Aeromonas* obtained in most plants is satisfactory, varying from 93% in Moroccan stabilization ponds (36) to 99.9% in a Belgian activated sludge plant (37). It should be noted that a significant number of potentially pathogenic aeromonads can be retained in dried sludge.

In essence, two factors may largely contribute to the incidence of *Aeromonas* strains in potable waters. First, aeromonads may be removed ineffectively and their numbers may even increase during the production process of drinking water. The latter phenomenon has been observed with sand filters containing significant loads of biodegradable components and with activated carbon filtration systems, which are believed to stimulate bacterial adherence and regrowth (38). In such cases, the introduction of a postchlorination step seemed absolutely necessary (38). Secondly, after growth of aeromonads has been frequently observed in several municipal distribution systems and this may be associated with biofilm formation (31). Several physicochemical parameters including water temperature and concentration of residual chlorine are known to influence the process of regrowth, whereas laboratory studies have suggested that the presence of low assimilable carbon concentrations can easily initiate growth of *A. hydrophila*. During the 1980s, a number of Dutch and Australian studies provided the first insights on the possible correlation between the high incidence of aeromonads in drinking water and an increase in *Aeromonas*-associated diarrheal cases. Other studies, although not directly linked to outbreaks of diarrhea, have shown that *Aeromonas* isolates recovered from drinking water supplies have the potential to exhibit significant cytotoxic and hemolytic activities (39). The majority of these strains were found to belong to the species *A. hydrophila* and *A. sobria* (*A. veronii* biovar sobria). As a result, health authorities in the Netherlands have defined so-called indicative maximum values for Aeromonas numbers in drinking water production, that is, 20 CFU/100 ml for water leaving the production plant and 200 CFU/100 ml for drinking water in the distribution system. According to Holmes and coworkers (31), a full understanding on the precise role of aeromonads in waterborne diarrhea requires many more outbreaks to be investigated in great detail.

Currently, only a limited number of reports are available on the isolation of aeromonads (i.e., *A. hydrophila*) from bottled mineral waters. An examination of 64 European still mineral waters did not reveal a trace of *Aeromonas* in any of the brands included. This observation could be explained by the fact that most aeromonads probably lack the potential to grow in nutrient-poor waters. Survival studies have revealed that an *A. hydrophila* strain was able to persist in filtered and filtered-autoclaved but not in unfiltered bottled water, indicating the inability of this organism to compete with the autochthonous microbial flora. On the other hand, *A. hydrophila* has been shown to survive for up to two months in double-distilled water inoculated with contaminating bacteria such as *Pseudomonas aeruginosa* and several *Enterobacteriaceae*.

Terrestrial Environments and Plants

Although it is assumed that *Aeromonas* is as widespread in terrestrial as in aquatic environments, only very few data are available on the presence of aeromonads in soil and sediments. In fact, the occurrence of mesophilic *Aeromonas* sp. has mainly been reported in metabolic studies on bioremediation of polluted factory grounds, mercury resistance adaptation in mine soils, environmental nitrogen cycles in soils and freshwater sediments, and the rhizosphere of bean plants. In addition, aeromonads have also been isolated as internally seedborne microorganisms from soybean and rice seed. Moreover, a survival study in artificially contaminated sterile or unsterilized soil has demonstrated that soil should be regarded as an important reservoir for mesophilic *Aeromonas* sp. and may play an important role in the spread of potentially pathogenic aeromonads (40).

Foods

In addition to their increased presence in potable water supplies, aeromonads have also been isolated from a wide range of foods including raw and processed meats, poultry, fish, seafood, dairy products, vegetables, and preprepared salads frequently (41). Moreover, it has been demonstrated that food isolates of *Aeromonas* can produce a wide range of potential virulence determinants such as hemolysins, cytotoxins, and exotoxins (42). Consequently, some *Aeromonas* species are now being recognized as possible foodborne pathogens, and a lot of research in this field is currently focusing on growth control and inactivation of aeromonads in foods (41). For instance, the fact that *Aeromonas* sp. are capable to grow at 4 to 5 °C has seriously questioned the purpose of refrigeration in the storage of spoilable foods. Similarly, it was demonstrated that *A. hydrophila* can survive but cannot grow on mixed vegetable salads stored in a modified atmosphere at 4 °C. Very few surveys have studied the possible sites of *Aeromonas* contamination in the line of food processing and packaging.

CONCLUSION

Over the past two decades, significant progress has been made in understanding the classification, the pathogenicity, and the ecology of aeromonads. With the aid of DNA/16S-rRNA based methods, new species have been described and better taxonomic insights were obtained in *Aeromonas* systematics. Next to the *Enterobacteriaceae*, *Aeromonas* sp. are now considered one of the major bacterial groups predominating in freshwaters worldwide.

The psychrophilic taxon *A. salmonicida* has been recognized as the primary causative agent of furunculosis, a salmonid disease that is increasingly being controlled using techniques other than antibiotic treatment including vaccination. In contrast, little is known about the true ecological relevance of mesophilic *Aeromonas* spp. in aquatic environments or their presumptive role as human opportunistic pathogens associated with sporadic cases and outbreaks of gastroenteritis. In this regard, ongoing and future research should primarily concentrate on the further optimization of virulence models and molecular subtyping methods to study the pathogenicity and epidemiology of aeromonads involved in food- or waterborne infections.

Arid and semiarid regions are characterized by their limited precipitation, less than 25 cm per year in deserts, up to about 75 cm per year in adjacent steppes and shrublands. Because of the limited availability of moisture, the landscape is dominated not by the growth of vascular plants as is typical in wetter climates, but by geomorphological features such as bare bedrock cliffs, ledges and platforms, talus slopes, alluvial fans, coarse soils overlain by desert pavement, and areas of shifting sands. These geological features are inhabited by special suites of microorganisms, which often form well-defined associations. Desert soil microorganisms are treated elsewhere, as are those associated with the formation of desert varnish. Here we focus on rock-inhabiting microorganisms associated with some of the harshest environments.

Rocks and stones provide several habitats for microbial growth (1,2). The epilithic habitat consists of the surface of the rock. In milder climates it can support a rich growth of bryophytes, lichens, and subaerial algae; in the most extreme deserts, in contrast, rock surfaces are essentially abiotic. The endolithic habitat, the focus of this article, consists of the interior of the rock. Golubic and coworkers (3) identified three types of endolithic organisms. Euendolithic organisms actively bore into the surface of the rock. Euendolithic cyanobacteria are common in aquatic systems, much less so in terrestrial systems. Euendolithic lichens are common on limestone and other materials readily dissolved by weak organic acids. Chasmoendolithic organisms inhabit cracks and fissures in weathered rock. Typically, these have a direct connection with the surface. Cryptoendolithic organisms inhabit the interstitial spaces of porous rocks. Because the organisms lie below the surface of the rock, only rocks composed of light-colored or translucent grains are colonized by cryptoendoliths. The hypolithic habitat consists of the lower surface of stones embedded in the soil.

Endolithic microorganisms are widely distributed in arid regions. Examples have been reported from the Middle East (4–7), central Asia (8–9), southern Africa (2,10–13), Australia (2,10), southwestern United States and Mexico (1,10,14,15), South America (2), the Arctic (16–18), and Antarctica (19–24). It should be noted that a report of chasmoendolithic cyanobacteria from the Atacama Desert was based on a specimen from the semiarid Guanagueros Peninsula in Chile, about 200 m from the sea and at an elevation of about 10 m above sea-level, and not from the Atacama (2). Despite their global distribution and their importance in the local ecosystems, we are only now beginning to understand the ecology of these organisms.

The key for understanding the ecology of endolithic organisms often lies in the physical parameters of the immediate environment. Changes in the basic parameters (temperature, light, and moisture) can occur within millimeters. Therefore, the environment experienced by endolithic microorganisms can differ greatly from not only the large-scale macroclimate, but also the microclimate, traditionally defined as the climate in the size range of plants and animals. To emphasize this point we have proposed the term *nanoclimate* to describe the climate in the millimeter range (2,25,26). Clearly, measurements of the nanoclimate must be made with instruments operating at the appropriate scale and with the appropriate resolution (23,25–27). At the same time, because of the rigid nature of the substratum, the insertion of probes changes the environment to a degree not seen in other microbial habitats, for example, soft aquatic sediments, operating at a similar scale. One way to reduce this problem is through the development of simple computer models of the system (28,29). As will be illustrated later, these allow us to both verify the results of our measurements and extend our results to other parts of the ecosystem.

Because of the technical difficulties of making these measurements, only a few endolithic systems have been studied thoroughly. We begin our discussion with a detailed summary of the endolithic microbial communities in the Ross Desert of Antarctica.

ENDOLITHIC MICROBIAL COMMUNITIES IN THE ROSS DESERT OF ANTARCTICA

The most intensively studied terrestrial endolithic communities are those found in the higher elevations of the frigid Ross Desert in the McMurdo Dry Valleys of Northern Victoria Land, by far the largest true desert on the continent of Antarctica (21,30). The landscape is characteristic of an extreme desert: exposed bedrock and stone, soil covered by a desert pavement of small stones, no obvious vegetation (Plate 1). Air temperatures are uniformly cold, reaching a daily mean of only $-5\,^{\circ}C$ at the height of summer (mid-January), fluctuating between $-20\,^{\circ}C$ and $-40\,^{\circ}C$ during winter (25,26). All precipitation is in the form of snow, much of which sublimes away before melting (25,26,31); the absolute accumulation of snow is unknown, but probably on the order of a few tens of centimeters (30). In this environment, the only visible life consists of a few lichens growing in protected niches on rock surfaces. Endolithic organisms dominate the ecosystem.

Endolithic Organisms and Associations

Cryptoendolithic Communities. The cryptoendolithic microbial flora inhabiting porous Beacon sandstones, the prevalent rock type in the area, is surprisingly diverse. To date, five different cryptoendolithic communities have been identified, two dominated by eukaryotic algae, three by cyanobacteria (21,22,30). Their basic characteristics are summarized below.

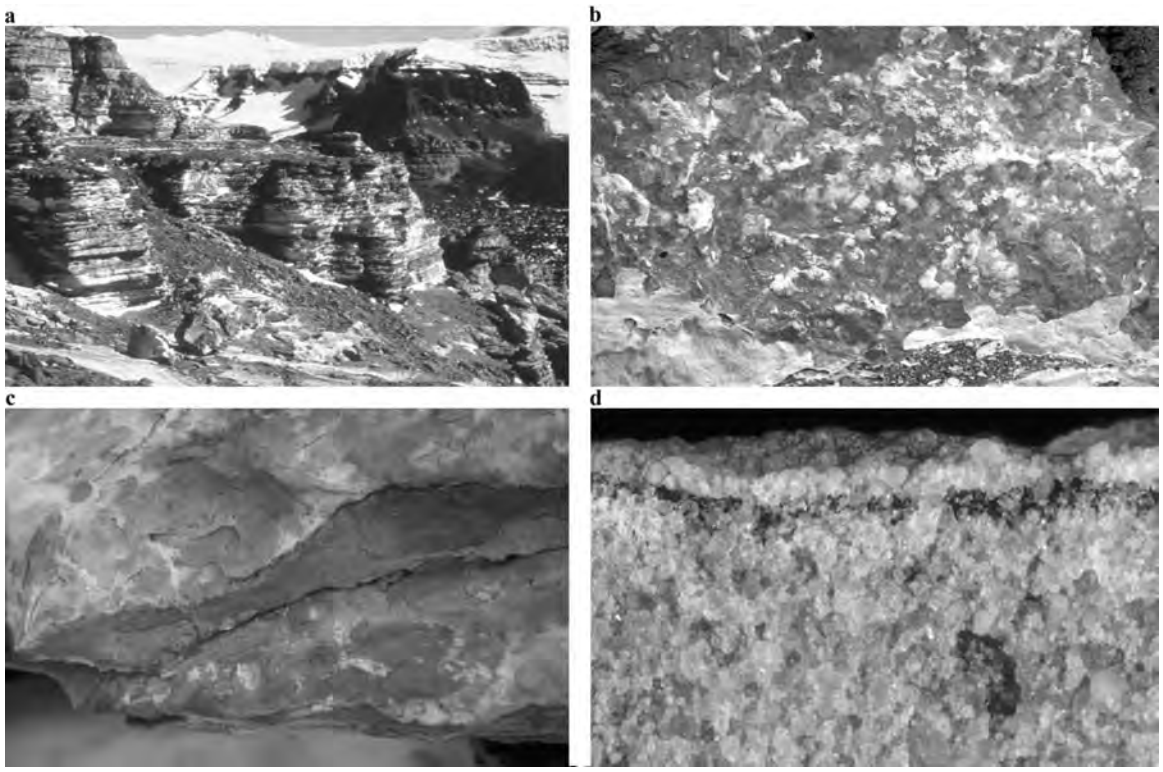

Plate 1. Endolithic communities in cold deserts. (**a**) Sandstone cliffs in University valley, Ross Desert (McMurdo Dry Valleys), Antarctica. Photo: E. I. Friedmann. See color insert.

The Lichen-Dominated Community. The lichen-dominated community is the most common and best-studied in Antarctica. It appears as a conspicuous zone of parallel colored bands extending the surface crust of the rock to a depth of about 10 mm (Plate 1). Typically, there is a black upper band, extending from just below the crust to a depth of about 1.5 mm, followed by a white band of variable thickness, often extending to a depth of more than 4 mm (29). In well-developed communities, below the white band there is a green band and sometimes a blue-green band. The brown stain characteristic of Beacon sandstones in the region is absent from the colonized zone, leaving a framework of colorless quartz grains. The stain is apparently leached from the zone as a result of oxalic acid production by the fungi (23,32).

Within the black and white bands are filamentous fungi and spherical green algae, which together form a cryptoendolithic lichen. In contrast to typical lichens, including euendolithic lichens, the cryptoendolithic lichens do not have a distinctive morphology. In addition, reproductive structures are rare, so that identification of the lichen species is difficult, if not impossible. Because appressoria and haustoria are both seen in field samples (21), it is thought that at least two lichen associations are present in the community. Several strains of fungi isolated from the community are capable of forming lichen associations with lichen-algae in the laboratory (33, Friedmann and Koriem, unpublished data). Other strains of fungi, especially thick-walled and dark-pigmented black yeasts, are not. These are common in the upper black zone of the community. In some instances, they dominate the black zone, in others, the black zone is dominated by dark-pigment hyphae of the lichen-forming fungi. The white zone is inhabited by nonpigmented fungi and eukaryotic algae, which together form a lichen association. The nonpigmented fungi in this zone are almost certainly a morphotype of the dark-pigmented lichen-forming fungi from the black zone. Parasymbiontic fungi are apparently absent from this layer. The photobionts of the lichen association are species of *Trebouxia* or *Pseudotrebouxia* (21,34). Work with cultures suggests that more than one species is

present in the Ross Desert community, but that each lichen association contains only one. At least some of the cryptoendolithic lichens are morphological variants of epilithic species found in the region (35).

The green band is created by a mixture of eukaryotic algae and cyanobacteria. The dominant species in this association is the green alga *Hemichloris antarctica* (36). Other taxa include the xanthophycean alga *Heterococcus endolithicus* (37), a species from the chlorophycean genus *Stichococcus*, and a single species of each of the cyanobacterial genera *Gloeocapsa* and *Chroococcidiopsis*. *Hemichloris antarctica* and *Heterococcus endolithicus* are endemic to Antarctica. The species of *Chroococcidiopsis* is similar to forms occurring in hot deserts (2,38,39). The cyanobacteria tend to occur in the deeper layers, with *Chroococcidiopsis* deeper than *Gloeocapsa*. Occasionally, *Chroococcidiopsis* forms a separate blue-green band below the green band. Nonpigmented fungi are often present in the green band, but there is no morphological evidence of a lichen association with any of the algae.

The psychrophilic yeast *Cryptococcus friedmannii* Vishniac has been isolated from rocks containing the cryptoendolithic lichen community (40), but apparently only occurs infrequently. Heterotrophic bacteria comprise a constant, but small, portion of the community; Greenfield (41) estimated their biomass at less than 1% of the total. Included are members of the genera *Micrococcus*, *Deinococcus*, *Brevibacterium*, *Arthrobacter*, *Geodermatophilous*, *Micromonospora*, and *Streptomyces* (42–44). Siebert and coworkers (45), after a detailed study of the metabolic requirements of 41 strains of heterotrophic bacteria isolated from the endolithic habitat, characterized the community as morphologically simple but physiologically diverse.

The Hemichloris Community. The *Hemichloris* community is similar in composition to the association forming the green band in the cryptoendolithic lichen community. The dominant, sometimes sole, phototroph is *H. antarctica*. It typically colonizes the lower surface of overhanging sandstone ledges. Presumably, the light reaching these surfaces is too low to support the development of the lichen community. The *Hemichloris* community does not produce a leached zone.

The Red Gloeocapsa Community. This community is characterized by the presence of a large (3 to 12 μm in diameter) species of *Gloeocapsa* with a reddish lamellated sheath and reddish or purple cytoplasm. It forms a dark purplish red band extending from a point just below the surface crust to a depth of one to several millimeters within. Accompanying the red *Gloeocapsa* is a smaller, yellowish *Gloeocapsa*. Occasionally, other cyanobacteria are also encountered, including additional species of *Gloeocapsa*, *Eucapsis*, and *Microchaete*. This community inhabits the same types of rocks and boulders as the lichen-dominated community, but occurs much less frequently. It produces a leached zone.

The Hormathonema-Gloeocapsa Community. This complex cyanobacteria-dominated community has only been found on Battleship Promontory, where it colonizes white sandstone boulders permanently wetted by snowmelt percolating through the dolerite rubble at the base of the rocks. This community is characterized by the presence of two parallel color bands below the rock surface. The upper dark brown or blackish gray band is dominated by a species of *Hormathonema* and/or a dark gray species of *Gloeocapsa*. Members of a yellowish brown species of *Gloeocapsa* and two species of *Anabaena* also occur in this band. The lower green band is dominated by a species of *Aphanocapsa*, occasionally accompanied by several species of *Gloeocapsa*, another species of *Anabaena*, and a species of *Lyngbya*.

The Chroococcidiopsis Community. The *Chroococcidiopsis* community was the first endolithic community discovered in Antarctica (19). It is characterized by the presence of *Chroococcidiopsis* as the sole phototrophic organism. It appears as a single green or brownish band just below the surface crust. This community occurs in extreme cold and dry habitats.

Chasmoendolithic Communities. Chasmoendolithic communities occur in a variety of rocks in the Ross Desert. Cracks in weathered granites, heavily silicified sandstones, and, to a lesser extent, weathered dolerites are inhabited by rhizomorph-like extensions of epilithic lichens and associations of cyanobacteria. In granites, the chasmoendolithic lichens sometimes form masses of nonpigmented fungal hyphae interspersed with green algae of the genus *Trebouxia* (21). The cyanobacterial chasmolithic association is usually dominated by members of the coccoid genera *Chroococcidiopsis* and *Gloeocapsa* (20).

The Physical-Chemical Environment

The Substratum. The cryptoendolithic community in the Ross Desert is primarily found in porous quartz sandstones of the Beacon Supergroup. This geologic formation is common in the region since the mountain ranges are all formed of its members overlying metamorphic and intrusive rocks, mainly granites and dolerites. Both outcrops and small boulders are colonized extensively. Colonized rocks usually have a grain size between 0.2 and 0.5 mm and a porosity of 8 to 15%, but the colonization of finer-grained samples can also occur (28,41). Fe^{+3}-containing oxyhydroxides, either as part of the matrix or as stains on individual crystals, give the rocks their characteristic yellow, orange, tan, or brown colors (46,47). Other elements detected in the matrix include aluminum, calcium, lead, magnesium, manganese, phosphorus, potassium, sodium, and titanium (21,48). The relative amounts of these elements are consistent with the suggestion that the matrix material is derived from weathered dolerite (46,49).

The surfaces of colonized rocks are usually covered by thin silicified crusts less than 1 mm thick. These crusts stabilize the surface and reduce the rate of wind erosion. They develop from the accumulation of windblown dust. The dust gradually changes into a layer that is less than 100 μm, covering primary stains and framework grains. The chemical and physical processes leading to the

conversion are poorly understood but thought to be related to those leading to the formation of desert varnish (46).

The Macroclimate. Selected parameters of the macroclimate were continuously monitored through the use of automatic weather stations at Linnaeus Terrace from 1984 to 1988, and at Battleship Promontory from 1986 to 1987. The relevant data from these stations have been summarized previously (25,26,30). Briefly, the Antarctic year can be divided into four seasons on the basis of position of the sun. In winter, mid-April to September, the sun remains below the horizon 24 hours a day. Air and surface temperatures vary gradually between $-20\,^{\circ}C$ and $-45\,^{\circ}C$ in response to the movement of large air masses. Because of the cold temperatures, winter snowfalls do not contribute moisture to the system. Spring begins when the sun first appears above the horizon, sometime in early September, and lasts until the sun remains above the horizon 24 hours a day, in mid-November. During this period, air temperatures rise to about $-10\,^{\circ}C$. Surface temperatures also rise, depending on composition and orientation. Colonized horizontal surfaces remain below $-5\,^{\circ}C$, whereas north-facing slopes can reach temperatures as high as $+5\,^{\circ}C$. Snowfalls occur, but again, because of the cold temperatures, do not contribute much moisture. In summer, which lasts from mid-November to mid-February, the sun is above the horizon continuously. Even so, air temperatures remain low, rarely reaching $0\,^{\circ}C$. Surface temperatures can be much higher because of solar heating, and temperatures in excess of $+15\,^{\circ}C$ have been recorded for north-facing slopes. There can be considerable diurnal fluctuation as the sun changes its position in the sky, and the temperatures of all surfaces drop below $0\,^{\circ}C$ for some time every day. Snowfalls occur irregularly. Moisture sensors in the rocks indicate that at least some of the snow melts and enters the ecosystem. Fall begins in mid-February, when the sun drops below the horizon for an increasing portion of time every day. Temperatures drop as diurnal solar heating is reduced. By mid-April, winter conditions prevail.

The Nanoclimate

The Temperature Regime. As indicated in the previous section, the temperature of a colonized surface is not the same as the air temperature measured by weather stations. Solar heating can raise the temperature significantly, as much as $20\,^{\circ}C$ above the ambient air temperature. The amount of heating depends on both the orientation and the albedo of the surface (25,26,28,50). Calculations indicate that the diurnal maximum temperature of a north-facing surface can be as much as $13\,^{\circ}C$ higher than the diurnal maximum of a south-facing surface (28). Given the generally low temperatures in the region, this difference can account for the absence of significant colonization on south-facing slopes (21,27,28,50). Light-colored surfaces, which would be advantageous from the perspective of the light regime, may not warm sufficiently, at least under the conditions at Linnaeus Terrace, to support colonization.

Early reports (50) suggested that there was a steep temperature gradient in the colonized zone and that this gradient might influence the observed banding pattern in the cryptoendolithic lichen community. This possibility was investigated further through the use of small probes (27) and computer models (28). The combination of the two techniques demonstrated conclusively that while there is a slight temperature gradient within the colonized zone, its magnitude is too small to influence the distribution of cryptoendolithic microorganisms. The original reports of a steep gradient probably resulted from the difficulty of making measurements at the scale of the nanoclimate. Rapid changes in air temperature just above the surface of the rock may contribute to the absence of epilithic lichens in this region (27,28).

The Light Regime. The flux of light incident on the surface depends on the season of the year, the time of day, and the orientation of the surface (25,29). Seasonal data have been summarized by Friedmann and coworkers (25). During the height of summer (December and January), the average daily maximum photosynthetic photon flux (PPF) varies between 1,100 and 1,250 $\mu mol\ m^{-2}\ s^{-1}$; maxima in excess of 1,850 $\mu mol\ m^{-2}\ s^{-1}$ have been recorded. The key for the endolithic community, however, is how much of the light penetrates the rock. Measured gross extinction coefficients for colonized rocks range from 1.2 to 3.0 mm^{-1} (29), equivalent to decreases in the incident flux of 70 to 95% per millimeter. Rocks with larger framework grains and higher porosities have lower extinction coefficients; increasing the amount of matrix material or the degree of colonization increases the extinction coefficient. Because reflection at the surfaces of individual grains is a major factor in the extinction of light, changing the relative index of refraction through the addition of meltwater significantly reduces the extinction coefficient.

Both the organisms and the matrix material absorb blue light more efficiently than red light. This results in a calculated tenfold enrichment in red wavelengths at a depth of a few millimeters (29).

Although it is useful for purposes of comparison to assume that the extinction coefficient for an individual rock is constant with depth, this assumption is clearly false. First, because the quartz grains absorb relatively little of the light reaching their interiors, large grains can act as windows and allow light to reach much greater depths locally. Second, the absorbing particles, such as iron compounds, pigmented fungi, different species of algae and cyanobacteria, are not distributed uniformly. The effects of these factors on the distribution of light cannot be easily measured. Computer models (29) indicate that the steepest light gradient occurs across the crust, with up to 90% of the incident light reflected or absorbed over a distance of less than 0.5 mm. The flux of light can be reduced by an additional 90% in the black zone, with about half of the decrease attributable to absorption by members of the community. Thereafter, the rate of decrease is lower because the white zone lacks both pigmented fungi and iron compounds. At the bottom of the colonized zone, the photon flux is only about 0.005% of the incident flux, equivalent to about 0.06 $\mu mol\ m^{-2}\ s^{-1}$ (PPF) at the diurnal maximum. At this level, the effect

of water in the pore spaces is especially significant. When rocks are saturated with water, the amount of light reaching the bottom layers is increased 40-fold to about 0.2% of incident or 2.4μmol m^{-2} s^{-1} (PPF) at the diurnal maximum.

Water. Snow is the sole source of water for the community (31), but not all surfaces accumulate snow equally. On steeply sloped surfaces, snow accumulates only above the small ledges formed by exfoliative weathering (50). Even on horizontal surfaces, small depressions are more effective in accumulating snow than flat surfaces. Once the snow melts and enters the rock, it can be retained for relatively long periods, days or even weeks (25,26,50). Several factors contribute to the retention of water. First, because of the low temperatures, the potential rate of evaporation is only on the order of 1 to 2 mm m^{-2} day^{-1} (28,50). Second, the surface crust may retard evaporation by restricting gas exchange (51), although some field data suggest otherwise (50). Third, the rock matrix is capable of absorbing and retaining water at high humidity (52). The availability of matric water within the rock, in contrast to the arid conditions at the surface, seems to be the primary reason for the absence of epilithic lichens in the region.

Even during the Antarctic summer, water freezes on a daily basis, thereby reducing its availability to the community (25). Freezing occurs whenever the rock temperature drops below −5 °C; the water does not melt again until the temperature exceeds 0 °C (53). The depressed freezing point results from the physical structure of the rock. A similar phenomenon occurs in frozen soils (54).

The wetter conditions in sandstones colonized by the *Hormathonema-Gloeocapsa* community on Battleship Promontory are associated with differences in the chemistry of the rocks (22,48). Because of the lower oxidation-state of iron, colonized Beacon sandstones on Battleship Promontory are lighter than colonized sandstones from other regions. In addition, the pH is higher, ranging from 7.3 to 8.2 instead of the more typical 3.7 to 5.8. The concentrations of calcium, magnesium, and metal oxides are also higher (48).

Nutrients. Inorganic nitrogen in the form of nitrate and ammonium ions is always present in the upper few millimeters of colonized rocks (41,55). The concentration of nitrates varies from 0.1 to 25.9 μg g^{-1} rock; the concentration of ammonium ions is usually less than 2 μg g^{-1} rock. The nitrogen reaches the rock surface from the atmosphere at a rate of about 20 mg N m^{-2} yr^{-1} (30); biological nitrogen fixation is absent or very rare (41,56). The addition of inorganic nitrogen in the form of ammonia, nitrate, and nitrite does not stimulate carbon incorporation, indicating that the low levels of nitrogen are not limiting to the community (49,56). Apparently, in all endolithic microbial communities, including those in hot deserts, nitrogen demand is low because of the low metabolic rates, and can be met by the influx of fixed nitrogen from the atmosphere (55).

Interactions with the Physical Environment

Causes of the Pattern of Zonation. The most conspicuous feature of any cryptoendolithic community is the distinctive zonation pattern. Much of the structure can probably be attributed to interactions of the community with the light regime. Light gradients can result in structured communities of photosynthetic organisms through the actions of two opposing mechanisms. At the upper end of an organism's distribution, excessive light results in photooxidative damage. At the lower end, light is not sufficient for growth. This process was demonstrated qualitatively by Weber and coworkers (13) in a study of hot desert endolithic cyanobacteria. In their study, fine-grained quartz sand was inoculated at the surface with *Chroococcidiopsis*. The cultures were then incubated under different light regimes. After five months, the cyanobacteria had formed a distinct layer 3 to 7 mm below the surface of the sand. Cultures exposed to higher light intensities formed deeper bands than those exposed to lower light intensities. Qualitative evidence of these mechanisms can be seen are evident in the growth of the lichen-dominated community in the Ross Desert. The dark pigmentation of the upper layer probably provides a measure of protection against photooxidative damage (1). Fungi in the lower layers, where the photon flux is much lower, are not pigmented.

Presence of *H. antarctica* below the lichen requires a little more explanation. In culture, *Hemichloris* grows well at photon fluxes of 30 μmol m^{-2} s^{-1} (PPF), well above what it experiences in nature. Why, then, is it so deep in the rock? Several answers have been suggested (29,30), but none has been demonstrated conclusively. It is possible that *Hemichloris* is less tolerant of photooxidative damage incurred while in the desiccated state, and thus can only survive in darker habitats. It is also possible that *Hemichloris* is driven to the lower levels by competition with the lichen organisms. The competition could take the form of a simple scramble for space, with the lichen growing faster, or it could involve a more active process such as the production of antimicrobial agents by the members of the lichen. Experimental studies with cultures have demonstrated that several strains of fungi from the lichen layer are capable of producing substances active against heterotrophic bacteria and against lichenized and nonlichenized algae isolated from the parent community (57).

Biomass. The biomass of the endolithic community has been measured as chlorophyll *a* (51,58), Kjeldahl nitrogen (51,52,59), ATP (60), lipid phosphate (61), and organic matter, either by combustion (51,61) or by direct observation (41). Measured values of chlorophyll *a* range from 1.7 to 130 mg m^{-2}. The conversion of chlorophyll values to total biomass is difficult because of variability in the ratio of the photosynthetic and nonphotosynthetic components of the community. Estimates of the total organic matter based on Kjeldahl nitrogen range from 32 to 180 g m^{-2}. These are somewhat lower than estimates based on combustion (34 to 655 g m^{-2}), and significantly higher than estimates based on ATP (0.02 to 8.8 g m^{-2}) and lipid phosphate (4.4 to 7.4 g m^{-2}).

At least some of the variation among different methods results from the fact that a significant fraction of each endolithic community is composed of dead cells, as demonstrated by Greenfield (41). The proportion of dead cells in a community is variable, related, in part, to the environmental parameters at the site (41,47,62,63). The samples used by Greenfield, with only 14 to 21% of the organic matter viable, were collected from the summit of West Beacon, one of the colder sites in the Ross Desert.

Weathering. Colonization of Beacon sandstones by the lichen-dominated community is associated with a distinctive mosaiclike weathering pattern on the surface. The pattern consists of a patchwork of colors ranging from white to brown over a terraced surface (Plate 1). The microterracing results from exfoliative weathering, in which pieces of crust and subsurface material flake off the rock (Fig. 1). Exfoliating flakes are irregular in shape, up to 50 mm across and 1 to 2 mm thick. A number of factors contribute to exfoliation, including the growth of the lichen between the grains, intermittent swelling of the lichen during times of hydration, freeze expansion, and mobilization of the matrix material (47). The principal method of mobilization seems to be solubilization by oxalic acid. Oxalic acid, commonly implicated in weathering by lichens, has been identified on the basis of ion chromatography and crystal morphology in SEM (44,64,65), GC/MS (32), and FT-Raman spectroscopy (23,66). The use of FT-Raman spectroscopy allowed Russell and his colleagues to demonstrate an accumulation of oxalate just above the green layer of the community, at the depth where exfoliation occurs (23). They suggested that the dissolution of matrix silicates by oxalate may be more important than the dissolution of metal oxides or the expansion of clusters of cells. Other organic acids may also play a small role in the weathering process; 29 of 36 strains of heterotrophic bacteria tested by Siebert and coworkers (45) released some sort of organic acid into the growth medium.

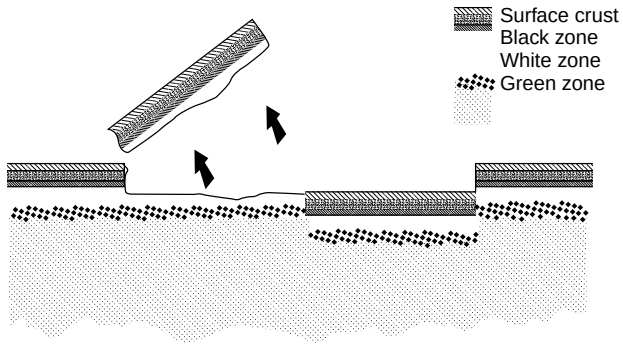

Figure 1. Diagrammatic representation of biogenous weathering in sandstones from the Ross Desert, Antarctica. From left to right: initial level of colonization, exfoliation of surface crust to biological activity, site of early exfoliation with microorganisms growing deeper into the rock substratum and the formation of a new surface crust, and a portion of the old surface crust at the initial level of microbial growth. Productivity and Growth. Gross productivity, as measured by the uptake of labeled bicarbonate in crushed rock samples, increases almost linearly with light up to a photosynthetic photon flux of about 200 μmol m^{-2} s^{-1} (56). Because the maximum light flux within the colonized zone is well below 200 μmol m^{-2} s^{-1}, the community is never light-saturated in its active state. This was confirmed by field measurements (56). Dark incorporation of labeled bicarbonate (56) or carbon dioxide (52,67) accounts for up to 10% of the total incorporation in the light. One of the lichen-forming fungi is responsible for at least a part of this incorporation. There is no evidence in support of chemoautotrophic growth (56). The rate of incorporation of bicarbonate is detectable at −8 and 30 °C, but not at −10 or 35 °C; the temperature optimum is 15 °C (56).

Net productivity, as measured by carbon dioxide gas exchange at the surface, occurs at surface photon fluxes as low as 100 μmol m^{-2} s^{-1} (PPF). The rate of uptake increases linearly up to at least 750 μmol m^{-2} s^{-1} (PPF), with no sign of light saturation (51,68). The maximum rates measured ranged from 0.22 to 0.78 mg carbon dioxide m^{-2} h^{-1} (51,68). The lower temperature limit is difficult to measure with any certainty, but also seems to be near −8 °C (51). Thus, −10 °C may be taken as the lower limit for significant metabolic activity by the community. The optimum temperature lies between −3 and 6 °C and the upper compensation point between 8 and 15 °C. The variation in these two numbers may represent the variation in the composition of the community, especially in the ratio of the photosynthetic to nonphotosynthetic components. It should be remembered that the optimum temperatures are rarely reached in nature and that the upper compensation point is only reached on north-facing slopes (25,68).

Annual gross and net productivity were estimated by coupling short-term laboratory measurements of photosynthesis with long-term field measurements of temperature and moisture conditions (68,69). Assuming that the organisms are metabolically active only at temperatures above −10 °C and only when liquid water is present, activity is restricted to an average of 700 to 800 hours per year in horizontal surfaces and 400 to 500 hours per year in north-facing slopes — the shorter period of activity in the sloped surface results from the reduced amount of snow accumulation on these surfaces. Annual net productivity in a well-colonized horizontal surface was estimated at about 600 mg C m^{-2} y^{-1} (equivalent to about 1,400 mg organic matter m^{-2} y^{-1}), which is about three times the net productivity of a sloped surface. At face value, these numbers indicate a low annual productivity in keeping with the harsh environment. The situation is actually more complicated. Johnston and Vestal (70) estimated the turnover time for organic matter in the community on the basis of the incorporation of carbon into phospholipids as 17,000 years. This is probably an overestimate of the turnover time because the temperature range below 5 °C, in which most of the net photosynthetic gain occurs, was not included in their calculations. A 10,000-year turnover time agrees with a 1,000-year residence time for carbon estimated from a radiocarbon determination (71,72). The net ecosystem productivity,

defined as the yearly accretion of organic matter, can be estimated as the quotient of biomass ($\sim$30 g C m^{-2}) and age ($\sim$10,000 years), yielding about 3 mg C m^{-2} y^{-1}. This amounts to about 0.05% of the net productivity and 0.025% of the gross productivity of the community (68). The missing material may represent the cost of remaining metabolically active in this environment, for example, the cost of compatible solutes lost during freeze-thaw cycles.

In the Ross Desert, microbial growth, a biological process, and exfoliative weathering, a geological process, seem to occur on approximately the same timescale (10^3 to 10^4 years). However, productivity measurements are typically made with mature communities. The question arises whether, after an exfoliation event with its concomitant loss of biomass, the microorganisms grow rapidly, fill the interstitial spaces in a short period of time, and then enter a period of slow or no growth, or grow slowly, but continuously, until the carrying capacity of the rock is reached. Sun and Friedmann (59) addressed this question by examining the relationship between biomass, as determined by Kjedahl nitrogen, and the color of the surface crust. Because exfoliation occurs within the leached, iron-free zone, new rock surfaces are white and the biomass of the cryptoendolithic community, having lost the dark-pigmented upper zones, is initially low. Over time, dust accumulates on the surface, resulting in an increasingly darker crust; thus the intensity of the surface provides a qualitative measure of the time since the last exfoliation. Sun and Friedmann found that biomass correlates with surface color, indicating that the community grows continuously throughout the long exfoliative cycle and that exfoliation occurs when the carrying capacity of the rock is reached.

Adaptations to the Environment. The microorganisms comprising the cryptoendolithic community do not seem to be well-adapted to the environment. Most of the strains tested are psychrotrophs, and several strains are capable of growth above 30 °C (36,37,42–45,73); true psychrophiles are present, but seem to be the exception. Two strains of the lichen-alga *Trebouxia*, the green alga *Hemichloris antarctica*, the xanthophycean alga *Heterococcus endolithicus*, the lichen fungi and some of the parasymbiontic fungi have temperature optimum between 15 and 20 °C (36,37,73), which is well above what is typically encountered during the active period. The temperature optimum for net photosynthetic activity by the community, between -2 and $+5$ °C, in contrast, is reached in nature. Apparently, the community is adapted to the environment, but the individual members are not.

This paradoxical situation can be explained if we consider the following facts. First, the temperature response curves of algae and fungi have different slopes, so the responses of the two groups do not parallel each other. Second, the temperature optimum of the fungi are usually higher than those of the algae. Third, fungal respiration continues to increase beyond the photosynthetic optimum of the algae. For a lichen community to exist in any given temperature range, the ratio of algae-to-fungi must be such that net production by the algae is greater than or equal to consumption by the fungi. In nature, the community as a whole adapts by altering the algae-to-fungi ratio to match the prevailing temperature conditions (Friedmann and Sun, unpublished data).

Extinction and Fossilization. The cryptoendolithic community exists on a tight energy budget, with no reserves to spare. The organisms living under a temperature regime far below their optimum seem to have reached the limits of their physiological potential. Maintenance of life depends on a precarious equilibrium of biological and physical processes. Even minor shifts in this equilibrium caused by a change in the orientation of the rock resulting in reduced insolation may cause extinction (47). Communities in all stages of deterioration can be found in the Ross Desert, and changes in cellular fine structure, from normal to stressed to dead cells, have been documented (23,62). Rock surfaces with extinct communities may become heavily silicified and resistant rock rinds may develop that incorporate and preserve the characteristic weathering patterns as trace fossils (47). The minimum age of such trace fossils has been estimated from quartz-rind thicknesses as ranging from about 7,000 to about 2 to 4 million years (47). It has been suggested that similar trace fossils may have been formed on the surface of Mars, preserving the last traces of a cooling and drying planet (2,47,62,74,75). Methods used to detect and analyze fossil and living endolithic communities may help in the search for life on Mars (23).

ENDOLITHIC COMMUNITIES IN THE COASTAL REGION OF ANTARCTICA

Cryptoendolithic communities are rare in coastal and maritime Antarctica, presumably because of the scarcity of suitable porous substrata. Chasmoendolithic communities are widespread and may include the major primary producers in the coastal deserts of Antarctica (76). Examples have been reported from ice-free coastal regions and nunataks in Queen Maud Land (77), MacRobertson Land (24,78), Marie Byrd Land (79,80), Princess Elizabeth Land (24), Victoria Land (20,21,78), Ross Island (81), and Signy Island (82). The most extensive studies have been made in the Vestfold Hills, Princess Elizabeth Land, and in the vicinity of Mawson Rock, MacRobertson Land.

Chasmolithic microorganisms inhabit a variety of rock types; the only requirements seem to be cracks in the stone, some light-colored mineral grains capable of transmitting light, and a supply of water. Colonized rocks types include weathered granites and anorthosites from Dufek Massif (20) and the granitic nunataks on the Edward VII Peninsula (80), weathered marbles at Gneiss Point and Marble Point (20,21), charnockite and quartz pebbles at Mawson Rock (24), and quartz-feldspathic gneisses and quartz pebbles in the Vestfold Hills (24). The growth pattern of the microorganisms is determined by the nonbiological weathering pattern of the rock. For example, vertical fissures are common in orthoquartzite, whereas granites and gneisses tend to crack parallel to the surface. In some cases, there are no obvious fissures, but just a network of small cracks. In this case, the growth pattern resembles that of the cryptoendolithic community.

The photosynthetic community in coastal Antarctica is much more diverse than that of the Ross Desert. More than 17 taxa of cyanobacteria and eukaryotic algae have been identified, although only four appear with any regularity (24,74,83). The green alga *Prasinococcus calcarius* is the most common constituent where ocean spray reaches the rock. In drier areas not reached by spray, members of the green alga genus *Desmococcus*, including a new species, *Desmococcus endolithicus* (84), are the most common taxa. Less frequently, a cyanobacterial community dominated by *Chroococcidiopsis* and an oscillatorian species develops; this community seems to have a higher moisture requirement and only develops in areas where a greater supply of meltwater is available (24). *Pseudococcomyxa simplex* was abundant as a chasmolith in an isolated boulder on the ice near the North Masson Range (85). On Signy Island, the relatively diverse chasmolithic community includes *Gloeocapsa gelatinosa*, *Merismopedia tenuissima*, *Nostoc punctiforme*, and *Plectonema battersii* (82).

The higher diversity of the coastal chasmolithic community, when compared with the Ross Desert communities, can be attributed to the milder climate. In the Vestfold Hills and on Mawson Rock, mean daily temperatures reach 2 °C in January (76,83). Signy Island is even warmer and temperatures can reach as high as 30 °C (86). In addition, winter snow accumulation is sufficient to provide a trickle of water over rock surfaces well into summer (24).

The distribution of chasmoendolithic colonization is determined primarily by wind direction; in the Vestfold Hills, the community develops almost exclusively on the leeward surfaces (24). Depressions in steep surfaces capable of capturing snowdrift enhance the development of the community.

ENDOLITHIC COMMUNITIES IN HOT ARID REGIONS

As indicated in the introduction, endolithic communities are widespread in hot arid regions. It is beyond the scope of this article to discuss each of these in detail. Instead, we will focus on three relatively well-characterized examples to illustrate the general features.

Endolithic Communities in the Middle East

The endolithic communities in the Negev Desert, southern Israel, were among the first reported from hot desert regions (1,4,5). The climate is typical of a hot desert (4,7). The yearly average temperature ranges from 21 to 35 °C in the south and east, 19 to 21 °C in the north. The annual precipitation ranges from a few millimeters in the south to a maximum of less than 20 cm in the Negev Highlands. Most of the rain is seasonal and limited to a few days during the winter. Moisture is also available in the form of fog and dew (4,7,87,88), especially in the northern parts of the desert.

Chasmoendolithic Communities. Chasmoendolithic microorganisms are found in weathered granites, dolomites, limestones, and quartz, where they can form extensive horizontal growths under surface flakes (1,4,7,89). The photosynthetic community, the only segment of the community studied in detail, is usually dominated by unicellular cyanobacteria, especially members of the genera *Chroococcus*, *Chroococcidiopsis*, and *Gloeocapsa*. However, a number of unicellular green algae and filamentous cyanobacteria occur with some regularity (4). This community is thought to be responsible for the exfoliative weathering of limestone and dolomite boulders in the region (1,7,89).

Cryptoendolithic Communities. Cryptoendolithic communities are found in porous Nubian sandstone and crystalline limestones throughout the region (5, Plate 2). They are typically dominated by a single species of cyanobacterium, almost always a member of the genus *Chroococcidiopsis*. However, other chroococcoid cyanobacteria, heterotrophic bacteria, and an occasional unicellular green alga may also be present (4,5). The community forms a green band, 0.1 to 2.5 mm thick, 0.1 to 3.0 mm below the surface of the rock. Well-developed communities frequently display a definite zonation pattern. In these cases, the upper layers are marked by the abundant growth of large colonies of cyanobacteria with pigmented sheaths and brownish cytoplasm. The pigmented sheaths probably indicate the presence of scytonemin, a compound demonstrated to provide protection against photooxidative and UV-induced damage in cyanobacteria (90,91). The upper boundary of this layer is usually sharply delimited. The lower limit is more diffuse, grading into a zone of scattered colonies with colorless sheaths and blue-green protoplasts.

Euendolithic Communities. Euendolithic lichens, especially the lichen species *Caloplaca aloiziza*, colonize the surface of limestone rocks and stones in the moister regions of the Negev (6,7,92,93). Extensive colonies give the surface of the rocks a characteristic gray color. Larger surfaces are overlain with a jigsaw-puzzle-like pattern derived from the boundaries of individual lichen colonies. The jigsaw-puzzle pattern is enhanced by the activity of terrestrial snails, which preferentially feed at the boundaries (6,94). The distribution of euendolithic lichens has been linked to the amount of rainfall, the orientation of the surface, and the size of the stone (6,7,93). The lower limit of the extensive development of the community seems to be a mean rainfall of about 30 cm y^{-1}. Wetter, cooler, north-facing surfaces are colonized by epilithic lichens, precluding their use by endolithic microorganisms. The size of the stone influences the amount of dewfall. Smaller stones cool more quickly and more completely than larger stones and, therefore, cause more dew to condense from the surrounding air (7,88). If the micro- and nanoclimates result in more than 450 hours per year of daylight imbibition time because of dew, epilithic lichens cover the surface of the stone. Lower amounts of dew and a lower cumulative daylight imbibition time (300 to 450 hours per year) favor the growth of endolithic lichens (7). Even lower cumulative daylight imbibition times seem to favor the growth of euendolithic fungi of the genus *Lichenothelia* and of communities of cryptoendolithic and chasmoendolithic

cyanobacteria and eukaryotic algae. *Lichenothelia* colonies can form in limestone rocks in the southern Negev where the annual precipitation is between 3 and 5 cm y^{-1} (11).

Free-living colonies of euendolithic cyanobacteria inhabiting characteristic pits and depressions in limestone rocks in the more arid regions of the Negev Highlands have been reported (6,11,93). These reports are somewhat controversial and require reexamination. One of us (EIF) examined samples of such pitted limestone rocks from the same vicinity and found dark hyphae from *Lichenothelia* or other fungi, but no cyanobacteria. However, a euendolithic filamentous species of the stigonematalean genus *Matteia* has been isolated from the Negev (95).

Endolithic Microorganisms as Indicators of Paleoclimates. The activity of lithobiontic, especially euendolithic, microbial communities leaves distinct traces on the surfaces of colonized rocks, even when the community is destroyed by burial or fire. To the extent that these communities are associated with particular macro- and microclimatic conditions, these traces can be used to evaluate past climatic conditions. This has been attempted for sites in Israel by Danin and his colleagues (6,93). According to their observations, the co-occurrence of certain communities correlates well with current climate conditions (93). Pitting by microfungi of the genus *Lichenothelia* and by cyanophilous lichens on stones and on boulders, for example, is indicative of the driest conditions. Epilithic lichens and the jigsaw-puzzle patterns formed by endolithic lichens (genus *Caloplaca*) indicate relatively moist conditions. Using this information, Danin (93) was able to document drier conditions in Israel during the pre-Neolithic (30,000 to 12,000 BP) and wetter conditions during the Neolithic (10,000 to 9,000 BP) period by examining the weathering patterns on boulders unearthed at archeological sites. Climatic conditions have remained relatively constant in Israel for the past 6,000 years.

Endolithic Communities in the southwestern United States and Mexico

Endolithic communities have been reported from the Sonoran Desert, Mexico (14,96), and Death Valley, California (1), but the most extensively studied are those of the Colorado Plateau, northern Arizona (15,97–99). The

climate in Colorado Plateau is somewhat milder than that of the Negev Highlands; the mean annual rainfall ranges from 20 to 30 cm y^{-1} and mean temperatures range from 10 to 13 °C (97). Measurements within colonized rocks indicate that the relative humidity in the colonized zone never drops below 60% and is usually in excess of 80%; temperatures can reach as high as 47 °C (99). The predominant rock types are quartz sandstones belonging to eight geologic formations; granites, limestone, quartzite, and siltstone are also present (15,98). Chasmolithic communities are found in all rock types. These are relatively depauperate, frequently monotypic stands of *Chroococcidiopsis* or related cyanobacterial taxa (98).

The cryptoendolithic community, in contrast, is relatively rich. At least twenty species of cyanobacteria and green algae are present (15). As is typical of cryptoendolithic communities, these form a more or less well-defined band extending from just below the surface crust to a variable depth within the rock, but never more than 2 mm (15). The depth of the community depends on the grain size, the porosity, and the color of the rock, presumably through interactions with light (15). The composition of the community seems to depend on the macroclimate. Rock outcrops associated with desert scrub communities, indicating the harshest macroclimates in the region, harbor cryptoendolithic communities dominated by cyanobacteria, usually members of the genus *Chroococcidiopsis*. The same is true of outcrops associated with grasslands. In outcrops of the same type of sandstone in conifer forests, which are slightly cooler and receive more rainfall (30 cm y^{-1} vs. 20 cm y^{-1}, the community can be dominated by green algae of the genera *Chlorococcum*, *Borodinella*, *Chlorosarcinopsis*, and *Tetracystis* (98).

The biomass of the community, measured as chlorophyll *a*, ranges from 8 to 140 mg m^{-2} (15,97); these values are similar to those reported for cryptoendolithic communities in Antarctica. The biomass depends in part on the color of the rock, with light sandstones harboring a larger community than dark sandstones (15,99). Photosynthetic activity by the community, as determined by the uptake of labeled bicarbonate, ranges from 0.13 to 0.89 mg carbon oxide dm^{-2} h^{-1}. Rates of carbon fixation vary with the season and the time of the day. Interestingly, during summer, photosynthetic activity is reduced at noon, perhaps indicating some degree of photoinhibition; this reduction was not seen during other seasons (99). However, the maximum photosynthetic photon flux in the algal zone should be less than 100 μmol m^{-2} s^{-1} (99). These values are comparable to the above ground rate of photosynthesis in the region (97).

Endolithic Communities in Southern Africa

Cryptoendolithic communities have been reported from the northeastern portions of the Orange Free State and from the Northern Province of South Africa (10,13,100). Two of these communities have been studied in some detail.

The Langjan Nature Reserve Community. The cryptoendolithic community in a large brown-colored quartz sandstone has been investigated by Weber, Wessels, and Büdel (13). The climate in the Langjan Nature Reserve is typical of dry savannah grassland, with limited seasonal precipitation and high summer temperatures. The mean annual rainfall is 34 cm y^{-1}, higher than in the Negev Desert or on the Colorado Plateau, with most of the rain falling between November and March. During the dry season, which is from May to September, monthly rainfall is less than 1 cm. Air temperatures vary from 0 to 42 °C; the annual mean temperature is 23 °C. Limited measurements at the beginning of the summer season indicate that rock temperatures in excess of 50 °C are common. Observations indicate that the rock may serve as a water reservoir, but this was not investigated in detail.

The community forms a blue-green band averaging 1.1 mm in thickness starting at an average depth of 1 mm. The community is composed primarily of cyanobacteria. The most abundant organisms are members of the genus *Chroococcidiopsis*. Filamentous cyanobacteria of the genera *Nostochopsis* and *Microcoleus* are also present, as are a number of fungi imperfecti. The latter do not seem to form lichen associations with the cyanobacteria. Chlorophyll *a* ranges from 0.05 to 71.8 mg m^{-2}, with a mean of 29 mg m^{-2}, C-content from 4 to 107 g m^{-2}, and N-content from 0.7 to 4.4 g m^{-2}, in the same range as other cryptoendolithic systems. Fluorescence measurements using intact rocks demonstrated that the community is probably not light-saturated in nature. However, if the surface of the rock is removed and the community exposed, light saturation occurs at a photosynthetic photon flux between 200 and 350 μmol m^{-2} s^{-1}, and photoinhibition may occur at fluxes below 1,200 μmol m^{-2} s^{-1}.

The Golden Gate Highlands National Park. The Golden Gate Highlands are located in northeastern Orange Free State, South Africa. Aspects of the endolithic communities in the park have been investigated by Wessels and his colleagues for a number of years (100–103). The climate in the region is relatively mild. Temperatures range from 13 to 25 °C in summer and from 0 to 15 °C in winter. The mean annual rainfall, about 76 cm y^{-1}, is more than double that of the previously discussed sites.

Euendolithic lichens, primarily of the genus *Lecidea*, are common in the large sandstone outcrops characteristic of the park (103). The same species colonize sandstones in the drier Mountain Zebra National Park (12). In Golden Gate Highlands National Park, they actively grow into the sandstone by dissolving the matrix material filling in the pore spaces and cementing the grains together (101). Some of the loosened grains are removed by insects during their life cycle (102). Wessels and coworkers (103) were also able to demonstrate increased mechanical strain in the rock as the result of the imbibition of moisture from the air in response to diurnal changes in relative humidity (103). As a result of these processes, biogenic weathering of Clarens sandstone can cause the removal of about 10 mm of material per hundred years (101).

A cyanobacteria-dominated community is found in the rear wall of shallow caves eroded into a stratum of Clarens sandstone overlain by a dolerite dike. The surface of the sandstone is effectively sealed by a light brown crust of sodium carbonate, sodium sulfate, and

recrystallized siliceous material (100). This ecosystem is unique in that the rock appears to be waterlogged throughout the year. Water enters the rock at the upper surface, which is not colonized by the community. Water percolates downward, reaching the community from the inside. The total amount of water available to the microorganisms was demonstrated inadvertently by the investigators when they chipped a sample from the surface of the rock and water began to seep out. Sufficient water was still available 18 months later to support a diverse epilithic community (100). In spite of the wet conditions, the cryptoendolithic community is similar to other such communities in arid regions. It forms a blue-green zone, 1 to 2 mm thick, 0.2 to 1 mm below the surface. The dominant organism is, again, a member of the genus *Chroococcidiopsis*, and biomass (chlorophyll *a*) ranges between 44.3 and 51.8 $mg\,m^{-2}$. Strains of *Chroococcidiopsis* isolated from Clarens sandstone raise the pH of the medium to almost 10. If such an increase occurred in nature, it would increase the solubility of silica and may contribute to the weathering of the sandstone (100).

COMPARISON OF ENDOLITHIC COMMUNITIES IN HOT AND COLD ARID REGIONS

Advantages of the Endolithic Habitat in Arid Regions

Endolithic communities develop wherever suitable rock types occur, in temperate regions as well as in arid lands, as can be seen in the diverse cryptoendolithic community inhabiting dolomite cliffs in southern Canada (104–106). Why, then, are endolithic communities more important in arid regions than in regions with a milder (moister) climate? In humid regions, rock surfaces are frequently covered by dense growths of epilithic cyanobacteria, algae, lichens, and lower plants (107). Such growths preclude the development of endolithic communities by limiting the amount of light reaching the habitat. Endolithic microorganisms can only form extensive growths where external conditions are too harsh to allow the development of epilithic communities. This factor must be the primary cause of the distribution patterns of epilithic and endolithic lichens observed in the Negev Highlands. It may also be responsible for the restriction of endolithic algae to the southern walls of the limestone O. L. Basilica in northeastern Belgium (108).

Given that the external environment is too harsh to support epilithic organisms, what protection is offered by the endolithic habitat? Temperature is probably not a major factor. As discussed previously, the temperature within the colonized zone is essentially the same as the temperature at the surface. The only difference is that very short-term temperature fluctuations at the surface are damped within the first millimeter or so (28). This may be important in cold deserts, where rapid fluctuations across the freezing point have been observed, but probably only plays a small role in hot deserts and temperate climates. More important are the moisture and the light conditions. In endolithic communities, especially cryptoendolithic communities, the internal environment is moister than the external. Two factors are at work. First, the surface crust reduces the rate of evaporation or, in the extreme case of the Clarens sandstone community, the rate of outflow. Second, the physical structure of the substratum helps to condense and hold water within the rock (52,103). Because the interior is moister, the endolithic community experiences a longer period of metabolic activity after each dewfall, rainfall, or snowmelt, and a longer cumulative imbibition time than the epilithic community. However, the crucial feature is probably the reduction in the amount of light reaching the community in the desiccated state. Cryptoendolithic communities are found at depths corresponding to photon fluxes less than 5% of direct sunlight. Even with these low light levels, the organisms in the upper portions of the community produce pigments, melanin and melanin-like compounds in cryptoendolithic fungi and scytonemin in cyanobacteria, associated with protection against high light (1,90,91). Apparently, the amount of photooxidative damage accumulated at the surface during the desiccated state is too great to be repaired during the short periods of activity. The organisms require a combination of screening by the material of the rock and by their own pigments to reduce the amount of damage to a manageable level.

Cryptoendolithic Cyanobacteria in Hot Deserts

The dominance of cyanobacteria, especially members of the genus *Chroococcidiopsis*, in hot desert cryptoendolithic communities is striking. Evidently, the conditions common on rock surfaces in hot climates, namely, temperatures of 50°C or more, high levels of insolation, and extreme dryness, are less tolerated by eukaryotic algae than by cyanobacteria (2,99). This is consistent with the dominance of epilithic cyanobacteria and cyanolichens on tropical inselbergs (107), with the increased role eukaryotic algae play in the milder portions of the Colorado Plateau (98), and with the dominance of eukaryotic cryptoendolithic lichens in the milder Antarctic desert. It is also possible that *Chroococcidiopsis* and other cyanobacteria have more efficient repair mechanisms. These would allow them to recover more quickly from damaged induced by desiccation or by photooxidation, and to use more efficiently the shorter periods of activity in hot deserts. In fact, desert strains of *Chroococcidiopsis* have been shown to survive doses of X rays as high as 15 kGy, at rates of survival cited as second only to those of strains of *Deinococcus radiodurans* (109). Note that neither of these suggestions implies that *Chroococcidiopsis* is well-adapted to the endolithic environment. Instead, it seems that *Chroococcidiopsis* is the complete generalist, with an almost unparalleled ability to live under a wide range of environmental extremes (39). However, because it is a generalist, it lacks the ability to compete with more specialized species, and only succeeds where they cannot survive.

CONCLUSION

Environmental conditions on the surfaces of rocks in arid regions can be so harsh that not even lichens cannot survive; in extreme cases, the surfaces are essentially

abiotic. Endolithic microorganisms in these regions find a protected niche under the surface, in structural cavities or in fissures. These microorganisms are not adapted to the environment in the strict sense of the word because their physiological optimum lie far from the conditions they are living in. Instead, they are adapted to tolerate the environmental extremes. Often they exist near the limits of their physiological potential, in which no further adaptation is possible.

ENDOSYMBIOSIS IN ECOLOGY AND EVOLUTION

DANIELE CORSARO

Recherche
Vandoeuvre-les-Nancy, France

Almost all the forms of life present endosymbiotic organisms, that is, microorganisms that have developed the ability to live in the body or in the cells of other organisms. Such endosymbionts have originated in several lineages, both prokaryotic and eukaryotic, and include both mutualistic and parasitic lifestyles. Symbiotic associations, earlier considered as a curiosity, in reality are widespread in nature (1) and play a key role in ecology. Especially of interest are those associations in which microorganisms have chosen the intracellular habitat of another cell as an ecologic niche (2). Major examples of the ecological importance of endosymbiosis are the associations of some fungi with plant roots, forming endomycorrhizae that aid the plant's acquisition of minerals, and the endosymbioses of algae with invertebrate animals in oligotrophic tropical seas, where they may be a very important source of nutrients and may also contribute to the formation of coral reefs. Moreover, an unexpected biodiversity has been discovered near the deep-sea hydrothermal vents, where a photosynthesis-independent ecosystem exists based on sulfur-oxidizing (thiotrophic) bacterial symbionts. The evolutionary importance of endosymbiosis

is also considerable. Indeed the endosymbiosis between a unique lineage of green alga and the glomalean fungi lies at the origin of the landplants that dominate the terrestrial ecosystems. Finally, intracellular symbioses have played a key role in the origin and evolution of the eukaryotes: it is actually noteworthy that two important eukaryotic organelles, the mitochondria and the plastids, are derived from highly integrated endosymbiotic bacteria. Thus, symbiosis may be considered not simply as a mutualistic relationship but also as a way for evolutionary creativity.

DEFINITIONS

Mutualism and Parasitism

The term symbiosis originally referred to any group of differently named organisms living together, whether both organisms derive a benefit (mutualism) or the benefit for one organism derives from a damage to another one (parasitism). However, sometimes the status of an organism is difficult to identify precisely, because the mutualistic or parasitic behavior may depend on a developmental stage, or on an environmental stress, such as a contact with an unnatural partner, or simply because of our limited knowledge of the association. In addition, a mutualistic or parasitic status may change with time. The bacterial group of the rickettsiae clearly illustrates these aspects. The rickettsiae are generally nonparasitic intracellular symbionts of arthropods and protists. But some species are important human or animal pathogens transmitted by ticks or other parasitic arthropods, causing typhus, spotted fevers or ehrlichioses. Closely related nonpathogenic rickettsiae exist, and their nonparasitic status depends primarily on the fact that the arthropod host never bites a vertebrate (3). It should be noted that the mitochondrion, a fundamental organelle of almost all the eukaryotes, seems to be derived from an ancestral intracellular bacterium belonging to the rickettsial group (4). By considering both mutualists and parasites as symbionts, we follow the original definition; this approach was also adopted by Smith and Douglas (1) in their important book. In cases in which the status is not clearly defined, we adopt the term "symbiont" or "biont" and its composed forms, for the smaller partner.

Symbiont, Host, and Terminology
