A brief overview is presented of various energy units; terminology; and basic concepts in energy conversion including pyrolysis, gasification, ignition, and combustion. Detailed sets of fuel properties of coal, agricultural biomass, and animal waste are presented so that their suitability as a fuel for the energy conversion process can be determined. It is also found that the dry ash free (DAF) heat values of various biomass fuels, including animal waste, remain approximately constant, which leads to a presentation of generalized results for maximum flame temperature as a function of ash and moisture contents. The cofiring technology is emerging as a cost-effective method of firing a smaller percentage of biomass fuels, with coal as the major fuel. Various techniques of cofiring are summarized. Gasification approaches, including FutureGen and reburn technologies for reduction of pollutants, are also briefly reviewed.

INTRODUCTION AND OBJECTIVES

The overall objective of this entry is to provide the basics of energy conversion processes and to present thermochemical data for coal and biomass fuels. Energy represents the capacity for doing work. It can be converted from one form to another as long as the total energy remains the same. Common fuels like natural gas, gasoline, and coal possess energy as chemical energy (or bond energy) between atoms in molecules. In a reaction of the carbon and hydrogen in the fuel with oxygen, called an oxidation reaction (or more commonly called combustion), carbon dioxide (CO_2) and water (H_2O) are produced, releasing energy as heat measured in units of kJ or Btu (see Table 1 for energy units). Combustion processes are used to deliver (i) work, using external combustion (EC) systems by generating hot gases and producing steam to drive electric generators as in coal fired power plans, or internal combustion (IC) engines by using the hot gases directly as in automobiles or gas turbines; and (ii) thermal energy, for applications to manufacturing processes in metallurgical and chemical industries or agricultural product processing.

Fuels can be naturally occurring (e.g., fossil fuels such as coal, oil, and gas, which are residues of ancient plant or animal deposits) or synthesized (e.g., synthetic fuels). Fuels are classified according to the phase or state in which they exist: as gaseous (e.g., natural gas), liquid (e.g., gasoline or ethanol), or solid (e.g., coal, wood, or plant residues). Gaseous fuels are used mainly in residential applications (such as water heaters, home heating, or kitchen ranges), in industrial furnaces, and in boilers. Liquid fuels are used in gas turbines, automotive engines, and oil burners. Solid fuels are used mainly in boilers and steelmaking furnaces.

During combustion of fossil fuels, nitrogen or sulfur in the fuel is released as NO, NO_2 (termed generally as NO_x) and SO_2 or SO_3 (termed as SO_x). They lead to acid rain (when SO_x or NO_x combine with H_2O and fall as rain) and ozone depletion. In addition, greenhouse gas emissions (CO_2, CH_4, N_2O, CFCs, SF_6, etc.) are becoming a global concern due to warming of the atmosphere, as shown in Fig. 1 for CO_2 emissions. Global surface temperature has increased by 0.6°C over the past 100 years. About 30%–40% of the world's CO_2 is from fossil fuels. The Kyoto protocol, signed by countries that account for 54% of the world's fossil based CO_2 emissions, calls for reduction of greenhouse gases by 5% from 1990 levels over the period from 2008 to 2012.

The total worldwide energy consumption is 421.5 quads of energy in 2003 and is projected to be 600 quads in 2020, while U.S. consumption in 2004 is about 100 quads and is projected to be 126 quads in 2020. The split

Table 1 Energy units and terminology

The section on energy Units and Conversion factors in Energy is condensed from Chapter 01 of Combustion Engineering by Annamalai and Puri [2005] and Tables.

Energy Units

1 Btu (British thermal unit) = 778.14 ft lb_f = 1.0551 kJ, 1 kJ = 0.94782 Btu = 25,037 $lbmft/s^2$

1 mBtu = 1 k Btu = 1000 Btu, 1 mmBtu = 1000 k Btu = 10^6 Btu, 1 trillion Btu = 10^9 Btu or 1 giga Btu

1 quad = 10^{15} Btu or 1.05×10^{15} kJ or 2.93×10^{11} kW h,

1 Peta J = 10^{15} J = 10^{12} kJ»0.00095 Quads

1 kilowatt-hour of electricity = 3,412 BTU = 3.6 Mj,

1 cal: 4.1868 J, One (food) calorie = 1000 cal or 1 Cal,

1 kJ/kg = 0.43 Btu/lb, 1 Btu/lb = 2.326 kJ/kg

1 kg/GJ = 1 g/MJ = 2.326 lb/mmBtu; 1 lb/mmBtu = 0.430 kg/GJ = 0.430 g/MJ

1 Btu/SCF = 37 kJ/m^3

1 Therm = 10^5 Btu = 1.055×10^5 kJ

1 m^3/GJ = 37.2596 ft^3/mmBTU

1 hp = 0.7064 Btu/s = 0.7457 kW = 745.7 W = 550 lbf ft/s = 42.41 Btu/min

1 boiler HP = 33475 Btu/h, 1 Btu/h = 1.0551 kJ/h

1 barrel (42 gal) of crude oil = 5,800,000 Btu = 6120 MJ

1 gal of gasoline = 124,000 Btu = 131 MJ

1 gal of heating oil = 139,000 Btu = 146.7 MJ, 1 gal of diesel fuel = 139,000 Btu = 146.7 MJ

1 barrel of residual fuel oil = 6,287,000 Btu = 6633 MJ

1 cubic foot of natural gas = 1,026 Btu = 1.082 MJ, 1 Ton of Trash = 150 kWh

1 gal of propane = 91,000 Btu = 96 MJ, 1 short ton of coal = 20,681,000 Btu = 21821 MJ

Emission reporting for pollutants: (i) parts per million (ppm), (ii) normalized ppm, (iii) emission Index (EI) in g/kg fuel, (iv) g/GJ, v) mg/m^3 of flue gas:

Conversions in emissions reporting: (ii) normalized ppm = ppm × (21-O_2% std)/(21-O_2% measured); (iii) EI of species k: C % by mass in fuel × mol Wt of *k* × ppm of species $k \times 10^{-3}$/{12.01(CO_2% + CO%)}, (iv) g/GJ = EI/ {HHV in GJ/kg}; (v) mg/m^3 = ppm of species *k* × Mol Wt of *k*/24.5

Volume of 1 kmol (SI) and 1 lb mole (English) of an ideal gas at STP conditions defined below:
Pressure at 101.3 kPa (1 atm, 14.7 psia, 29.92 in.Hg, 760 Torr) fixed; *T* changes depending upon type of standard adopted

Scientific (or SATP, standard ambient *T* and *P*)	US standard (1976) or ISA (International standard atmosphere)	NTP (gas industry reference base)	Chemists-standard-atmosphere (CSA)
25°C (77°F)	15°C (60°F)	20°C(68°F), 101.3 kPa	0°C (32°F),
24.5 m^3/kmol (392 ft^3/lb mole); $\rho_{air,SATP}$ = 1.188 kg/m^3 = 0.0698 lb_m/ft^3	23.7 m^3/kmol (375.6 ft^3/lb mole); $\rho_{air,ISA}$ = 1.229 kg/m^3 = 0.0767 lb_m/ft^3	24.06 m^3/kmole or 385 ft^3/lb mole; $\rho_{air,NTP}$ = 1.208 kg/m^3 = 0.0754 lb_m/ft^3	22.4 m^3/kmol (359.2 ft^3/lb mole), $\rho_{air,CSA}$ = 1.297 kg/m^3 = 0.0810 lb_m/ft^3

is as follows: 40 quads for petroleum, 23 for natural gas, 23 for coal, 8 for nuclear power, and 6 for renewables (where energy is renewed or replaced using natural processes) and others sources. Currently, the United States relies on fossil fuels for 85% of its energy needs. Soon, the U.S. energy consumption rate which distributed as electrical power (40%), transportation (30%), and heat (30%), will outpace the growth in the energy production rate, increasing reliance on imported oil. The Hubbert peak theory (named after Marion King Hubbert, a geophysicist with Shell Research Lab in Houston, Texas) is based upon the rate of extraction and depletion of conventional fossil fuels, and predicts that fossil-based oil would peak at about 12.5 billion barrels per year worldwide some time around 2000. The power cost and percentage use of coal in various U.S. states varies from

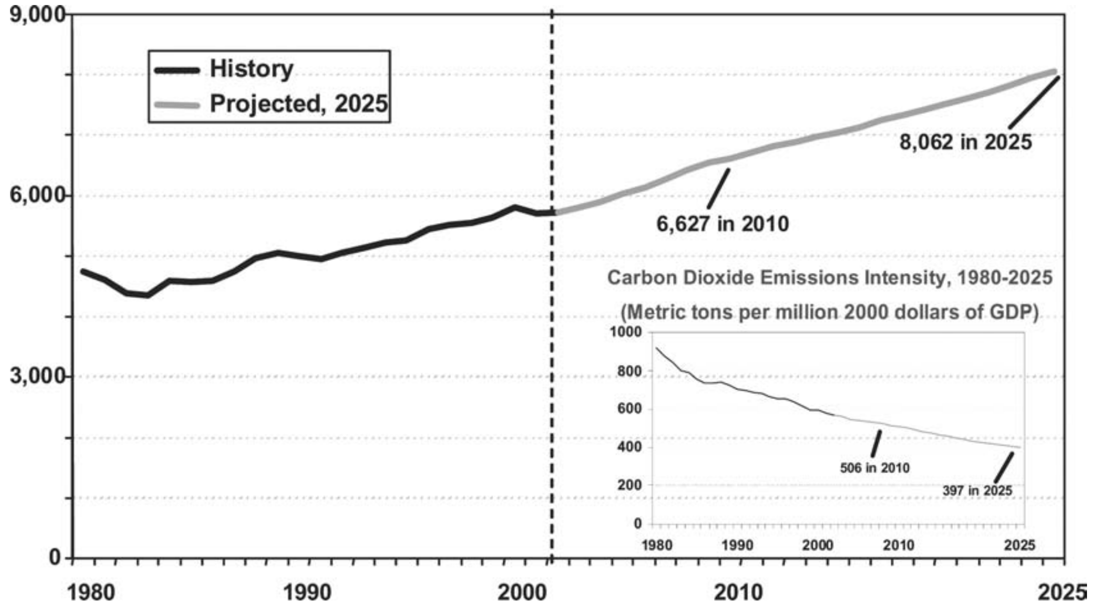

Fig. 1 Total CO_2 emission in million metric tons per year: History and Projected 1980–2025. Source: From DOE-EIA (see Ref. 1).

10 cents (price per kWh) at 1% coal use for power generation in California to 48 cents at 94% use of coal in Utah.

Biomass is defined as "any organic material from living organisms that contains stored sunlight (solar energy) in the form of chemical energy."[1] These include agro-based materials (vegetation, trees, and plants); industrial wastes (sawdust, wood chips, and crop residues); municipal solid wastes (MSWs), which contain more than 70% biomass (including landfill gases, containing almost 50% CH_4); and animal waste. Biomass is a solid fuel in which hydrogen is locked with carbon atoms. Biomass production worldwide is 145 billion metric tons. Biomass now supplies 3% of U.S. energy, and it could be increased to as high as 20%. Renewable energy sources (RES) include biomass, wind, hydro, solar, flowing water or hydropower, anaerobic digestion, ocean thermal (20°C temperature difference), tidal energies, and geothermal (a nonsolar source of energy), and these supply 14% of the world demand. The RES constitute only 6%, while coal, petroleum, and natural gas account for 23%, 40%, and 24%, respectively. About 9% of the world's electricity is from RES, and 65% of the electricity contributed by biomass. About 97% of energy conversion from biomass is by combustion. Many U.S. states have encouraged the use of renewables by offering REC (Renewable Energy Credits). One REC = 1 MW/h = 3.412 mmBtu; hence the use of 1 REC is equivalent to replacing approximately 1500 lb of coal, reducing emission of NO_x and SO_x by 1.5 lb for every 1 REC, assuming that emissions of NO_x and SO_x are 0.45 lb per mmBtu generated by coal. Several emission-reporting methods and conversions are summarized in Table 1. Recently, H_2 is being promoted as a clean-burning, non-global-warming, and pollution-free fuel for both power generation and transportation.

Fig. 2 shows a comparison between biomass and hydrogen energy cycles. In the biomass cycle, photosynthesis is used to split CO_2 into C and O_2, and H_2O into H_2 and O_2, producing Hydrocarbons (HC) fuel (e.g., leaves) and releasing O_2. The O_2 released is used to combust the HC and produce CO_2 and H_2O, which are returned to produce plant biomass (e.g., leaves) and O_2. On the other hand, in the hydrogen cycle, H_2O is disassociated using the photo-splitting process to produce H_2 and O_2, which are then used for the combustion process. The hydrogen fuel can be used in fuel cells to obtain an efficient conversion. Photosynthesis is water intensive; most of the water supplied to plants evaporates through leaves into the atmosphere, where it re-enters the hydrology cycle.

This entry is organized in the following format: (i) coal and biosolid properties; (ii) coal and biosolid pyrolysis (a process of thermal decomposition in the absence of oxygen), combustion, and gasification; (iii) combustion by cofiring coal with biosolids; (iv) gasification of coal and biosolids (a process that includes pyrolysis, partial oxidation due to the presence of oxygen, and hydrogenation); and (v) reburn for NO_x reduction.

FUEL PROPERTIES

Fuel properties play a major role in the selection, design, and operation of energy conversion systems.

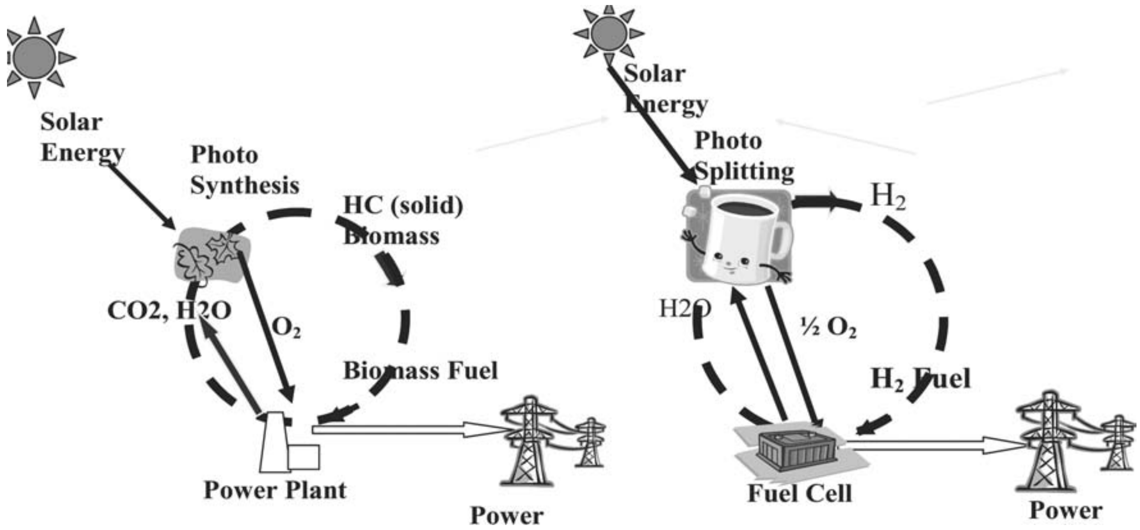

Fig. 2 Comparison of biomass energy and H_2 energy cycles.

Solid Fuels

The primary solid fuel widely used in power plants is coal containing combustibles, moisture, and intrinsic mineral matter originating from dissolved salts in water. During the "coalification" process, lignite, the lowest rank of coal (low C/O ratio), is produced first from peat, followed by sub-bituminous (black lignite, typically low sulfur, noncaking), bituminous (soft coal that tends to stick when heated and is typically high in S), and finally anthracite (dense coal; has the highest carbon content, >90%, low volatile <15%) with a gradual increase in the coal C/O ratio. The older the coal, the higher its rank. Anthracite (almost carbon) is the highest-ranked coal, with a high heating value. To classify coals and ascertain the quality of coal, it is essential to perform proximate and ultimate analyses according to American Society of Testing Materials (ASTM) standards.

Proximate Analysis (ASTM D3172)

A solid fuel consists of combustibles, ash, and moisture. Combustibles together with ash are called the solid content of fuel. A proximate analysis provides the following information: surface moisture (SM) or dry loss (DL), i.e., moisture in air-dried coal; the inherent moisture in the coal (M); volatile matter (VM; produced by pyrolysis, a thermal decomposition process resulting in release of water, gases, oil and tar); fixed carbon (FC; skeletal matter left after release of volatiles); mineral matter (MM; inert collected with solid fuel); and heating value (HV). On combustion, the MM may be partially oxidized or reduced, and the material left after combustion of C and H in the fuel is called ash (CaO, $CaCO_3$, Fe_2O_3, FeO, etc).

Table 2 shows comparative proximate analyses of coal, advanced feedlot biomass (FB, low-ash cattle manure; see "Coal and Bio-Solids Cofiring"), and litter biomass (LB, chicken manure).[2] Feedlot manure has higher moisture, nitrogen, chlorine, and ash content than coal. With aging or composting, the VM in manure decreases as a result of the gradual release of hydrocarbon gases or dehydrogenation, but fuel becomes more homogeneous.

Ultimate/Elemental Analysis (ASTM D3176)

Ultimate analysis is used to determine the chemical composition of fuels in terms of either the mass percent of their various elements or the number of atoms of each element. The elements of interest are C, H, N, O, S, Cl, P, and others. It can be expressed on an "as received" basis, on a dry basis (with the moisture in the solid fuel removed), or on a dry ash free (DAF) basis (also known as the moisture ash free basis MAF). Tables 3 and 4 show the ultimate analyses of various types of coal and biomass fuels.[3] While nitrogen is not normally present in natural gas, coal has 1%–1.5%; cattle manure and chicken waste contain high amounts of N (Table 2).

Heating Value (ASTM D3286)

The gross or higher heating value (HHV) of a fuel is the amount of heat released when a unit (mass or volume) of the fuel is burned. The HHV of solid fuel is determined using ASTM D3286 with an isothermal jacket bomb calorimeter. For rations fed to animals and animal waste fuels, the HHV for DAF roughly remains constant at about 19,500 kJ/kg (8400 Btu/lb),[4] irrespective of stage of decomposition of animal waste. The HHV can also be

HHV_{est}: Boie Equation. CO_2 in g/MJ or kg/GJ = C content in % × 36645/{HHV in kJ/kg}. CO_2 in lb per mmBtu = Multiply CO_2 in (g /MJ) or kg/GJ by 2.32. N in g/MJ or kg/GJ = N% × 10000/{HHV in kJ/kg}.
For NO_x estimation, multiply N content in g/MJ by 1.15 to get NO_x in g/MJ which assumes 35% conversion of fuel N.
For SO_2 estimation, multiply S content in g/MJ by 2 to get SO_2 in g/MJ assuming 100% conversion of fuel S (Multiply HHV in kJ/kg by 0.430 to get Btu/lb).
*Organic sulfur; **by difference.

[a] HHV based on Boie equation.

[b] Ref. 20; [Adapted from Refs. 3 and 17] See foot note of Table 3.2 for conversions to English units and estimation of NO_x and SO_2 emissions.

estimated using the ultimate analysis of the fuel and the following empirical relation from Boie[5]:

$$\mathrm{HHV_{fuel}(kJ/kg\ \ fuel)} = 35,160\ Y_C + 116,225\ Y_H - 11,090\ Y_O + 6280\ Y_N + 10465\ Y_S \quad (1)$$

$$\mathrm{HHV_{fuel}(BTU/lb\ \ fuel)} = 15,199\ Y_C + 49,965\ Y_H - 4768\ Y_O + 2700\ Y_N + 4499\ Y_S, \quad (2)$$

where Y denotes the mass fraction of an element C, H, O, N, or S in the fuel. The higher the oxygen content, the lower the HV, as seen in biomass fuels.

Annamalai et al. used the Boie equation for 62 kinds of biosolids with good agreement.[6] For most biomass fuels and alcohols, the HHV in kilojoules per unit mass of stoichiometric oxygen is constant at 14,360–14,730 kJ/kg of O_2 (6165–6320 Btu/lb of O_2).[7]

Estimate of CO_2 Emission

Using the Boie-based HVs for any fuel of known elemental composition, one can plot the CO_2 emission in g/MJ (Fig. 3) as a function of H/C and O/C ratios.[8] Comparisons for selected fuels with known experimental HVs are also shown in the same figure. Coal, with H/C ratio ≈ 0.5, releases the highest CO_2, while natural gas (mainly CH_4) emits the lowest CO_2. Because the United States uses fossil fuels for 86% of its energy needs (100 quads), the estimated CO_2 emission is 6350 million ton/year, assuming that the average CO_2 emission from fossil fuels is 70 kg/GJ (methane: 50 kg/GJ vs coal: 90 kg/GJ). Fig. 1 seems to confirm such estimation within a 10% error.

Flame Temperature

Fig. 4 shows a plot of maximum possible flame temperature vs moisture percentage with combustion for biomass fuels. The result can be correlated as follows[4]:

$$T(\mathrm{K}) = 2290 - 1.89\ \mathrm{H_2O} + 5.06\ \mathrm{Ash} - 0.309\ \mathrm{H_2O\ Ash} - 0.180\ \mathrm{H_2O_2} - 0.108\ \mathrm{Ash}^2 \quad (3)$$

$$T(^\circ\mathrm{F}) = 3650 - 3.40\ \mathrm{H_2O} + 9.10\ \mathrm{Ash} - 0.556\ \mathrm{H_2O\ Ash} - 0.324\ \mathrm{H_2O_2} - 0.194\ \mathrm{Ash}^2 \quad (4)$$

The adiabatic flame temperature decreases if the ash and moisture contents increase.

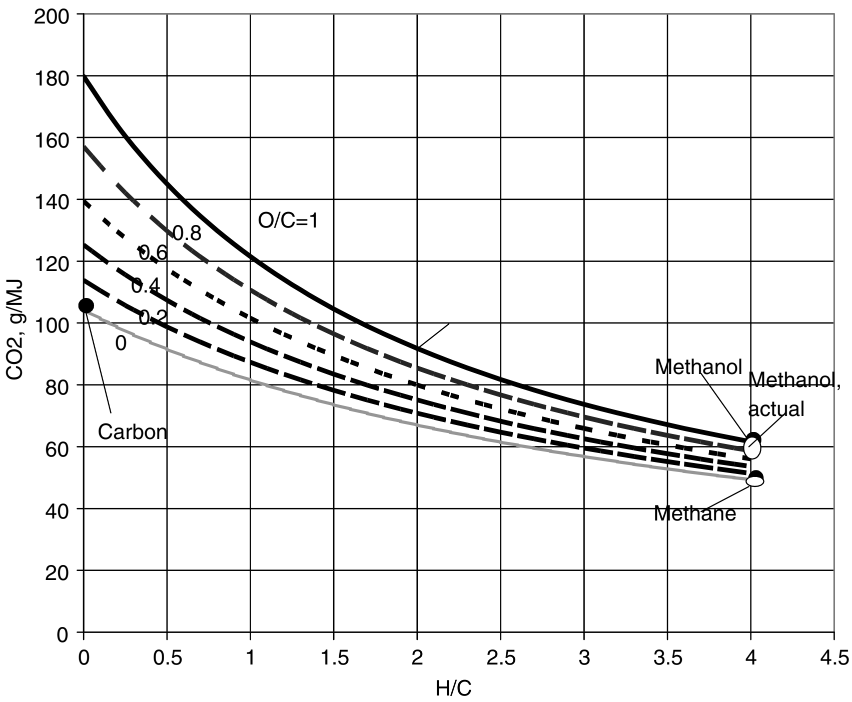

Fig. 3 Emission of CO_2 as a function of H/C and O/C atom ratios in hydrocarbon fuels.
Source: Adapted from Taylor and Francis (see Ref. 8).

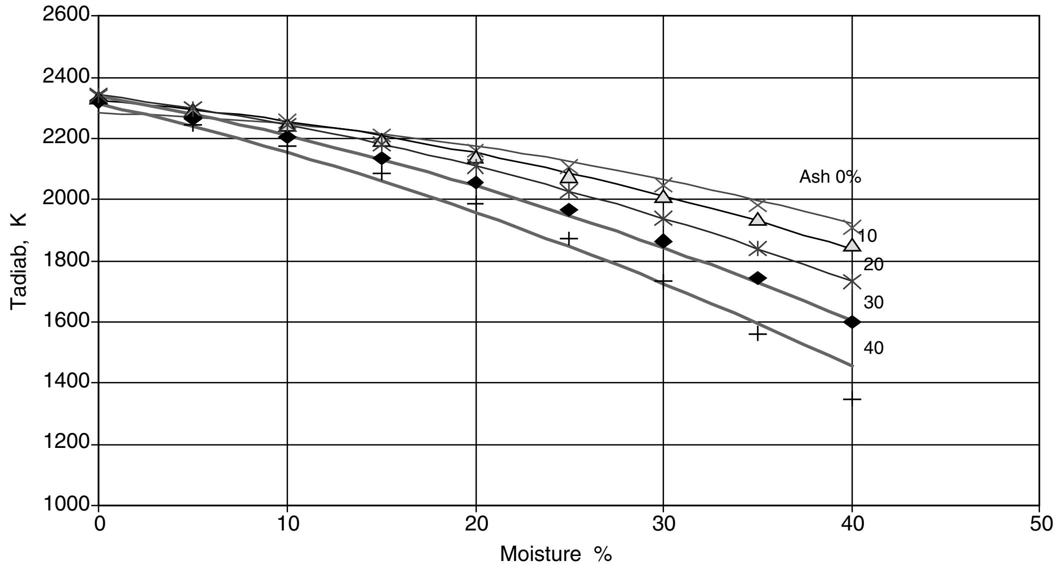

Fig. 4 Correlation of adiabatic flame temperature with moisture and ash contents.

Flue Gas Volume

The flue gas volume for C–H–O is almost independent of O/C ratios. The fit at 6% O_2 in products gives the following empirical equation for flue gas volume (m^3/GJ) at SATP[8]:

$$\text{Flue gas}_{vol}(m^3/GJ) = 4.96\left(\frac{H}{C}\right)^2 - 38.628\left(\frac{H}{C}\right) + 389.72 \quad (5)$$

$$\text{Flue gas}_{vol}(ft^3/mmBtu) = 184.68\left(\frac{H}{C}\right)^2 - 1439.28\left(\frac{H}{C}\right) + 14520.96 \quad (6)$$

Liquid Fuels

Liquid fuels, used mainly in the transportation sector, are derived from crude oil, which occurs naturally as a free-flowing liquid with a density of $\rho \approx 780\ kg/m^3$–$1000\ kg/m^3$, containing 0.1% ash and 0.15%–0.5% nitrogen. Crude oil normally contains a mixture of hydrocarbons, and as such, the "boiling" temperature keeps increasing as the oil is distilled. Most fuel oils contain 83%–88% carbon and 6%–12% (by mass) hydrogen.

Gaseous Fuels

The gaseous fuels are cleaner-burning fuels than liquid and solid fuels. They are a mixture of HC but dominated by highly volatile CH_4 with very little S and N. Natural gas is transported as liquefied natural gas (LNG) and compressed natural gas (CNG), typically at 150–250 bars. Liquefied petroleum gas (LPG) is a byproduct of petroleum refining, and it consists mainly of 90% propane. A low-Btu gas contains 0–7400 kJ/SCM (Standard Cubic Meter, 0–200 Btu/SCF, standards defined in Table 1); a medium-Btu gas. 7400–14,800 kJ/SCM (200–400 Btu/SCF); and a high-Btu gas, above 14,800 kJ/SCM (more than 400 Btu/SCF). Hydrogen is another gaseous fuel, with a heat value of 11,525 kJ/SCM (310 Btu/SCF). Because the fuel quality (heat value) may change when fuel is switched, the thermal output rate at a fixed gas-line pressure changes when fuels are changed.

COAL AND BIOMASS PYROLYSIS, GASIFICATION, AND COMBUSTION

Typically, coal densities range from 1100 kg/m^3 for low-rank coals to 2330 kg/m^3 for high-density pyrolytic graphite, while for biomass, density ranges from 100 kg/m^3 for straw to 500 kg/m^3 for forest wood.[9] The bulk density of cattle FB as harvested is 737 kg/m^3 (CF) for high ash (HA-FB) and 32 lbs/CF for low ash (LA-FB).[10] The processes during heating and combustion of coal are illustrated in Fig. 5, and they are similar for biomass except for high VM. The process of release of gases from solid fuels in the absence of oxygen is called pyrolysis, while the combined process of pyrolysis and

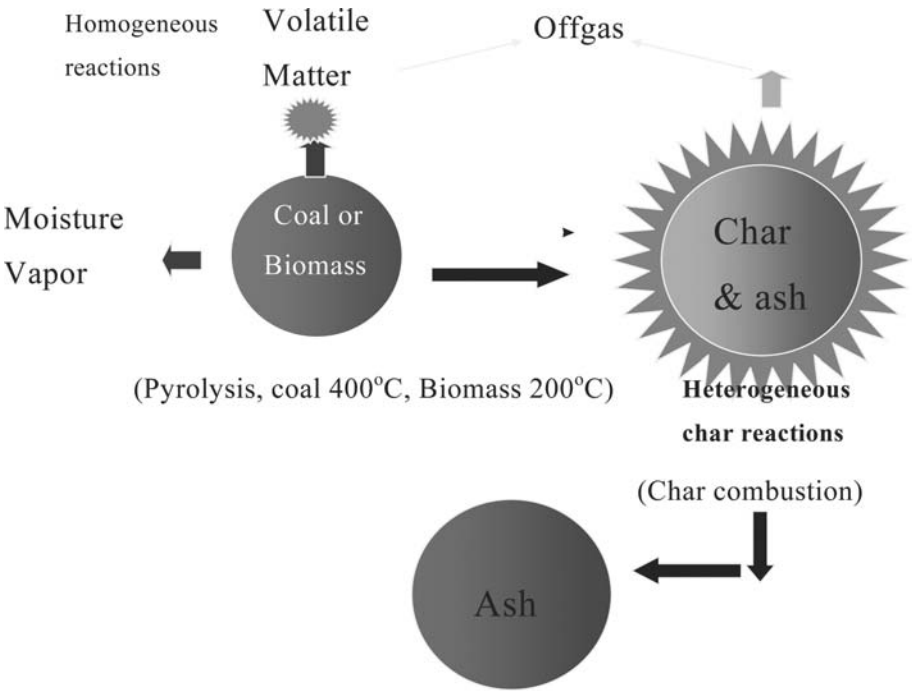

Fig. 5 Processes during coal pyrolysis, gasification, and combustion.

partial oxidation of fuel in the presence of oxygen is known as gasification. If all combustible gases and solid carbon are oxidized to CO_2 and H_2O, the process is known as combustion.

Pyrolysis

Solid fuels, like coal and biomass, can be pyrolyzed (thermally decomposed) in inert atmospheres to yield combustible gases or VM. While biomass typically releases about 70%–80% of its mass as VM (mainly from cellulose and hemicellulose) with the remainder being char, mainly from lignin content of biomass, coal releases 10%–50% of its mass as VM, depending upon its age or rank. Typically, a medium-rank coal consists of 40% VM and 60% FC, while a high-rank coal has about 10% VM. Bituminous coal pyrolyzes at about 700 K (with 1% mass loss for heating rates <100°C/s), as in the case of most plastics. Pyrolytic products range from lighter volatiles like CH_4, C_2H_4, C_2H_6, CO, CO_2, H_2, and H_2O to heavier molecular mass tars. Apart from volatiles, nitrogen is also evolved from the fuel during pyrolysis in the form of HCN, NH_3, and other compounds or, more generally, XN.

Sweeten et al. performed the thermogravimetric analysis (TGA) of feedlot manure.[4] The results are shown in Fig. 6. In the case of manure, drying occurred between 50 and 100°C, pyrolysis was initiated around 185°C–200°C for a heating rate of 80°C/min, and the minimum ignition temperature was approximately 528°C. The gases produced during biomass pyrolysis can also be converted into transportation fuels like biodiesel, methanol, and ethanol, which may be used either alone or blended with gasoline.

Volatile Oxidation

Once released, volatiles (HC, CO, H_2, etc.) undergo oxidation within a thin gas film surrounding the solid fuel particle. The oxidation for each HC involves several steps. The enveloping flame, due to volatile combustion, acts like a shroud by preventing oxygen from reaching the particle surface for heterogeneous oxidation of char. Following Dryer,[11] the one-step global oxidation of a given species can be written as

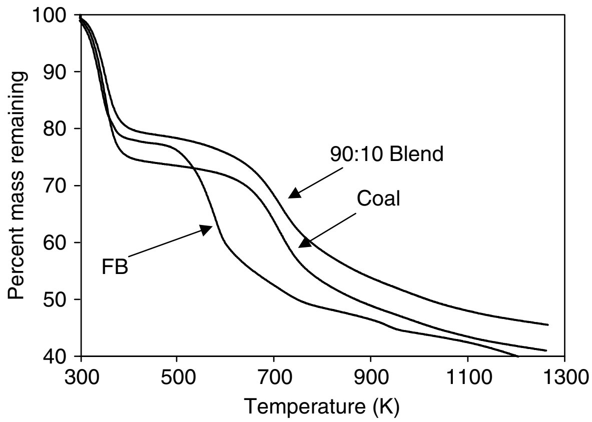

Fig. 6 Thermo-gravimetric analyses of Feedlot Biomass (FB or cattle manure), coal, and 90:10 coal: FB blends.
Source: From Elsevier (see Ref. 4).

Em–Energy Con

$$\text{Fuel} + \upsilon_{O_2} O_2 \xrightarrow{\text{Oxidation}} \upsilon_{CO_2} CO_2 + \upsilon_{H_2O} H_2O \quad (7)$$

$$-\frac{d[\text{Fuel}]}{dt}, \frac{\text{kg}}{\text{m}^3\ \text{sec}} = A \exp\left(\frac{-E}{RT}\right)\left[Y_{\text{fuel}}\right]^a\left[Y_{O_2}\right]^b, \quad (8)$$

where [ ] represents the concentration of species in kg/m^3, Y the mass fraction, A the pre-exponential factor, E the activation energy in kJ/kmole, and a and b the order of reaction; they are tabulated in Bartok and Sarofim for alkanes, ethanol, methanol, benzene and toluene.[11]

Char Reactions

The skeletal char, essentially FC, undergoes heterogeneous reactions with gaseous species. The heterogeneous combustion of carbon or char occurs primarily via one or more of the following reactions:

Reaction I. $C + \frac{1}{2}O_2 \rightarrow CO$

Reaction II. $C + O_2 \rightarrow CO_2$

Reaction III. $C + CO_2 \rightarrow 2\ CO$

Reaction IV. $C + H_2O \rightarrow CO + H_2$

Assuming a first-order reaction for scheme I, the oxygen consumption rate is given as

$$\dot{m}_{O_2} \approx \pi d_p^2 B_I T^n \exp\left(-\frac{E}{R_V T_p}\right)\rho_\infty Y_{O_2,w}. \quad (9)$$

The dominant oxygen transfer mechanism at high temperatures is via reaction I with an E/R (a ratio of activation energy to universal gas constant) of about 26,200 K, where $B_I = 2.3 \times 10^7$ m/s and $n = 0.5$ to 1. Reaction II has an E/R of 20,000 K, and $B_{II} = 1.6 \times 10^5$ m/s. Reaction III, the Boudouard reduction reaction, proceeds with an E/R of about 40,000 K. The reduction reactions, III and IV, may become significant, especially at high temperatures for combustion in boiler burners. Reaction with steam is found to be 50 times faster than CO_2 at temperatures up to 1800°C at 1 bar for 75–100 micron-sized Montana Rosebud char.[12] The combustible gases CO and H_2 undergo gas phase oxidation, producing CO_2 and H_2O.

Ignition and Combustion

Recently, Essenhigh et al. have reviewed the ignition of coal.[13] Volatiles from lignite are known to ignite at $T > 950$ K in fluidized beds. Coal may ignite homogeneously or heterogeneously depending upon size and volatile content.[14,15] A correlation for heterogeneous char ignition temperature is presented by Du and Annamalai, 1994.

Once ignited, the combustion of high volatile coal proceeds in two stages: combustion of VM and combustion of FC. Combustion of VM is similar to the combustion of vapors from an oil drop. The typical total combustion time of 100-micron solid coal particle is on the order of 1 s in boilers and is dominated by the time required for heterogeneous combustion of the residual char particle, while the pyrolysis time ($t_{pyr} = 10^6 (\text{s/m}^2) d_p^2$) is on the order of 1/10th–1/100th of the total burning time. Since bio-solid contains 70%–80% VM (coal contains 10% VM), most of the combustion of volatiles occurs within a short time (about 0.10 s).

For liquid drops and plastics of density ρ_c, simple relations exist for evaluating the combustion rates and times. If the transfer number B is defined as

$$B = \frac{c_p\{T_\infty - T_w\}}{L} + \frac{Y_{O_{2,\infty}}}{\nu_{O_2}}\frac{h_c}{L}, \quad (10)$$

where $T_w \approx$ TBP for liquid fuels; $T_w = T_g$, the temperature of gasification for plastics; L is the latent heat for liquid fuel and $L = q_g$, heat of gasification for plastics; $Y_{O_{2,\infty}}$, is the free-stream oxygen mass fraction; ν_{O_2} is the stoichiometric oxygen mass per unit mass of fuel (typically 3.5 for liquid fuels); and h_c is the lower heating value of fuel; then the burn rate ($\dot{m}$) and time (t_b) for spherical condensates (liquid drops and spherical particles of diameter d_p and density ρ_c) are given by the following expressions:

$$\dot{m} \approx 2\pi \frac{\lambda}{c_p} d_p \ln(1 + B) \quad (11)$$

$$t_b = \frac{d_0^2}{\alpha_c}, \quad (12)$$

where

$$\alpha_c = 8 \frac{\lambda}{c_p} \frac{\ln(1 + B)}{\rho_c} \quad (13)$$

and c_p and λ are the specific heat and thermal conductivity of gas mixture evaluated at a mean temperature (approximately 50% of the adiabatic flame temperature).

The higher the B value, the higher the mass loss rate, and the burn time will be lower. The value of B is about 1–2 for plastics (polymers), 2–3 for alcohols, and 6–8 for pentane to octane. The burn time of plastic waste particles will be about 3–4 times longer than single liquid drops of pentane to octane (≈gasoline) of similar diameter.

COMBUSTION IN PRACTICAL SYSTEMS

The time scales for combustion are on the order of 1000, 10, and 1 ms for coal burnt in boilers and liquid fuels burnt in gas turbines and diesel engines. Coal is burnt on grates in lumped form (larger-sized particles, 2.5 cm or greater with a volumetric intensity on the order of 500 kW/m^3), medium-sized particles in fluidized beds (1 cm or less, 500 kW/m^3), or as suspensions or pulverized fuel (pf; 75 micron or less, 200 kW/m^3) in boilers.

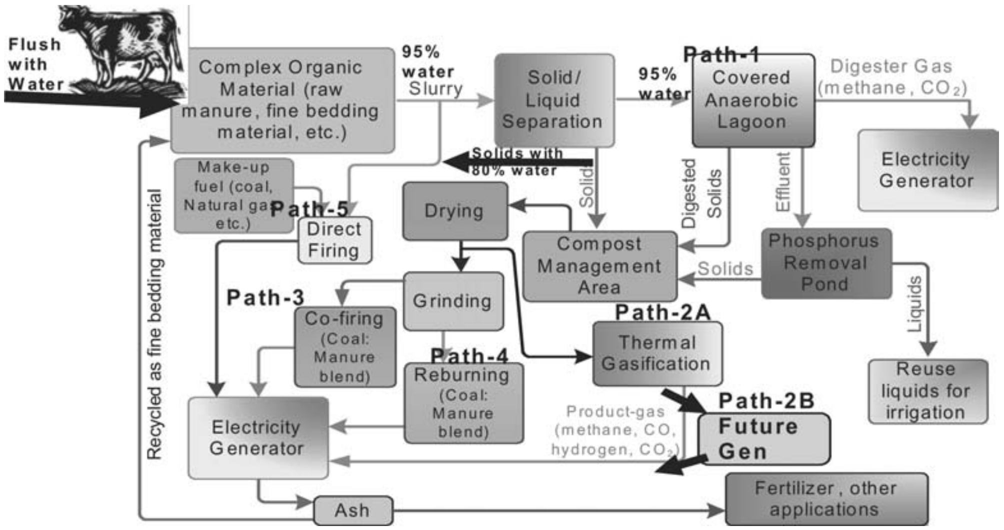

Fig. 7 Flow chart showing several energy conversion options for a typical dairy or cattle operation.

Apart from pyrolysis, gasification, and combustion, another option for energy conversion (particularly if solid fuel is in slurry firm, such as flushed dairy manure), is the anaerobic digestion (in absence of oxygen) to CH_4 (60%) and CO_2 (40%) using psychrophylic (ambient temperature), mesophyllic (95°F) and thermophyllic (135°F) bacteria in digesters.[10] Typical options of energy conversion, indicated in Fig. 7, include anaerobic digestion (path 1, the biological gasification process), thermal gasification with air to produce CO, HC, CO_2 (path 2A) or with steam to produce CO_2 and H_2 (path 2B), cofiring (path 3), reburn (path 4; see "Reburn with Bio-Solids"), and direct combustion (path 5).

Suspension Firing

In suspension-fired boilers, solid fuel is pulverized into smaller particles ($d_p = 75$ μm or less) so that more surface area per unit mass is exposed to the oxidant, resulting in improved ignition and combustion characteristics. Typical boiler burners use swirl burners for atomized oil and pulverized coal firing, while a gas turbine uses a swirl atomizer in highly swirling turbulent flow fields. A swirl burner for pf firing is shown in Fig. 8. The air is divided into a primary air stream which transports the coal (10%–20% of the total air, heated to 70°C–100°C to prevent condensation of vapors and injected at about 20 m/s to prevent settling of the dust, loading dust and gas at a ratio of 1:2) and a secondary air stream (250°C at 60–80 m/s) which is sent through swirl vanes, supplying the remaining oxygen for combustion and imparting a tangential momentum to the air. In wall-fired boilers, burners are stacked above each other on the wall; while in tangential-fired boilers, the burners are mounted at the corners of rectangular furnaces.

Stoker Firing

The uncrushed fuel [fusion temperature <1093°C (2000°F); volatile content >20%; sizes in equal proportions of 19 mm × 12.5 mm (3/4 in. × ½ in.), 6.3 mm × 3.2 mm (½ in. × ¼ in.), 3.2 mm × 3.2 mm (¼ in. × ¼ in.)][16] is fed onto a traveling chain grate below to which primary air is supplied (Fig. 9), which may be preheated to 177°C (350°F) if moisture exceeds 25%. The differential pressure is on the order of 5–8 mm (2–3 in.). The combustible gases are carried into an over-fire region into which secondary air (almost 35% of total air at three levels for low emissions) is fired to complete combustion.

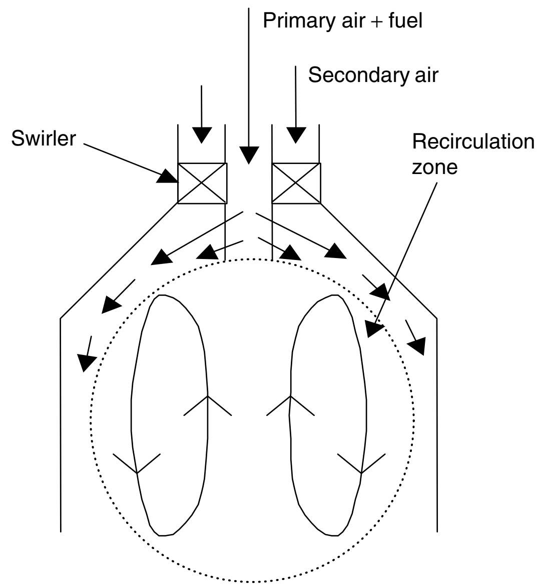

Fig. 8 Pulverized Fuel (pf) fired swirl burner.

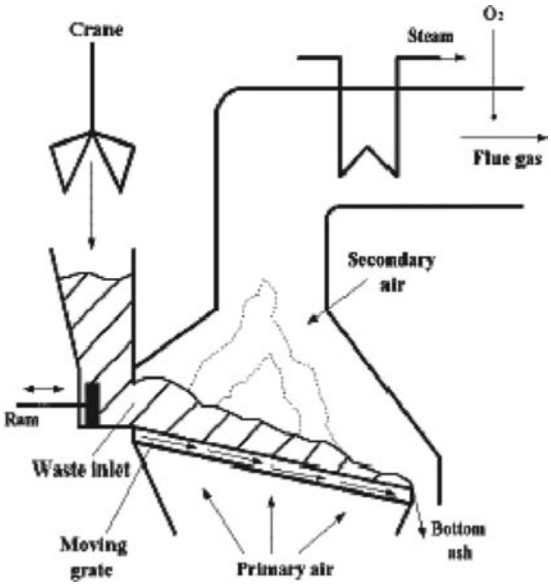

Fig. 9 Schematic of stoker firing.
Source: From Ref. 39.

The over-fire region acts like a perfectly stirred reactor (PSR). It is apparent that solid fuels need not be ground to finer size.

Fixed Bed Combustor

The bed contains uncrushed solid fuels, inert materials (including ash), and processing materials (e.g., limestone to remove SO_2 from gases as sulfates). It is fed with air moving against gravity for complete combustion, but the velocity is low enough that materials are not entrained into the gas streams. Large solid particles can be used.

Fluidized Bed Combustor

When air velocity (V) in fixed bed combustor (FXBC) is increased gradually to a velocity called minimum fluidization velocity V_{mf}, the upward drag force is almost equal to the weight of the particle, so that solids float upward. The bed behaves like a fluid (like liquid water in a tank), i.e., it becomes fluidized. If $V > V_{mf}$, then air escapes as bubbles and is called a bubbling fluidized bed combustor (BFBC). The bed has two phases: the bubble phase, containing gases (mostly oxygen), and the emulsion phase (dense phase, oxygen deficient), containing particles and gas. Many times gas velocity is so high that gaseous combustibles produced within the bed burn above the bed (called free board region), while solids (e.g., char and carbon) burn within the bed. Fluidized Bed Combustor (FBC) is suitable for fuels which are difficult to combust in pf-fired boilers.

Circulating Fluidized Bed Combustor (CFBC)

When air velocity in FBC is increased at velocity $V \gg V_{mf}$, particles are entrained into the gas stream. Since the residence time available to particles for combustion is shorter, unburned particles are captured using cyclones located downstream of the combustor and circulated back to the bed.

The residence time (t_{res}) varies from a low value for pf-fired burners to a long residence time for fixed-bed combustors. The reaction time (t_{reac}) should be shorter than t_{res} so that combustion is complete. The reaction time includes time to heat up to ignition temperature and combustion. The previous section on fuel properties and the homogenous (e.g., CH_4, CO oxidation) and heterogeneous (e.g., carbon oxidation) reaction kinetics can be used to predict t_{reac} or burn time t_b.

COAL AND BIO-SOLIDS COFIRING

General Schemes of Conversion

Most of the previously reviewed combustion systems typically use pure coal, oil, or gas. The same systems require redesign for use with pure biomass fuels. A few of the technologies, which utilize bio-solids as an energy source, are summarized in Annamalai et al.[17] These technologies include direct combustion (fluidized beds), circulating fluidized beds, liquefaction (mostly pyrolysis), onsite gasification for producing low to medium Btu gases, anaerobic digestion (bacterial conversion), and hydrolysis for fermentation to liquid fuels like ethanol.[18,19]

Cofiring

Although some bio-solids have been fired directly in industrial burners as sole-source fuels, limitations arose due to variable moisture and ash contents in bio-solid fuels, causing ignition and combustion problems for direct combustion technologies. To circumvent such problems, these fuels have been fired along with the primary fuels (cofiring) either by directly mixing with coal and firing (2%–15% of heat input basis) or by firing them in between coal-fired burners.[20–24]

Cofiring has the following advantages: improvement of flame stability problems, greater potential for commercialization, low capital costs, flexibility of adaptation of biomass fuels and cost effective power generation, mitigated NO_x emissions from coal-fired boilers, and reduced CO_2 emissions. However, a lower melting point of biomass ash could cause fouling and slagging problems.

Some of the bio-solid fuels used in cofiring with coal are cattle manure,[25,26] sawdust and sewage sludge,[21] switch grass,[20] wood chips,[24,27] straw,[22,28] and refuse-derived fuel (RDF).[21] See Sami et al. for a review of literature on cofiring.[7]

Coal and Agricultural Residues

Sampson et al. reported test burns of three different types of wood chips (20%, HHV from 8320 to 8420 Btu/lb) mixed with coal (10,600 Btu/lb) at a stoker (traveling grate) fired steam plant.[24] The particulate emission in grams per SCF ranged from 0.05 to 0.09. An economic study, conducted for the 125,000 lb/h steam power plant, concluded that energy derived from wood would be competitive with that from coal if more than 30,000 tons of wood chips were produced per year with hauling distances less than 60 mi. Aerts et al. carried out their experiments on cofiring switch grass with coal in a 50-MW, radiant, wall-fired, pulverized coal boiler with a capacity of 180 tons of steam at 85 bar and 510°C (Fig. 10). The NO_x emissions decreased by 20%, since switchgrass contains lesser nitrogen (Table 4).[20] It is the author's hypothesis that a higher VM content of bio-solids results in a porous char, thus accelerating the char combustion process. This is validated by the data from Fahlstedt et al. on the cofiring of wood chips, olive pips and palm nut shells with coal at the ABB Carbon 1 MW Process Test Facility; they found that blend combustion has a slightly higher efficiency than coal-only combustion.[27]

Coal and RDF

Municipal solid waste includes residential, commercial, and industrial wastes which could be used as fuel for production of steam and electric power. MSW is inherently a blended fuel, and its major components are paper (43%); yard waste, including grass clippings (10%); food (10%); glass and ceramics (9%); ferrous materials (6%); and plastics and rubber (5%). Refer to Tables 5 and 6 for analyses. When raw waste is processed to remove non-combustibles like glass and metals, it is called RDF. MSW can decompose in two ways, aerobic and anaerobic. Aerobic decomposition (or composting) occurs when O_2 is present. The composting produces CO_2 and water, but no usable energy products. The anaerobic decomposition occurs in the absence of O_2. It produces landfill gas of 55% CH_4 and 45% CO_2.

Coal and Manure

Frazzitta et al. and Annamalai et al. evaluated the performance of a small-scale pf-fired boiler burner facility (100,000 Btu/h) while using coal and premixed coal-manure blends with 20% manure. Three types of feedlot

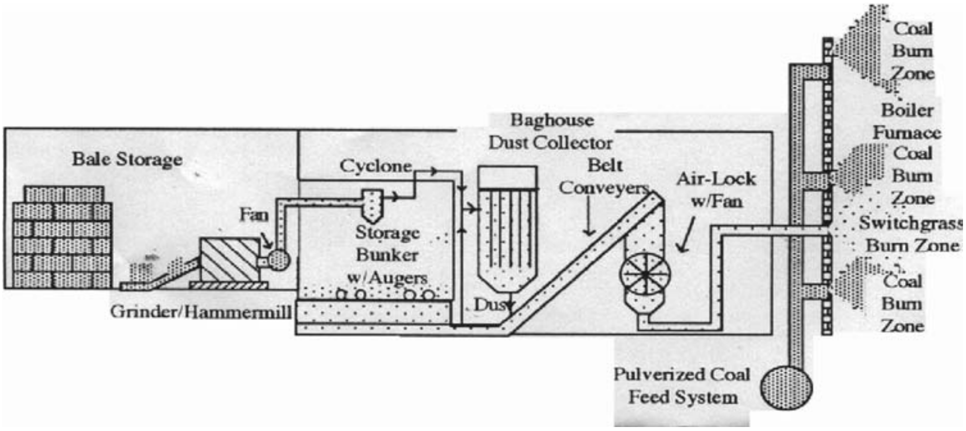

Fig. 10 A cofiring Scheme for coal and biomass (Alternate Fuel Handling Facility at Blount St. Generating Station). Source: From Ref. 20.

Em—Energy Con

manure were used: raw, partially composted, and fully composted. The burnt fraction was recorded to be 97% for both coal and coal-manure blends.[25,26]

NO_x Emissions

During combustion, the nitrogen evolved from fuel undergoes oxidation to NO_x; and this is called fuel NO_x to distinguish it from thermal NO_x, which is produced by oxidation of atmospheric nitrogen. Unlike coal, most of the agricultural biomass being burned is very low in nitrogen content (i.e., wood or crops), but manure has a higher N content than fossil fuels. A less precise correlation exists between cofiring levels on a Btu basis and percent NO reduction under cofiring. The following Eq. (valid between 3 and 22% mass basis cofiring) describes NO_x reduction as a function of cofiring level on a heat input basis:

$$NO_x \text{ Reduction } (\%) = 0.0008\ (COF\%)^2 + 0.0006\ COF\% + 0.0752, \tag{14}$$

where COF% is the percentage of co-firing on a heat input basis. The mechanisms used to reduce NO_x emissions by cofiring vary between cyclone firing and PC firing.

Fig. 11 shows the percentage reduction in NO with percentage cofiring of low-N agricultural biomass fuels. This relationship does not apply to high-N biofuels such as animal manure.

Fouling in Cofiring

Hansen et al. investigated the ash deposition problem in a multi-circulating fluidized bed combustor (MCFBC) fired with fuel blends of coal and wood straw.[25] The Na and K lower the melting point of ash. For ash fusion characteristics see Table 7. Rasmussen and Clausen evaluated the performance of an 80-MW co-generation power plant at Grenaa, Denmark, fired with hard coal and bio-solids (surplus straw from farming). Large amounts of Na and K in straw caused superheater corrosion and combustor fouling.[29] Annamalai et al. evaluated fouling potential when feedlot manure biomass (FB) was cofired with coal under suspension firing.[30] The 90:10 Coal:FB blend resulted in almost twice the ash output compared to coal and ash deposits on heat exchanger tubes that were more difficult to remove than baseline coal ash deposits. The increased fouling behavior with blend is probably due to the higher ash loading and ash composition of FB.

Table 5 Chemical composition of solid waste

GASIFICATION OF COAL AND BIO-SOLIDS

Gasification is a thermo-chemical process in which a solid fuel is converted into a gaseous fuel (primarily consisting of HC, H_2 and CO_2) with air or pure oxygen used for partial oxidation of FCs. The main products during gasification are CO and H_2, with some CO_2, N_2, CH_4, H_2O, char particles, and tar (heavy hydrocarbons). The oxidizers used for the gasification processes are oxygen, steam, or air. However, for air, the gasification yields a low-Btu gas, primarily caused by nitrogen dilution present in the supply air. Syngas ($CO+H_2$) is produced by reaction of biomass with steam. The combustible product, gas, can be used as fuel burned directly or with a gas turbine to produce electricity; or used to make chemical feedstock (petroleum refineries). However, gas needs to be cleaned to remove tar, NH_3, and sulfur compounds. The integrated gasification combined cycle (IGCC) (Fig. 12),

Em—Energy Con

for combined heat and power (CHP), and traditional boilers use combustible gases from gasifiers for generation of electric power.

Typically in combined cycles, gaseous or liquid fuel is burnt in gas turbine combustors. High-temperature products are expanded in a gas turbine for producing electrical power; a low-temperature (but still hot) exhaust is then used as heat input in a boiler to produce low-temperature steam, which then drives a steam turbine for electrical power. Therefore, one may use gas as a topping cycle medium, while steam is used as fluid for the bottoming cycle. The efficiency of a combined cycle is on the order of 60%, while a conventional gas turbine cycle has an efficiency of 42%.[31] Commercial operations include a 250-MW IGCC plant at Tampa, Florida, operating since 1996; a 340-MW plant at Negishi, Japan, since 2003; and a 1200-MW GE-Bechtel plant under construction in Ohio for American Electric Power, to start in 2010.[31]

There are three basic gasification reactor types: (i) fixed-bed gasifiers (Fig. 13); (ii) fluidized-bed gasifiers, including circulating-bed (CFB) or bubbling-bed; and (iii) entrained-flow gasifiers. The principles of operation are similar to those of combustors except that the air supplied is much below stoichiometric amounts, and instead of a combination of steam, air and CO_2, air can also be used. The oxidant source could also include gases other than air, such as air combined with steam in Blasiak et al.[32]

FUTUREGEN

FutureGen is a new U.S. initiative to build the world's first integrated CO_2 sequestration and H_2 production research power plant using coal as fuel. The technology shown in Fig. 14 employs modern coal gasification technology using pure oxygen, resulting in CO, C_nH_m (a hydrocarbon), H_2, HCN, NH_3, N_2, H_2S, SO_2, and other combinations which are further reacted with steam (reforming reactions) to produce CO_2 and H_2. The bed materials capture most of the harmful N and S compounds followed by gas-cleaning systems; the CO_2 is then sequestered and H_2 is used as fuel, using either combined cycle or fuel cells for electricity generation or sold as clean transportation fuel. With partial oxidation of gasification products and char supplying heat for pyrolysis and other endothermic reactions (i.e, net zero external heat supply in gasifier), the overall gasification reaction can be represented as follows for 100 kg of DAF Wyoming coal:

Reaction V $$C_{6.3}H_{4.4}N_{0.076}O_{1.15}S_{0.014} + 8.14\ H_2O(\ell) + 1.67\ O_2 \rightarrow 6.3\ CO_2 + 10.34\ H_2 + 0.038\ N_2 + 0.014\ SO_2$$

It is apparent that the FutureGen process results in enhanced production of H_2, using coal as an energy source to strip H_2 from water. For C–H–O fuels, it can be shown that theoretical H_2 production (N_{H_2}) in moles for an empirical fuel CH_hO_o is given as $\{0.4115\,h - 0.6204\,o + 1.4776\}$ under the above conditions. For example, if glucose $C_6H_{12}O_6$ is the fuel, then empirical formulae is CH_2O; thus, with $h=2$, $o=1$, $N_{H_2}=1.68$ kmol, using atom balance, $CH_2O + 0.68\ H_2O(\ell) + 0.16\ O_2 \rightarrow CO_2 + 1.68\ H_2$.

REBURN WITH BIO-SOLIDS

NO_x is produced when fuel is burned with air. The N in NO_x can come both from the nitrogen-containing fuel

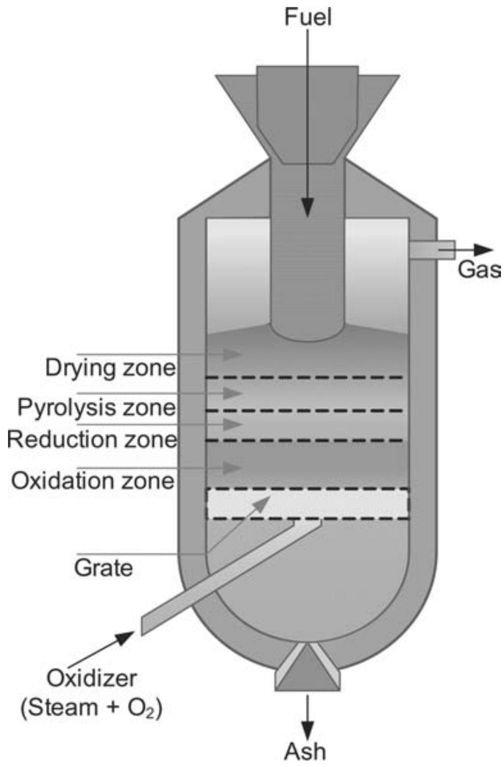

Fig. 13 Updraft fixed-bed gasifier.

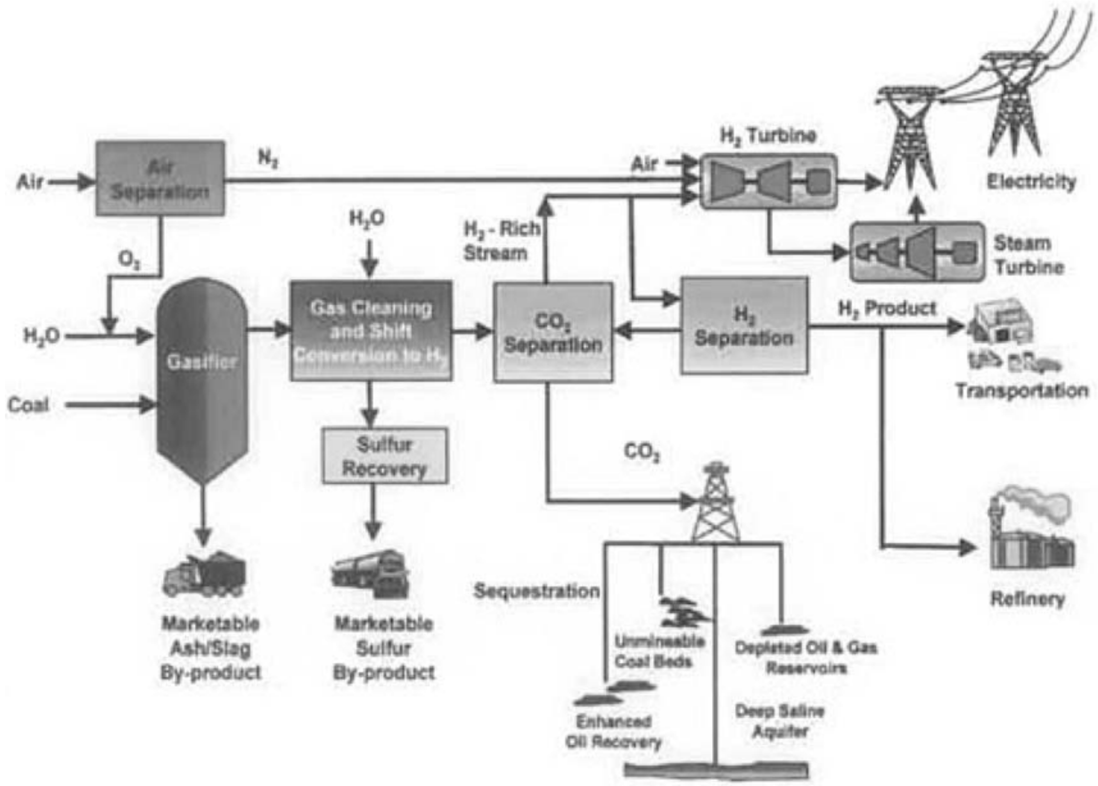

Fig. 14 FutureGen layout.

compounds (e.g., coal, biomass, plant residue, animal waste) and from the N in the air. The NO_x generated from fuel N is called fuel NO_x, and NO_x formed from the air is called thermal NO_x. Typically, 75% of NO_x in boiler burners is from fuel N. It is mandated that NO_x, a precursor of smog, be reduced to 0.40–0.46 lb/mmBtu for wall and tangentially fired units under the Clean Air Act Amendments (CAAA). The current technologies developed for reducing NO_x include combustion controls (e.g., staged combustion or low NO_x burners (LNB), reburn) and post-combustion controls (e.g., Selective Non-Catalytic Reduction, SNCR using urea).

In reburning, additional fuel (typically natural gas) is injected downstream from the primary combustion zone to create a fuel rich zone (optimum reburn stoichiometric ratio (SR), usually between SR 0.7 and 0.9), where NO_x is reduced up to 60% through reactions with hydrocarbons when reburn heat input with CH_4 is about 10%–20%. Downstream of the reburn zone, additional air is injected in the burnout zone to complete the combustion process. A diagram of the entire process with the different combustion zones is shown in Fig. 15. There have been numerous studies on reburn technology found in literature, with experiments conducted, and the important results summarized elsewhere.[33] Table 8 shows the percentages of reduction and emission obtained with coal or gas reburn in coal-fired installations and demonstration units.

The low cost of biomass and its availability make it an ideal source of pyrolysis gas, which is a more effective reburn fuel than the main source fuel, which is

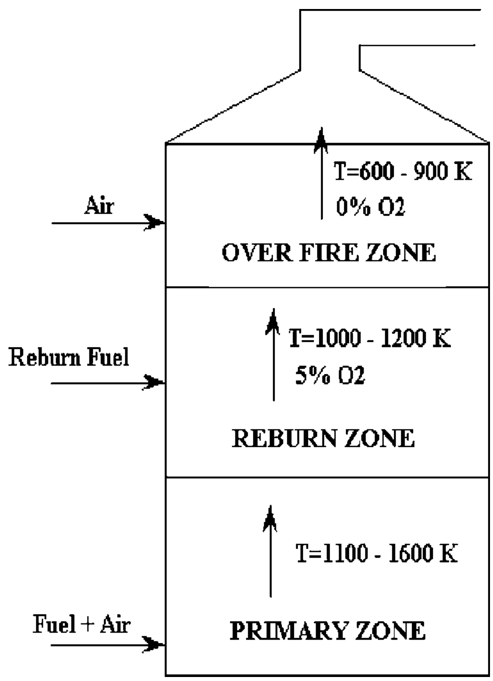

Fig. 15 Schematic of reburn process.

typically coal. Recently, animal manure has been tested as a reburn fuel in laboratory scale experiments. A reduction of a maximum of 80% was achieved for pure biomass, while the coal experienced a reduction of between 10 and 40%, depending on the equivalence ratio.[34] It is believed that the greater effectiveness of the feedlot biomass is due to its greater volatile content on a DAF basis and its release of fuel nitrogen in the form of NH_3, instead of HCN.[35]

Energy Efficiency: Developing Countries

U. Atikol
H.M. Güven
Energy Research Center, Eastern Mediterranean University, Magusa, Northern Cyprus

Abstract
Statistics and projections show that not only the rate of energy consumption, but also the carbon emissions of developing countries are rising very fast. The rate of increase in the capacity needs in developing countries can be decreased in two steps. First, the component associated with the old infrastructure should be dealt with; and second, the application of end-use energy efficiency measures should be put in effect. The energy efficiency technologies that are available in the industrialized countries may not always be feasible for transfer to developing countries. Readily available economic and social indicators, supported by more detailed end-use research, can be used to determine which technologies are suitable for a given developing country. Case studies performed in Northern Cyprus and Turkey show that in Northern Cyprus, transfer of these technologies would be more successful in the residential and commercial sectors, whereas in Turkey, they would be more feasible for the industrial sector.

INTRODUCTION

The quest for energy efficiency dates back to 1973, at which time the Oil Producing and Exporting Countries (OPEC) placed an embargo on crude oil during the war in the Middle East. Until that year, most developed countries had experienced decades of low energy prices and plentiful fuel supplies; consequently, high and growing per capita use of energy was of little concern to most governments. In 1979, there was another interruption in supplies when U.S. President Jimmy Carter announced a ban on oil imports from Iran after the hostage crisis began at the U.S. embassy in Tehran. Subsequently, rapidly rising energy costs and interruptions in supplies forced re-evaluation of existing policies. In most developed countries, conservation and efficiency improvements to energy systems became an important component of energy policy, due not only to the realization that the world is vulnerable to interference with its energy supplies, but also to awareness that excessive use of fossil fuels is causing vital damage to the world ecosystem.

In the United States before the 1973 crises, both primary energy and electricity consumption increased at almost the same rate as the Gross National Product (GNP). (The Gross National Product is the dollar value of all goods and services produced in a nation's economy, including goods and services produced abroad). After that year, however, high oil prices led to progressive energy policies, and the demand was halted (see Fig. 1). Between 1973 and 1986, the rate of growth of electricity use decreased, growing only 2.5% per year, or 3.2% per year less than projected by pre1973 trends.[1] In 1986, projected electricity use was 50% higher than actual electricity use, indicating a savings of 1160 TWh. The gap between the two trends is referred to as JAWS, coined by Rosenfeld.

Since 1970, the growth of electricity consumption has been around 3.5% for the countries in the Organization for Economic Cooperation and Development (OECD), (Organization for Economic Cooperation and Development countries are Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Japan, Luxembourg, The Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the United States.) while that of developing countries has been 8.2%. For the OECD countries, this growth is almost parallel with the growth of their Gross Domestic Product (GDP). (Gross Domestic Product is a measure of the value of all goods and services produced by the economy. Unlike GNPs, GDP includes only the values of goods and services earned by a nation within its boundaries). In the developing countries, however, electricity generation rose much faster than the GDP. While the total GDP (in U.S. dollars) increased slightly over twofold between 1970 and 1989, electricity generation grew more than fourfold.[2]

It was rather fortunate that there was ample scope for improvements in energy efficiency. Insulation and other measures, such as using more efficient air conditioners, were applied to reduce space heating and air conditioning requirements. The wide use of household appliances meant a large market for more energy-efficient electric motors, compressors, water heaters, and other equipment. In transportation, improvement in fuel use was also achieved for new vehicles. In industrialized countries,

Keywords: Developing countries; Energy efficiency; Demand-side management; Energy planning; Technology transfer.

several mechanisms were developed to implement the changes; two important ones were the introduction of utility demand-side management (DSM) and the establishment of energy service companies (ESCOs) backed up with accurate data collection and improved codes and standards. Recently, distributed power and renewable energy (RE) technologies have been promoted by the introduction of new legislation.

In developing countries, these mechanisms do not exist, mainly due to lack of institutional formation, technical expertise, and sufficient infrastructure. In this article, there will be an attempt to evaluate these problems with suggestions for possible solutions.

TRENDS IN WORLDWIDE ENERGY DEMAND

In a report prepared by the Energy Information Administration,[3] the International Energy Outlook 2000 (IEO2000), much of the growth in worldwide energy use is projected for the developing world (Fig. 2a). In particular, energy demand in developing Asia and Central and South America is projected to more than double between 1997 and 2020. Both regions are expected to sustain energy demand growth of more than 3% annually throughout the forecast, accounting for more than 50% of the total projected increment in world energy consumption and 83% of the increment for the developing world alone. World carbon emissions are projected to rise from 6.2 billion metric tons in 1997 to 8.1 billion metric tons in 2010 and to 10 billion metric tons in 2020, according to the IEO2000. This analysis does not take into account the potential impact of the Kyoto Protocol. (The Kyoto Climate Change Protocol is a treaty signed by 83 countries and the European Union that requires reductions or limits to the growth of carbon emissions within the Annex I countries between 2008 and 2012. The Annex I countries under the protocol are Australia, Bulgaria, Canada, Croatia, the European Union, Iceland, Japan, Liechtenstein, Monaco, New Zealand, Norway, Romania, Russia, Switzerland, Ukraine, and the United States. Turkey and Belarus are Annex I countries that did not commit to quantifiable emissions targets under the protocol). In this forecast, world carbon emissions will exceed their 1990 levels by 40% in 2010 and by 72% in 2020. Emissions in the developing countries accounted for about 28% of the world total in 1990, but they are projected to make up 44% of the total by 2010 and nearly 50% by 2020. As a result, even if the Annex I countries were able to meet the emissions limits or reductions prescribed in the Kyoto Protocol, worldwide carbon emissions still would grow substantially. The increase is expected to be caused both by rapid economic expansion, accompanied by growing demand for energy, and by continued heavy reliance on coal (the most carbon intensive of the fossil fuels), particularly in developing Asia.

There is an expected increase in electricity consumption worldwide by 76% in the IEO2000 reference case, from 12 trillion kWh in 1997 to 22 trillion kWh in 2020. Long-term growth in electricity consumption is expected to be strongest in the developing countries of Asia, followed by those of Central and South America. Those two regions alone account for 52% of the world's net electricity consumption increment in the IEO2000 reference case (Fig. 2b). Rapid growth in population and income, along with greater industrialization and more

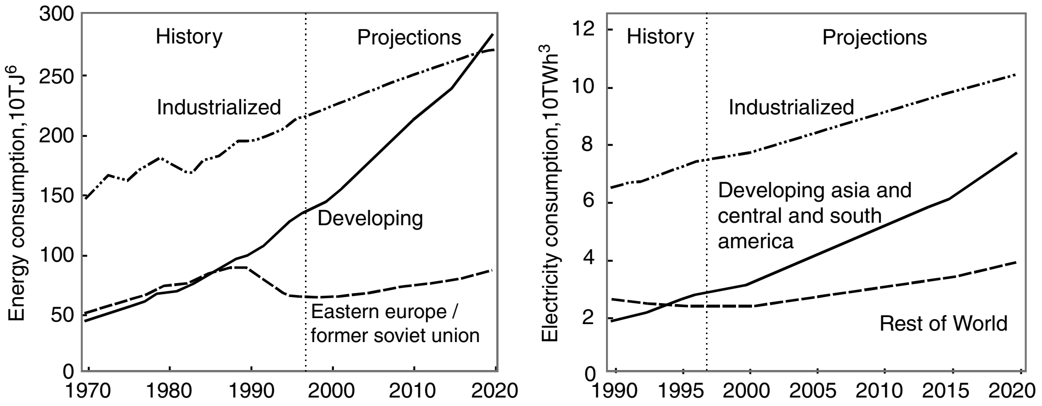

Fig. 2 World energy and net electricity consumption by region, 1970–2020.

household electrification, are responsible for the increase.

Developing countries need energy to raise productivity and improve the living standards of their populations. Traditionally, developing countries have addressed their energy needs by expanding their supply base, with little attention to the efficient use of energy. This approach has been raising serious financial, institutional, and environmental problems. The magnitude of these problems has been underlining the need for improving the efficiency with which energy is currently used and produced in developing countries.

Factors contributing to the rapidly rising energy consumption in developing countries include population growth, economic growth, and increased consumer demand.

Population Growth in Developing Countries

The world population is just over 6 billion and is projected by the U.S. Bureau of Census[4] to reach 9.1 billion in 2050. Over the next two decades, the population of the developing world is projected to increase by nearly 1 billion, to almost 6 billion total, while that of the industrialized countries will increase by only 50 million, to 1 billion total.[3] By 2050, the population of the less-developed regions could reach 7.75 billion or more.[5] Developing countries then could account for 85% of the global population. The increase in population between 1998 and 2050 for the developing countries would be 64%, and this alone would account for a large increase in their energy consumption by 2050, even if per capita consumption remained at current levels.

Economic Growth in Developing Countries

Securing higher living standards for this rising population requires rapid economic growth, further increasing the demand for energy services. The steady increase in per capita energy consumption in developing countries is due merely to economic growth, which includes urbanization, increased use of commercial fuels instead of traditional biomass fuels (such as wood, crop residues, and animal dung), and increased use of energy-intensive materials. When annual per capita energy consumptions of the industrialized and developing countries are compared, it is observed that the gap between them is more than 4.5 million tons of oil equivalent (TOE).[3] This shows that the developing countries have a long way to go to increase their living standards to those of industrialized countries. Closing this gap will lead to astronomic increases in the world energy consumption. This is the inevitable and unavoidable eventuality that may lead to catastrophic environmental consequences. Therefore, utilizing energy as efficiently as possible and trying to use cleaner sources of energy is absolutely essential.

Accelerated Consumer Demand

In recent years, modern manufacturing techniques and improved materials have sharply lowered the real costs of consumer goods such as radios, refrigerators, and televisions. In the 1990s, for example, a study[6] revealed that the real cost of refrigerators decreased by a factor of 5 between 1950 and 1990. Similarly, in Northern Cyprus, due to the decreasing cost of air conditioners by a factor of 2.5 between 1996 and 2006, not only the number of residences, but also the number of small to medium-size enterprises using them increased dramatically. Global distribution systems have also increased the accessibility of these appliances. Thus, people in developing countries can purchase these goods at a far earlier stage in the development cycle (as measured by per capita GDP) than did people in today's industrial countries. The rapidly increasing use of these consumer goods has a strong impact on residential electricity use, creating additional demand at peak times.

ENERGY AND DEVELOPING COUNTRIES

Developing countries need energy to raise productivity and improve the living standards of their populations. Traditionally, developing countries have addressed their energy needs by expanding their supply base, with little attention to the efficient use of energy, which led to the need to expand the supply base frequently. This approach, however, raises serious financial, institutional, and environmental problems. The magnitude of these problems underlines the need for improving the efficiency with which energy is currently used and produced in developing countries.

The magnitude of funding needed for the required power supply projects is growing so fast that these projects have little chance of being mobilized. The power sectors in developing countries frequently experience a wide range of institutional problems, including excessive staffing, inadequate management, weak planning, poor maintenance, deficient financial monitoring, and few incentives to improve efficiency of operation.[7] This raises questions about the ability of this key sector to continue expanding rapidly even if financial resources were available. The continuous increase in energy consumption (fossil-fuel combustion in modern industry, transport, and electricity generation) causes air pollution and contaminates water supplies and land. On the other hand, nonfossil energy sources may also cause environmental damage. Hydroelectric development often involves the flooding of vast areas of land, with a resulting loss of agricultural land, human settlements, fish production, forests, wildlife habitats, and species diversity. Therefore, using energy as efficiently as possible should be an essential part of the planning process.

ENERGY EFFICIENCY IMPLEMENTATION BARRIERS

As the demand for electricity increased and the global climate change issues caused governmental concern, energy efficiency attracted attention in some developing countries. Difficulties were experienced in the implementation of these energy efficiency measures and programs, however. The implementation barriers were identified as follows:[8,9]

- Lack of central coordination and institutional formation
- Lack of awareness and general misinformation
- Lack of technical information and expertise
- Inappropriate pricing policies
- Lack of capital
- Lack of appropriate laws
- Taxes and tariffs that discourage energy efficiency activities
- Poor infrastructure
- Customs and maintaining the status quo.

CHALLENGES AND REWARDS OF IMPLEMENTATION OF ENERGY EFFICIENCY IN DEVELOPING COUNTRIES: RESIDENTIAL, COMMERCIAL, AND INDUSTRIAL SECTOR CASE STUDIES AND EXAMPLES

How Economic Development Is Measured

The statistical information that indicates the level of economic development can be used in the DSM decision-making process. Economic development can be measured through a number of social, economic, and demographic indexes (indicators). The following indicators are often used to measure the economic development of a country:

- *Per capita income*. This is a statistic that is seldom readily available, and GNP or GDP per capita is often used instead. According to 1999 GNP per capita, calculated using the World Bank Atlas method,[9] the following grouping of countries is possible: low-income, $755 or less; lower-middle-income, $756–$2995; upper-middle-income, $2996–$9265; and high-income, $9266 or more.
- *Per capita purchasing power*. This is a more meaningful measure of actual income per person, because it includes not only income, but also the price of goods in a country. It is usually measured in per capita GDP. Per capita GDP can be expressed both by using the current exchange rates in USD and by using the current purchasing power parities (PPPs). Purchasing power parities are the number of currency units required to buy goods equivalent to what can be bought with 1 unit of the currency of the base country or with 1 unit of the common currency of a group of countries.
- *Economic structure of the labor force*. In the United States and Western Europe, fewer than 2% of the workers are engaged in agriculture, whereas in certain African nations, India, and China, more than 70% of the laborers are in this sector. More than 75% of U.S. laborers are engaged in wholesaling, retailing, professional and personal services (including medical, legal, and entertainment), and information processing (such as finance, insurance, real estate, and computer-related fields).[10]
- *Consumer goods purchased*. The quantity and quality of consumer goods purchased and distributed in a society

also provide a good measure of the level of economic development in that society. Televisions, automobiles, home electronics, jewelry, watches, refrigerators, and washing machines are some of the major consumer goods produced worldwide on varying scales. The ratio of people to television sets in developing countries is 150 to 1, for example, and the ratio of the population to automobiles is 400 to 1. In California, the ratio is almost 1 to 1 for these consumer items.[10] The number of consumer goods such as telephones and televisions per capita is a good indicator of a country's level of economic development.

- *Education and literacy of a population*. The more men and women who attend school, usually the higher the level of economic development in a country. The literacy rate of a country is the percentage of people in the society who can read and write.
- *Health and welfare of a population*. Measures of health and welfare, in general, are much higher in developed nations than in les- developed ones. One measure of health and welfare is diet. Most people in Africa do not receive the United Nations' daily recommended allowance of diet. People in less-developed countries also have poor access to doctors, hospitals, and medical specialists.
- *Per capita energy consumption*. The energy consumption of the population is a good indicator of a country's level of economic development.

Transfer of Energy Efficiency Technologies

There may be more indicators of economic development to list, but what is sought for purposes of making energy policy is (preferably) a list of readily available indicators for deciding on the feasibility of the transfer of energy efficiency technologies. In a previous study,[9,11] a similar analysis was carried out for DSM technology transfer to developing countries.

Indicators such as GDP, per capita energy consumption, installed capacity, capacity factor, growth rate, income distribution, and carbon emissions will only give an idea about the level of the economic development of the country in question. More information is needed for choosing the correct DSM options. Details on the characteristics of end uses, which are seldom available in developing countries, would be a very useful indicator. These data can be obtained by monitoring, auditing, or surveying. In a recent study,[9] it was found that surveying is the least time-consuming low-cost method to obtain such data. To generalize the method, the indicators can be grouped under two headings: macro- and micro-level indicators (see Fig. 3).

The macro indicators are those that will be useful in determining which of the following categories the developing country belongs to. The categories are as follows:

- Advanced developing countries—middle-income countries that are advanced industrially
- Developing countries—low-income and lower-middle-income countries that are developing
- Least developed countries—low-income countries that are either not developing or developing very slowly.

The determination of which category a country belongs to is based on a cross-check of macro- and micro-level indicators. The execution of the decision-making is carried

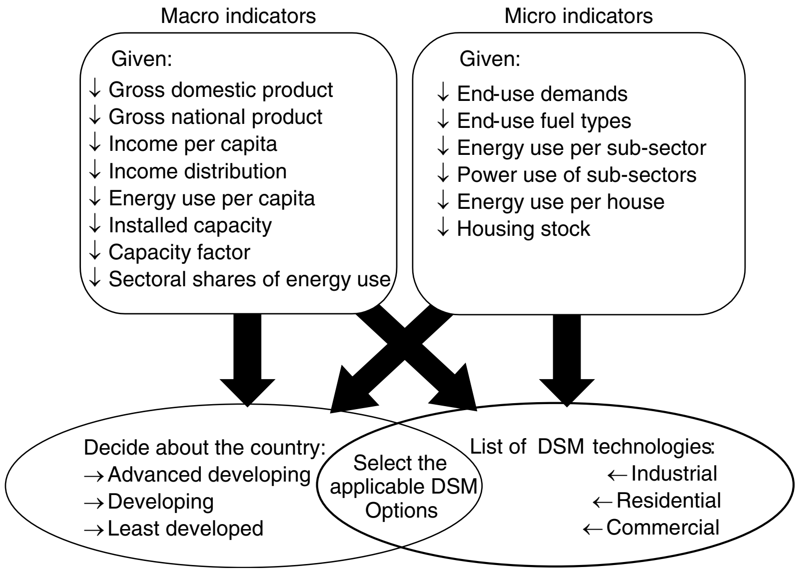

Fig. 3 Macro- and micro-level input variables used in decision-making for the most applicable DSM options in any developing country. Source: From Eastern Mediterranean University and Elsevier Science (see Refs. 9 and 11).

out through the consideration of the variables shown in Fig. 3. Using the end-use information, the available DSM options can be determined from the pool of DSM technologies. Then the applicability of the DSM technologies to the country in question is examined further by using information about the category of the country. The final decision is made by checking the cost-to-benefit ratio of the applicable DSM program.

Finally, the implementation of the DSM programs is evaluated, and if there are any doubts about their success, more surveys may be conducted to update the data at the micro level.

Reducing Power Capacity Needs

In developing countries, the slow-occurring technology transfer and, hence, delayed energy efficiency improvements in all sectors may lead to exaggerated power demand. In Turkey, the growth of installed power capacity has been greater than that of the GNP projected between 1968 and 2003 (see Fig. 4). In 1997, installed power was almost three times greater than it should have been with the GNP-projected levels; and in 2003, installed power was almost four-and-a-half times greater than those levels. The gap between the two trends (shaded area in Fig. 4) is a common feature of the developing countries. It is the reverse of JAWS, which was described for developed countries in the introduction. To close the gap between the two trends, in Fig. 4, the old infrastructures that are associated with the energy services should be renewed both at the power supply side and at the demand side. Therefore, this gap is referred to as an excess energy consumption (EXEC) gap.

The traditional method of meeting the demand with little attempt to rebuild the infrastructure and increase the efficiency of energy services needs to be revised in developing countries. Traditionally, the policy-makers in developing countries believed that the opportunity in power reduction lay in reducing the EXEC. The opportunity for power reduction is not limited to this amount, however. As the replacement of the old infrastructure continues, ways of improving energy efficiency at customer level and, hence, further reducing the power capacity requirements at the utilities and achieving the JAWS, a feature of developed countries, should also be considered. The gap between the maximum installed power and the minimum that can be achieved is called the energy-saving opportunity gap (ESOG).[12] The energy-saving opportunity in developing countries lies in reducing both EXEC and JAWS (i.e., ideally ESOG = EXEC + JAWS).

Case Studies of DSM Implementation

The two countries examined were Northern Cyprus and Turkey.[11] The flow chart in Fig. 5 shows a simplified approach that was applied for determining the best applicable DSM technologies for Northern Cyprus and Turkey. In this simple approach, the GNP per capita income of the country in question was used to determine the income level of the country. At the same time, a decision was made about the industrial development level of the country. For this reason, the shares of electricity consumption were used. This synthesis was carried out at the macro level, leading to setting priorities on considering

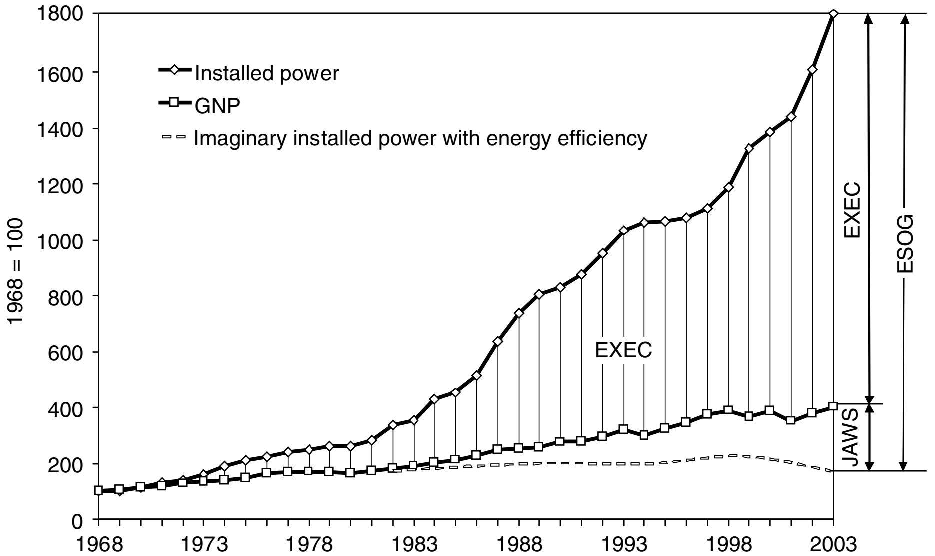

Fig. 4 Economic and power capacity developments of Turkey between 1968 and 2003.

Energy Eff–Serv

the sectors with the best applicability of DSM options. To determine the specific DSM options to apply, however, detailed information on the end uses was required. Therefore, a survey was conducted for this purpose, and DSM programs were proposed.

Northern Cyprus, being a small island, is not an industrially advanced country. Sector-based electricity consumption shares are given as 35% for residential, 18.74% for commercial, and 9.39% for industrial sectors.[11] The great majority of the population (approximately 70%) is employed in the services sector; hence, the DSM measures are best selected for the residential and commercial technologies. The 1996 GNP per capita being $4222 USD, Northern Cyprus is an upper-middle-income country according to the World Bank criterion. The population is highly educated, and the literacy rate is almost 100%. With these macro indicators, it was decided that the residential and commercial sectors would have the best potential for load reduction and that the DSM technology transfer should be considered for these sectors. Surveys were conducted in both sectors to determine the micro indicators leading to the selection of the DSM options to apply.

In the residential sector, statistical information was obtained on the number of electrical appliances and their time of use, and end-use load curves were obtained. It was discovered that electrical water heaters demanded 50 MW at the winter peak hour (19:00), which constituted 45% of the 110-MW peak. The other shares of end-use demands of the winter peak were estimated to be 28% for space heating, 9% for television sets, 7% for lighting, and 5% for refrigeration. Demand-side management programs concerning the water heating, space heating, and lighting activities were proposed. The programs proposed were estimated to defer the need for a new 60 MW power unit worth $100 million (U.S. dollars) for at least 19 years at an expense of $12 million (U.S. dollars).[14]

The diversity of the commercial buildings and their end uses in Northern Cyprus preclude the adoption of the approach used in the residential sector. Not only do the system sizes for end uses vary greatly, but also, their time of use may vary for different building types. The problem can be simplified by selecting a segment of the commercial sector. In Northern Cyprus, the tourism sector was selected, being the segment in the commercial sector that consumes the most electricity. According to the surveys conducted, the power demand of this sector is greater during the summer season due to the heavy use of air conditioners. Air-conditioner use in the hotels constituted 27% of the utility load in summer. The proposed DSM technology transfer to this sector could reduce the summer peak by 11% at a total cost of $5,60,000 (U.S. dollars).[15]

Turkey, on the other hand, is an advanced developing country due to its past two decades of industrial development. The primary energy consumption share of its industrial sector is currently 29% and is expected to reach 40% in 2020. Due to its nonuniform income distribution, however, the 1999 GDP per capita is $2807 USD, which makes Turkey a lower-middle-income country. The level of education is low, and a rebate program on replacing incandescent lamps with compact fluorescent lamps (CFLs) in the residential sector is not expected to be as successful as in Northern Cyprus, especially in the low-income homes. The macro indicators of Turkey imply that the transfer of DSM technology would be best selected from the industrial options. Micro indicators such as end-use fuel types, average grid losses at 20%, and the magnitude of power and rate of heat demands of the factories pointed to sizable energy gains from a cogeneration program. A more detailed study[16] showed that by replacing the nuclear program with the cogeneration program, Turkey not only would save $72.6 billion (U.S. dollars), but also would reduce total primary energy demand by 11% in 2020.

CONCLUSIVE COMMENTS

Statistics and projections show that not only the rate of energy consumption, but also the carbon emissions of developing countries are rising very fast. In 2001, carbon dioxide emissions from industrialized countries were 49% of the global total, followed by developing countries at 38% and Eastern Europe/Former Soviet Union (EE/FSU) at 13%. If business continues as usual, by 2025, developing countries are projected to account for the largest share of world carbon dioxide emissions, at 46%, followed by the industrialized world at 42% and the EE/FSU at 12%.[17] To save the world, it is essential not only to transfer the latest energy efficiency technologies to the developing countries to achieve substantial reductions in energy consumption, but also to explore ways of rebuilding their poor infrastructure.

On the other hand, energy efficiency technologies, which are successfully used in many industrialized countries, may not always be feasible to apply in developing countries. Some DSM technologies may be easily transferable to some developing countries but not applicable in others.

Compact fluorescent lamps, for example, which were offered as a DSM measure in some developing countries, may not be suitable for other developing countries. In Turkey, the squatters, who are low-income people, probably would find this program luxurious, and even if they were given a full rebate, they might prefer selling the lamps rather than using them for themselves. On the other hand, in the villages of Bangladesh, 90% of the energy required for lighting is supplied from petroleum products; only 10% comes from electricity. Therefore, CFLs cannot be worthy of any consideration as a DSM option.

It is possible that some countries, although having a lower per capita income than others, may be industrially advanced, and the DSM technologies devised for the industrial sector may be more suitable than those for the residential sector. Turkey, for example, falls into the category of "industrially advanced developing country," and applying DSM measures in the industrial sector would be more successful and have more impact on the utility load management of the country.

Statistical information on end uses is also very useful in determining the suitability of the proposed energy efficiency or DSM technology. In Northern Cyprus, it was discovered that the largest demand for electricity came from domestic water heating. In South Africa, figures as high as 40%–50% of the monthly electricity use of an average middle-to-upper-income household were quoted for water heating. DSM technologies regarding efficient water heating would be most appropriate for these countries, but in many other countries, this may not be the case. In Thailand, for example, the highest potential savings could come from improving the energy efficiency of the refrigerators, the reason being the intense use of old-technology, inefficient refrigerators.

Therefore, it can be concluded that to apply energy efficiency technology transfer to developing countries, the social and economic realities of these countries need to be taken into account, along with the technical applicability of the programs. The approach should be twofold: First, the economic and social state of the country should be determined; and second, the suitability of the energy efficiency options with the highest potential savings should be determined.

Energy Efficiency: Information Sources for New and Emerging Technologies

Steven A. Parker
Pacific Northwest National Laboratory, Richland, Washington, U.S.A.

Abstract
The purpose of this entry is to share a list of useful organizations that provide reliable information on new and emerging energy-efficient technologies based on research and experience. Experienced energy managers may use the information provided by these organizations to enhance their knowledge and understanding, thereby improving their energy management programs. The scope is limited to publicly available and open-membership organizations that deal with new and emerging energy-efficient technologies, strategies, and products. The sources identified should not be considered exhaustive, but rather a first step "go to" list suggested by the author when searching for useful information on new and emerging energy-efficient technologies.

BACKGROUND

There are many strategies that can be used to reduce energy consumption and costs. These strategies might include:

- Awareness programs to motivate users and occupants to change behaviors that result in saved energy;
- Operations and maintenance programs, including commissioning to keep equipment running efficiently and to optimize run times;
- Training programs to educate people on how to reduce energy consumption and costs;
- Equipment procurement programs to buy the most efficient equipment available (rather than the cheapest first cost) to minimize life-cycle costs, which include energy costs;
- Commodity procurement programs to buy the least expensive energy source available; and
- Energy-efficient technology programs to replace existing or conventional equipment with more efficient equipment. This strategy also includes new and emerging energy-efficient technologies.

An effective energy management program will likely use many, if not all, of these strategies.

Removing old, inefficient equipment and replacing it with newer, more energy-efficient equipment is one method of reducing a site's energy consumption and costs. Two questions that are often asked include: "Which energy-efficient technology should I select?" And, just as important, "From what list of alternatives should I consider?"

The answer to the first question should be "I should select the alternative with the lowest life-cycle cost." The answer to the second question may be more difficult. If you do not place a new technology on the list of alternatives, it can never be selected. One issue with new and emerging technologies is the concern about risk and reliability. When something is new, it is perceived to have more risk. "It claims to be more energy efficient, but I have not seen it in operation. Does it really work? Will it work here? Will it work in this application? Is my maintenance team ready to work with this new technology?" These are all important and relevant questions.

The time it takes for a new technology to be accepted to the point of being considered conventional can be surprising. Take, for example, the fluorescent T-8 lamp and electronic ballast. How many years did it take for this technology to be seen as conventional for standard office lighting configurations and to fully penetrate the market? Think of the energy savings that could have been realized if this technology would have fully penetrated the market in only 5–10 years instead of 15–20 years. The same is true for all new equipment end uses (cooling, heating, ventilation, water heating, battery chargers, etc.). New technologies take a long time to fully penetrate the market and considerable energy may be saved if this transitory period were reduced.

Of course, balanced against the potential energy reduction is the potential for risk. Not every new technology will be cost effective and survive the market process. The way an experienced energy manager manages the risk, or at least better understands the risk, is to evaluate the new technology on a limited basis before it is mass deployed. This is the purpose of research, evaluations, demonstrations, pilot projects, and case

Keywords: New technology; Energy-efficient technology; Emerging energy-efficient technology; Energy efficiency; Energy-efficient equipment; State-of-the-art technology.

studies. With these actions, experienced energy managers can look before they leap, and in some cases, benefit from the lessons learned from others.

INTRODUCTION

Finding useful and reliable information on new and emerging energy-efficient technologies can be daunting, even for the experienced energy manager. Today, more than ever, a lot of information is available. There are books, professional associations with journals, magazines, e-newsletters, other periodicals, and the gamut of Internet Web sites. A lot of the information available is even well intended. One of the problems is that there is too much information to sort through. Finding the right type of information on the right subject can be difficult.

There are several reasons why it is difficult to find good information on new and emerging energy-efficient technologies. First and foremost, there may be little information on the technology and its potential effectiveness because the product is new. Second, collecting, analyzing, and reporting information on technologies or equipment can be expensive and time consuming. Third, many tests may be performed in-house, and may not be publicly available. Even with these barriers, there is a lot of information out there. In addition to their regular, full-time duties, energy managers can spend years building up a network of sources and resources.

There are a number of periodicals that can be used as sources for information on new and emerging energy-efficient technologies. In addition to journals provided through membership organizations, there are a number of low-cost and no-cost periodicals, many of which can be very useful in learning about new technologies or new approaches to energy efficiency. Unfortunately, there are so many periodicals that it may be impossible for any energy manager to stay on top of their reading list.

The purpose of this entry is to share a list of useful sources. This is not a list of sources on energy management—that list would be too long—but a list of sources (organizations) that specifically deal with new and emerging, energy-efficient technologies, strategies, and products. The sources identified in this entry should not be considered exhaustive. In fact, to keep its length manageable, this list has purposely been limited to sources within the United States. The author acknowledges that there are many organizations outside the United States performing similar useful services and many organizations, both public and private, that perform a lot of good research and provide a host of useful services in the area of energy efficiency. The list of sources included in this article may be considered an initial or first step or a go-to list suggested by the author in your search for useful information on new and emerging energy-efficient technologies.

Sources are not one-size-fits-all. Not every source does everything. The reader will find that some sources are more research- and development-oriented and focus on pre-commercial technologies, while others are more focused on enhancing the deployment of commercially-available technologies. Some sources are research-oriented, while others are more applied. In addition, some sources simply document results, whereas other sources document more detailed analysis, expand on the lessons learned, or offer guidance and tools to support future applications. You may also find different definitions for the terms "new" and "emerging," as well as "technology."

It is the author's hope that the reader will benefit from the information made available on these proactive organizations. Furthermore, it is the author's hope that more organizations will take proactive steps and make even more (reliable) information on new and emerging energy-efficient technologies publicly available.

UNITED STATES GOVERNMENT AGENCIES AND PROGRAMS

While some believe we should be spending more, the United States federal government supports a lot of research and development in the area of energy efficiency and renewable energy. Because the federal government supports a lot of this work, it is also a good source for information on new and emerging energy-efficient technologies. The information, however, can be difficult to find. This section identifies several sources of information within the federal government.

U.S. Department of Energy

Obviously, one of the largest sources of information on energy-efficient technologies is the U.S. Department of Energy (DOE). Within the DOE, there are three major offices that the advanced energy manager should be aware of—the Office of Energy Efficiency and Renewable Energy (EERE), the Office of Fossil Energy (FE), and the Office of Electricity Delivery and Energy Reliability (OE).

Each of the DOE program offices plays a unique role in the larger energy picture. FE deals primarily with power generation; OE deals primarily with electric delivery and infrastructure; and EERE deals primarily with end use. However, you will find some overlap among the DOE program offices. For example, distributed generation (renewable energy, fuel cells, cogeneration, etc.) is one of those technology sets that can be found in several programs.

Energy Efficiency and Renewable Energy

Simply put, the EERE mission is to strengthen America's energy security, environmental quality, and economic vitality in public–private partnerships that:

- Enhance energy efficiency and productivity;
- Bring clean, reliable, and affordable energy technologies to the marketplace; and
- Make a difference in the everyday lives of Americans by enhancing their energy choices and quality of life.

EERE manages and supports a wide variety of energy research, development, and deployment activities. EERE (www.eere.energy.gov) consists of 10 major program offices:

- Biomass Program (www.eere.energy.gov/biomass)
- Building Technologies Program (www.eere.energy.gov/buildings)
- Federal Energy Management Program (www.eere.energy.gov/femp)
- FreedomCAR and Vehicle Technologies Program (www.eere.energy.gov/vehiclesandfuels)
- Geothermal Technologies Program (www.eere.energy.gov/geothermal)
- Hydrogen, Fuel Cells, and Infrastructure Technologies Program (www.eere.energy.gov/hydrogenandfuelcells)
- Industrial Technologies Program (www.eere.energy.gov/industry)
- Solar Energy Technologies Program (www.eere.energy.gov/solar)
- Weatherization and Intergovernmental Program (www.eere.energy.gov/wip)
- Wind and Hydropower Technologies Program (www.eere.energy.gov/windandhydro)

Each of these program offices publishes or supports the publication of several reports every year. Many of these publications are available through the DOE Web site. Because the Web site is rather large, use the search engine.

While a large part of DOE is actively involved in the research and development of new, energy-efficient technologies, there are three specific subprograms that the author would like to highlight: the Industrial Technologies Program's inventions and innovations, Building Technologies Program's emerging technologies, and the Federal Energy Management Program's new technologies.

Inventions and Innovation (I&I), part of the DOE Industrial Technologies Program, provides grants to independent inventors and small companies with sound ideas for energy-efficient technologies. Distinct from other federal grant programs, I&I provides grantees not only with funding, but with additional resources such as training, market assessments, technical assistance, access to promotional events and materials, and special contacts to aid in commercialization endeavors. Although I&I is part of the Industrial Technologies Program organization, their mission is cross cutting; I&I supports energy efficiency and renewable energy technology development in focus areas that align with 10 EERE programs. For more information on I&I, see www.eere.energy.gov/inventions.

Emerging Technologies, part of the DOE Building Technologies Program (BTP), advances the research and development of the next generation of energy-efficient components, materials, and equipment. To help near-term emerging technologies overcome market introduction barriers, the program uses a combination of strategies, including demonstration/evaluation and technology procurement. These strategies are designed to increase buyer confidence and build demand for new energy-efficient technologies. For more information on BTP's Emerging Technologies, see www.eere.energy.gov/buildings/emergingtech.

The DOE Federal Energy Management Program (FEMP) supports a limited number of technology demonstrations through their new technology activities, which are designed to provide independent performance data to federal decision-makers and support timely federal adoption of energy saving and environmentally beneficial technologies. While these publications are developed to benefit the federal energy and building manager, they are useful to any energy manager wishing to advance their energy management program. For more information on FEMP's new technology publications, see www.eere.energy.gov/femp/technologies/tech_demos.cfm.

Office of Fossil Energy

According to the FE Web site (www.fossil.energy.gov), the primary mission of DOE's Office of Fossil Energy is to ensure that we can continue to rely on clean, affordable energy from our traditional fuel resources. Fossil fuels supply 85% of the nation's energy, and FE is working on such priority projects as pollution-free coal plants, carbon sequestration, FutureGen, more efficient power generation, more productive oil and gas fields, and the continuing readiness of federal emergency oil stockpiles.

While FE deals primarily with fossil fuels and source fuels for power generation, a significant amount of fuel-cell-related R&D is supported by this DOE office. If you are looking for information on fuel cells, do not overlook this important source.

Office of Electricity Delivery and Energy Reliability

According to the OE Web site (www.oe.energy.gov), their mission is to lead national efforts to modernize the electric grid, enhance the security and reliability of the energy infrastructure, and facilitate recovery from disruptions to the energy supply. OE is a relatively new office within the DOE that was formed when the Office of Energy Assurance and the Office of Electric Transmission and Distribution combined. Research and development programs within OE include: security and reliability of the transmission infrastructure, distributed energy, transmission grid modernization, energy storage, and superconductivity. New technologies related to the utility grid, including grid reliability and GridWise, are supported through this office. In addition, the distributed energy programs support distributed generation, combined heat and power, and thermally activated technologies.

DOE National Laboratories

To accomplish its mission, the DOE maintains several national laboratories and technology centers (www.energy.gov/organization/labs-techcenters.htm). Of the 13 DOE national laboratories, 11 are actively involved in EERE-supported research, development, and deployment activities (www.eere.energy.gov/site_administration/doe_labs.html). All publicly available reports published by DOE national laboratories are available through the National Technical Information Service (NTIS) at www.ntis.gov/search.

Each DOE national laboratory has specialty or focused areas of research, although there is considerable overlap in some areas. While the DOE national laboratories may be performing world-class research, their Web sites may not fully identify the breadth or depth of their knowledge and the information available. This is where nothing beats a good professional network or a (series of) well placed telephone calls.

Office of Scientific and Technical Information

At the DOE Office of Scientific and Technical Information (OSTI) (www.osti.gov), you can search for DOE research results and find out about ongoing research projects. OSTI makes R&D findings available to DOE researchers and the public.

U.S. Environmental Protection Agency

Under the U.S. Environmental Protection Agency (EPA), the Office of Air and Radiation, and the Office of Atmospheric Programs (OAP) is the Climate Protection Partnership Division (CPPD). The CPPD (www.epa.gov/cpd) promotes greater use of energy-efficient products and practices in the residential, commercial, and industrial sectors through the ENERGY STAR® partnership program (www.energystar.gov). The Division's programs, such as Climate Leaders (www.epa.gov/climateleaders), provide information, technical assistance, and recognition for environmental leadership to organizations as they develop strategies and take advantage of proven opportunities to reduce their greenhouse gas emissions. CPPD also encourages investments in efficient, clean technologies, such as combined heat and power (CHP) (www.epa.gov/CHP) and green power (www.epa.gov/greenpower) from renewable resources.

ENERGY STAR is a joint program of the EPA and the DOE. In 1992, the EPA introduced ENERGY STAR as a voluntary labeling program designed to identify and promote energy-efficient products to reduce greenhouse gas emissions. The ENERGY STAR label is now on major appliances, office equipment, lighting, home electronics, and more. EPA has also extended the label to cover new homes and commercial and industrial buildings.

[Note from the author: While I would trust the information on the ENERGY STAR Web site (www.energystar.gov) and information published by EPA and DOE; I would not trust any product or claim just because it had an ENERGY STAR label. ENERGY STAR is a voluntary program with a marketing foundation, and it is not difficult to find their logo being utilized by others to make unsubstantiated claims.]

U.S. Department of Commerce

The Department of Commerce is a very diverse organization within the federal government. Within the Department of Commerce, Office of Technology Administration, however, are two specific organizations an advanced energy manager should be aware of. These are the National Technical Information Service (better known as NTIS) and the National Institute of Standards and Technology (better known as NIST).

National Technical Information Service

The National Technical Information Service (NTIS) is part of the U.S. Department of Commerce's Technology Administration. NTIS' primary purpose is to assist U.S. industries to accelerate the development of new products and processes, as well as helping the United States maintain a leading worldwide economic competitive position. NTIS is the largest central resource for government-funded scientific, technical, engineering, and business-related information available today. They have information on more than 600,000 information products covering over 350 subject areas from over 200 federal agencies. To search the NTIS library for federal reports and documents published since 1990, go to www.ntis.gov/search/

National Institute of Standards and Technology

The National Institute of Standards and Technology (NIST) is a nonregulatory federal agency within the U.S. Commerce Department's Technology Administration. NIST's mission is to develop and promote measurement, standards, and technologies to enhance productivity, facilitate trade, and improve the quality of life. NIST consists of four primary programs. Of specific interest to energy efficiency are the NIST laboratories (www.nist.gov/public_affairs/labs2.htm) and the

Advanced Technology Program (www.atp.nist.gov). The NIST laboratories conduct research that advances the nation's technology infrastructure and is needed by U.S. industry to continually improve products and services. The Advanced Technology Program accelerates the development of innovative technologies for broad national benefit by cofunding R&D partnerships with the private sector.

Other Federal Agency Sources

As a result of legislation, every federal agency has an internal energy management organization and/or program working toward a series of energy-efficiency goals. In response to these demands, several federal agencies are performing in-house research on new and emerging energy-efficient technologies to identify those technologies that can best serve the goals of the agency. Some of this information is publicly available on agency Web sites (although it can be very difficult to find), while other agencies have found it necessary to keep the information on internal-access-only intranets.

Department of Defense, Fuel Cell Program

There are a number of energy-efficiency research and development programs within the U.S. Department of Defense (DOD), each serving specific DOD missions. While most of the energy-efficiency programs serve internal DOD objectives, the DOD fuel cell program (dodfuelcell.cecer.army.mil) has provided significant benefit to the overall advancement and commercialization of fuel cells. The DOD fuel cell program is managed by the U.S. Army, Corps of Engineers, Engineer Research and Development Center (ERDC), Construction Engineering Research Laboratories (CERL). The DOD fuel cell projects Web site provides information guides, demonstration results, and information on the climate change (fuel cell) rebate program.

STATE AGENCIES AND UNIVERSITY PROGRAMS

While the federal government has some very substantial research, development, and deployment programs for new and emerging energy-efficient technologies, several state agencies and university programs are also excellent resources and are often closer to technologies ready for commercial deployment.

While the resources are good, this presents a case where perspective, or bias, should be considered by the reader. State energy offices focus on the priorities of the state. Furthermore, climate factors can also skew results. Support infrastructure and product availability may also be regional. For example, a dehumidification technology demonstrated in Orlando will have significantly different findings in San Francisco. Similarly, sunny California is subject to both high electric energy and electric demand rates. Therefore, you may find considerable information supporting the technical appropriateness and cost effectiveness of a technology such as photovoltaic energy. The results will be significantly different for an application in the Pacific Northwest, where solar radiation has different technical factors and both energy and demand rates are notably lower. The author's point is that many factors can support the appropriateness of a new technology: end-use application, energy, peak demand, average demand, climate, location, and infrastructure are just some of these factors.

Almost every state in the United States has a state energy office. The experienced energy manager should become familiar with their local state energy office and the services it offers. In addition, there are several universities with energy-research programs. This section does not purport to be all inclusive; however, the following state and university programs are particularly noted for performing research and making publications available on new and emerging energy-efficient technologies.

California Energy Commission

The California Energy Commission (CEC) is one of the largest state energy programs. The CEC (www.energy.ca.gov) has program offices on energy efficiency, renewable energy, transportation energy, and significant research and development activities. Some CEC programs appear to be larger than their DOE counterparts.

Public Interest Energy Research

The California Energy Commission's Public Interest Energy Research (PIER) program creates state-wide environmental and economic benefits by supporting energy research, development, and demonstration (RD&D) projects that will help improve the quality of life in California by bringing environmentally safe, affordable, and reliable energy products and services to the marketplace. PIER includes a full range of RD&D activities that will advance science or technology not adequately provided by competitive and regulated markets. The PIER Web site is located at www.energy.ca.gov/pier.

While PIER is involved in RD&D, they are not involved—at least not directly—in the commercialization or deployment of technologies. In some cases, you may find that local utilities become involved with new technologies that achieve successful results from PIER demonstrations. For this reason, local utilities can be good sources for information. In California, the major utilities have collaborated to form the Emerging Technology Coordinating Council (ETCC). The ETCC is discussed in more detail later in this entry.

Energy Center of Wisconsin

The Energy Center of Wisconsin (www.ecw.org) is a private, nonprofit organization dedicated to improving energy sustainability, including support of energy efficiency, renewable energy, and environmental protection. The Energy Center of Wisconsin provides objective research, information, and education on energy issues to businesses, professionals, policymakers, and the public. The Energy Center's education department supports comprehensive energy education programs.

They offer hundreds of publications on a myriad of energy-efficiency topics and host a unique collection of industrial fact sheets and many other research materials. The Energy Center also has a comprehensive collection of energy-related library materials, many of which are available through their Web site.

Florida Solar Energy Center

The Florida Solar Energy Center (FSEC) is a state-supported renewable energy and energy-efficiency research, training, testing, and certification institute. FSEC (www.fsec.ucf.edu) is a research institute of the University of Central Florida (UCF) and functions as the state's energy research, training, and certification center. FSEC's mission is to research and develop energy technologies that enhance Florida's and the nation's economy and environment, and to educate the public, students, and practitioners on the results of the research. FSEC has gained national and international recognition for its wide range of research, education, training, and certification activities. FSEC maintains a wide variety of technical articles, research reports, newsletters, and public information documents. Their joint-use research library is reported to be one of the largest repositories of energy publications in the nation.

Iowa Energy Center

The Iowa Energy Center (www.energy.iastate.edu) invests its resources to create a stable energy future for the state of Iowa. The Iowa Energy Center works quietly and steadily, producing dividends that support Iowa communities, businesses, and individuals. Most of the Iowa Energy Center's activities are spent on energy-efficiency research, demonstrations, and education projects. These projects address energy use in agriculture, industry, commercial businesses, municipalities, and residential areas. The Iowa Energy Center is constantly at work seeking opportunities to improve the total energy picture of the state, its businesses, and communities.

The National Building Controls Information Program (www.buildingcontrols.org) was established by the Iowa Energy Center with support from the EPA to facilitate the adoption of energy-efficient building control products and strategies through testing, demonstration, education, and dissemination of product information. A special Web site, DDC Online (www.ddc-online.org), was developed by the Iowa Energy Center and is reported to be the most complete, unbiased listing available of direct-digital controls (DDC) vendors and information related to DDC systems.

New York State Energy Research and Development Authority

The New York State Energy Research and Development Authority (NYSERDA) is a public benefit corporation created by the New York state legislature. NYSERDA (www.nyserda.org) has been cited by the DOE as being among the best government research organizations in North America. NYSERDA's principal goal is to help all New York state utility customers solve their energy and environmental problems while developing new, innovative products and services that can be manufactured or commercialized by New York state firms, through which NYSERDA supports a wide assortment of research and development in energy-efficient technologies. Many of NYSERDA's technical reports are available through their Web site (www.nyserda.org/publications). In addition, many of NYSERDA's reports are available from NTIS.

Rensselaer Polytechnic Institute, Lighting Research Center

The Rensselaer Polytechnic Institute, Lighting Research Center (LRC) is a university-based research center devoted to lighting (www.lrc.rpi.edu). The LRC is a reliable source for objective information about lighting technologies, applications, and products. The LRC provides training programs for government agencies, utilities, contractors, lighting designers, and other lighting professionals. LRC programs cover a range of activities, including both laboratory testing of lighting products and real world demonstration and evaluation of lighting products and designs. They conduct research into energy efficiency, new products and technologies, lighting design, and human factors issues.

Washington State University, Energy Programs

The Washington State University (WSU) Energy Program (www.energy.wsu.edu) is a self-supported department within the university's extension service. The WSU Energy Program provides support to other national and local energy organizations, such as EnergyIdeas.org. The program has developed a significant library of materials on new and emerging technologies.

EnergyIdeas.org provides comprehensive information about commercial, industrial, and residential energy efficiency. You will find actual customer questions with detailed answers, case studies, reports, and articles on topics ranging from appliances and lighting to motors and solar energy. The EnergyIdeas Web site is sponsored by the nonprofit Northwest Energy Efficiency Alliance (www.nwalliance.org) and it is managed by the WSU Energy Program.

More on University Programs

There are several universities that operate energy management research programs. Each major university energy program will have specialty or focused areas of research. Unfortunately, there does not appear to be a composite index identifying the universities and their points of contact. Furthermore, while the university programs may be performing world-class research, their Web sites may not fully identify the breadth or depth of their knowledge. This is where nothing beats a good professional network or a well-placed telephone call.

MEMBERSHIP ORGANIZATIONS AND ASSOCIATIONS

There are a number of membership associations. Some membership organizations are associations of companies, while others allow individual membership. Both types of organizations add value to the field of energy management. In addition to supporting research, training, and publications, several of these organizations can also respond to special inquiries from members. The following is a nonexhaustive list of membership associations and other associations that may be useful to members in obtaining information on new and emerging energy-efficient technologies.

Alliance to Save Energy

The Alliance to Save Energy (ASE) (www.ase.org) is a nonprofit coalition of business, government, environmental, and consumer leaders. The Alliance to Save Energy supports energy efficiency as a cost-effective energy resource under existing market conditions and advocates energy-efficiency policies that minimize costs to society and individual consumers, and lessen greenhouse gas emissions and their impact on the global climate. To carry out its mission, the Alliance to Save Energy undertakes research, educational programs, and policy advocacy; designs and implements energy-efficiency projects; promotes technology development and deployment; and builds public–private partnerships in the United States and other countries. Although the ASE is very policy-oriented (and, therefore, very politically oriented), it does support several technical programs.

American Council for an Energy-Efficient Economy

The American Council for an Energy-Efficient Economy (ACEEE) (www.aceee.org) is a nonprofit organization dedicated to advancing energy efficiency as a means of promoting both economic prosperity and environmental protection. ACEEE conducts in-depth technical and policy assessments, organizes conferences, and publishes books and reports. While ACEEE is not a membership organization, they do send out notices of publications, conferences, and other activities. ACEEE sponsors several events, but they are probably most noted for the biennial Summer Study on Energy-Efficient Buildings. Recently, ACEEE has also been organizing a biennial Summit on Emerging Technologies in Energy Efficiency.

Consortium for Energy Efficiency

The Consortium for Energy Efficiency (CEE) (www.cee1.org) is a nonprofit, public benefits corporation that promotes energy-efficient products and services. CEE develops initiatives for its members to promote the manufacture and purchase of energy-efficient products and services. CEE's goal is to induce lasting structural and behavioral changes in the marketplace, resulting in the increased adoption of energy-efficient technologies.

E Source

E Source Companies LLC (www.esource.com) is a membership-based information services company. E Source information services provide member organizations with unbiased, independent analysis of retail energy markets, services, and technologies. According to their Web site, E Source serves as a high-value filter of the torrent of information on developments in the energy services marketplace, sorting through the hype and providing clients with concise strategic insights and in-depth technology assessments. The E Source core products and services are offered through an integrated package of membership benefits. Additional services for energy service providers, including multiclient studies and focused research services, may be purchased.

Professional and Trade Associations

There are a number of professional and trade membership associations. Professional and trade associations provide their members benefits such as journals, publications, and training, as well as a professional network. Some organizations also sponsor certification programs, conferences and trade shows, technical research, or other benefits. The following is a nonexhaustive list of professional and trade membership associations with significant ties to advancing the field of energy management through the research, development, deployment, assessment, and/or the use of new and emerging energy-efficient technologies.

- Association of Energy Engineers (AEE), www.aeecenter.org
- American Institute of Architects (AIA), www.aia.org
- American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE), www.ashrae.org
- American Society of Mechanical Engineers (ASME), www.asme.org
- California Commissioning Collaborative (CCC), www.cacx.org
- Fuel Cells 2000, www.fuelcells.org
- Gas Appliance Manufacturers Association (GAMA), www.gamanet.org
- Geothermal Heat Pump Consortium, www.geoexchange.org
- Geothermal Resources Council (GRC), www.geothermal.org
- Illuminating Engineering Society of North America (IESNA), www.iesna.org
- Institute of Electrical and Electronics Engineers (IEEE), www.ieee.org
- Institute of Industrial Engineers (IIE), www.iienet.org
- International Facility Management Association (IFMA), www.ifma.org
- International Ground-Source Heat Pump Association (IGSHPA), www.igshpa.okstate.edu
- National Council on Qualifications for the Lighting Professions (NCQLP), www.ncqlp.org

UTILITY ENERGY CENTERS AND RESEARCH PROGRAMS

Many if not most utilities perform research on new and emerging energy-efficient technologies. However, much of this research is designed to support in-house programs. On the other hand, some utilities work aggressively with their customers to research, demonstrate, and deploy these new technologies. Even if the information is not made publication-ready, the experienced energy manager will benefit from establishing an active and on-going relationship with local utility customer account-service representatives. Through the account representatives, the energy manager will learn of the utility's involvement in new and emerging technologies and can benefit from the lessons learned.

California Statewide Emerging Technology Program

The statewide Emerging Technologies (ET) program seeks to accelerate the introduction of "near market-ready" energy-efficiency innovations that are not widely adopted by utility customers in California. Four investor-owned utilities (Pacific Gas and Electric, San Diego Gas and Electric, Southern California Edison, and Southern California Gas) and the California Energy Commission (CEC) are working together cooperatively to pool resources and knowledge for project selection and results dissemination.

The ET program consists of two main components: (1) demonstration and information transfer and (2) participation in the ETCC. The demonstration component provides technology assessments and information to utility customers and industry, often in the form of technology demonstrations at customer facilities. The ETCC coordinates activities and information among the utilities. The ETCC also maintains a Web site listing projects and summary results in its database (www.etcc-ca.com).

The ETCC is charged with administrating California utility, ratepayer-funded programs for energy-related research and energy-efficient emerging technologies. The ETCC coordinates among its members to facilitate the application of energy-efficient emerging technologies that will transform the market and benefit California ratepayers.

The Emerging Technologies project database contains a compilation of technologies and applications that are part of either current or recent projects that council members have sponsored. The database also contains information about the technologies, their applications, and the resulting assessments from member projects.

Energy Design Resources

Energy Design Resources (www.energydesignresources.com) offers energy design tools, software, design guides, case studies, and more. Their goal is to educate architects, engineers, lighting designers, and developers about techniques and technologies, making it easier to design and build energy-efficient commercial and industrial buildings in California. Energy Design Resources is funded by California utility customers and administered by Pacific Gas and Electric Company, Sacramento Municipal Utility District, San Diego Gas and Electric, Southern California Edison, and Southern California Gas under the auspices of the California Public Utilities Commission.

Lighting Design Lab

The Lighting Design Lab (www.lightingdesignlab.com) works to transform the Northwest lighting market by promoting quality design and energy-efficient technologies. The Lighting Design Lab accomplishes its mission through education and training, consultations, technical assistance, and demonstrations. The Lighting Design Lab is sponsored by the Northwest Energy Efficiency Alliance, Seattle City Light, Puget Sound

Energy, Snohomish County Public Utility District, British Columbia Hydro, and Tacoma Power.

Sacramento Municipal Utility District, Customer Advanced Technologies Program

The Sacramento Municipal Utility District (SMUD) Customer Advanced Technologies (CAT) program is a research and development program designed to encourage customers to use and evaluate new or underutilized technologies. According to one presentation, CAT provides the following benefits: it helps customers sort fact from fiction, identify the most promising technologies through direct, first-hand experience, and avoid making major investments in technologies that do not work. Unlike many R&D programs, research is accomplished through implementing real world demonstration projects (instead of laboratory testing). Completed demonstration projects include lighting technologies, light emitting diodes (LEDs), building envelopes, heating ventilation, and air-conditioning (HVAC) systems, as well as a wide variety of other technologies. Reports describing the results for many of these projects are available through their Web site (www.smud.org/education/cat/index.html).

Southern California Edison, Energy Centers

Southern California Edison (SCE) operates two energy centers (www.sce.com/RebatesandSavings/EnergyCenters)—the Agricultural Technology Application Center (ATAC) and the Customer Technology Application Center (CTAC). Both facilities offer hands-on demonstrations of the latest state-of-the-art technologies, as well as workshops, classes, and interactive displays.

Southern California Gas Company, Energy Resource Center

The mission of the Energy Resource Center (ERC) is to serve as a one-stop "idea shop" where customers can find the most efficient, cost-effective, and environmentally sensitive solutions to their energy needs. The ERC showcases innovations in resource-efficient designs, materials, and equipment to help businesses make informed choices about energy consumption and conservation. For more information, see www.socalgas.com/business/resource_center/erc_home.shtml.

OTHER SOURCES OF INFORMATION

The following organizations are worthwhile sources that did not fit into any of the previous categories.

Centre for Analysis and Dissemination of Demonstrated Energy Technologies

The Centre for Analysis and Dissemination of Demonstrated Energy Technologies (CADDET) is an international information source that helps managers, engineers, architects, and researchers find out about renewable energy and energy-saving technologies that have worked in other countries. Along with its sister program, GREENTIE (www.greentie.org), CADDET ceased collecting new information at the end of March 2005. Nevertheless, the information currently remains available through the Web site (www.caddet.org). CADDET's objective was to enhance the exchange of information on new, cost-effective technologies that have been demonstrated in applications such as industry, buildings, transport, utilities, and agriculture. The information was not only collected and disseminated to a very wide audience; it was also analyzed to provide a better understanding of the benefits of the technologies.

Portland Energy Conservation, Inc.

Portland Energy Conservation, Inc. (PECI) considers itself passionate about energy efficiency. Their mission is to help everyone use energy more effectively. PECI assists clients in the promotion of energy-efficient practices and technologies that benefit both businesses and individual consumers. PECI helps clients deliver long-term energy savings by helping transform markets through education and incentive programs that build demand for more efficient products and services. PECI's Web-based library (www.peci.org) offers considerable information on commissioning, as well as operations and maintenance.

CAVEAT EMPTOR

It is important to remember that the Internet is a tool and not a source. Almost anyone has the capability to make information available through the Internet. Furthermore, not every article in a periodical or presentation at a conference undergoes rigorous peer review. Every source has an intent or purpose when making information available. It is important to understand the source to determine potential bias (or perspective) and the reliability of the information. Even if the intent is altruistic, the reader needs to be aware of the qualifications, or basis, of the source, as well as any potential bias.

While each of the organizations identified in this entry provide publications or other informational sources about new and emerging energy-efficient technologies, as with all things new, there are risks. Some risks are minimized by evaluating new technologies on a limited basis before they are deployed on a larger scale. Demonstrations and pilot projects allow users to "look before you leap" when applying new technologies.

Many of the organizations identified in this entry are doing their part to get information on new and emerging energy-efficient technologies into the hands of energy managers, design engineers, building owners, and others, and they are encouraging them to consider the new technologies so that they may save energy, reduce costs, reduce emissions, or achieve other objectives.

The reader should also understand that most of these organizations are not making guarantees and implying endorsements. For example, those who claim endorsements from federal agencies are misleading the public. Furthermore, publications provided by these organizations are not substitutes for sound engineering or due diligence on the part of the reader. These programs do strive to be accurate and responsible. Remember, their objectives are to help.

New and emerging technologies are also subject to change. It is important to note the date of the publication or other information source. Publications usually offer a snapshot of a technology at a given time. As time passes, technologies, costs, maintenance recommendations, and even manufacturers change. In many cases, this can be a good thing; manufacturers can make numerous improvements to the equipment as more is learned about the technology and its operation. However, there may be other changes. New manufacturers may develop a product line that may not have been in that business when the report was published. Other manufacturers, who were known at the time of publication, may relocate, merge, consolidate, drop the product line, or even go out of business. Readers must continue to do their homework.

Energy managers and facility staff need to be wary. *Caveat emptor*, let the buyer beware, definitely applies. Readers are encouraged to check the original sources and follow up with other users. Do not rely on third-hand sources (for example, a government report should be checked out from a government source and not from a second- or third-party distributor).

CONCLUSIONS

Energy management is a diverse and growing field. As a result, there are many more sources available to the energy manager beyond those identified in this article. The organizations identified in this article are simply the ones this author turns to first when seeking useful information about an emerging or unknown technology. Many organizations are involved in innovation, research, and development. Many other firms are involved in assessment, experimentation, validation, training, and other forms of deployment. The energy manager can benefit from each of these organizations' contributions.

Technologies are continuously evolving. Efficiencies are improving, controls are improving, and maintenance is being simplified. New and emerging energy-efficient technologies can be used to help the experienced energy manager achieve and surpass their goals. Trying something new may not be risk-free, but these programs are doing their part to assist experienced energy managers.

Disclaimer

The information contained in this article is based on the author's 25 meandering years in energy management. The information does not purport to be comprehensive or complete, but is provided in the hope that it may be of some use to the reader. Any source provided in the entry should not be interpreted as an endorsement, just as any source not provided in this entry should not be considered a negative endorsement. If you do not want to use the information contained in this entry in the spirit in which it is intended, then do not use it. The reader should also be aware that there is a difference between 25 years of experience and 1 year of experience 25 times over. The author is unsure where he fits in the spectrum.

ACKNOWLEDGMENTS

The Pacific Northwest National Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under contract DE-AC05-76RL01830.

Energy Efficiency: Low Cost Improvements

James Call
James Call Engineering, PLLC, Larchmont, New York, U.S.A.

Abstract
In most energy efficiency initiatives, one is blessed with a number of energy-saving projects, all competing for a company's limited corporate resources. The various projects are typically interrelated; one of them, if implemented, would impact the others. They have a wide range of implementation costs and related energy-saving impacts—that is, they have different payback periods. If the quickest payback projects are done first, their savings will be unavailable to "subsidize" long payback projects. Thus, the long payback projects will have to fend for themselves in their fight for capital budget allocations. The end result may free up capital for other company projects in completely different areas.

This is why low-cost/no-cost energy projects are so valuable: they not only save money in their own right, but also set up a level playing field for the ongoing prioritization of corporate resources generally. Fourteen low-cost/no-cost projects from actual field experience are described as examples of the kind of projects that can introduce big savings up front and, thus, change the business case for long payback projects subsequently considered.

BACKGROUND

Longer-Term Consequences of Implementing Low-Cost Options First

If low-cost, quick-payback solutions are bundled in with longer-payback projects, the quick-payback projects can inadvertently subsidize the longer-payback projects that overlap on some of the benefits.

Consider a case in which an $1800, 12-channel "smart" time clock (holidays, sun tracker, outside air temperature sensor, etc.) would reduce energy costs by 25% and have a 2-mo payback. Alternatively, an $80,000, full-featured Energy Management System (EMS), if implemented alone, would reduce energy costs by 30% and have a 5-year payback. The issue is that if the 12-channel smart time clock is installed first, it co-opts the "savings" from the EMS project, stretching the EMS payback to perhaps 20 years. This is because the EMS also has a smart time clock inside it, as one of its many features, and that single feature was mostly why the EMS seemed attractive in the first place.

It generally will be impossible to develop a fair and accurate business case for a longer-payback system if low-cost, quick-payback solutions are "reserved" to bundle in with them.

Put another way, mixing in low-cost, quick-payback approaches to sweeten the case for longer-payback projects is analogous to improving a $5 bottle of wine by mixing it with a $90 bottle—a strategy perhaps to be avoided ambitiously.

Corporate Payback Analyses Should Include All Company Opportunities

In asking energy projects to compete for corporate resources (i.e., in comparing payback periods), companies will generally want to compare all projects, not just other energy projects. A proposed energy savings project, for example, should undergo comparison with projects in other departments, such as Advertising and New Product Development.

Maintaining or Improving Comfort and Safety Must be Addressed in All Analyses

In all projects, of course—low cost, no cost, or otherwise—employee comfort and safety, and compliance with applicable codes, must be attended to. Such requirements obviously should have the final say in all project decisions and implementations.

EXAMPLES FROM THE FIELD

Safety First

Any implementation project must put safety first. The engineering, design, and implementation should be done by qualified professionals only and with the greatest attention to safety.

Following are summaries of a number of low-cost/no-cost opportunities that have been encountered in actual

Keywords: ASHRAE 12; ASHRAE 62; Comfort and safety; Cost accounting feedback; Open loop; Payback period; Prioritize.

energy cost reduction initiatives. These are the kinds of opportunities that frame the issues in comparing payback periods and prioritizing competing projects.

Replace Lugs on Time Clocks to Reestablish Night Setback

Surprisingly, many buildings with installed time clocks have their OFF lugs removed and, thus, let the HVAC systems run 24/7. They were removed for reasons that probably seemed compelling, or at least expedient, at the time.

In a 100,000-ft^2. office building, for example, employees working late at night or on weekends had complained some years previously that the HVAC was not on and that it was too cold, or too hot. This was because the building was in the scheduled setback mode during off hours. As an expedient solution to this issue, the Building Services Department simply removed the OFF lugs on the 7-day time clock. Because energy expense was added in with numerous other overhead expenses and then charged back to about 20 departments on a square-foot basis, the sudden increase in energy costs went unnoticed for a number of years.

To reclaim the lost savings from the abandoned night and weekend setback, a low-cost solution was implemented in the following steps:

1. Replace the OFF lugs on the master time clock to run the HVAC 6:00 a.m. to 7:00 p.m. 5 days a week.
2. Install latching relays across the existing time clock's low-voltage outputs for the 12 building zones of interest, and wire their latch trigger circuits to user-accessible pushbuttons.
3. Provide a labeled "red button" in an accessible place (by the copy machine) in each of the 12 zones, and let employees know that if they come in to work during off hours, they should simply push the button, and their zone will come on for up to 6 h. Later, if the zone shuts OFF, employees should push the button again to turn on the zone for 6 more hours.
4. Provide a reset to the latch coil circuit by putting a $100 time clock in series with the latch current that turns OFF 1 min every 6 h.
5. Provide high-temperature and low-temperature "night setback" thermostats, which would ensure that the space did not get extremely hot in summer or so cold as to freeze pipes or fan coils in winter.

This solution cost under $1000, was implemented in 1 month, and saved more than $30,000 per year, giving it a nominal payback period of a couple of weeks.

Fig. 1 is a photo of the relay logic as actually constructed, and Fig. 2 shows the pushbutton setup that triggers the temporary comfort cycle.

Fig. 1 Relay logic to cycle certain zones, temporarily, with timed-out latch release.

Tighten Schedules When Possible

Building systems may be set on an automatic schedule that, upon review, can be substantially tightened without affecting employee comfort. A good way to determine the optimum schedule is to make a manual count of cars in the parking lot—say, every 15 min around the beginning and end of the business day. A rough hand-drawn plot of arrivals per quarter-hour period will indicate when the space should be ready to satisfy, say, 98% of the people. The optimum "be ready" time likely will not occur at an even quarter-hour (e.g., 7:30 a.m.), and if the existing schedule is in fact set at such even times (as most are), there is probably an opportunity to reduce energy usage.

Data loggers are invaluable in determining the warming and cooling curves of a building. The curves generally have the characteristic shape of the classical capacitor charge and discharge (i.e., an exponentially decaying rise or fall toward a final value).

A longer lead time may be needed on Monday mornings, of course, or any time when the building levels have drifted greatly during the off hours. Given the usual 30–90 min that most spaces need to achieve the target temperature, conditions would still be fairly comfortable, plus or minus 15 or 20 min of the actual target time.

Update Schedules to Reflect Current Building Use

During a 1:00 a.m. visit to a commercial office space as part of an energy audit, it was noticed that a large wing of the building was still running the HVAC system, even though the rest of the building had gone into night setback, as was expected, from the time clock.

Upon investigation, it was determined that the time clock did indeed have the zone still ON until 2:00 a.m. each weekday night, while all the other zones shut OFF at 7:00 p.m. It turned out that the zone still running formerly

Fig. 2 User pushbutton to start temporary comfort period.

was used by a second shift in a data entry department that finished at 2:00 a.m. That was no longer the case, but the time clock had never been reset when the late shift was discontinued. It had been more than 4 years since the late shift had used the space.

Because the cooling tower and the entire chiller plant were interlocked to run when any zone called for cooling, resetting the time clock to reflect the current schedule saved an estimated $8000 per summer.

Shut Off Boiler in Summer by Installing a Dedicated Domestic Hot Water Heater

Domestic hot water for a company's 10 bathrooms was provided by a loop in the building's main boiler running through a heat exchanger. Thus, the main boiler was kept on all summer, at a cost of some $25,000 per year for gas.

The solution was to install a 60-gal dedicated hot water tank for domestic hot water and to shut off the main boiler during the summer. The dedicated tank was fitted with a mixing valve, expansion tank, and pump to address ASHRAE 12[1] requirements.

The improvement took 2 months to implement, cost some $4000, and had a payback period of less than 3 months.

Reduce Gross System Overcapacity by Shutting off Equipment as Appropriate

It is not unusual to find gross overcapacity in HVAC systems. The reasons behind this appear to include

- "Rounding up" in each serial design step when the building was originally built. That is, installed overcapacity may have resulted from the cumulative effect of what the building owner initially saw as the load, then the design engineer's safety factor, and finally installing 7.50-ton units when the nominal calculation showed 6.74 ton.
- Building use changes since the original design.
- Accumulation of ad hoc package systems additions, over the years, to meet special needs.

The following two examples illustrate low-cost/no-cost approaches that were used to reduce overcapacity:

a. *Retiring a Package Unit and Attaching the Served Ductwork to a Nearby Remaining Unit*: A company's office space had three package air conditioners, each with dual 5-ton compressors. Theoretical calculations, which were confirmed by actual tests using loggers, determined that the installed cooling capacity was more than 3 times the required amount for cooling comfort on the hottest day of the year. Moreover, one of the units had been scheduled for replacement due to its age and unreliability.

To eliminate the need for the unit's replacement and reduce electric demand at the same time, the following steps were implemented:

1. Confirmed by field measurements that there would be sufficient air volume from the other two good units if the old unit were retired.
2. Decommissioned the old unit and relocated its discharge ductwork over to one of the adjacent remaining good units.
3. Rebalanced the served space.

The result was a savings of more than $12,000 of averted costs to replace the old unit, as well as a 20% drop in electric demand.

Energy Eff–Serv

b. *Run Only One Compressor in Two-Compressor Package Units*: A 90,000-ft^2. office building had 30 rooftop package units, each controlled by a local thermostat in the related zone. Calculations, confirmed by loggers, indicated that the building as a whole had well over twice the cooling capacity needed even for the hottest day of the year. Twenty of the 30 rooftop units had 2 (hermetically sealed) compressors, typically 5 or 7.5 ton each. In their related zones, two-stage T-stats would bring on the first and then the second compressor as needed. On morning startup or on very hot days, however, the T-stats would bring the second compressor on, even though the general cooling overcapacity in the building would have eventually (in about 15 min) taken care of the entire load without the second compressor's being needed. That is, the two-stage T-stat was unduly "impatient."

The overcapacity was corrected as follows:

- To reduce the excess capacity, the second-stage low-voltage control wire was simply cut, and the open ends were taped off. The cut was made about 1 in. back from the screw terminal connector, leaving an "audit trail" for future service personnel in case anyone ever wanted to reinstate the redundant disconnected compressor. Indeed, the "extra" compressor then became a potential spare unit that could easily replace the other compressor should it ever fail.
- It can be appreciated that each modified roof top unit would be left running more air across both the condenser coil and the DX coil than was actually needed, but even so, the improvement in occupant comfort and electric demand reduction was dramatic. Fig. 3 shows the two-compressor unit with the cover removed.

Fig. 3 Two-compressor HVAC package unit where one compressor was not needed.

Resolve Systems Fighting Each Other

Days in the spring and fall present probably the most challenging building-comfort control issue. Building managers sometimes cope by running both heating and cooling systems at the same time, sometimes for weeks. This situation almost always presents significant energy saving opportunities, which may be hidden if the heating and cooling systems fight each other to a comfortable standoff.

Approaches to break the standoff include automating the summer–winter cutover. Relatively inexpensive boiler controls use inputs from outside air temperature and/or the space ambient temperature to decide when to go into so-called warm-weather shutdown. Setting the chiller's startup temperature a few degrees higher than the boiler's warm-weather shutdown point will create a useful dead band (i.e., a gap in temperature between shutting down the boiler and starting the chiller).

The dead-band concept leads to significant energy savings, because neither active heating nor active cooling is going on.

Relocate Thermostats to the Areas That They Serve

A company renovated its space by building out new offices but leaving the dropped ceiling unchanged. After the renovation, HVAC diffusers in the ceiling served some areas totally walled off from their controlling thermostats. As a result, certain spaces became grossly overcooled, with their ambient temperature dropping as low as 62°F (in the summer) because there was no way to close the feedback loop from the T-stat to the HVAC unit.

A project to relocate T-stats to their controlled spaces was completed for less than $500. The payback was estimated at about 2 months, although the real payback was improved employee comfort.

Reduce Lag/Lead Triggered by Thermostat Cases

To prevent tampering, vented steel boxes (which are commonly sold for this purpose) had been installed over thermostats in a company's office space. Even so, there were occupant complaints of being too hot and too cold.

By placing small data loggers inside and outside the metal boxes, and then comparing their readings on the same chart, it was discovered that the space ambient temperature was oscillating wildly around the set point. The following scenario was identified:

1. On summer-morning startup, the HVAC unit would cool the space to the comfort-level set point of 73°F in 20 min.
2. Because the metal box cover was initially warm and had considerable thermal mass, however, it took about 40 min for the space temperature signal to reach 73°F.

3. This introduced a 20-min lag in the feedback loop, thus allowing the HVAC to overshoot grossly. The space temperature would drop to 62°F by the time the metal cover and the enclosed thermostat were down to 73°F.
4. At this point, the HVAC would cycle off, but the process would begin again in the opposite direction as the room heated. The metal box kept the thermostat cool until the room was nearly 80°F.

This energy-saving and comfort-improvement opportunity was addressed simply by removing the metal boxes and using stop lugs (which were found already available inside the thermostat) to limit manual tampering to plus or minus 2°F. Then the T-stat, with its quick time constant thus restored, could control the room's ambient temperature accurately.

Use Small Dedicated AC Units to Cool Server Closets, Rather Than Run the Whole Chiller Plant

A company scheduled an HVAC operation in its 90,000-sq.-ft. building during normal business hours. The HVAC system included a 300-ton chilled-water plant supplying some 14 air handlers.

After the building was wired for local area network (LAN) access, two network server closets (small rooms, actually) were provided for LAN infrastructure equipment; these closets required air conditioning continuously. At that point, the company began to run the two air handlers serving the equipment areas on a 24/7 basis. This also meant, of course that the 300-ton chiller plant and associated pumps would be on continuously. Moreover, because only 2 of the 14 air handlers were running, the 300-ton chiller plant tended to short cycle, even after the compressor controls had unloaded as many cylinders as they could.

To address the energy saving opportunity of shutting off the chiller plant and its associated large pumps, a dedicated 2.5-ton AC unit was installed in each server room. These were "split mini" units (air handlers wall mounted and cooled by a DX coil).

Fig. 4 Dedicated AC air-handler DX unit in computer server room.

Total installed cost (the two units themselves, plus installation labor for both) was less than $12,000. Because the units removed the need to cool two entire building zones during weekends and off hours, however, the payback period was estimated at less than 6 months. Fig. 4 shows a typical wall-mounted air handler, the DX side, as installed.

Tighten Leaky Outside Air Dampers

Logger data from morning warmups taken in each of 7 zones (relating to the 7 air handlers in a company's building) showed that 5 of the zones reached comfortable levels in 40 min, whereas 2 of the zones took nearly twice as long. When the warmup curves were plotted on the same graph, distinctly different slopes were shown. It was appreciated that the original capacities of the air handlers might be different for each area, of course, but CO_2 monitoring also showed much lower levels of CO_2 concentrations in the slow-warming spaces even though occupancy density was about the same.

These findings suggested that the outside air dampers in the two long-warmup zones were not closing or were open way above the normal minimum for fresh air.

Subsequent inspection showed that in one of the suspect zones, the damper actuator linkage was slack, and in the other zone, the actuator shaft had broken off inside the air handler.

Repairs were made in less than 2 h, and the heating bill dropped by about 8%, giving the project a payback period of less than 1 week.

Reduce Fan Speeds by Adjusting Variable-Speed Pulleys When Appropriate

Reducing fan speeds (consistent with ASHRAE 62[2] and building comfort requirements) is a common energy saving opportunity. Although it can be done, when applicable, by retrofitting with variable-speed drives, a lower-cost approach is simply to adjust the variable-speed pulley that often already exists on the drive motor shaft.

Pulley adjustment produces a fixed reduction, as opposed to the wide range of variable speeds provided by new variable-speed drives, but the savings impact vs the difference in cost between the two approaches often suggests the low-cost pulley adjustment as at least a first step. Then the business case can be evaluated to see whether there are enough savings left to justify new drives.

Reset on Ambient Air Temperature When Appropriate

A company's HVAC VAV system was designed to provide a single fan discharge temperature of 60°F and

Fig. 5 Use of T-fitting to pick off fan discharge temperature signal to control fan coil valves.

then rely on the VAV box in each zone to control the space by releasing more or less of this fixed-temperature air (with a preset maximum and minimum amount). This is very near to running the system "open loop" except for the (considerable) action of the VAV boxes.

There were days and conditions during occupied periods, however, when no zone in the entire building needed 60°F air—when all zones became cold on a winter morning, for example. (This discussion assumes that the building had already undergone a warmup cycle where all VAV boxes and fan coil hot water valves were 100% open.)

An energy-saving and comfort-improvement solution is to control fan discharge air temperature based on ambient air temperature. Under this approach, there are two complementary feedback loops in play; the return air T-stat informs fan discharge air temperature, and the zone T-stats control the VAV boxes. The savings result from the fact that the VAV boxes will, on average, not need to try so hard to control the space, because they will have more appropriate air. Thus, they will be more closed (i.e., expelling less air and, thus, reducing fan horsepower). This assumes that fan volume is reduced by throttling or by lowering fan speed.

Fig. 5 shows how the pneumatic signal for Fan Discharge Temperature was picked off simply by tapping into the line to the Fan Discharge Temperature panel gauge line. The signal was routed to the existing Receiver-Controller.

Optimize the Strategy for Manual Light Switches

Short of installing occupancy sensors, companies have used a number of low-cost approaches that can save energy on lighting. They include

- Relocate light switches to the spaces they serve. Light switches sometimes are located far from the spaces they control—in some cases, on other floors. Understandably, this leads users to turn lights on, just to be sure, even when they will not be working near the lights. Consider relocating switches to obvious positions close to where users will enter and leave the affected space.
- Discourage users from turning on every light in the place when the first one arrives. When switches are arranged in banks of 4, 6, or even 8, there is a strong tendency of the first person who arrives each morning to turn all the switches on, even lighting a whole floor for an extra 1 or 2 h per day. By labeling the switches with the zones they cover (and/or relocating them as just described) and by suggesting to users that they turn on just what they need, important savings can be found.
- Leave a few selected fluorescent units on 24/7 as night lights. Understandably, users leaving a lighted space at night would not turn off lights if that left them in total darkness. An energy-saving solution is to provide lighting levels sufficient for a safe exit by identifying intermittently spaced fluorescent (or other approved energy-efficient) lights to be wired on 24/7. Although some energy will be used all the time, on balance, there can be savings from the larger majority of lights that can then be turned off. When adequate night lights are implemented, place friendly signage by key light switches reminding the last person out to shut off the lights.

Provide Actionable Cost-Accounting Feedback to Users

When the company's cost-accounting system inadvertently hides energy costs from users and managers, savings opportunities will invariably be missed.

A cost-accounting system with the following features can go a long way toward addressing this situation:

- Show both dollars and usage (gals, therms, kWh, kW, etc.) on the same report.
- Separate the impact of varying prices from the impact of varying usage.
- In a column adjacent to actual dollars and usage, display dollars and usage adjusted for weather, number of days in the billing period, and/or changes in the space served. The impact of weather can be estimated by setting up a regression model in which at least one of the independent variables is heating degree days or cooling degree days, thus allowing an apples-to-apples comparison over different periods.
- Track the overall building impact of energy-saving improvements by comparing results to a base year (e.g., the year before a formal energy initiative began).

Use a realistic but easy-to-understand measure, such as Btu per square foot.

CONCLUSION

This paper explored the consequences of implementing low-cost/no-cost energy-saving projects before considering longer-payback projects. A number of examples of such low-cost/no-cost projects and approaches were reviewed.

When a company lets energy projects compete for funds in terms of the whole company's needs, as opposed to considering only the impact on the energy or building services department, low-cost/no-cost approaches, done first, create a reordering of project priorities. Indeed, the success of low-cost approaches may even make subsequent investment in long-payback projects unwarranted.

Energy Efficiency: Strategic Facility Guidelines☆

Steve Doty
Colorado Springs Utilities, Colorado Springs, Colorado, U.S.A.

Abstract
The intent of this article is to offer a convenient list of strategic guidelines to help steer new building designs toward energy efficiency. It is hoped that the project owner, interested in achieving greater than average savings, will provide this list to the design team as part of their project intent instructions. To encourage its use and acceptance, emphasis is placed on keeping the list at a manageable size, with only proven solutions.

Through a top-down approach, using this document as a convenient tool, building owners can set the expectations of energy frugality, create positive changes in building practices, and reward themselves with operational savings.

INTRODUCTION

The old saying "an ounce of prevention is worth a pound of cure" is very applicable to creating energy efficient buildings. The economic realities of retrofitting existing buildings usually result in only the worst ones getting attention, with the average ones left to their life cycle. By contrast, evaluating improvements to designs that exist only on paper has a much smaller economic barrier to change, that being the differential cost from the standard designs. This simple fact makes it easier to create a new efficient building than forcing an older one to be more efficient.

A one-size-fits-all approach is not expected to work for every area of the country, nor for every business segment. Design practices, standard of care, and things that make practical sense will vary by region along with the climate differences and the business it serves. The content of this document was originally prepared for building owners in the Colorado Springs area, and will need local amending for use in other areas like Miami, Florida (all cooling, no heating), and Alaska (all heating, no cooling), and especially in areas with persistent high humidity. Still, many of the concepts presented will be applicable to many areas. One referenced text[1] provides recommendations by climate zone, acknowledging the regional differences. Local adjustments aligned with the eight climate zones are suggested, but beyond the scope of this text. As a starting point, basic allowances have been made to adapt climate-dependent criteria to other areas as follows:

- For most humidity-dependent heating ventilating and air conditioning (HVAC) operations, a distinction is made for climates that are either below 65°F or above 75°F wet bulb temperatures. Interpolation and judgment for points in between is required.
- Evaporative cooling constraints are unique and presented very conservatively, erring on the side of occupant comfort. The climate distinction presented is outdoor air consistently below 52°F wet bulb and below 42°F dew point. (This will no doubt be debated by some designers in semi-arid climates. However, experience has shown that at moisture levels much above these values it becomes increasingly hard to *guarantee* comfort all the time. Since the choice to use evaporative cooling is a large fork in the road for the customer, presenting conservative parameters is deliberate and are sure to work. If evaporative cooling is chosen in "fringe" climates, a supplemental conventional cooling system integrated into the first stage of evaporative cooling is suggested).
- Glazing U-value limits are relaxed in areas where HVAC heating is not used. Note that this suggests double pane windows anywhere HVAC heating is used.
- Glazing shading coefficients are relaxed in areas where HVAC cooling is not used, but are otherwise strict. Solar loads drive peak electrical demands if nothing else.

These climate-dependent items will no doubt be a work in progress, and so they are marked with an asterisk (*) with suggested criteria in *italics* for convenience in editing. I did my best!

To the owner who may use this: not all of the suggestions will apply to all buildings, but many of them will. Don't worry that a number of these won't make sense in your particular building—but do ask the design team to

explain which measures do not apply, and why. Doing so will reinforce your intentions to achieve operational savings by smart design decisions up front, and motivate the design team to make a good effort to accommodate.

THE FACILITY GUIDE SPECIFICATION AND THE TOP-DOWN APPROACH

The approach used for this article is to tabulate a list of suggested "Dos and Don'ts," suitable for use in a facility **guide specification**. A guide specification is a hand-out document given to a design team at the beginning of a project to provide general instructions and owner preferences. The owner handing out the guidelines has more of an effect on the end result than the same suggestions made from a lone team member, hence the term **top-down**. These instructions are then integrated into the other governing documents and codes that eventually form the design. Traditional guide specifications, used by national accounts, campuses, and large facilities, spell out preferred manufacturers, acceptable types of piping, valves, light fixtures, pavement, etc. The concept of energy efficient guidelines in the owner's guide specification is a natural and overdue extension of an existing document. Even if the owner does not have a guide specification to add this to, the listed items in this document can be used in stand-alone fashion to serve the same purpose and provide the same benefit to the owner.

More Top-Down Features

Beginning at the point of use is a common theme for all energy engineers. In the case of the office building, stipulating temperature values can have a pronounced effect on energy use. The indoor temperatures become design parameters that calculations and equipment sizing hinge upon. A design that requires 72°F summer indoor conditions will be larger and use more energy than one designed for 76°F, and yet with proper attire and humidity control, 76°F is a very reasonable temperature. A 72°F design can save energy by turning up the thermostat, but a 76°F design will additionally conserve first-cost dollars. Many designers are reluctant to push the comfort envelope for fear of reprisal against them, and that is where the top-down support concept comes in. With management support, and some education and encouragement, paradigms can slowly change.

Integrated Design

With more creative design solutions such as **integrated design**, more options are apparent to design teams now than in the past. This concept acknowledges cases where decisions in one trade (e.g., electrical or architectural) benefit another trade (e.g., mechanical). It may seem odd, but traditional design practices are compartmentalized by trade, and haven't always allowed the big-picture benefits to find their way to the owner. This is partly due to traditional fee structures where design fees are influenced by the cost of construction; the resistance to downsizing anything becomes obvious in this light. The integrated design process allows an extra expense in one trade to be considered if it produces a corresponding savings in another trade. To avoid redesign costs, this is best implemented with emphasis on group schematic designs (to air out the ideas early), as well as requiring good cost-estimating skills on the design team. A good architect is needed who can be receptive to new ideas, flexible, encourage the integration process, and also know enough to call a halt to the options at some point to maintain a reasonable schedule and finish the job without escalating design fees. By carefully selecting the design team members, constructive opportunities will come from this process which are usually well worth the effort. Examples of integrated design concepts follow, many of them revenue-neutral with sustained energy benefits for "free."

- The added cost of high performance suspended film windows can be offset in some climates by the elimination of perimeter fin-tube heating.
- Downsizing cooling systems in conjunction with reduced lighting power design.
- Downsizing cooling systems in conjunction with improved window shading coefficients, films, or exterior shading systems.
- Downsizing heating and cooling systems by using 1% or 2% ASHRAE design outdoor weather conditions[2] instead of 0.4%, allowing the temperature to drift up a few degrees for a few hours of the year.
- Downsizing a boiler or hot water unit by virtue of selecting higher efficiency equipment. Since output is the design driver, it is often possible to utilize the next smaller size unit, but at higher efficiency, to achieve the same result.
- Downsizing primary heating and cooling equipment in conjunction with upgrades in envelope elements like insulation or, especially, window shading.
- Downsizing primary heating and cooling equipment in conjunction with heat recovery systems.
- Downsizing fan and pump motors, and primary cooling equipment, by increasing duct and pipe sizes, filter areas, coil areas, etc. as the trade-off for using less transport energy. Note that the extra heat of transport energy elements, especially fans, often drives the equipment size up a notch.
- Downsizing overhead lighting and HVAC cooling via an owner commitment to a greater use of task lighting.

Table 1 Equivalent rate of return values for various simple payback

	ECM PROJECT LIFE			
	5YEAR	10 YEAR	15 YEAR	20 YEAR
SIMPLE PAYBACK	IRR	IRR	IRR	IRR
2	40.0%	49.0%	50.0%	50.0%

5		15.0%	**18.0%**	19.4%
6		10.6%	14.5%	**15.8%**
7		7.0%	11.5%	13.0%
8		4.3%	9.0%	11.0%
SPB typ 9		1.8%	7.1%	9.2%
10-yr max 10			5.5%	7.7%

Simple Payback vs. Internal Rate of Return
payback periods noted for various project lifespans that achieve greater than 15% rate of return

Derivation: Internal Rate of Return (IRR) is that interest rate where the present worth of the savings is equal to the initial investment.

$P = A * (P/A, i, n)$

$$P = A * \frac{(1+i)^n - 1}{i\,(1+i)^n}$$

so, for some value of i,

$$P/A \text{ (simple payback)} = \frac{(1+i)^n - 1}{i\,(1+i)^n}$$

In addition to downsizing, integrated design can be used as an investment tool, with utility use reduction as the return. If sufficient funding exists, the owner can allow upgrades with identifiable costs and annual savings to be proposed, with a stipulated payback period such as 2–5 yr, to capture the fruit that is just above the proverbial low-hanging level. For example, an upgrade with a 10 yr life and a 4 yr simple payback is an equivalent internal rate of return of 21%, which is an attractive return for investment dollars.

To the energy engineer: be *sure* of your calculations, and even derate them, before leading your owner out with borrowed money (Table 1).

Sustainability

The guideline includes instructions to the owner's staff as well as designers and contractors. This is because the construction of a well-performing building is not the end of the story. The energy and water use of the building will also depend upon user habits at the points of use, and interaction with the building occupants is a vital component for program success. While many endeavors begin a long slide in performance after inception, it is a further intent of this document to encourage **sustainability** of operations. To this end, the suggestions for thorough documentation, commissioning, maintenance, and occupant education are included, and require an ongoing commitment by the owner.

STRATEGIC FACILITY GUIDELINES FOR IMPROVED ENERGY EFFICIENCY IN NEW BUILDINGS

Purpose

- Implementation of the contents of this guideline will reduce facility energy use by 30–50% when compared with ASHRAE 90.1 Base Building and Minimum Local Energy Codes.
- Suggested use of this document is for the project owner interested in achieving the stated savings to provide to the design team as part of their project intent guidance.

General

- Design document submittals must include detailed narrative descriptions of system functionality, features, limitations, design assumptions, and parameters, for use by the owner. The narratives will be detailed enough to provide benefit to subsequent design teams, and will be written to be informative and useful to building operations personnel. The narrative will be provided as a deliverable with the schematic design, and will be updated with each subsequent design delivery including design development (DD) and construction documents (CD) phases. In its final form, this document shall be placed on the first sheet of the drawing set behind the title page, so that the information is retrievable years later when all that is available to facility operations are the drawings. Design assumptions include number of people, indoor and outdoor HVAC design conditions, foot-candles of illumination, hours of operation, provisions for future expansion (if any), roof snow load, rainfall rates, etc. that all define the capabilities of the building.
- All equipment schedules, including HVAC, plumbing, lighting, glazing, and insulation shall be put onto the drawings and shall not reside in the specification books, so that the information is retrievable years later when all that is available to facility operations are the drawings.
- Design thermal insulation values and glazing properties that affect energy use (U-value, shading coefficient, etc.) shall be clearly noted on the drawings.

- Project commissioning that includes identifying measurable energy savings goals and monitoring the design and construction activities with these as project intent items, with early detection and notification of any project changes that impact energy use or demand.
- Project final payment contingent upon:
  - Receipt of accepted accurate as-built drawings, with accuracy verified by owner and signed by the contractor.
  - Receipt of accurate and complete operations and maintenance (O/M) manuals, with certified factory performance data, repair parts data, and vendor contact information for all energy consuming equipment, including all HVAC and lighting equipment and controls.
  - Receipt of test and balance report that demonstrates design intent is met for air, water, and ventilation quantities, showing design quantities, final adjusted quantities, and percent variance. This would include all variable air volume (VAV) box minimum settings shown, including both heating and cooling balanced air quantities. This would also include any equipment performance testing that was specified for the project.
  - Verification by the owner that the test and balance settings include permanent markings and hence these settings can be preserved over time.
  - Receipt of on-site factory-authorized start-up testing for primary HVAC equipment including chillers and boilers, with efficiency and heat/cool performance figures and heat exchanger approach temperatures to serve as baseline. The submitted reports would include as a minimum heating/cooling output, gas/electric energy input, heat exchanger approach temperatures, water and air flows.
  - Receipt of control shop drawings with detailed descriptions of operation.
  - Acceptance testing of the automatic control system using the approved sequence of operation, and verification that the sequences are fully descriptive and accurate. Acceptance testing also includes review of the control system man-machine interface provisions to become familiar with each adjustable point in the system. Acceptance is by the owner, who will witness each sequence as part of the turnover training requirements.
- Building design must prevent negative pressure condition, unless safety considerations require it.
- Electric resistance space heating, air heating, and water heating are not allowed, unless there is no means to get natural gas to the site.
- Portable space heaters not allowed, unless required for an approved emergency measure.

Energy Use, Overall Performance

- Using ASHRAE 90.1 or local energy code as a baseline, demonstrate through computer modeling that the building energy use will be at least 30% less than this value.

Irrigation Water Use, Overall Performance

- Using standard Kentucky Bluegrass sod and average regional rainfall rates as a baseline, demonstrate that irrigation use for the property will be 50% or less of this value.

Test and Balance

- Balance using "proportional balancing," a technique that strives to reduce throttling losses, which permanently energy transport penalties (pump and fan power).
- Any motor over 5 hp found to be throttled with a resistance element (valve or damper) more than 25% must be altered by sheave change or impeller trim to eliminate lifelong energy waste from excessive throttling losses.
- All 3-phase motor loads, including HVAC equipment, must include voltage balance verification as part of the test and balance (TAB) work. Voltage imbalance of more than 1% indicates unbalanced electrical service in the building and unacceptable efficiency losses.
- Vertical return air shafts serving multiple floors require a balancing damper at each branch outlet to proportion the return air by floor.
- Air flow performance testing for all Air Conditioning and Refrigeration Institute (ARI) certified HVAC factory packaged unitary equipment greater than 5-tons capacity. Heating and cooling performance and efficiency verification is assumed via the ARI certification process.
- Heating efficiency, cooling efficiency, and air flow performance testing for all HVAC *split system* equipment greater than 5-tons capacity or 200,000 Btuh input heating capacity.
- Water flow performance testing for all ARI certified factory packaged water chillers. Cooling performance and efficiency verification is assumed via the ARI certification process.
- Water flow and combustion efficiency testing for all boiler equipment.
- Combustion efficiency testing for all boiler equipment unless factory startup is provided on site.
- Cooling tower thermal performance verification is assumed via the Cooling Tower Institute (CTI) certification process.

Electrical Service

- Provide separate utility metering for electric, gas, and water for the building, separate from other buildings.
- Electrical transformer conversion efficiency not less than 95% efficient at all loads from 25% to 100% capacity. Dry-type transformers National Electrical Manufacturers Association (NEMA) TP-1 compliant.
- Locate transformers in perimeter areas that do not require air conditioning for cooling.
- Power factor (PF) correction on large motor loads, for overall building PF of 90% or better. Large mechanical equipment can be provided with the correction equipment. If motor loads are segregated, this can be done at the switchgear.
- Arrange switchgear and distribution to allow metering of the following electrical loads (requires segregating loads):
  — Lighting.
  — Motors and Mechanical.
  — Plug Loads and Other.

Envelope

- Orient buildings long dimensions E–W where possible to reduce E–W exposure and associated solar load.
- Provide building entrance vestibule large enough to close one door before the next one opens (air lock).
- Where thermal breaks are used, the thermal break material must have thermal conductivity properties an order of magnitude better than the higher conductivity material it touches, and must be at least 1/2 in. thick.
- *Minimum wall insulation 25% *beyond ASHRAE 90.1 values, but not less than R-19*. Insulation is generally not expensive during new construction. Incorporate exterior insulation system (outboard of the studs) for at least one-half of the total R-value, to avoid thermal short circuits of standard metal stud walls, which derate simple batt insulation system by approximately 50%, e.g., a standard stud wall with R-19 batts between the studs yields an overall R-9.5.
- *Minimum roof insulation R-value 25% *beyond ASHRAE 90.1 values, but not less than R-30*. Insulation is generally not expensive during new construction. Select insulation that will retain its thermal properties if wet, e.g., closed cell material.
- Glazing meeting the following requirements:
  — Thermal breaks required.
  — *U-factor of 0.35 or less *where HVAC heating is provided*.
  — *Low-E coatings on east- and west-facing glass *where HVAC cooling is provided*.
  — *Max shading coefficient of 0.2 *where HVAC cooling is provided*. Note: any combination of tinting, coating, awnings, or other exterior shading can be used to achieve this. This is to say that no more than 20% of the heat energy from the sunlit glazing is to get into the building.
  — Glazing not more than 25% of gross wall area.
- Skylight/Clerestory elements must meet the following requirements:
  — Thermal breaks required.
  — Triple pane (layer) construction with sealed air space(s).
  — Overall U-value of 0.25 or less.
  — *Skylight shading coefficient must be 0.2 or less *where HVAC cooling is provided*.
  — *Low-E coating *where HVAC cooling is provided*.
- Skylight/Clerestory area not to exceed 5% of roof area.
- Return plenums and shafts designed with an air barrier for leakage not exceeding 0.25 CFM/ft^2 of building envelope surface area at 50 Pa (Energy Efficient Building Association (EBBA) criteria). Shaft construction requires field testing and verification.
- Building envelope devoid of thermal short circuits. Provide thermal break at all structural members between outside and inside surfaces.
- Building leakage testing required (new buildings), with no more than 0.25 CFM/ft^2 of building envelope surface area at 50 Pa (EBBA criteria).
- Utilize lower ceilings to reduce necessary light input power for equivalent light levels at the work surface.
- Utilize reflective (light) color interior colors for ceilings, walls, furniture, and floors, to allow reduced lighting power for comparable illumination. It can take up to 40% more light to illuminate a dark room than a light room with a direct lighting system.
- Good reflectance parameters to use when picking interior surfaces and colors follow. If these values are used and the lighting designer is informed of it, the integrated design process will allow reduced lighting power to achieve the desired light levels.
  — Min 80% reflective ceiling.
  — Min 50% reflective walls.
  — Min 25% reflective floor and furniture.
- Provide operable blinds for vision glass.

Lighting

- Follow ASHRAE 90.1 or local energy code requirements for lighting power budget guidelines, and verify that designs are lower than these limits while meeting current applicable Illuminating Engineers Society of North America (IESNA) lighting illumination requirements.
- Utilize task lighting and less on overhead lighting for desk work.
- Provide separate circuits for perimeter lights within 10 ft of the wall, to allow manual or automatic light harvesting.

- Use 1-2-3 switching for large open interior area spaces.
- Use ballast that will tolerate removing at least one bulb with no detriment.
- Where occupancy sensors are used, provide "switching ballast" that will tolerate large numbers of on–off cycles without bulb or ballast life span detriment.
- Use electronic ballast instead of magnetic ballast.
- Use ballast factor in the lighting design to improve lighting system efficiency. Because the ballast mostly determines how many watts are used, ballast choice is critical to achieving best energy efficiency.
- Coordinating light output with "ballast factor" is an excellent tool for providing optimum light levels and energy use.
- Use high power factor ballast, with minimum PF of 95% at all loads.
- Occupancy sensors in conference rooms, warehouses, and multifunction rooms. Also in locker rooms and restrooms, but with some continuous manual switched lighting in these areas.
- Photo-cell controlled lights in the vicinity of skylights.
- Do not use U-tube fluorescent lights, due to high replacement bulb costs.
- Do not use incandescent lights.
- Outdoor lighting on photocell or time switch.

Motors and Drives

- All motors meet or exceed EPACT-1992 efficiency standards.
- Variable frequency drive (VFD) on all HVAC motors larger than 10 hp that have variable load.
- Motor nameplate horsepower (hp) not more than 20% higher than actual brake horsepower served (i.e., do not grossly oversize motors).

HVAC

- Provide HVAC calculations and demonstrate equipment is not oversized. Equipment selection should not be more than 10% greater capacity than calculated values indicate.
- HVAC calculations will include both maximum and minimum heat/cool loads and equipment shall be designed to accommodate these load swings, maintaining heat/cool efficiency equal to or better than full load efficiency at reduced loads down to 25% of maximum load, e.g., equipment capacity will track load swings and energy efficiency will be maintained at all loads.
- Provide necessary outside air (OA), but no more than this. Excess ventilation represents a large and controllable energy use. Reduce exhaust to minimum levels and utilize variable exhaust when possible instead of continuous exhaust. Reduce "pressurization" air commensurate with building leakage characteristics. If the building is tested to low leakage as indicated herein, there should be little need for this extra air, or the heat/cool energy it requires. Design controls to dynamically vary outside air with occupancy.
- VAV box primary heating cubic feet per minute (CFM) shall be not higher than the cooling minimum CFM. This is to say the VAV box primary damper will *not* open up during heating mode.
- Zoning:
  - Design HVAC zoning to require heating *or* cooling, not both. This will improve comfort and also reduce the inherent need for simultaneous heating and cooling.
  - Do not zone any interior areas together with any exterior areas.
  - Do not zone more than three private offices together.
  - Do not zone more than one exposure (N, S, E, and W) together.
- Design and control settings for ASHRAE Standard 55 comfort envelope, which indicates 90% occupant comfort. Appropriate temperatures will vary depending on humidity levels. For example, in Colorado Springs (dry) the following space temperatures are appropriate:
  - 71°F heating.
  - 76°F cooling.
  - Facilities may institute a range 68–72°F heating and 74–78°F cooling, provided that a 5° dead band is kept between the heating and cooling settings.
- Do not heat warehouses above 60°F.
- Do not cool data centers below 72°F.
- Do not use electric resistance heat.
- Do not use perimeter fin-tube hydronic heating.
- **In cooler climates* where HVAC economizers are used, designs should normally favor air-economizers over water-economizers since the efficiency kW/ton is better for the air system. The water economizer "free cooling" includes the pumping and cooling tower fan horsepower, as well as the air handler fan. If the air handler fan power is considered required regardless of cooling source, the air-side economizer is truly "free" cooling.
- **In very dry climates, with outdoor air wet bulb temperatures consistently less than 52°F and dew point consistently less than 42°F*, evaporative cooling (direct, indirect, or direct-indirect) should be used in lieu of mechanical refrigeration cooling, as long as indoor humidity of 40% rH or less can be maintained. To the water consumption issue, it is this author's opinion that water is a renewable resource and does not disappear from the planet like fossil fuels do, and hence this technology should be used without environmental resources concern.
- Packaged HVAC cooling equipment not less than SEER-13 or EER-12, as applicable.

- *Air-side economizers for all rooftop equipment, regardless of size, *for climates with design wet bulb temperatures below 65°F.*
- Avoid duct liner and fiber-board ducts due to higher air friction and energy transport penalties.
- Insulate all outdoor ductwork to R-15 minimum.
- Use angled filters in lieu of flat filters, to reduce air friction loss.
- Reduce coil and filter velocities to a maximum of 400 fpm to lower permanent air system losses and fan power.
- Avoid series-fan-powered VAV boxes.
- For fan-powered VAV boxes, use energy conservation measure (ECM) motors to achieve minimum 80% efficiency. Although the motors are not large, when there are many of them this efficiency benefit is significant.
- Heat recovery for any 100% outside air intake point that is greater than 5000 CFM when the air is heated or cooled.
- Air filter requirements:
  - Terminal units (fan coils, fan powered boxes, unit vents): 20% (1-in. pleated). Note: this may require an oversize fan on small terminal equipment, and not all manufacturers can accommodate.
  - Air handlers with 25% or less OA: 30%—MERV-7
  - Air handlers with 25–50% OA: 45%—MERV-9
  - Air handlers with more than 50% OA: 85%—MERV-13
  - Provide manometers across filter banks for all air handlers over 20 tons capacity. Equip manometers with means to mark the "new-clean" filter condition, and change-out points.
- *Air-cooled condensing units over 25 tons, provide evaporative precooling, *for climates with design wet bulb temperatures below 65°F.*
- Make-up meter for all hydronic systems to log system leaks and maintain glycol mix.
- Separate systems for 24-7 loads to prevent running the whole building to serve a small load.
- *Direct evaporative post cooling for all chilled water systems, *for climates with design wet bulb temperatures below 65°F.*
- Require duct leakage testing for all ducts 2 in. w.c. design pressure class or greater.
- For process exhaust and fume hoods, design for variable exhaust and make-up.
- Utilize general exhaust air as make-up for toilet exhaust and other exhaust where possible.
- Dedicated outside air system (DOAS) for large office facilities (over 50,000 SF) with VAV systems, allowing ZERO minimum settings for all VAV boxes. This will eliminate the VAV reheat penalty, and the internal zone over-cooling effect from VAV minimums which often requires running the boilers throughout the year for comfort control.
- Separate interior and exterior VAV zoning for open-plan rooms to utilize zero-minimums in the interior spaces.
- Do not use grooved pipe fittings in hydronic heating or cooling piping systems to prevent operating central heating and cooling equipment year-round on account of these fittings.
- Verify that all manufacturer's recommended clearances are observed for air cooled equipment.
- Humidification:
  - Do not humidify any general occupancy buildings such as offices, warehouses, or service centers.
  - In data centers *only*, humidification should not exceed 30–35% rH.
  - Where humidification is used, humidifiers should be ultrasonic, mister, or pad type, and should not be electric resistance or infrared type.
  - Do not locate humidifiers upstream of cooling coils, to avoid simultaneous humidification—dehumidification.
  - Where humidification is used, provide for elevated apparatus dew point of cooling coils or other means to prevent simultaneous humidification—dehumidification.
- Dehumidification:
  - Do not dehumidify below 45% rH.
- Provide performance and efficiency testing of package heating and cooling equipment over 7000 CFM or 20 tons or 500,000 Btu input heating units with factory authorized equipment representatives. Test figures to include on-site gross heat/cool output, fuel and electrical input, and efficiency, compared to advertised values.

Energy Transport Systems—Energy Budget

- For HVAC air systems, the maximum energy transport budget will be:
  - No less than 10 Btu cooling and heating delivered to the space per Btu of fan energy spent at design conditions.

    This will generally steer the design toward generous sizing of sheet metal ducts, air handler cabinetry, coils and filters, higher efficiency fans (0.7 or better), and higher system differential temperatures to reduce air flow rates, but it will result in greatly reduced lifetime energy use since it lowers the bar of system pressure.
  - Fan hp limitation from:

    Cooling fan hp max input

$$= \frac{\text{Cooling Btu gross output}}{(10 \times 3413 \times \text{motor eff})}.$$

Energy Eff–Serv

— Air hp limitation from:

$$\text{Cooling fan hp max budget} \times \text{fan eff}.$$

— TSP limitation from:

$$\text{TSP} = (\text{air hp} \times \text{fan eff} \times 6360)/\text{CFM}.$$

For example, a 100-ton HVAC air system using 80% e motor, 70% e fan, and 350 CFM per ton would be limited to 44 hp motor load and 3.9 in. w.c. TSP. NOTE: for systems with both supply and return fans, the transport energy considers both combined as the "fan."

- For HVAC water systems, the maximum energy transport budget will be:
  — No less than 50 Btu cooling and heating delivered to the space per Btu of pump energy spent, at design conditions.
  This will generally steer the design toward generous sizing of piping, strainers, coils, and heat exchangers, higher efficiency pumps (0.75 or better) and higher system differential temperatures to reduce water flow rates, but will result in reduced lifetime energy use since it lowers the bar of system pressure.
  — *Pump hp limitation from*:

$$\text{Cooling pump hp max input} = \frac{\text{Cooling Btu gross output}}{(50 \times 3413 \times \text{motor eff})}.$$

— *Water hp budget from*:

$$\text{Pump max hp} \times \text{pump eff}$$

— *HEAD limitation from*:

$$\text{HEAD} = (\text{water hp} \times \text{pump eff} \times 3960)/\text{GPM}.$$

Hydronic Circulating Systems

- Heating: minimum 40° dT design, to reduce circulating flow rates and pump hp.
- Cooling: minimum 16° dT design, to reduce circulating flow rates and pump hp.

Boilers and Furnaces

- No atmospheric burners.
- No standing pilots.
- Design hydronic system coils to return water to the boiler at or below 140°F water with a minimum of 40°F temperature drop. This will reduce circulating pump energy and improve boiler efficiencies.
- Minimum efficiency of 85% at all loads down to 25% load.
- For heating load turn-down greater than 4:1, provide modular boilers or a jockey boiler.
- For multiple boilers sharing multiple pumps, provide motorized valves to cause water flow to occur *only* through the operating boiler.
- Provide stack dampers interlocked to burner fuel valve operation.

Chillers

- *Water-cooled centrifugal efficiency 0.5 kW/ton or less with 70°F condenser water and 45°F chilled water *for climates with design wet bulb 65°F and lower. 0.58 kW/ton or less with 85°F condenser water and 45°F chilled water in climates where design wet bulb temperatures are above 75°F.*
- *Water-cooled centrifugal units able to accept 55°F condenser water at 3 gpm per ton, all loads. *Beneficial in dry climates with design wet bulb temperatures less than 65°F and typical wet bulb temperatures less than 50°F.*
- *Water-cooled positive displacement units 0.7 kW/ton or less with 70°F entering condenser and 45°F chilled water *for climates with design wet bulb 65°F and lower 0.81 kW/ton or less with 85°F condenser water and 45°F chilled water in climates where design wet bulb temperatures are above 75°F.*
- Do not provide chilled water temperatures less than 45°F. Select cooling coils to provide necessary cooling with 45°F chilled water or higher.
- Air-cooled chiller efficiency 1.0 kW/ton or less with 95°F entering air.
- *Air-cooled chillers over 25 tons, provide evaporative precooling *where design wet bulb temperatures are less than 65°F.*

Cooling Towers

- Selected for 7°F approach at design wet bulb and 0.05 kW/ton or less fan input power. This will steer the design toward a larger free-breathing cooling tower box with a small fan, minimizing parasitic losses from the cooling tower fan. Cooling tower fan kW/ton should not be more than one-tenth of the chiller it serves.
- *Set condenser water temperature set point not higher than 70°F *for climates with design wet bulb 65°F and lower. For climates with higher wet bulb temperatures,*

design to 7°F above design wet bulb with reset controls to lower the setting whenever conditions permit.
- Water treatment control for minimum seven cycles of concentration to conserve water.
- Specify cooling tower thermal performance to be certified in accordance with CTI STD-201.

Air-Cooled Equipment and Cooling Towers in Enclosures

- Locate to prevent air short-circuiting and associated loss of thermal performance. Rule of thumb is the height of the vertical finned surface projected horizontally. The fan discharge must be at or above the top of the enclosure, the distance to the enclosure walls should be as indicated above, and there should be amply sized inlet air openings in the enclosure walls as low as possible.

Ground Source Heat Pumps

- Coefficient of performance (COP) 4.0 or higher at 40°F entering water.
- EER 17 or higher at 80°F entering water.
- No electric resistance heating.

Controls

- Design OUT all simultaneous heating and cooling through the use of proper zoning, interlocks, and dead bands. This includes all constant volume systems and terminal unit systems. VAV systems inherently have an overlap which should be minimized by water and air reset in heating season, prudent use of minimum VAV box settings, and consideration of systems that separate the outside air from the supply air (SA).
- Programmed start–stop for lighting and HVAC systems with option for temporary user overrides. Use these controls to prevent unnecessary operating hours.
- Lock out air flows for conference rooms and intermittent occupancy rooms by interlocking VAV box to close with occupancy sensors.
- Lock out chiller operation below 50°F, except for data centers or humidity-sensitive areas that cannot use outside air for cooling.
- Lock out boiler operation above 60°F, unless space temperatures cannot be maintained within the specified ranges any other way.
- *All cooling by air economizer below 55°F *for climates with design wet bulb 75°F and lower*.
- Night setback for heating. Suggested temperature for unoccupied time is 60°F.
- No night set-up for cooling—no cooling operation in unoccupied times for general occupancy buildings. If building temperature rise during unoccupied times can cause detriment, then limit off-hours cooling operation to 85°F indoor temperature.
- Reset boiler hot water temperature settings in mild weather.
- *Reset chilled water temperature settings in mild weather, *provided that outdoor air dew point is below indoor dew point levels*. Refrigeration savings generally exceeds increases in pump power.
- Provide appropriate interlock for all exhaust fans to prevent infiltration of outside air from uncontrolled exhaust fans that operate in unoccupied times.
- All analog instruments—temperature, pressure, etc. other than on–off devices—must be calibrated initially (or verified for non-adjustable devices). Merely accepting out-of-the-box performance without verification is not acceptable.
- Two-year guarantee on calibration, with 18-month re-calibration of all analog inputs.
- Air handler control valves with a residual positive seating mechanism for positive closure. Use of travel stops alone for this is not acceptable.
- For terminal units and heating/cooling hydronic water flow rates less than 10 gpm, use characterized ball valves for control valves instead of globe valves or flapper valves, for their inherent improved long-term close-off performance. This will reduce energy use from simultaneous heating and cooling.
- Valve and damper actuator close-off rating at least 150% of max system pressure at that point, but not less than 50 psid (water) and 4 in. w.c. (air).
- Dampers at system air intake and exhaust with leakage rating not more than 10 CFM/ft^2 at 4 in. water column gage when tested in accordance with Air Movement and Control Association (AMCA) Standard 300.
- Water coil control valve wide open pressure drop sizing not to exceed the full flow coil water-side pressure drop.
- Provide main electrical energy and demand metering, and main gas metering. Establish baseline and then trend; log kBtu/SF, kWh/SF-yr, and kW perpetually and generate alarm if energy use exceeds baseline.
- Implement demand-limiting or load leveling strategies to improve load factor and reduce demand charges. Stagger-start any large loads, e.g., morning warm-up or cool-down events. Use VFDs to limit fan, pump, and chiller loads to 90% during peak hours, etc.
- Independent heating and cooling set points for space control.
- Space temperature user adjustment locked out or, if provided, limited to ±2°F.

- 5°F dead band between space heating and cooling set points to prevent inadvertent overlap at zone heat/cool equipment, and from adjacent zones.
- 5°F dead band between air handler heating and cooling (or economizer) set points, e.g., preheat coil cannot share a single, sequenced, set point with the economizer or cooling control.
- Provide separate lighting and HVAC time schedules.
- For chillers (condenser) and hot water boilers, use temperature sensors to log heat exchanger approach values, to prompt predictive maintenance for cleaning fouled heat exchange surfaces. New-equipment approach will be the baseline value, and approach temperature increases of 50% will prompt servicing.
- Interlock heating and cooling equipment in warehouses serving doorway areas to shut off when roll-up doors are open to reduce waste.
- Optimization routines:
  - — Automatically adjust ventilation rates for actual people count.
  - — Optimal start to delay equipment operation as long as possible.
  - — Demand limiting control point that will limit all VFD-driven air handler fans components to a maximum of 90% max output in summer. This will cause system temperatures to drift up slightly during extreme weather, but will reduce electrical demand for this equipment (and the cooling equipment it serves) compared to full output operation, during times when utility demand is highest. Do not oversize equipment capacity to compensate for this requirement.
  - — Optimal static pressure setting based on VAV box demand, not a fixed set point. This is a polling routine.
  - — **For areas with design wet bulb temperatures below 65°F only*, optimal SA reset that will reset the SA temperature set point upward from 55°F to 62°F for VAV systems during heating season, to reduce reheat energy. This can either be from two methods.
    - * *Method 1*. Basic Optimization. When the main air handler fan is below 40% of capacity and OA temperature is below 40°F.
    - * *Method 2*. Fully Optimized. Polling VAV boxes (at least 80% of the boxes served are at minimum air flows).
  - — Do not reset SA temperature from return air. Do not reset SA temperature during cooling season.
  - — Reset condenser water temperature downward when outdoor conditions permit, using the lowest allowable condenser water the chiller can accept.

Plumbing

- Max shower flow 1.5 gpm.
- Max bathtub volume 35 gal.
- Max urinal water flow 0.5 gpf, or waterless.
- Max lavatory water flow 0.5 gpf.
- Metering (self closing) or infrared lavatory faucets.
- Avoid single lever faucets since these encourage complacency for the use of hot water.
- All domestic hot water piping insulated.
- Heat trap in domestic hot water main outlet piping.
- If a circulating system is used, provide aquastat or timer to prevent continuous operation.
- Max domestic hot water temperature for hand washing 125°F.
- Gas water heaters in lieu of electric where natural gas is available.
- Domestic water heater equipment separate from the building boiler and heating system to prevent year-round operation of central heating equipment.
- Water fountains instead of chilled water coolers.
- Operate the building at reduced pressure (such as 50 psig) instead of 70 psig, to reduce overall usage. Verify that design maintains at least 10 psig over the required minimum pressure at all flush valves.

Management and Maintenance Activities to Sustain Efficiency

- Management support
  - — Create buy-in from the building occupants. Distribute information to building occupants to raise awareness of energy consumption, especially communicating that the user's habits are an essential ingredient to overall success, and are useful and appreciated. This would be in the form of occasional friendly and encouraging reminders of how user participation is helping, fun facts, etc. along with estimated benefits from behavior changes. Provide measured results whenever available.
  - — Enforce temperature setting limitations, including the explanation of why this is helpful and also why it is reasonable. Encourage seasonal dress habits to promote comfort and conservation together.
  - — Prohibit space heaters.
  - — For offices, utilize LCD monitors and the software-driven "monitor power-off" feature, since the monitor represents two-thirds of the whole personal computer (PC) station energy use.
  - — Track monthly energy and water use and maintain annual graphing lines, comparing current and prior years. Establish new benchmark curves after major renovations, alterations, or energy conservation projects. Compare annual use with benchmark and

verify that building energy and water usage per SF is not increasing. Report results to the building occupants as an annual energy use report for their feedback.
— Escrow (save) approximately 5% of the replacement cost per year for the energy consuming equipment in the facility that has a normal life cycle, such as HVAC systems, lighting systems, and control systems. This will allow 20-year replacement work without "surprises" to sustain efficient building operations.
— For leased office space, show the tenants their utility costs to increase awareness and encourage conservation by the users. The typical industry arrangement is to build in utilities into the lease price, so the tenants do not see a separate utility bill. Although the customers are paying for the utilities, having those costs clearly shown will reduce the complacency in utility use.

- Chillers:
  — Owner provides annual equipment "tune up," including cooling efficiency testing and heat exchanger approach measurements.
  — Owner adjusts temperature settings or cleans heat exchangers, or adjusts water flows whenever cooling efficiency tests are less than 90% of new-equipment values. For example, if the new equipment benchmark is 0.5 kW/ton, then a measurement of 0.5/0.905 = 0.55 kW/ton would trigger corrective action.
- Boilers:
  — Owner provides annual equipment "tune up," including combustion efficiency testing and heat exchanger approach measurements.
  — Owner adjusts temperature settings, cleans heat exchangers, or adjusts air-fuel mixture whenever combustion efficiency tests are less than 95% of new-equipment values. For example, if new equipment benchmark is 80%, then a measurement of $0.8 \times 0.95 = 0.76$ would trigger corrective action.
- HVAC air coils:
  — Owner changes filters at least quarterly, and verifies there are no air path short circuits allowing air to bypass the filters.
  — Owner cleans HVAC coils whenever there is any sign of visible accumulation or if air pressure drop is found to be excessive.
- HVAC air-cooled condensers:
  — Owner provides location free from debris, leaves, grass, etc. and adequate spacing for free "breathing" and no recirculation.
  — Owner cleans heat exchange surfaces annually.
- Controls:
  — Owner re-evaluates system occupancy several times each year, to reduce unnecessary HVAC and lighting operating hours.
  — Owner re-evaluates control set points each year including space temperature settings, duct pressure settings, SA temperature settings, reset schedules, and heating and cooling equipment lock-out points.
  — Owner re-calibrates control instruments each two years other than on–off devices.
  — Owner cycles all motorized valves and dampers from open to closed annually, and verifies tight closure.
  — Owner cycles all VAV box dampers from open to closed annually and verifies that the control system is responsive, since these often have a short life and can fail without the user knowing it.

CONCLUSIONS

The listed items in this document are intended to supplement traditional facility guide specifications, as a tool to help steer new building designs toward sustained low energy use.

It is easier to design efficiency into a new building than to retrofit an existing one, for practical and monetary reasons. While we continue to search for ways to upgrade existing buildings, we should influence the new buildings as much as possible for the long term benefits. Engineers and architects alone may understand the benefits and opportunities available, but may not be effective at altering the default course of events for new building designs. The most effective way to assure energy savings as a built-in feature is through a top-down approach where owner support conveys efficiency as a design team priority. The energy-efficient design commitment is made more effective through the use of integrated design, and commissioning can be an effective tool to be certain the design intentions are realized through construction. The sustained energy efficiency goal requires an ongoing commitment from the owner, maintenance staff, and building occupants, and includes training, appreciation, and feedback.

Abstract
Advances in new equipment, new processes, and new technology are the driving forces in improvements in energy management, energy efficiency, and energy-cost control. Of all the recent developments affecting energy management, the most powerful technology to come into use in the past several years has been information technology (IT). The combination of cheap, high-performance microcomputers and emerging high-capacity communication lines, networks, and the Internet has produced explosive growth in IT and its application throughout our economy. Energy Information Systems (EIS) have been no exception. Information technology and Internet-based systems are the wave of the future. This entry will introduce basic principles, structures, and definitions, and will also show examples for typical EISs.

ENERGY INFORMATION SYSTEMS

The philosophy "If you can measure it, you can manage it" is critical to a sustainable energy management program. Continuous feedback on utility performance is the backbone of an Energy Information Systems (EIS).[1] A basic definition of an EIS is equipment and computer programs that allow users to measure, monitor, and quantify the energy usage of their facilities and to help identify energy conservation opportunities.

Everyone has witnessed the growth and development of the Internet—the largest computer communications network in the world. Using a Web browser, one can access data around the world with a click of a mouse. An EIS should take full advantage of these new tools.

EIS PROCESS

There are two main parts to an EIS: (1) data collection and (2) Web publishing. Fig. 1 shows these two processes in a flow-chart format.

Data Collection

The first task in establishing an EIS is to determine the sources of the energy data. Utility meters monitored by an energy management system or other dedicated utility-monitoring systems are a good source. The metering equipment collects the raw utility data for electric, chilled and hot water, domestic water, natural gas, and compressed air. The utility meters communicate to local data storage devices by preprocessed pulse outputs; by 0–10 V or 4–20 mA analog connections; or by digital, network-based protocols.

Data gathered from all the local data storage devices at a predefined interval (usually on a daily basis) are stored on a server in a relational database (the data warehouse). Examples of relational databases are FoxPro, SQL, and Oracle. A variety of methods are used to retrieve these data:

Modem connection. A modem connection uploads the data from the local data storage device to the energy data server. Typically, the upload takes place on a daily basis, but it may occur more frequently if needed.

LAN or WAN network connection. A local area network (LAN) or a wide area network (WAN) connection established between computers transfers energy data files to the energy data server.

FTP network connection. File transfer protocol (FTP) is an Internet protocol used for transferring files from one computer to another. It moves the energy data files from the local data storage devices to the energy data server.

When the energy data have been transferred to the energy data server, an update program reads all the various data files and reformats them in a format that is used by the Web publishing program.

Web Publishing

To publish the energy data on an Intranet or on the Internet, client/server programming is used. The energy

Keywords: Energy information system; Internet; Meters; Utility data; Web publishing.

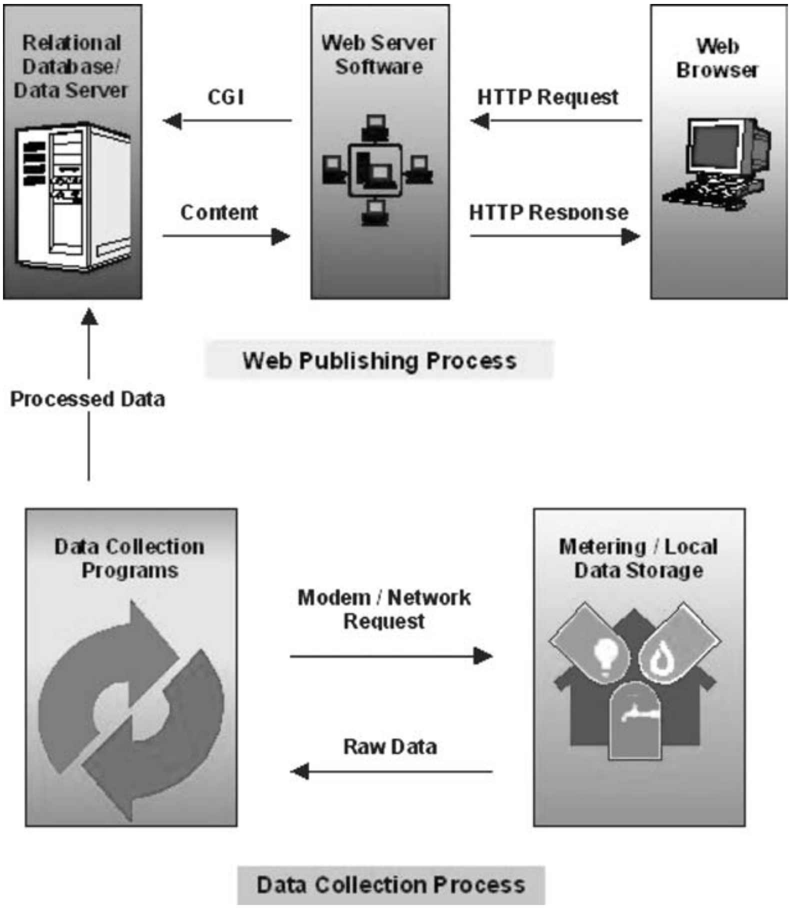

Fig. 1 EIS schematic.

data are stored on a central computer—the server—and wait passively until a user makes a request for information using a Web browser—the client. A Web-publishing program retrieves the information from a relational database and sends it to the Web server, which then sends it to the client Web browser that requested the information.

Many software choices are available for the Web-publishing process. One choice uses a server-side Common Gateway Interface (CGI) program to coordinate the activity between the Web server and the Web-publishing program. CGI is a method used to run conventional programs through a Web browser.The Web-publishing client/server process for an EIS uses the steps below (see Fig. 1):

1. A user requests energy information by using a Web browser (client) to send an hypertext transfer protocol (HTTP) request to the Web server.
2. The Web server activates the CGI interface program, which then starts the Web-publishing program.
3. The Web-publishing program retrieves the information from the relational database, formats the data in hypertext markup language (HTML), and returns it to the CGI interface program.
4. The CGI interface program sends the data as HTML browser content to the Web server, which sends the content to the Web browser that requested the information.

This entire process may take only seconds, depending on the speed of the client computer's connectoin to the Web.

PROGRAMMING CHOICES FOR EIS WEB PUBLISHING

Server-Side Programs

Server-side programs are programs that run on the network server. CGI programming is the most fundamental way to access relational database information over the Internet or an Intranet and to display dynamic content. This is important to any EIS because the amount of data involved will undoubtedly require processing with a relational database of some kind.

FoxWeb is a small CGI program that connects to a Visual FoxPro database application. The application then calls any number of custom-designed queries and procedures to return results to the browser as HTML. More information about FoxWeb is available at www.foxweb.com

Perl (practical extraction and report language) is an application used for CGI programming. Applications written in Perl will work on any operating system. It also has the ability to connect to many types of databases. A good source for information on Perl is www.perl.com

ColdFusion is a server-side application that uses a ColdFusion server. The server executes templates containing a mixture of HTML and ColdFusion instructions and then returns the results to the browser as pure HTML.

Active Server Pages (ASP) are also a popular choice recently. The ASP program on the Windows Web server will automatically interpret Web pages with the extension.asp. The Web pages are a mixture of ASP instructions, Visual Basic code, and HTML.

Java Servlets are Java programs that run on a Web server and build Web pages. Java is the latest of a long line of higher-level programming languages such as Fortran, Pascal, and C++. It is also portable across operating systems. Java Servlets written for one Web server on one operating system will run on virtually any Web server and on any operating system.

Java Server Pages (JSP) are similar to ASP except that the pages consist of Java code instead of Visual Basic code. This makes the code portable across operating systems. The Web pages typically have the extension.jsp. This tells the Web server to interpret the embedded Java code like any other Java Servlet. Information about Java Servlets and JSP is available on this Johns Hopkins University Web site: www.apl.jhu.edu/~hall/java

Hypertext Preprocessor (PHP). In an HTML document, PHP script (similar syntax to that of Perl or C) is enclosed within special PHP tags. Because PHP is embedded within tags, the author can jump between HTML and PHP (similar to ASP and ColdFusion) instead of having to rely on heavy amounts of code to output HTML.

Any organization wishing to develop an EIS should carefully consider which server-side applications to use. The decision should be a practical one rather than a popular one. All of the criteria below should be part of the evaluation process:

- What operating system is predominantly available to the facility?
- What programming languages are support personnel willing to work with?
- What applications are compatible with the existing database?
- How much of the budget is available to spend?

Client-Side Programs

Client-side applications can create a deeper level of interactivity within Web pages. Scripting languages such as JavaScript and VBScript are less complex versions of other languages, such as Java and Visual Basic, respectively. They reside within the HTML of a Web page and provide a great deal of functionality that HTML itself cannot. Scripts such as these validate input, control the cursor programmatically, and do much more.

Dynamic HTML (DHTML) is the result of scripting languages taking advantage of the extensions common to the latest browsers to make the pages change after they are loaded. A good example of this is a link that changes color when the user places the mouse pointer on it. Much more dramatic effects are possible using DHTML. However, the two most popular browsers—Internet Explorer and Netscape—interpret DHTML differently. Good information about DHTML is available at www.dynamicdrive.com

Cascading Style Sheets (CSS) are special HTML features that allow much more flexibility in formatting elements of a Web page. The ability of CSS to describe the style of an element only once rather than every time you display the element provides a separation of content and presentation. This makes Web pages less complex, much smaller, and therefore faster to load. Beware that CSS is fully supported only in the latest versions of browsers (4.0 and later).

Java applets are small Java programs that are stored on a Web server and called from the HTML in a Web page. Statements in the HTML pass to the applet parameters that affec its functionality. Unlike what it does with Java Servlets, the browser downloads the applet and runs it using the browser's own operating system rather than the operating system of the Web server. Free Java applets are widely available on the Internet. KavaChart applets are very useful for charting trends in data. KavaChart applets are available at www.ve.com

Extensible markup language (XML) is a metalanguage that has many uses. A metalanguage is a language used to explain another language. Extensible markup language organizes data in a predefined format for the main purpose of sharing between or within computer systems. Furthermore, its uses include data organization and transfer, data presentation, data caching, and some that probably have not been invented yet. More information about XML is available at http://xml.com

Developers can use any or all of these to enhance the content of an EIS. Three important points to remember about using client-side applications to enhance browser content are

- Many client-side applications require later versions of browsers to work correctly. Be sure that all your users are using the required browser versions.

- Many client-side applications are available free. Search the Internet before spending resources to develop custom client-side applications.
- Client-side applications will make your Web pages more complex, which adds to development and maintenance costs. Be sure to weigh the benefits of these enhancements against their costs.

Choosing EIS Web-Publishing Tools

We might define tools, in this case, as utility applications that require more configuration effort than programming effort. There are some exceptions, of course. In any case, tools fall into three categories:

- Open-source or free
- Purchased
- Developed

Tools perform such functions as batch emailing, charting, scheduling application run times, and enabling database-to-Web connectivity. The relational database and Web server are also tools.

Batch email applications can be of any category. There are good free ones and purchased ones. Some email servers have batch-processing capability, and some do not. Purchased batch email applications are relatively inexpensive. They have some variations in features, such as whether or not they will send HTML or attachments. They are also easy to develop.

Charting tools are really too complex to warrant developing. There are some very good free and open-source charting tools that have all the features of purchased ones.

The EIS needs scheduling programs to launch data collection applications at predefined times. Some operating systems have scheduling programs built in, but they may be difficult to configure. A purchased version is probably the best choice, because the cost will be quite low.

Some applications do most of the database-to-Web connectivity. These applications either require purchase or (in the case of the free applications) a great deal of programming. The purchased applications are a good choice because much of the error reporting is part of the application. The purchased versions can be very expensive or relatively inexpensive. Each database has its own connectivity options, so much of this decision rests on which relational database is used.

The database used is likely a purchased one or may actually be open-source. Open-source databases like MySQL are competing with the best of the others. Commercial relational database systems range in cost from very inexpensive (Microsoft Access) to very expensive (Oracle).

Open-source Web servers like Apache are available for some operating systems and are very widely used and reliable. Others are free with operating systems such as Microsoft Internet Information Server (IIS). Some are also commercially available for a few hundred dollars. The Web-server choice depends mostly on the operating system of the server itself.

The EIS tools will likely be a mix of open-source, purchased, and developed applications. It is important to consider budget constraints, operating systems, and support when deciding which tools and what types of tools to use. Always plan for compatibility among all the tools the EIS will use.

EIS Choice: Purchase or Do It Yourself

Up to this point in this entry, we have gone "under the hood" and provided details on the processes and software tools needed to create a custom EIS. However, users may not be willing to invest the time and effort required for this do-it-yourself approach.

Numerous companies provide an EIS for an ongoing monthly service fee. The services available range from monthly utility billing data processing and analysis to interval data recorded from submeters for utility cost allocation and load profiling. The advantage of this approach is that the user does not get involved with the details and operation of the EIS, but instead is able to work with the EIS service provider to develop the utility data reports most helpful to the user's operation. An ongoing monthly service fee is a function of the amount of data processed; the more meters or bills processed, the higher the monthly fee. There are additional costs for customizing any reporting from the standard reports already created by the EIS service provider. Ultimately, the monthly cost for the EIS service would have to be justified by the benefit from the EIS reports provided.

The do-it-yourself approach works well for users that either have sufficient IT software personnel in house or that can hire an IT consultant to develop and maintain their own custom EIS. However, having adequate IT resources is only half the battle. The user also needs to create an EIS requirements document that defines what data need to be collected and at what frequency, as well as a list of report outputs. As explained earlier in this entry, the software choices for developing the EIS are numerous, which can result in debates among IT personnel as to which system is best. The best solution will be the one that will result in the desired EIS for the least cost in the least amount of time. The energy manager can help facilitate this decision (and prevent IT gridlock) by estimating the cost, advantages, and disadvantages of each approach.

The decision between the EIS service approach and the do-it-yourself approach will be based on several factors, but it will ultimately be based on the ongoing cost to operate the EIS.

UTILITY REPORT CARDS: EIS EXAMPLE

The Utility Report Cards (URC) program[2] is a Web-based EIS that reports and graphs monthly utility data for schools. The URC was developed and prototyped by the Florida Solar Energy Center (FSEC)[3] using Orange County Public Schools (OCPS)[4] utility data. Each month, the EIS automatically generates a Web-based report and emails it to school staff to examine the school's electricity usage (energy efficiency) and to identify schools with high-energy consumption for further investigation. The easy-to-use Web-style report includes hyperlinks allowing users to (1) drill down into further meter details, (2) display graphs for a 12-month comparison with prior-year data, (3) filter the data to show selected schools, and (4) re-sort the data to rank schools based on the data selected. The URC is also for teachers and students to use as an instructional tool to learn about school energy use as a complement to the energy education materials available through the U.S. Department of Energy's EnergySmart Schools program (ESS).[5] To run the URC, go to www.utilityreportcards.com and click URC Live.

URC Data Collection

On a monthly basis, the OCPS utilities (Orlando Utilities Commission[6] and Progress Energy[7]) electronically transmit to FSEC the OCPS utility data, which then adds it to the URC relational database. Because there was no consistency between the utility's data format, FSEC created a custom program called URC_DPP (URC Data Processing Program) that processes each utility's data file separately and loads the data into a common Oracle database.

Florida Solar Energy Center sends an email to a designated email address at OCPS, with a copy of the current month's URC embedded in the email message. Then OCPS forwards this email to its internal email distribution list for the OCPS staff. This procedure makes it easy for users, because all they need to do is click the hyperlinks in the URC email to produce graphs and detailed reports.

URC Web-Publishing Program

The URC program is informative, intuitive, and flexible for all users. It takes advantage of extensive use of hyperlinks that create graphs and detailed reports from an overall summary report listing all schools. Users are able to view graphs and see the electric consumption patterns simply by clicking hyperlinks in the URC Web page.

When the user selects the URC Live hyperlink, a summary report (see the example in Fig. 2) shows totals for each school type in the entire school district—primary (elementary) schools, middle schools, high schools, etc.—as the rows in the report. The data presented in the columns include the electric consumption (kWh), the cost (dollars), and the efficiency (Btu/ft^2). To provide meaningful comparisons to the same time in the prior year, the URC program divides the data by the number of days in the billing period to produce per-day values. The URC also allows the user to change the values shown to per-month

UTILITY REPORT CARDS

Electric Per Day — ORANGE COUNTY PUBLIC SCHOOLS — << February 2004 >>

	Consumption (kWh/day)			Cost ($/day)			Efficiency (Btu/sq ft/day)		
School Type	Current Period	Previous Period	Percent Change	Current Period	Previous Period	Percent Change	Current Period	Previous Period	Percent Change
Regular Primary School	178,073	181,162	-2 %	$ 13,923	$ 12,012	16 %	146	149	-2 %
Regular Middle School	121,735	124,550	-2 %	$ 9,119	$ 7,984	14 %	139	142	-2 %
Regular High School	168,196	167,136	1 %	$ 12,135	$ 10,121	20 %	161	160	1 %
Special Other	6,351	6,092	4 %	$ 479	$ 404	19 %	143	137	4 %
Vocational High School	5,910	6,572	-10 %	$ 469	$ 448	5 %	106	118	-10 %
Grand Total ORANGE COUNTY PUBLIC SCHOOLS	480,266	485,511	-1 %	$ 36,125	$ 30,969	17 %	148	150	-1 %

On — Denotes Increase From Previous Year

On — Denotes Decrease From Previous Year by ◀ 0 % ▶ or more

Fig. 2 Overall school-district summary page.

figures (the per-day values multiplied by 30 days). Fig. 2 shows the overall school-district summary report for February 2004.

The URC program interface makes the program easy to use, considering the enormous amount of data available. The top-down approach lets users view different levels of data from the overall districtwide summary to individual meters in a single school. For example, the user can click a school type to display the details for each school. Fig. 3 shows the result of clicking the hyperlink Regular High School: A Report on All High Schools in the Database for February 2004. The report is sorted based on the percent change in kilowatt-hour usage from the prior-year levels. The schools that changed the most are at the top of the list. Re-sorting the schools is accomplished simply by clicking the column title. To produce the report shown in Fig. 3, the original report sorted by the efficiency percentage change was re-sorted by clicking the consumption percentage change column.

Graphing is accomplished by clicking any current period value in the report. To display a 12-month graph for Apopka Senior High School, clicking the number 22,399 would produce the graph shown in Fig. 4. Note that the consumption levels are significantly higher than prior-year levels for this school. Focusing on the reasons for this increase should be the next step for the OCPS facility personnel. When it is determined that the increase is not due to other factors, such as increased enrollment or extreme weather, personnel can consider making adjustments to the energy management system controls to turn the trend around.

URC Web-Program Details

Two Web programs make up the URC application interface. One is for reporting, and one is for graphing. The programs are written in PHP. "Hypertext preprocessor is a widely-used Open Source general-purpose scripting language that is especially suited for Web development and can be embedded into HTML," according to PHPBuilder.com. This means that the PHP application itself is not for sale. It is developed and supported solely by volunteers. What makes it an attractive choice is that the developers' code is part of the HTML page itself. Hypertext preprocessor is ideal for connecting to databases and running SQL queries return dynamic content to a Web page.[8]

Using PHP, the reports accommodate both novice and expert users. Hyperlinks in the reports pass values back into the same two programs in a recursive manner, using

UTILITY REPORT CARDS

Electric Per Day — ORANGE COUNTY PUBLIC SCHOOLS — << February 2004 >>

Regular High School	Consumption (kWh/day)			Cost ($/day)			Efficiency (Btu/sq ft/day)

Energy
Eff–Serv

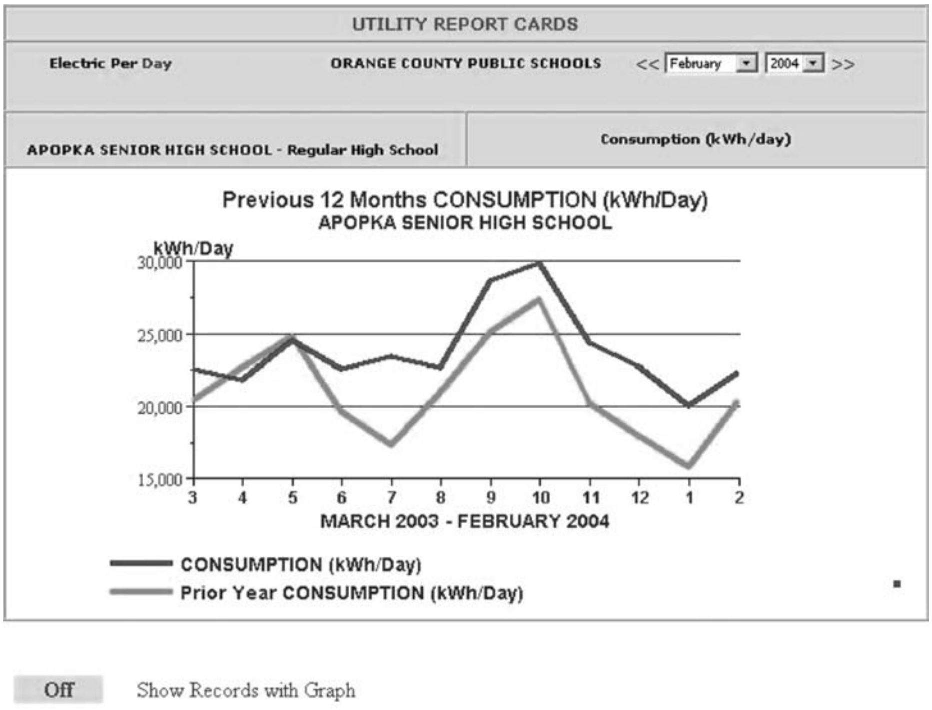

Fig. 4 Apopka Senior High School 12-month kWh graph.

the CGI query string. These values are processed by a set of predetermined rules built into the program by the developer to change the appearance of the reports incrementally to suit the user. The hyperlink construction includes messages using the onMouseOver event to explain the action of the hyperlink. Total and subtotal lines provide summary information. Data that show an increase or decrease from the previous year are flagged with a different background cell color. The user can define percentage criteria for marking decreases from the prior year because this is helpful in tracking progress toward a particular goal, such as a 5% decrease from the previous year. Graphs are created using KavaChart, a collection of Java applets available from Visual Engineering at www.ve.com.[9]

CONCLUSION

Today's energy manager needs to be knowledgeable about the basic principles and concepts of IT because it is a fast-growing area of new systems and services. Web-based EISs provide users feedback on how and where energy is consumed. Building automation systems control the devices that use energy. Together, these two systems provide the energy manager the tools needed for a successful energy management program.

Energy Management: Organizational Aptitude Self-Test

Christopher Russell
Energy Pathfinder Management Consulting, LLC, Baltimore, Maryland, U.S.A.

Abstract
Human, technical, and financial criteria all contribute to a manufacturer's ability to build wealth through energy management. Collectively, these attributes constitute a "culture" and receptiveness not only to energy management, but to operational efficiency in general. Manufacturers will enjoy a wider range of energy management options by nurturing several key organizational attributes, including staff awareness, competence, leadership, commitment, and removal of institutional barriers. This entry offers a typology and self test of corporate "aptitudes" for energy management. This discussion is based on the author's observation and research (The author served as director, industry sector, for the Alliance to Save Energy in Washington, DC from 1999 to 2006. His work included (1) over 40 workshops serving industrial energy users, each attracting 25 to over 120 participants; (2) presentations at 30 industry conferences; and (3) over 30 articles for trade press. All of these activities have generated communications with hundreds of individuals, all of whom add another dimension to the cumulative story of industrial energy management). Until these theories can be properly tested, readers are asked to merely consider this persuasive argument.

LIST OF ATTRIBUTES THAT FACILITATE CORPORATE-WIDE ENERGY MANAGEMENT

Fundamental business viability. The manufacturer's front office stability is important. Companies that are the subject of a merger or acquisition, labor disputes, bankruptcy, or severe retrenchment may have fundamental distractions that will interfere with the attention that energy management deserves. A preponderance of such conditions indicates management turmoil that makes energy management impractical.

Replication capacity. Manufacturers with multiple facilities should spread knowledge of energy efficient techniques and compare their ongoing results. The ability to cooperate across multiple sites and across departmental boundaries is required to maximize industrial energy management potential.

Energy leadership (or "champion"). Successful energy improvements are usually led by an "energy champion," a manager that (i) understands both engineering and financial principles (ii) communicates effectively both on the plant floor and in the boardroom, and (iii) is empowered to give direction and monitor results.

Energy market capability. This dimension is straightforward: does the corporation wish to purchase energy through open-market activity or procure as usual from the local utility? If open markets are the choice, the corporation should be prepared to maintain sophisticated search and verification procedures to support its contracting activities. Purchasing decisions should reflect the collaboration of procurement, production, and maintenance personnel.

Leadership intensity. Quality of operations should be demanded, facilitated, and recognized by top officers of the corporation. Adoption of professional and industry standards, such as ISO 9000, are helpful in attaining this attribute. Energy-smart operations will hold employees accountable for adherence to energy management goals and other quality standards.

Pride intensity. Energy efficiency is very much dependent on the behavior of line workers. Employees' awareness of their impact on energy costs must be achieved. A positive, can-do attitude on the part of staff is helpful in attaining potential energy savings. Rewards and recognition can be harnessed to good effect.

Fiscal protocol. Financial considerations involve far more than invoice quotes. Are purchasing decisions made on first-cost or lifecycle costs? Which department pays for improvements and which claims the savings? Do savings count only fuel bill impacts or do they include the value of material waste minimization and greater capacity utilization? What criteria determine adequate payback?

Engineering protocol. Successful energy management depends on an ability to understand energy consumption. This requires benchmarking, documenting, comparing, remediating, and duplicating success stories. Internal skills, procedures, and information services are engaged. The likelihood of building value through energy efficiency varies directly with the depth of these technical capabilities.

In the absence of an energy management process, energy expense control is reduced to one-dimensional efforts. Many manufacturers (either wittingly or not) settle for something less than full energy efficiency potential due to a lack of time, interest, or understanding. The approach

Keywords: Energy; Energy efficiency; Energy management; Industry; Manufacturing; Risk management.

taken by individual manufacturers is very much a function of their organizational attributes and business culture.

PREVAILING ENERGY MANAGEMENT STRATEGIES

The aim of this section is to present the range of typical energy management strategies practiced by industry. Every manufacturer employs some energy management strategy, even if the choice is to do nothing about energy consumption. Consequently, every manufacturing organization adopts one or more of these strategies:

- *Do Nothing*. Ignore energy improvement. Just pay the bill on time. Operations are business-as-usual or "that's the way we've always done it." The result is essentially "crisis management" in that energy solutions are induced by fire-drill emergencies and undertaken without proper consideration of the true costs and long-term impacts.

  Who does this? Companies that do not understand that energy management is a strategy for boosting productivity and creating value. Or, companies that are subject to merger, buy-out, bankruptcy, union disputes, relocation, or potential closure. Or, companies that are extremely profitable and don't consider energy costs to be a problem.
  PROs: you don't have to change behavior or put any time or money into energy management.
  CONs: you don't save anything. Income is increasingly lost to uncontrolled waste. Because you don't inventory your energy usage, you are exposed to volatility in energy markets. You are less prepared to adapt to evolving emissions compliance agendas and you are less capable of spotting opportunities presented by new technologies. Because you don't monitor anomalies in energy flow data, you are more susceptible to lapses in mechanical integrity and plant reliability.

- *Price Shopping*. Switch fuels and shop for lowest fuel prices. No effort to upgrade or improve equipment. No effort to add energy-smart behavior to standard operating procedures.

  Who does this? Companies that "don't have time" or "don't have the money" to pursue improvement projects. Or, these companies truly believe that fuel price is the only variable in controlling energy expense.
  PROs: you don't have to bother plant staff with behavioral changes or create any more work in the form of data collection and analysis.
  CONs: lack of energy consumption knowledge exposes the subject company to a variety of energy market risks. You don't know where your waste occurs nor do you identify opportunities to boost savings and productivity. You are also exposed to energy market volatility and emissions and safety compliance risks.

- *Occasional O&M Projects*. Make a one-time effort to tune-up current equipment, fix leaks, clean heat exchangers, etc. Unable/unwilling to make capital investments. Revert to business-as-usual O&M behavior after one-time projects are completed.

  Who does this? Companies that are insufficiently organized to initiate procedural changes or make nonprocess asset investments. They cannot assign roles and accountabilities for pursuing ongoing energy management.
  PROs: you spend very little money when just pursuing quick, easy projects.
  CONs: savings are modest and temporary because you don't develop procedures for sustaining and replicating your improvements. Familiar energy problems begin to reappear. Energy bills begin to creep back up.

- *Capital Projects*. Acquire big-ticket assets that bring strategic cost savings, but beyond that, day-to-day O&M procedures and behavior are business-as-usual.

  Who does this? This strategy is adopted by companies that believe that advanced hardware is the only way to obtain real, measurable savings. Similarly, they believe that operational and behavioral savings are "weak" and not measurable. However, they have the fiscal flexibility to acquire strategic assets that boost productivity and energy savings.
  PROs: obtain fair to good savings without having to change behavior or organize a lot of people.
  CONs: forfeit savings attributable to sustained procedural and behavioral efforts. Also, savings from the new assets may be at risk if adequate maintenance is not applied.

- *Sustained Energy Management*. Merge energy management with day-to-day O&M discipline. Diagnose improvement opportunities and pursue these in stages. Procedures and performance metrics drive improvement cycles over time.

  Who does this? Companies with corporate commitment to quality control and continual improvement, well-established engineering and internal communications protocol, and staff engagement through roles and accountabilities.
  PROs: maximize savings and capacity utilization. Increased knowledge of in-plant energy use is a hedge against operating risks. Greater use of operating metrics will also improve productivity and scrap rates while reducing idle resource costs.

CONs: you need a lot of in-house talent, cooperation, and a capable energy "champion" to do this.

It is beyond the scope of this entry to comment on which strategies are predominantly encountered in industry. Anecdotal evidence suggests that all industrial energy management strategies can be categorized per one of these five selections. It is also possible for firms to practice multiple strategies simultaneously—for example, price shopping for low-priced fuel commodities in concert with a capital-projects focus.

It should be noted that most of the ten of the experiences documented in the Alliance's corporate energy management case study series can be categorized as "sustained energy management." As such, these companies integrate energy management with day-to-day operating procedures and accountabilities.

ENERGY MANAGEMENT PATHFINDING: MATCHING STRATEGIES WITH CORPORATE ATTRIBUTES

This section will build on the theory of corporate receptiveness to energy management, as presented above. The energy management strategies available to a manufacturer are a function of its organizational attributes, as summarized in Table 1. Note that this is currently presented as theory.

Examples for interpreting this Table 1 manufacturer should have attained the attributes of "fundamental viability," "leadership intensity," "fiscal protocol," and "engineering protocol" in order to effectively pursue capital projects as a single-site energy reduction strategy.

Alternatively, a manufacturer that has attained "fundamental viability," "replication capacity," "leadership intensity," "pride intensity," "engineering protocol," and has an "energy champion," should be capable of pursuing both the occasional O&M projects and sustained energy management strategies across multiple sites. In this instance, the company may wish to start with the lesser strategy (O&M projects) and evolve into the practice of sustained energy management.

This typology presumes that energy management for multisite organizations is more demanding than it is for single-site companies. Accordingly, adoption of a certain strategy by a multisite organization requires all the organizational attributes that a single-site organization would be expected to muster, plus the capacity to replicate.

Managers that are contemplating improved energy management are encouraged to consider the case study results and theory presented in this paper. To act on this information, the steps are to:

Table 1 Theory: matching corporate attributes to energy management strategies

	Organizational attributes							
	Fundamental viability	**Replication capacity**	**Energy champion**	**Energy market capability**	**Leadership intensity**	**Pride intensity**	**Fiscal protocol**	**Engineering protocol**

Sustained energy management	Required		Required		Required	Required		Required
Strategies for replicating energy reduction at multiple sites								
Do nothing								
Price shop		Required		Required				
Capital projects	Required	Required	Required		Required		Required	Required
Occasional O&M projects	Required	Required	Required		Required	Required		
Sustained energy management	Required	Required	Required		Required	Required		Required

Source: From The alliance to save energy.

- Refer to Appendix A, "Determining an Organization's Aptitude for Energy Management." Note which organizational attributes have been substantially attained by the subject company.
- Compare the attained attributes to the information in Table 1. The presence (or absence) of certain attributes determines which energy management strategies are available to the subject company.
- Use these findings to understand what the subject organization can or cannot achieve in terms of energy management.

Keep in mind that this exercise indicates what a manufacturer can expect from energy management given its current organizational attributes and business culture. There may be a desire to evolve to a higher level of energy management than what the current organization allows. What if a manager wants to advance energy management in his or her organization? There are windows of opportunity. An obvious example is when energy market turmoil brings top management's attention to fuel costs. Also, take advantage of annual planning sessions or strategic reorganizations to propose the kind of organizational processes needed to practice sustained energy management. Remember that energy cost control is as much dependent on people as it is on technology.

CONCLUSION

Volatile energy markets are here to stay, and so are competitive and regulatory pressures. Energy price movements will put some manufacturers out of business, while others will decide to move offshore. Surviving manufacturers will not only provide superior products and service, but they will maximize value through operating efficiencies. Energy efficiency is an indispensable component of wealth creation.

Energy procurement strategies such as shopping for low energy prices and supply contracts are only partial solutions to soaring energy expenses. Management of consumption is an underappreciated opportunity. While technology is the foundation for managing consumption, it is the human dimension that makes technology work. Organizational procedures, priorities, and accountabilities are crucial to energy management.

A manufacturer's ability to manage energy consumption is ultimately a function of organizational attributes and corporate culture. This entry advances "energy management pathfinding" concepts. Appendix A presents the criteria that define seven distinct organizational attributes needed for energy management. While sustained, day-to-day energy management is recommended for providing the greatest and most durable value, and it is also the most demanding in terms of operational character. Many companies will find that they are suited for strategies that are less challenging but may also provide less value. The same management diagnostic presented in this entry serves as a pathfinder for matching organizational characteristics with appropriate energy management strategies.

APPENDIX A

Determining an Organization's Aptitude for Energy Management

This Appendix serves two purposes:

- To further define the organizational attributes that a manufacturer needs to pursue energy management as a continuous-improvement process, and
- To determine if a subject organization has substantially attained each of the organizational attributes listed ("Fundamental Viability," "Replication Capacity," etc.).

Please see below. For each attribute, a number of conditions are posed in a bulleted list. When considering a subject company, ask: are most or all of these conditions true? If the answer is yes, then the subject company has substantially attained that attribute. The degree of attainment for each attribute varies directly with the number of considerations that can be affirmed for each attribute. There are no scores, per se. If the subject company has attained a majority of the bulleted considerations listed under an attribute, consider that attribute to be substantially attained.

The range of topics covered by these conditions would be best answered by a high-level manager or perhaps a team of managers. After this exercise, note all of the attributes that have been substantially attained. Compare those results to Table 1. That table indicates which energy management strategies are available to the company, given its organizational attributes.

Fundamental Viability

Your plant capacity is generally stable or growing.
Your company is not currently experiencing excessive turnover of managerial and corporate personnel.
Strikes or other labor-related work stoppages are not considered an ongoing concern for management.
Your company is not the current subject of a merger or acquisition attempt.
Your company is not in receivership, Chapter 7, or Chapter 11 status.

Replication Capacity

Your company operates more than one manufacturing facility.

Your manufacturing processes and products are mostly similar across all plants.
Your facilities are designed and operated per one standard; standards do not significantly vary by facility for asset selection, procedures, and management styles.
Staff members from different plants (or divisions) regularly collaborate to share their common issues and solutions.
Maintenance management is set up to serve multiple sites; individual sites adhere to centralized maintenance planning and procedures.
Your corporation currently uses (or is it willing to use) contract vendors for ongoing energy management.

Energy Champion (Note: All of These Conditions Must be Met to Have a True "Energy Champion")

Your lead energy person has thorough knowledge of technology and staff capabilities at the facility level.
Your lead energy person can prepare financial analyses to support engineering proposals and convincingly present these to top managers.
Your lead energy person applies more than 50% of his or her time to energy issues.
Your lead energy person can give direction or at least influence decision making by general managers.
Your lead energy person understands utility tariff structures and administers relations with utility providers.

Leadership Intensity

Your organization actively maintains disciplines of excellence such as Six Sigma, ISO 9000, or Total Quality Management.
Process technologies, procedures, or staff expertise are a selling point in marketing your products.
Current and future environmental impacts from manufacturing operations are a concern to your top management.
A corporate officer consistently reviews cost and quality performance data for all facilities.
To most of your corporate leaders, "energy efficiency" is perceived as an "opportunity" as opposed to a "hassle".
Staff compensation, raises, and rewards are impacted by their stewardship of energy, raw materials, and other inputs.
Production metrics are integral to performance evaluations for facility managers and staff.
Your facilities are subject to public scrutiny or "good citizenship" expectations.

Pride Intensity

All or most plants are consistently high performers with respect to health and safety compliance.
Most plant-floor staff members are well trained for their jobs.
Staff turnover is not considered to be a problem.
Your typical plant worker philosophy can be described as "do what's right" instead of "do what's easy."
You describe your plant equipment as "well maintained" as opposed to "poorly maintained."
To most of your facility staff, "energy efficiency" means "opportunity" as opposed to "hassle."
Key facility personnel maintain professional certifications.
Your organization prescribes and enforces technical training for facility personnel.

Fiscal Protocol Intensity

Asset purchases are judged primarily by life-cycle costs (acquisition plus life-time operating, maintenance, etc.), instead of first costs (cost of acquisition).
Your organization uses (or is willing to use) leases and other off-balance sheet methods to finance major acquisitions.
Your organization's investing strategy seeks large payback as opposed to fast payback.
Most of your facilities take utility tariffs into account when planning their operating times.
Facilities invest in plant improvements (as opposed to simply fixing what's broken).
Energy-related capital project proposals assigned a hurdle rate equal to or lower than other project proposals.
Any energy savings are returned to the facilities that successfully implement capital improvements.
Your facility managers understand utility tariffs and their role in determining energy expenses.

Energy Market Capability

Your company is willing to make an on-going effort to use energy marketing services to obtain lowest-cost energy commodities and risk-hedging securities.

Engineering Protocol Intensity

Your facilities maintain a scheduled maintenance routine for powerhouses, motor drives, pumps, compressed air, and similar utilities.
Your facilities maintain a protocol for responding to anomalies in operating performance data.
Your chief engineers are comfortable with using software to analyze engineering issues.

Plant managers develop (or help to develop) project proposals for capital budgeting purposes.
Your facilities maintain procedures for safety, health, and waste management.
Most or all of your facilities maintain an action plan for improving process efficiencies.
Your organization maintains a database or archive that documents engineering problems and solutions.
Your facilities track the volume of factor inputs required per unit of production.
Your facilities monitor scrap or error rates.
Your annual budgets include factor inputs and production targets as well as dollar figures.
Production, inputs, and cost-performance data are created and utilized at the facility level.
Your engineering problems and emergencies are generally unpredictable and unique as opposed to predictable and recurring.
Company-wide production stats are made available to all facility staff by publication, discussion, or graphic display.

Energy Master Planning

Fredric S. Goldner
Energy Management & Research Associates, East Meadow, New York, U.S.A.

Abstract
Energy master planning (EMP) is the process of transitioning an organization's culture from the traditional "fixed cost, line item" view of energy to one in which energy is recognized as both an opportunity and a risk that that can be managed. An EMP can guide an organization in longer-range planning of energy cost reduction and control as part of facility maintenance, management, and design. Though an EMP encompasses traditional efforts to cut energy costs, it also includes many steps not usually taken under conventional, technically oriented energy management, including energy procurement, energy-related equipment purchasing, measurement and verification (M&V), staffing and training, communications, and setting energy consumption targets and tracking/feedback loop systems. A critical difference between energy master planning and traditional energy management is an orientation toward the future. An EMP deals with a longer timeframe than just simple payback periods and goes beyond merely reducing energy use. EMP requires sustained commitment from top levels of an organization down through the rank and file, a dedicated energy manager, and creation of an energy team with membership from across the organization.

INTRODUCTION

Developing an energy management program or more broadly energy master planning (EMP) is the process of transitioning an organization's culture from the traditional "fixed cost, line item" view of energy to one in which energy is recognized as the opportunity and risk that it has become.

An EMP can guide an organization in longer-range planning of energy cost reduction and control as part of their facility maintenance, management, and design. An EMP can even lead the energy budget to be recognized as a potential profit center and source of opportunity rather than just another business expense. An EMP moves beyond the confines of traditional engineering to include energy procurement, energy-related equipment purchasing, measurement and verification (M&V), staffing and training, communications, and setting energy consumption targets and tracking/feedback loop systems. The long-term perspective goes beyond simply cutting last year's energy use. It makes energy awareness part of the everyday operation and "mindset" of the organization.

If you're thinking this doesn't apply to your firm or clients because you're too small, think again. This approach works for an organization as small as a single site to an owner with half a dozen small buildings to Fortune 100 companies. The effort and level of detail vary, respectively, but the approach is basically the same. The good news is that there are resources available to assist professionals and the organizations they serve to understand the EMP process and get started on this path.

To be successful an organization must treat energy in the same business-like manner that they do all other major expenses, such as labor and materials. "If you can measure it, you can manage it"[1] is the catch phrase of Paul Allen, the energy manager at Disney World, who has been instrumental in implementing one of the most successful EMPs in the country. "Energy is a competitive opportunity… Winners manage it effectively!" is the driving force of another highly successful program at Owens Corning. Many other organizations throughout this country and across the globe have recognized that to achieve significant and sustained energy cost control, organization needs to make energy management an integrated part of their business/operations. There are various ways to pursue the process, but a key requirement is an interdisciplinary mix of engineering/technical, behavioral, and organizational or management components. The EMP must be integrated into the basic business operations.

Keywords: Strategic; Energy management; Bottom line; Upper management; Profit center; Buy-in; Commitment; Long-term; Integrated; Energy accounting; Business planning; Road map.

UNEXPECTED BENEFITS

One of the most potent driving factors in many organizations' efforts to address energy issues is increased profitability that can be realized through reduced/optimized energy expenditures. Beyond the "bottom line" impacts, an EMP can also provide an organization with a more secure energy supply, reduced downtime of systems, improved equipment availability, reduction in maintenance costs/premature system replacement expenditures, and overall productivity gains. Additional benefits that have been documented include quality-of-life improvements, enhanced product quality, better operational safety, reduced raw material waste in industrial plants, and increased rentability in commercial facilities. An often overlooked outcome of an EMP is the reduction of emissions, among other environmental impacts that help organizations become perceived as better corporate citizens.

As more companies move toward an integrated corporate strategy that links environmental, economic, and social considerations, the results of an EMP can be used to considerable public relations advantage. Ratings in one of the sustainability indices and publication of an annual sustainability report (using, for example, the Global Reporting Initiative guidelines) can give an organization a higher standing in the business community and can result in a higher level of trust by stockholders.

A PROCESS FOR OPTIMIZATION

Though energy prices are volatile, and energy security is often far from reliable, facilities now face leaner operating funds and increased directives to do more with less. Optimizing a facility's operations budget frequently means cutting energy costs. But how do you do so without cutting occupant comfort or productivity? How do you know where to start and what steps to take? And how do you persuade upper management that energy costs can be controlled?

While the general goal of an EMP is the same as that of conventional energy management, the two disciplines are far from identical. Traditional energy management, which is technically oriented, is essentially centered around the boiler or mechanical room. Energy master planning, on the other hand, is a business management procedure for commercial, institutional, and industrial operations. With this approach, it is not enough simply to manage installations. The process involves:

- Developing strategies
- Creating processes to fulfill those strategies
- Identifying barriers and finding procedures to overcome them
- Creating accountability
- Providing feedback loops to monitor and report progress.

Clarification of the terminology for these disciplines is important, as the terms mean different things to different people. In other English-speaking nations, for example, the defining feature of "energy management" is the emphasis on integration with business practices to analyze, manage, and control energy. In the U.S., however, "energy management" has traditionally referred to developing technical and operational measures involving equipment handled by facility managers—not processes such as energy procurement and business planning usually handled by purchasing agents, production personnel, and corporate economists. A typical U.S. energy manager's responsibility rarely extends much beyond utility bill analysis, an occasional energy audit, or managing installation of system upgrades.

Though an EMP encompasses traditional efforts to cut energy costs, it also includes many steps not usually taken under standard energy management. Rather than being just equipment-oriented, an EMP starts long before a comprehensive energy audit and extends beyond commissioning of new systems. An EMP may be thought of as a road map to savings that starts before and continues after energy-efficiency measures are involved. Why do you need such a map? Because you can't get there if you don't know where "there" is. How many of us are willing to undertake a trip that will have costs and risks (like any business or personal decision) if we don't know where we are going? A map makes clear not just your final destination, but also how to get there—and it leaves no question about the starting point.

An EMP is a process to organize and improve your existing energy-related resources and capabilities. Resources, in this case, include standard operating procedures, institutional memory, and actual records (such as energy bills, plans and blueprints, and energy contracts). Capabilities include facilities staff familiar with mechanical room equipment, consultants for energy costs or usage, energy cost accounting and management systems, and meters and software that monitor them. Once organized and integrated, these resources and capabilities become powerful tools for managing energy and producing savings.

TODAY'S PRACTICES FOUND WANTING

Current thinking about managing energy often falls short of the EMP perspective. Today's energy management frequently reflects a short-term crisis mentality: A facility manager or energy manager concentrates on whatever immediate 'fires' have to be put out at his facility. By contrast, with an EMP mindset, the energy manager might first look to increase the efficiency of systems already in place and then move ahead to lay a solid foundation for improving performance via tight energy specs and training.

Current thinking is also often characterized by piecemeal 'solutions' that lead to short-sighted component replacement. When equipment breaks down, it gets replaced without anyone's asking whether this is the best option, long-term. Typically, business thinks in a quarterly mindset because of the short budget cycles of our economic system. That kind of "right now and right here" viewpoint creates situations in which life-cycle thinking is not possible because potentially higher initial costs are visible, but potential benefits tend to be invisible. As a result, when first cost becomes the main criterion for purchasing, such a focus distorts planning and decision-making. Too often, facilities choose the cheapest solution, based on the current quarter's budget, without realizing it could cost them more later.

A critical difference between energy master planning and conventional energy management is an orientation toward the future. With an EMP, you don't just look to increase the efficiency of systems already in place. Instead, you plan for new or changed loads based on your detailed information about the facility's long-term business strategy and projected growth.

Energy master planning deals with a longer timeframe than just simple payback periods. For example, typical financial constraints for a commercial building upgrade often dictate a 2- to 3-year timeframe. Energy master planning, however, looks deeper than simple payback and goes beyond merely reducing energy use. Therefore, an energy professional with an EMP considers life-cycle costs and views long-range planning of energy cost minimization/optimization as part of overall facility maintenance, management, and design. To sustain the savings over time, an EMP calls for hiring an energy manager/coordinator and setting up an energy team. But who is this energy leader? Not simply the facility manager wearing yet another hat, but rather, a highly trained and, often, certified specialist with sufficient acumen and expertise to understand, handle, and maintain whatever new energy systems and practices are to be put in place. Willingness to identify (from within the organization) or hire an individual with the required qualifications and to define his or her responsibility as managing energy rather than managing the facility is a requisite indication of senior management's true commitment to energy master planning. The policy guidance needs to come from senior management levels to convey "buy-in" throughout the management structure of the organization.

IMPROVING BUSINESS AS USUAL

Energy master planning is one way of creating a new norm of "business as usual," taking its cues from time-tested business management practices. For example, rather than carrying out upgrade projects with a defined start and end point, an energy manager uses processes that continue to turn up new sources of savings. This requires a level of creativity for identifying and capturing new opportunities. If a chiller replacement is needed in Building A, for instance, a better approach might be to expand the capacity of the existing central chilled water plant in Building B and run piping from Building B to Building A.

Without an EMP, the Purchasing department often buys equipment and energy, rather than the Facilities department. And Facilities is so busy handling emergencies that they have little interaction with other departments in the organization, let alone industry groups or other end users. An EMP avoids either departmental isolation and turf wars by including representatives from such departments on the energy team. The team consists of more than an energy manager, facilities personnel, and design and construction specialists. To be effective, it needs to incorporate representatives from every department in the organization impacted by energy. This may mean including purchasing, accounting, engineering, environmental affairs, maintenance, legal, health and safety, corporate relations, human resources and training, public relations and marketing, and members from the rank and file (hourly employees).

Energy master planning is a significant challenge. It often rejects the status quo and may question existing components of an organizational culture that do not support energy master planning. If you have always done something one way, you don't necessarily have to perpetuate what could be a costly mistake. For example, using outdated specs (e.g., calling for T12 lamps instead of T8) allows inefficiency to continue.

ORIGINS OF THE AMERICAN EMP APPROACH

A common set of energy master planning definitions and processes has taken root in English-speaking countries other than the US. In the United Kingdom, the energy master planning concept has been practiced for well over a decade and vigorously promoted by the government's Action Energy program. It has been so successful that Canada, New Zealand, and Australia have each adapted the process to their own conditions.

In the US, there are a few recent models cover some, but not all, aspects of energy master planning. management system for energy (MSE) 2000 is a specialized quality improvement standard (like ISO 14000), developed by Georgia Tech. It's an American National Standards Institute (ANSI)-approved management system for energy that covers all sectors, not only buildings. Georgia Tech offers a certificate program to train energy professionals in this standard. The Association of Energy Engineers delivers the Developing an Energy Management Master Plan and Creating a Sustainable Energy Plan Workshops to both 'real' and 'virtual' end users. Live presentations and online seminars present an energy master planning approach with strong emphasis on integration with business strategy.

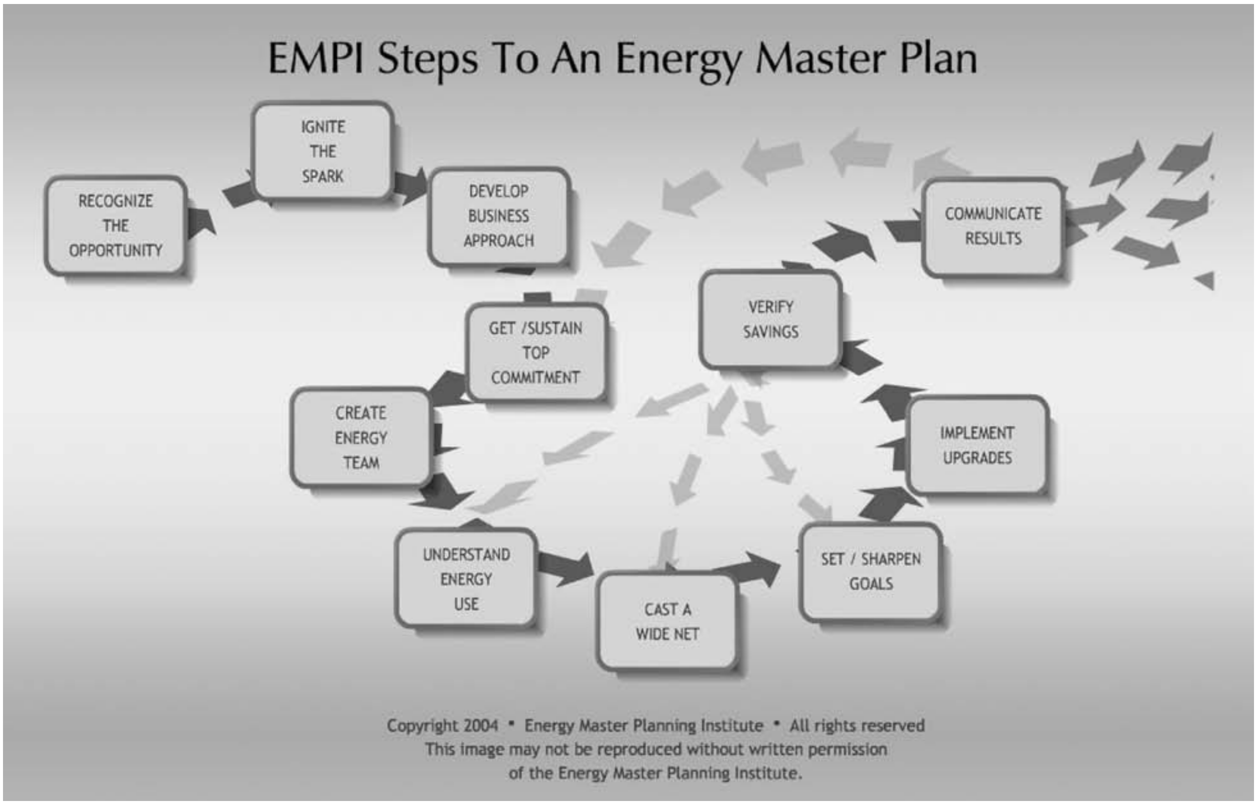

Fig. 1 Energy Master Planning Institute (EMPI) steps to an energy master plan (EMP).

STEPS TO AN ENERGY MASTER PLAN

To fill this gap in the U.S., the Energy Master Planning Institute (EMPI) was established and has developed a set of steps that lay out the process for applying energy master planning to a commercial, institutional, or industrial facility (See Figure 1). This model, which builds on accepted international approaches, offers US organizations a broad and integrated business approach for managing energy that is both strategic and sustainable.

The steps presented in Figure 1 appear sequential, but built into the energy master planning process are series of feedback loops, evident in figure 1. These should not be overlooked, as they guarantee the viability of the process and offer many points for input from internal and external stakeholders, from the Chief Executive Officer (CEO) to boiler room personnel, and from the local community to organizational peers across the country.

Recognize the Opportunity

This is where the process starts—becoming aware of the facility's major energy-related opportunities and challenges. Whether it's the facility manager or the energy manager, whoever takes the initial action must define the opportunities and challenges succinctly so they can be clearly communicated. When the leader creates and implements an EMP, that plan can actually generate a revenue stream and gain recognition for the leader's contribution to the company's bottom line. By integrating energy concerns into the overall corporate business strategy, the energy budget will come to be seen as a potential profit center and source of opportunity—and not just an uncontrollable expense.

Ignite the Spark

Since top executives in an organization are the ultimate decision-makers, particularly concerning funding, it's critical to spark their attention early in the process. It's unlikely that the facility manager (or the energy manager, if there is one), has direct access to upper management, so the right individual to make the pitch to the CEO or Chief Financial Officer CFO must be identified. This could be someone along your management chain, or a consultant or board member or a senior officer in another department who can sell an idea at the top. To find the right person, it's important to understand the decision-making structure of your organization as well as the vision, mission, and long-term business plan.

Develop a Business Approach

To get access to senior executives and persuade them to listen to a new idea, you must speak to them in their own language—dollars/ft^2/year savings, not kWh. Since most executives have not been introduced to the bottom-line value of energy master planning, your task is to change management culture so executives no longer view energy as an uncontrollable expense. Part of the marketing message is that managing energy is no different from tracking, controlling, and accounting for the costs of raw materials, IT, personnel, safety, or the corporate fleet.

Obtain and Sustain Top Commitment

Without question, this step is the most difficult in the energy master planning process. Serious commitment from senior management means providing ongoing financial resources and personnel with appropriate credentials. A one-time memo of support is not effective. To secure top executive commitment, you must show how an EMP can support key business goals, such as growth, customer satisfaction, or a sharper competitive advantage. You might, for instance, explain that lower operating costs and increased energy efficiency can bring a higher level of occupant comfort, which, in turn, can mean a lower worker absentee rate–and, possibly, a greater employee retention rate. To gain top executive commitment, make sure that CEO and CFO see the dollar savings highlighted in the energy team's regular reports.

Top management commitment is the single most important goal in an effective and lasting EMP. Not only is it crucial to have this commitment, it must also be obvious to everyone throughout the organization. Top management should participate in the program start-up and continue to reinforce that commitment periodically with both words and actions. Such organizations as Walt Disney have achieved this top-level buy-in and gained significant and lasting bottom-line results from energy master planning.

Create an Energy Team

A middle manager in your organization may declare that energy master planning is only the responsibility of the Facilities department. However, when an energy team represents the company's broad interests, energy concerns can be successfully integrated into the overall business plan. Every department that's impacted by the organization's energy use should be invited to participate on the team. This includes:

- Facilities
- Construction/engineering
- Purchasing
- Accounting
- Inventory
- Environmental, health, safety
- Legal
- Public affairs
- Property/asset management
- Leasing/real estate
- Risk management
- Security
- Financial service

This should result in the creation of an Energy Committee. Depending on the size of the organization, there may be separate Technical and Steering Energy Committees. In addition to representatives from the departments listed above it is important to include members of the rank & file (hourly employees or line workers). By including such folks in the planning process it allows not only those individuals, but their peers as well, to become aligned with the EMP objectives and particular initiatives during the early stages. Having these employees on the team helps the rest of the rank and file staff (who will be needed to carry out many of the activities) see the energy program as something other than 'just another management flavor of the month'. It also increases success, as feedback from these employees often helps address many of the nuts-and-bolts "bugs" in advance.

The energy team should be headed by an Energy Manager or coordinator. The Energy Manager needs to have a mix of technical, people, and communications skills, and must be enthusiastic. He or she should thoroughly understand the organization's operations and should report to someone as close to the top of the organization as possible, so he or she has the clout need to get things accomplished.

Understand the Organization's Energy Use

Conduct disciplined information analysis. Collect and use metered–not just billed–energy data, and analyze it with software designed to manage energy costs. "Fully understanding current energy use practices–the when, where and how much of energy consumption–in detailed qualitative terms is an essential precondition to energy management master planning."[2] For example, to determine exactly where the energy is going, specify and install sub-metering and a data acquisition system. Such tools will help you monitor and collect, as well as analyze, the meter data for electricity, fossil fuels, steam and condensate, and water. For loads of several hundred kW, it's advantageous to use interval meters that allow a close look at 15-minute interval or hour-by-hour use of energy, so you can see where peaks and valleys in usage occur. This kind of metering is also essential for internal billing. Besides establishing points of excessive usage, it can also help manage loads and pinpoint efficiency opportunities.

Cast a Wide Net

Casting a wide net means looking beyond the central plant for savings opportunities, such as lighting, office equipment, elevators, and localized process loads. It means making construction and equipment specs energy-conscious and creating ways to "enforce" such specs. For example, specifying T8 lamps for efficiency upgrades is not sufficient. The architecture, design, and construction staff should build T8s into their specs for non-energy-related upgrades, such as converting a library to training rooms. Casting a wide net also means revising inventory and purchasing practices to support energy efficiency. As in the example above, to ensure that the new installation continues to function properly, the purchasing specs need to list T8s, not T12s.

Set or Sharpen Goals

Once the organization's energy use is determined, strategic thinking linked to the long-term growth objectives will determine how much energy you should aim to save, where the savings should come from, and when those savings should occur. The energy manager along with the energy team, proposes a phase-one timetable with quantifiable goals to reduce energy use and operating and energy costs. Senior management, however, must mandate the goals and schedule or they carry no weight. Ideally, the CEO, CFO, or the Board issues a position calling for measurable reductions at the end of a 3-year fiscal cycle, based on current use: a percentage reduction in peak electrical demand across the entire facility, a reduction in annual kWh consumption of electricity, and a reduction in overall British Thermal Unit (BTU) for fuel per gross square foot. Lesser annual goals will help keep progress on track. A key is to set achievable goals, and then work to meet or beat them.

Implement Upgrades

Because energy managers generally have experience with efficiency upgrades, it is critical not to fall into old patterns of sporadic efforts and a piecemeal approach, with an eye on the quickest payback. To carry out an EMP, start the upgrade process with a comprehensive energy audit—not just a walk-through—to determine which upgrades will give the best results, not just the best rate-of-return. For example, in a commercial building operation, to avoid a rush upgrade for a new tenant, pre-audit all your buildings so you know what work needs to be done before that tenant signs their lease. Or, if you're considering recommissioning, look at it from the longer-term energy master planning perspective. Recommissioning may not be sufficient, as it means only the existing systems would operate more efficiently. But what if they need to be ripped out as part of the upgrade?

Don't fall into the common trap of focusing just on the high-profile, capital-intensive, projects. While a new chiller or micro-turbine cogeneration system may be a good photo opportunity, focusing on the less visible details can often provide the lion's share of savings through lower-cost measures that improve operations & maintenance (O&M) or maintenance and management practices.

Verify Savings

Once the upgrade process is underway, you must first validate the savings with a recognized technique such as the International Performance Measurement & Verification Protocol (IPMVP or MVP). However, instead of following the M&V protocol after the fact, build measurement and verification into the design—that is, install it as part of the upgrade—so you can identify the savings as soon as the device is turned on. Then, set up an energy accounting system that tracks usage and savings, thereby providing objective accountability. All too often energy management activities are not perceived as being of value because the energy team did not plan ahead and position themselves and theirs efforts for recognizable success. A North American floor coverings manufacturer reported how "in the past we would complete a project to find that we did not have the baseline or operational data to judge whether the project was successful."[3] How willing will management be to fund the next energy related project or initiative if the energy team cannot prove that prior efforts actually saved what was projected?

With an energy accounting system, everyone on the energy team will be working from the same data, and you can prepare regular progress reports, plus quarterly reports to the CFO and an annual report to the Board. This is critical: The energy team must account for the savings—or lack of savings–to senior management, using a feedback process so goals and targets can be reset if they aren't met. Use this process to verify energy use and to help identify any new opportunities for savings, and then to fine-tune your goals. If you fall short of your targets, you need to figure out why. Or perhaps you did meet your targets, but parts of the data were wrong. Perhaps the metering is off, or the energy accounting system needs readjustment. Regularly scheduled feedback from these reports will keep the energy master planning process up-to-date and realistic and will ensure accountability. One approach that has been successfully used in many organizations is the use of "energy report cards" and "intra-organizational listings/scorecards". Produced by the energy manager and sent out to all facilities/operating groups/departments on a monthly basis, these tools inform as well as motivate, based on the certainty that no one wants to be on the bottom of the list.

Communicate Results

Successful implementation of all stages of the EMP can be a useful vehicle for departmental—and personal—recognition. With a representative of the corporate PR office already on the energy team—enlist that individual's expertise for internal and external communications. Inform the organization's Board about the financial savings and improved asset value. Let the staff and community know about the environmental benefits. Apply for energy awards for national recognition in your sector. And use the good will generated by the success to keep the energy master planning process moving forward.

TIPS FOR SUCCESS

From these steps to an EMP, two points emerge as the most critical to success.

The first is ensuring buy-in from the top, with a long-term commitment and binding, formal statement of energy policy for the organization. Commitment to action also means that senior executives support the people in the middle—delegating authority to the energy manager or facility manager. If the EMP lacks commitment from the top down, no amount of effort by the energy manager will make it succeed. Once you've caught executives' attention, keep energy master planning on their radar screen by having the energy team build it into the organization's business plan. Such a commitment must also be apparent. Top management must continue to be seen (by all levels of staff) reaffirming their commitment, lest the EMP be perceived as just another short-term initiative of the organization.

The second critical component is line-management accountability, making specific individuals accountable for sustaining the savings. On the management side, executives need to mandate quantifiable goals and targets, strengthened by obligatory deadlines. Such requirements should even be built into job descriptions and evaluated as part of annual performance standards reviews. Likewise, incentives can be offered through these same personnel standards for individuals who meet their energy goals. Employee teams with day-to-day knowledge of the facility's operation can also be organized to identify additional opportunities for savings. At the upper level of the organization, corporate accountability for successful energy management can be communicated (and made public) through such mechanisms as the Global Reporting Initiative, especially in firms with sustainability principles that follow a "triple bottom-line".

CONCLUSION

Energy master planning is an effective and long-term shift in organizational cultures to address and adapt to the impact energy resources can have on their competitive posture and economic success. Energy is a universal raw material and is essential to the operation of almost every commercial, institutional, governmental, and even non-profit organization. Significant changes to the basic structure of the energy supply chain and significant energy price volatility, driven by a wide range of political and physical events (e.g., climate change, weather), have made energy both a competitive opportunity and a risk requiring active long-term planning to manage. Energy master planning requires buy-in from top levels of an organization down through the rank and file, selection/hiring of a dedicated energy manager, and creation of an energy team with membership from across the organization. This team must be given the resources and top-level access to develop and implement long-term planning for procurement and operations throughout the organization that places a premium on lasting energy-use reductions and cost optimization, rather than "burst" efforts that provide quick and quickly forgotten energy management efforts.

Successful organizations do not exist on a quarterly basis. They plan for the long-term in all aspects of their operations. Experience has shown that organization-wide adoption of EMP is effective in optimizing energy costs and needs to ensure competitive posture and success in the long-term business reality in which organizations exist. This is the new bottom line for energy.

Energy Project Management

Abstract

Today's energy projects are becoming ever more complicated technically, beginning to involve more people, and beginning to include more integrated components and systems. As the complexity of an individual project increases, so does the importance of project management. Even if the responsibilities for project management are outside the business organization, good project management principles apply. To successfully manage an energy project, the project manager must have a plan by which he or she can direct project activities; the tools to document agreements and project work; the ability to facilitate communication; and the skills to manage the project's technical side (cost and schedule) as well as the project's human side (conflict resolution, team building, and gaining commitment from stakeholders). The process of energy project management is discussed here along with several tools that can assist managers in developing their own energy projects.

INTRODUCTION

Energy project management was once simple—meeting costs and schedules were considered sufficient. That is no longer true, and it is imperative that good project management principles are used and that the energy business owner remains intimately involved. The goal of this article, written for the energy business owner and the energy business project manager, is to discuss key requirements for successfully managing an energy project.

Today's energy projects are technically complicated, involve many people and disciplines, and consist of numerous integrated components and systems. In an energy project, the up-front sales and marketing, initial energy data collection, and data analysis take a tremendous amount of time and effort. After those efforts, there is often an assumption that project implementation will take care of itself. Of course that is not the case, and a poorly managed project will not deliver the intended results.

There are also time and cost advantages to good energy project management. Buildings last for 30–50 years and errors and omissions grow in importance and cost over time.

It is also less expensive to pay attention to project management than to ignore it. This allows potential problems to be identified and solved earlier and at a lower cost. The general rule is that if an item costs $1 to correct while the project is just an idea, it costs $10 during project definition, $100 during project design, $10,000 during project start-up, and $100,000 after the project is up and running.

To successfully manage an energy project, an energy project manager needs a plan by which he or she can direct project activities; the tools needed to document the agreements, the actual project work, and to facilitate communication; and the skills to manage the technical side (cost and schedule) and the human side (conflict resolution, gaining commitment) of the project. This article will introduce basic energy project definitions, an energy project management plan, and the tools and skills necessary for the successful energy project.

DEFINITIONS

Commissioning. The systematic process of assuring by verification and documentation—from the design stage to a minimum of one year after construction—that all building facility systems perform interactively in accordance with the design documentation and intent and with the owner's operational needs, including the preparation of operation personnel.

Energy project management plan. A set of organized activities, each having a definite beginning and end, that when completed by a project team, deliver a specific business objective.

Milestone. Key, high-level summary activities that must be completed by a set date.

Operation. Business operation for which the energy project was performed.

Keywords: Energy project management; Commissioning; Start-up; Project stages; Performance bid; Energy efficiency; Schedule risk analysis.

Energy Project Stage	Stage Deliverables
Conceptual Stage	▪ Project's general description or project brief, ▪ Needs basis, ▪ Return on Investment (ROI) estimate, such as a Life Cycle Cost Analysis (LCCA), ▪ Initial cost range, ▪ Initial benefit range (including intangibles, where appropriate), ▪ Initial project timing, ▪ Project Charter, ▪ Initial project management team.
Definition Stage	▪ Detailed project scope, ▪ Detailed project cost, ▪ Initial project funding strategy, ▪ Bid process strategy, ▪ Updated Return on Investment (ROI) or Life Cycle Cost Analysis (LCCA), ▪ Project Management strategy, ▪ Final Project management team, ▪ Initial project schedule, ▪ Initial delivery plan, ▪ Initial skilled resource personnel plan, ▪ Initial communication plan, ▪ Initial operational and maintenance training plan, ▪ Major risk and challenges, ▪ Initial contingency plans.
Design Stage	▪ Detailed engineering designs, ▪ Detailed project plan and schedule, ▪ Detailed skilled personnel resource plan, ▪ Risk analysis and contingency plan, ▪ Financing plan, ▪ Operations and maintenance plan, ▪ Commissioning plan, ▪ Operations plan, ▪ Building modeling as appropriate,

Fig. 1. Energy project stages and deliverables.

	▪ Sustainability analysis and design plan, ▪ Bid for funding.
Construction Stage	▪ Detailed construction schedule, ▪ Detailed construction personnel resource plan, ▪ Coordination plan for sub-contractors providing different system components, ▪ Construction communication plan, ▪ Initial start-up and ongoing operations plan, ▪ Updated operational and maintenance training plan.
Delivery Stage	▪ Detailed start-up schedule, ▪ Detailed operational and maintenance personnel resource plan, ▪ Detailed start-up and ongoing operations plan, ▪ Detailed turnover plan, ▪ Updated operational and maintenance training plan, ▪ Project Post mortem.

Fig. 1 (*Continued*)

Project stage. A logical sequence of activities, milestones, and deliverables.

Schedule risk analysis. Equipment and computer programs that let users measure, monitor, and quantify schedule impact on their energy project and help identify schedule risks and opportunities.

ENERGY PROJECT MANAGEMENT PLAN

The energy project management plan is the roadmap for the project. It is a set of organized activities, each having a definite beginning and end, intended to meet a specific business objective when completed by a project team. To make the management of the process easier, project activities are divided into separate structured stages.

Each project stage contains a logical sequence of activities, milestones, and deliverables required to achieve the project objectives. The milestones are key, high-level summary activities that must be completed by a set date, and are linked to the success criteria for each particular stage. The number of stages and milestones is dependent upon the energy project plan length and complexity. The deliverables ensure that all prerequisite work is completed prior to moving to the next stage of the project. Transitions from one stage to the next are times to assess and review both the stage just completed and the project plan.

Fig. 1 illustrates the typical stages and deliverables in an energy project plan.

The plan's main purpose is to provide the roadmap for specific project activities, but it is also a collaboration, alignment, and communication tool. It details which activities are happening at what time, who is involved, and what is happening next. It is also an acknowledgement tool—recognizing when the project team has achieved milestones and when it is on track to delivering the overall project objectives. When the energy project plan is well crafted, the plan followed, and the success criteria realized, an energy project manager can produce maximum results in delivering the overall project objectives.

Conceptual Stage

The conceptual stage is the beginning of an energy project. Its deliverables are broad and are intended to evaluate the project's appropriateness for the business and its needs by answering two key questions:

- "Is this project worth a level of investment?"
- "How does this project further our business plan and mission?"

Business stakeholders answer these questions and develop the initial cost estimate. At this point, there is uncertainty in the project scope and associated costs. While strategic level decisions can be made with these numbers, the conceptual stage costs should not be used as the project cost commitment.

If the project is a fit for the business, a project summary or project brief is written and then reviewed with key stakeholders. The project brief reviews have two purposes—to educate and to gain alignment and commitment to the proposed project. Once the project has commitment from all appropriate parties, a project charter is created. The project charter includes much of the same information as the project brief, as well as the names of the project team and project authorization signatures. It is the official document authorizing the project manager to begin work. Once the charter is approved, the project moves into the first tactical stage—definition.

Definition Stage

This is the stage at which the "how?" and the "when?" for an energy project are defined. "Definition" requires the largest amount of documentation and the most deliverables of any stage and it builds on information from the conceptual stage. Project work and scope is identified for each step in the project.

The scope detail includes electrical and mechanical layout, as well as civil and structural where appropriate, and the general layout of major pieces of equipment, piping, and electrical systems. A physical inspection of the planned location is recommended so that obstacles can be identified as early as possible. For LEED certification (U.S. Green Building Council's Leadership in Energy and Environmental Design), as well as for good business practice, all interactions between building systems should also be taken into consideration from this point forward. A third party "owner's agent" or "commissioning agent" is also a valuable team member who can ensure that the building is both designed and constructed in an energy efficient way and that the finished product meets the project objectives.

The initial personnel resource plan for the project should be completed as early as possible, including a decision on whether to have the project managed by in-house personnel or to use project management services provided by an outside vendor. Remaining personnel are identified iteratively during the scope refinement and activity identification stage and include core project team members, technical resource members, support members, operating department members, and outside vendor or resource team members. All personnel, titles, and general responsibilities should be summarized in a single contact document for wide distribution throughout the project and the business.

Once the project personnel are named and engaged, a communication plan is developed. The plan specifies how project information will be collected, what information will be disseminated, who the information will go to, and when the information should be communicated. A RACI chart (discussed in "Collaboration and Alignment Tools") provides structure to this communication plan throughout the project.

All project activities are planned for during the definition stage and it is critical to remember that the construction and training activities inherent in energy projects involve large numbers of people—so the human elements of the project must be considered at all times. Due diligence in definition provides a basis for all downstream work and provides important details for communication with all personnel involved in the project. This is the first stage where all people involved will have enough detail to see what the project will really look like, how it will impact them, and what steps should be taken to minimize the impact on existing business operations.

Another face of the critical human element in energy projects that carries heavy operational impact is training of the operational and maintenance personnel. Training should be planned during the definition stage and is developed by the following model:

- Step 1—Identify the new tasks and activities.
- Step 2—Identify the skills to support the Step 1 tasks.
- Step 3—Identify the knowledge and demonstration to show mastery of the Step 2 skills.
- Step 4—Identify the training required to accomplish Step 3.

Once the steps are identified, corresponding theoretical and practical project activities are incorporated into the project schedule.

Another key milestone document in this stage is the delivery plan, which includes success criteria for the project completion substages of start-up, full-going, and turnover. The success criteria are negotiated and mutually agreed to by both the project team and the business operation. The delivery plan documents what the project team is promising to provide for the operation and what the operation promises to provide for the project. When designed well, the delivery plan is a powerful communication tool that can engender agreement among all partners throughout the life of the project.

Start-up criteria are designed to demonstrate that equipment and processes can function at the engineered design rates, quality, and efficiency, usually for a normal business operating shift. Start-up is led and mainly staffed by the energy project team members with operations personnel assisting.

The full-going criteria are designed to demonstrate that the equipment, processes, and people are capable of running at the engineering design rates, efficiencies, and specified quality for 2–7 days. Full-going is led by either project team or operational personnel, but staffed by operational personnel.

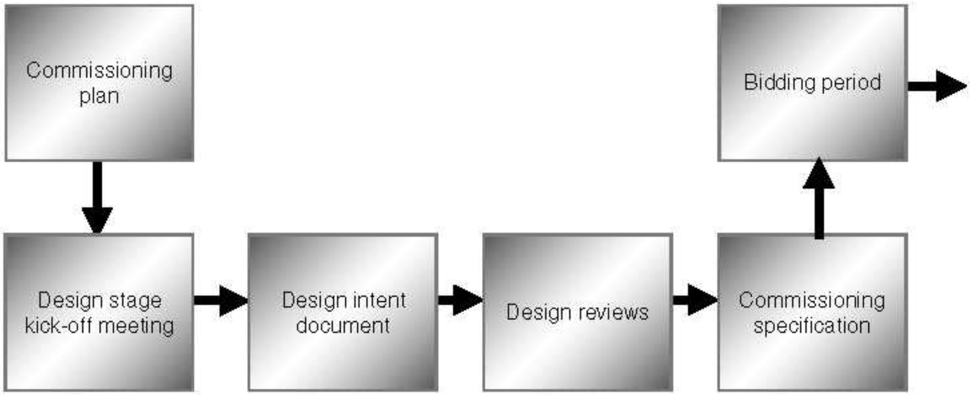

Fig. 2 Design stage commissioning activities.
Source: From Sebesta Blomberg and Associates, Inc., and Current-C Energy Systems, Inc. (see Ref. 1).

Turnover criteria additionally include the personnel performance criteria (operational and maintenance), training criteria (operational and maintenance), documentation criteria, and the resolution of any outstanding items such as study or research items. Once all of the turnover criteria are achieved, the system is turned over to the operational personnel and the project personnel's work is nearly complete; it remains only to complete any outstanding follow-up activities and conduct a project postmortem.

Also during the definition stage, a baseline project schedule should be developed with broad participation by the project team, operational personnel, outside resources, logistics resources, etc. The process used is to list the project stages and individual activities in each stage until all of the project activities are identified. The activities should then be linked to one another by identifying each activity's predecessors and successors and finally, durations should be assigned to each activity using 3-pt duration estimates (minimum, probable, maximum) to support the use of schedule risk analysis (see Ref. 2). This critical step yields an assessment of the statistical probability of completing the project by a certain time and is extremely helpful when analyzing the impact of scope or resource changes on a project.

The final steps in the definition stage are to update the cost estimate, finalize the funding strategy and methodology for the project, and determine the preferred bid structure.

Design Stage

The design stage goal involves development of designs for all equipment, processes, and systems. This stage frequently involves outside resources with expertise in detailed engineering design and often requires additional study or research in an effort to predict the operation and interaction of the full energy project on a small scale. Techniques such as pilot projects and system modeling may provide critical information as well as initial training for both project and operational and maintenance personnel and can also gain valuable input and commitment into the project. When engineers, who design the equipment and systems and know how they should operate, work with operational and maintenance personnel, who know how the equipment will really be operated, the results are sometimes surprising.

For energy projects, the interplay between initial cost and long-term expenses (utility, maintenance, and other) is also a critical part of the design stage. For example, a component with a 1-year life costing \$1000 may be upgraded to a component with a 5-year life that costs \$2000.

Energy system commissioning is the next step in design—it is the systematic process of assuring by verification and documentation from the design stage to a minimum of one year after construction that all building facility systems perform interactively in accordance with the design documentation and intent and with the owner's operational needs. Commissioning ensures that the energy project gives the business the promised results from the project including documentation, testing, and training. Specific commissioning activities are included as appropriate in the start-up, full-going, and turnover plans. Integrated design stage commissioning activities as practiced by companies such as Sebesta Blomberg are shown in Fig. 2.

Bid Preparation

It should be noted that bid preparation is an ongoing task that is parallel to the definition phase. It is treated separately here because of its complexity and importance.

The main types of bids in energy projects are design/build, fixed bid, not-to-exceed, performance bids, and hybrids. The appropriate type of bid depends upon such criteria as the type of energy project, the level of design detail, technological complications, the schedule, funding available, and complexity of the project.

Design/build bids are the best choice when scope is not well defined and there are many unknowns—either in scope or personnel experience. The disadvantage is that

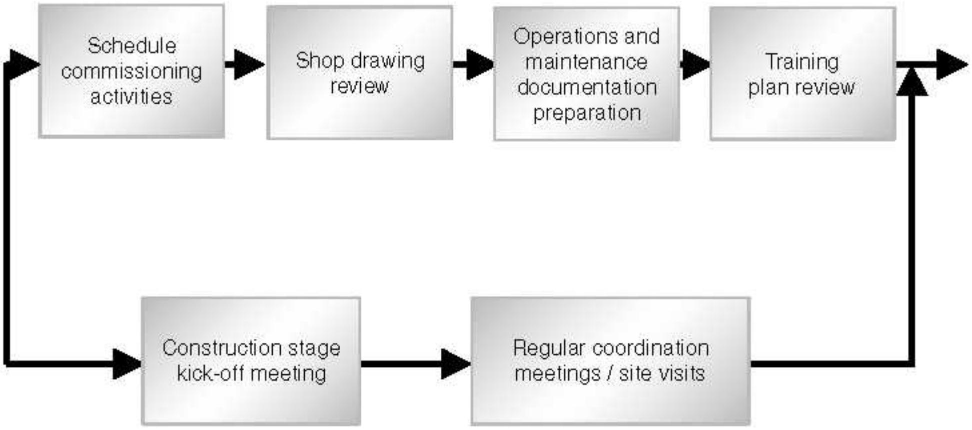

Fig. 3 Construction stage commissioning activities.
Source: From Sebesta Blomberg and Associates, Inc., and Current-C Energy Systems, Inc. (see Ref. 1).

design/build costs grow proportionally as the scope changes, with the costs passed through to the project. Consequently, the design/build bid can be the highest priced, but it provides greater flexibility to handle the issues or scope changes during the project.

Fixed bid is the best choice when the scope is well defined. There are few unknowns and project personnel are experienced enough to strongly defend and enforce the agreed upon scope of work and remove excessive contingency fees from the bid price. Scope additions or changes not requested by the operation result in those additional costs coming out of the bidder's pocket. Consequently, the fixed bid can be the lowest priced option while also providing the least flexibility.

The not-to-exceed bid is a hybrid. A project with a well-defined scope uses the fixed bid methodology and one with a less defined scope uses the design/build methodology. There is an added line item for the estimated cost of scope changes. A not-to-exceed bid is usually higher than a fixed bid, but lower than the eventual design/build bid.

Performance bid (or performance contract, "PC") is also a hybrid and combines any of the above methodologies with energy efficiency performance, which gives the supplier an incentive to ensure that the project meets the promised business objectives. In the energy project industry, an endless variety of different techniques have evolved for particular situations or needs, but they share the characteristic that the project is paid for partly based upon its adherence to prespecified performance criteria, and the contractor covers part of the risk for the project performing as promised.

Finally, the bid can also be affected by regulatory compliance and energy efficiency standards or regulations. New energy project equipment must meet the current regulatory requirements and existing equipment may have to be upgraded if it will be linked to the new equipment. ASHRAE standards for energy efficiency are used as standards in some jurisdictions, and as the U.S. Green Building Council's LEED certification and EnergyStar plaques for "high performance" or "green" buildings become more popular, those standards, processes, and procedures should also be included in the bid process.

Construction Stage

Traditionally this is when 'project management' starts, although as we have seen that it is really the fifth stage in the process. The goal of the construction stage is to build and install the equipment and processes for the project and the deliverables include schedules, resource plans, and refinements and adjustments to the communication and delivery plans.

For the detailed construction plan, the operator must decide whether to manage the construction in-house or to employ a general contractor for construction management and then choose the format for the construction schedule (number of days/week and hours/day). Once these are decided, the construction personnel needs are broken down by specific trade skills; union and nonunion workers; roles and responsibilities of core construction personnel, sub-contractors, and operational resources; and a schedule of the resources is produced.

The communication plan is updated with a plan for communicating daily and weekly construction activities and other information, including a feedback loop for rapid adjustments to construction schedule changes. Energy system commissioning activities continue, and are shown in Fig. 3.

Delivery Stage

The delivery stage can be the most chaotic stage as it includes the initial start-up, training, and turnover of the equipment and processes to the operation. The goal is to get everything started up as designed (rate, efficiency, and quality), provide training for all operational and maintenance personnel, turn over the equipment and processes, and close out the project. In a manner similar to the construction

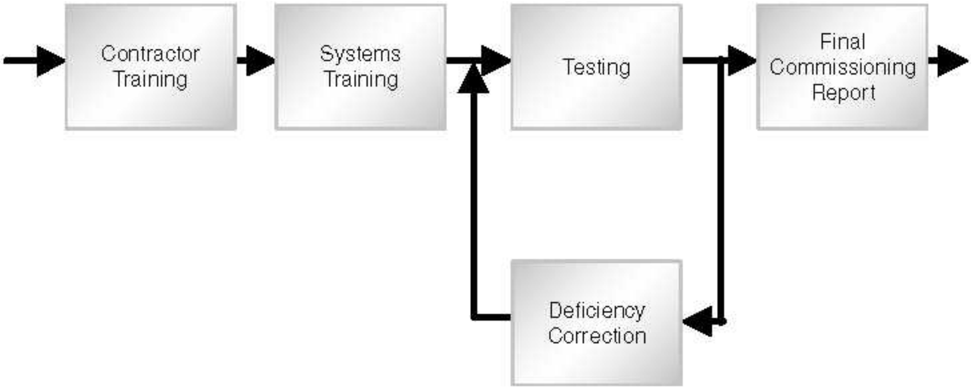

Fig. 4 Delivery stage commissioning activities.
Source: From Sebesta Blomberg and Associates, Inc., and Current-C Energy Systems, Inc. (see Ref. 1).

stage, the project delivery personnel needs are broken down by specific trade skills, roles and responsibilities, and a schedule of when each set of the personnel resources will be needed. The personnel requirements at this point are very large, especially from the ongoing operation.

The project schedule will have previously identified training activities, personnel, and schedules; start-up, full-going, and turnover activities personnel and schedules; and delivery stage commissioning activities (illustrated in Fig. 4). During the project delivery stage, those plans are followed as they have been adjusted during the previous project management stages, and the project is then completed.

Upon completion of the delivery activities, the achievement of the delivery criteria, and the turnover of the project to the operation, the project team conducts a postmortem on the project. The purpose of the postmortem is to celebrate the successes, identify the lessons learned, and to document both of these so that the next project has an even greater chance of success.

The commissioning activities extend—with the operational personnel—past the closure of the main project during the warranty period for the equipment. The postproject commissioning activities are illustrated in Fig. 5.

TOOLS FOR ENERGY PROJECT MANAGEMENT

Tools can make it easier and faster to execute project tasks, provide a standard methodology, enhance communication, and minimize confusion. The following are examples of typical tools used during energy projects.

Scope Tools

The first set of tools help manage energy project scope and provide documentation for both the equipment included in the project and for the activities that the project team will perform during the project. They include:

- Project brief.
- Project charter.
- Start-up, full-going, turnover.
- Scope change management.

The project charter, introduced in "Conceptual Stage", defines the project and provides a means to secure both understanding and commitment from all stakeholders. A sample format is shown in Fig. 6.

As the project proceeds, the start-up, full-going, turnover tool is the most important communication tool between the formal project team and the business operation. It documents the agreements between the two organizations regarding equipment performance, system performance, training completion, etc. and it is the basis for declaring portions of the project complete and for releasing project personnel. This tool must be created specifically for each project, but an example is shown in Fig. 7. For each process, the tool lists the project equipment and processes and determining performance criteria for the start-up, full-going, and turnover.

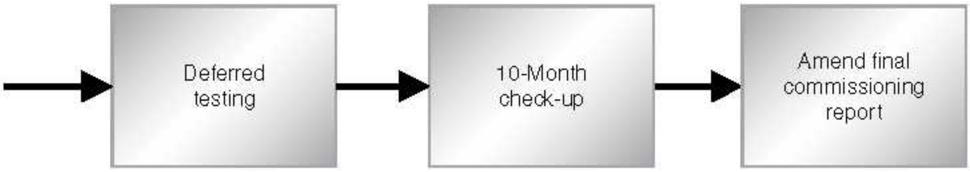

Fig. 5 Warranty period commissioning testing.

Scope management is an ongoing challenge as scope change requests come from all personnel involved in the project. Criteria should be established to sort out small, inconsequential change requests from larger ones having greater impact and a standardized scope change tool should be developed for approval and documentation. For larger change requests, a formal review should evaluate the change's impact on the project's cost, schedule, and other related systems. Its impact on the schedule can then be quantitatively evaluated using a schedule risk analysis.

START-UP, FULL-GOING, TURNOVER TOOL			
	Start-up criteria	Full-going criteria	Turnover criteria
Process #1- includes Equipment #1 and Equipment #2	Run 8 continuous hours at 80% efficiency, producing 90% quality	Run 7 continuous days, 24 hours/day at 85% efficiency, producing 95% quality	- Start-Up and Full-Going criteria are met. - Operational and maintenance personnel trained and qualified on required skills. - Equipment documentation and files established and in the operation including (drawings, manuals, spare parts lists, etc.).

Fig. 7 An example of the start-up, full-going, turnover tool.

Scheduling Tools

The scheduling tools for energy projects are generally computerized and include two basic types—project scheduling software and schedule risk analysis software. Project scheduling programs project the project delivery date by linking together individual activity durations and dates from the project team to create a critical path schedule. With such a program, the impact on the schedule end date caused by interim changes becomes very clear.

After a project schedule has been created, it can be analyzed for schedule risk. Even though traditional critical path schedules are designed to show the most important activities in the project schedule, they do not take uncertainty into account. Consequently, if activities do not occur as predicted, the critical path may change, and with it the focus of the project team (see Ref. 2).

Schedule risk analysis uses 3-pt duration estimates for each activity (minimum, probable, and maximum), creating a distribution of durations for each activity. The analysis is conducted by using statistical techniques to create a new distribution of project end dates and probabilities, quantifying the probability of completing the project on time.

More importantly, for each simulation, the critical path, the critical path activities, and the activities that most effect the project end date are noted and summarized as they are calculated. From schedule risk analysis, they remain the important activities even as the project schedule changes. The project manager therefore has fewer key activities to focus on for the successful delivery of the project.

Collaboration and Alignment Tools

One of the challenges during an energy project where systems and variables are interactive is the volume of information and the number of decisions handled each and every day. No individual can be involved in every aspect of the project, and a tool such as RACI helps prevent gaps and overlaps in project team activities. RACI stands for:

- Responsible—who owns the project or the problem.
- Accountable—who must sign-off or approve the activity, and who the responsible person reports to.
- Consult—who provides input but isn't responsible for the activity.
- Inform—who needs be told but not consulted about the activity.

To use the RACI tool, identify the areas of decisions or tasks/activities involved in the energy project, identify the roles involved in the project, and complete the tool by filling in the Rs, As, Cs, and Is. Ideally, for any individual activity, only one person should have the 'R.' As the tool is

	Project sponsor	Project manager	Operation resource	Technical resource	Support resource
Project activity #1	A	R	I	C	I
Project activity #2	R	C	C	C	I
Project activity #3	C	C	R	I	C

Fig. 8 RACI chart.
Source: From Legacy business records project-library and archives Canada, 2005.

completed for each activity, task gaps and overlaps become quickly visible—allowing the project team to resolve them (Fig. 8).

SKILLS FOR ENERGY PROJECT MANAGEMENT

The energy project manager needs both technical project management skills and people project management skills to deliver a project on time, on budget, and with excellence.

Technical Project Management Skills

The technical project management skills have a long history and are well understood, and they include:

- Scope definition.
- Scope management.
- Scheduling.
- Cost management.

These skills are critical to managing the nuts and bolts of the project. Training for the technical project management skills is wide-spread and readily available from such organizations as the Association of Energy Engineers (AEE) and others. For this reason, technical skills are not addressed in this paper.

Personnel Management Skills

As project circumstances change, people skills can add a new layer of effectiveness for a project manager. For energy efficiency projects where multiple technical disciplines are included as core parts of the team, people skills are even more critical. Energy project managers must be skilled at choosing their project team, gaining commitment to the project, and resolving conflict (see Ref. 3).

The first critical decision is the composition of the project team. Each individual's qualifications, skills, attitude, and commitment should all be considered. For example, a person who has great technical skills but who treats team members poorly should be considered only after careful thought as to the amount of time the project manager is willing to spend listening to complaints and refereeing between team members, and contingency plans should be developed to minimize problems. Unresolved people issues tie up personnel and their productivity, slowing down both the quality and the completion of the project.

The energy project manager should also evaluate the team's communication and people skills. A good project team can produce trust and handle confrontation. It can almost be said that the team becomes the human representation of the project and it must be trained and prepared to handle people responsibilities as competently as technical responsibilities.

One key for energy project managers is gaining the commitment and cooperation of the operational personnel. Gaining commitment to a project is a process, not an initial announcement followed by informational updates. People go through a predictable process in becoming committed to something and the faster the project manager can recognize the process, the faster they can foster commitment.

When a new energy project is first proposed, the stakeholders, project team, and operational people all have an emotional reaction, although the reactions vary and change as they find out more about the project and its impact. If the project provides them with tangible benefits, they become committed very quickly. For many people, however, the stated benefit is a positive business benefit with no obvious personal impact. Consequently, the typical first reactions are either indifference or anger, and the energy manager should never confuse indifference with commitment.

Indifference is characterized by a "wait and see" attitude and when comments like "I've seen all of this before and I'll see it again" or "Hmm—we'll just see if they really can do what they say they can do" are made. As people progress through indifference, they often become angry and focus that anger on the energy project manager who is the visible symbol of the project. Complaints fly and the project is described as "terrible". The project manager must at this point remain positive and committed, which can be a challenge as it often seems few people are on his or her side. The project manager can even be tempted to avoid conversations with those who are angry, hoping that avoidance and time will smooth away their anger. Unfortunately, this is usually counterproductive, as motives are created to explain the project manager's avoidance and the situation spirals down.

Paradoxically, it is at this point that project managers have an opportunity to listen and learn. At the time, listening is likely to seem like the long, slow way to move the project forward but, once people feel they have been heard, they often move from saying "the entire project is awful", to "the project won't work because…". The "because" is very important, and it is important that the project manager hear and recognize this change in order to actively involve people and bring them the rest of the way to commitment. Once they agree to help be part of solving the "because", they are committed to the project. Energy projects bring change, and change always causes conflict. The project manager must be the first one to pull out a hidden conflict and set it squarely on the table for resolution. He or she must be completely intolerant of arguments vs. resolution and expect the same from the entire team.

CONCLUSION

Today's energy project manager needs to understand the plan, the tools, and the skills necessary to successfully manage the complete energy project—from costs and schedules to conflict resolution and commitment. A well-defined project management plan sets out a path that defines, creates, measures, and documents success. Using project management tools makes the process easier and leaves a trail of documentation regarding project decisions. A project manager with both technical and human skills is able to effectively manage both scope and people issues, saving time and money. Whether the project is managed in-house or a contract energy project manager is used, these three areas provide the energy project manager with what is needed to successfully deliver an energy project.

Energy Service Companies: Europe

Silvia Rezessy

Abstract
Energy service companies (ESCOs) are important agents to promote energy efficiency improvements. This entry attempts to address a major gap identified in the process of conducting the first in-depth survey of ESCO businesses in Europe: the lack of common understanding and terminology related to types of energy service providers, contractual and financing terms, and the implications of different models. It provides the key terminology related to energy services, ESCOs, contractual models, and financing structure.

INTRODUCTION

Energy service companies (ESCOs) are important agents to promote energy-efficiency improvements. The initial ESCO concept started in Europe more than 100 years ago and then moved to North America. In the past decade, Europe has seen an increased interest in the provision of energy services that has been driven by electricity and gas restructuring and the push to bring sustainability to the energy sector. The actual market for energy-efficiency services in Western Europe was estimated to be 150 million euro per annum in 2000, while the market potential for Western Europe was estimated to be 5–10 billion euro per annum (these estimates are according to our definitions of ESCO, energy performance contracting (EPC), and third-party contracting (TPF) (see definitions later), and do not include energy supply) (Bertoldi et al. 2003 and references herein).[2,14] A survey of the U.S. ESCO industry estimates ESCO industry project investment reaching $1.8–$2.1 billion U.S. in 2000, with industry revenue growing at 9% per year in the period 1996–2000—down from almost 25% in the previous 5 years.[6]

This entry attempts to address a major gap identified in the process of conducting the first in-depth survey of ESCO businesses in Europe: the lack of common understanding and terminology related to types of energy service providers, contractual and financing terms, and the implications of different models. It provides the key terminology related to energy services, ESCOs, contractual models, and financing structure, pointing at the implications of different choices.

This entry uses terminology agreed upon after a long process of consultation undertaken in 2004 (the entire report is available for free download at http://energyefficiency.jrc.cec.eu.int/pdf/ESCO%20report%20final%20revised%20v2.pdf) and early 2005 with major stakeholders in Europe and the United States. The entry builds on the status report "ESCOs in Europe," published in 2005 by Directorate General Joint Research Center of the European Commission. The report has covered the 25 member states of the European Union (EU), the New Accession countries Bulgaria and Romania, Switzerland, and Norway.[1]

ENERGY SERVICES, ENERGY SERVICE COMPANIES, AND PROJECT ELEMENTS

Energy services include a wide range of activities, such as energy analysis and audits, energy management, project design and implementation, maintenance and operation, the monitoring and evaluation of savings, property/facility management, energy and equipment supply, and provision of service (space heating/cooling, lighting, etc.).

Consultant engineering companies specialized in efficiency improvements, equipment manufacturers, energy suppliers or utilities, which provide energy services for a fixed fee to final energy users or as added value to the supply of equipment or energy, are referred to as *Energy Service Provider Companies (ESPCs)* (note that this is a very different use of the acronym ESPC common in North America, where it means energy service performance contracting). Energy service provider companies may have some incentives to reduce consumption, but these are not as clear as in the ESCO approach (see explanations below). Often, the full cost of energy services is recovered in the fee, so the ESPC does not assume any risk in case of underperformance. Energy service provider companies are

Keywords: Energy service companies; Energy performance contracting; Financing models.

paid a fee for their advice/service rather than being paid based on the results of their recommendations.[13] Principally, projects implemented by ESPCs are related to primary energy conversion equipment (boilers, combined heat and powers [CHPs]). In such projects, the ESPC is unlikely to guarantee a reduction in the delivered energy consumption because it may have no control of or ongoing responsibility for the efficiency of secondary conversion equipment (such as radiators, motors, and drives) and no control of the demand for final energy services (such as space heating, motive power, and light).[12]

Energy service companies also offer these same services. Energy service companies are fundamentally different from ESPCs, and ESCOs' activities can be distinguished from ESPCs' activities in the following ways:

- Energy service companies in Europe guarantee the energy savings and the provision of the same level of energy service at a lower cost by implementing an energy-efficiency project (in North America, ESCOs do not necessarily guarantee energy savings. If they do, the document that specifies this guarantee is called an energy savings performance contract). A performance guarantee can take several forms. It can revolve around the actual flow of energy savings from a project; it can stipulate that the energy savings will be sufficient to repay monthly debt service costs for an efficiency project; or it can stipulate that the same level of energy service will be provided for less money.
- The remuneration of ESCOs is tied directly to the energy savings achieved.
- Energy service companies typically finance (or assist in arranging financing) the installation of an energy project that they implement by providing a savings guarantee.
- Energy service companies may retain an ongoing operational role in measuring and verifying the savings over the financing term.

Typically, a project developed and implemented by an ESCO includes the following elements/steps:

- Site survey and preliminary evaluation
- Investment-grade energy audit
- Identification of possible energy-saving and efficiency-improving actions
- Financial presentation and client decision
- Guarantee of the results by proper contract clauses
- Project financing
- Comprehensive engineering and project design and specifications
- Procurement and installation of equipment; final design and construction
- Project management, commissioning, and acceptance
- Facility and equipment operation and maintenance for the contract period
- Purchase of fuel and electricity (to provide heat, comfort, light, etc.)
- Measurement and verifications (M&V) of the savings results.

The investment-grade audit (IGA) deserves special attention. The traditional energy audit does not sufficiently consider how implemented measures will behave over time. Because auditors must consider the conditions under which measures will function during the life of the project, an IGA builds on the conventional energy audit. Unlike the traditional energy audit, which assumes that all conditions (related to system, payback, and people) remain the same over time, an IGA attempts to predict a building's energy use more accurately by adding the dimension of a risk assessment component, which evaluates conditions in a specific building or process. Aspects of the IGA include risk management, the "people" factor, M&V, financing issues, report presentation guidelines, and master planning strategies.[9]

FINANCING OPTIONS

Three broad options for financing energy-efficiency improvements can be distinguished. The approach to financing is just one factor that shapes the structure of an EPC. Other factors relevant for the type of financing arrangements and repayment structures include the allocation of risks, the services contracted, and the length of the contract.[11]

Energy service company financing refers to financing with internal funds of the ESCO; it may involve use of its own capital or funding through debt or lease instruments. Energy service companies rarely use equity for financing, as this option limits their capability to implement projects on a sustainable basis.

Energy-user/customer financing usually involves financing with internal funds of the user/customer backed by an energy savings guarantee provided by the ESCO. For instance, a university can use its endowment fund to finance an energy project, in which the energy savings are guaranteed by an ESCO. Energy-user/customer financing may also be associated with borrowing in the case when the energy user/customer, as a direct borrower, has to provide a guarantee (collateral) to the finance institution. The provision of collateral by the consumer itself is what distinguishes customer financing from third-party financing (TPF).

Third-party financing refers mostly to debt financing. As its name suggests, project financing comes from a third party (e.g., a financial institution) and not from internal funds of the ESCO or of the customer. The finance institution may either assume the rights to the energy savings or take a security interest in the project equipment.[13] Two conceptually different TPF arrangements are associated with EPCs, and the key difference between them is which party borrows the money: the ESCO or the client.

- The first option is that the ESCO borrows the financial resources necessary for project implementation.
- The second option is that the energy-user/customer takes a loan from a financial institution, backed by an energy savings guarantee agreement with the ESCO. The purpose of the savings guarantee is to demonstrate to the bank that the project for which the customer borrows will generate a positive cash flow (i.e., that the savings achieved will certainly cover the debt repayment). Thus, the energy savings guarantee reduces the risk perception of the bank, which has implications for the interest rates at which financing is acquired. The cost of borrowing is strongly influenced by the size and credit history of the borrower.

When the ESCO is the borrower, the customer is safeguarded from financial risks related to the project's technical performance because the savings guarantee provided by the ESCO is either coming from the project value itself or is appearing on the balance sheet of the ESCO; hence, the debt resides on someone else's balance sheet (ESCO's or financial institution's). Both public and private customers can benefit from off-balance-sheet financing because the debt service is treated as an operational expense and not a capital obligation; therefore, debt ratings are not impacted. For highly leveraged companies, this is important, because the obligation not showing up on the balance sheet as debt means that company borrowing capacity is freed.[10] However, different countries apply various conditions that need to be met for financing to be viewed as an operating lease, for example. Unless those conditions are met, financing is automatically considered to be a capital lease. Therefore, parties seeking financing first need to inquire about the country-specific conditions for operational financing.

Large ESCOs with deep pockets (hence, high credit ratings) have started to prefer TPF to their own funds because their costs of equity financing and long-term financing are often much greater than what can be accessed in the financial markets. Also, if an ESCO arranges TPF, its own risk is smaller. This would allow for a lower cost of money for the same level of investment, so more money would be assigned to the project.[8] The cost associated with nonrecourse project financing by a third party (e.g., one in which project loans are secured only by the project's assets) is the highest, as it entails more risk and, hence, higher interest rates.[13]

Furthermore, as already mentioned, equity contributions from the ESCO are often deemed undesirable by ESCOs, as they tie up capital in a project. This emphasizes the fundamental concept that an ESCO is a service company and not a bank or a leasing company. The primary reason that ESCOs do not and should not provide project financing with internal funds is that it makes their balance sheets look like they are banks and not a service companies. Local practices, the inability of customers to meet financiers' creditworthiness criteria, and costs of equity financing are some of the factors that determine whether ESCOs will provide financing (debt or equity).[8] Small or undercapitalized ESCOs, which cannot borrow significant amounts of money from the financial markets, prefer their role not to be financing energy-efficiency investment.

ENERGY PERFORMANCE CONTRACTING MODELS

Energy performance contracting is a form of creative financing for capital improvement that allows funding energy-efficiency upgrades from cost reductions. Under an EPC arrangement, an external organization (ESCO) develops, implements, and finances (or arranges financing for) an energy-efficiency project or a renewable energy project and uses the stream of income from the cost savings or the renewable energy produced to repay the costs of the project, including the costs of the investment. Essentially, the ESCO will not recover all of its costs unless the project delivers all of the energy savings guaranteed. The approach is based on the transfer of technical risks from the client to the ESCO based on performance guarantees given by the ESCO. In EPC, ESCO remuneration is based on demonstrated performance; a measure of performance is the level of energy or cost savings, or the level of energy service. Therefore, EPC is a means to deliver infrastructure improvements to facilities that lack energy-engineering skills, manpower or management time, capital funding, an understanding of risk, or technology information. Cash-poor yet creditworthy customers, therefore, are good potential clients for EPC. Fig. 1 illustrates the EPC concept.

Energy performance contracting is usually distinguished from energy supply contracting (delivery contracting) that is focused on the supply of a set of energy services (e.g., heating, lighting, motive power) mainly via outsourcing the energy supply. Chauffage (see details later in this entry) includes supply contracting. In contrast, EPC typically targets savings in production and distribution.

Energy performance contracting is risk management and effective ESCOs have learned to use project financial structures to help manage the risks. Below we examine different contracting models and the conditions under which they deliver at their potential.

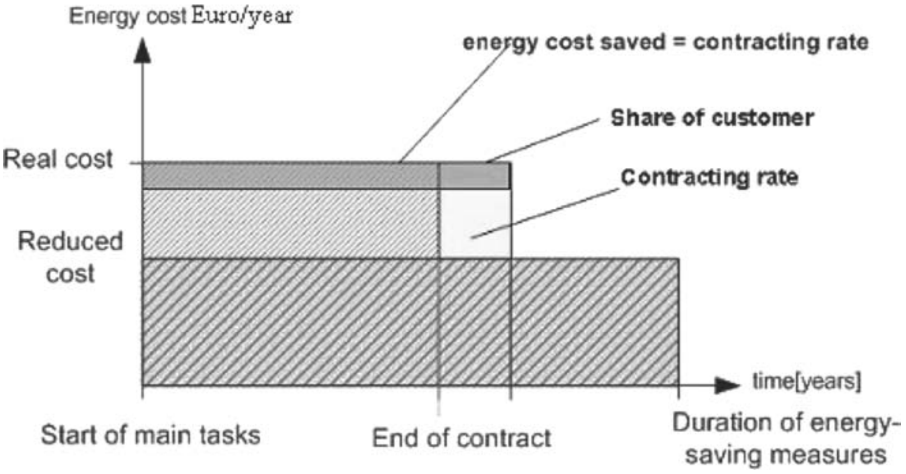

Fig. 1 Energy performance contract. *Note: Note that on this graph, real cost refers to the initial cost, while the contracting rate depicts the cost savings, which in this case are shared between the customer and the energy service company (ESCO) (see the explanation on shared savings). Source: From Berlin Energy Agency.

Guaranteed Savings and Shared Savings

Fig. 2 illustrates the relationships and risk allocations among the ESCO, customer, and lender in the two major performance contracting models: shared savings and guaranteed savings. Brief descriptions are also given. An important difference between guaranteed and shared savings models is that in the former case, the performance guarantee is the level of energy saved, whereas in the latter, this is the cost of energy saved.[7,11]

Under a guaranteed savings contract, the ESCO assumes the entire design, installation, and savings performance risks but does not assume credit risk of repayment by the customer. Consequently, guaranteed savings contracts are not usually applicable to ESCO financing provided internally or through TPF with ESCO borrowing. The projects are financed by the customers, who can also obtain financing from banks, from other financing agencies, or a TPF entity. The key advantage of this model is that it provides the lowest financing cost because it limits the risks of the financial institutions to their area of expertise, which is assessing and handling customers' credit risk. The customer repays the loan and assumes the investment repayment risk (the financing institution [FI], of course, always has some risk for loan nonpayment. The assessment of a customer's credit risk is done by the FI; it is one of the factors that define interest rates). If the savings are not enough to cover debt service, the ESCO has to cover the difference. If savings exceed the guaranteed level, the customer typically pays an agreed-upon percentage of the savings to the ESCO (however, changes in energy consumption (e.g., business expansion or changes of processes or production lines) are likely to bring increased energy that can deteriorate the targets. Conversely, a contraction of business (e.g., an empty wing of a hotel) or a smaller production output will result in energy savings. Therefore, crucial issues to consider involve setting the baselines and associated growth projections, setting the system boundary and conditions, and preventing leakages. A clause in the contract that allows either party to reopen and renegotiate the baseline to reflect current conditions can solve this problem).

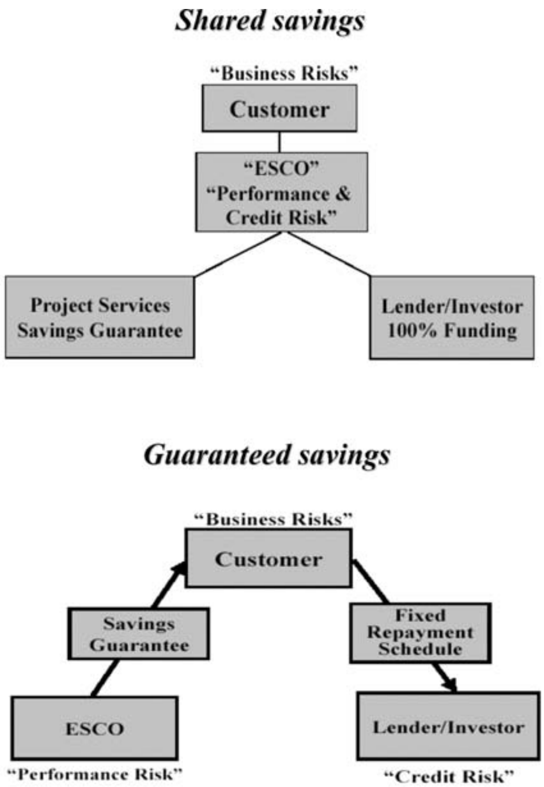

Fig. 2 Major types of performance contracting models/ repayment options. Under a shared savings contract, the cost savings are split for a predetermined length of time in accordance with a prearranged percentage. There is no standard split, as this depends on the cost of the project, the length of the contract, and the risks taken by the energy service company (ESCO) and the consumer. Under a guaranteed savings contract, the ESCO guarantees a certain level of energy savings and in this way shields the client from any performance risk.
Source: From Joint Research Centre, European Commission (see Ref. 4).

Energy Eff–Serv

Usually, the contract also contains a proviso that the guarantee is good (i.e., the value of the energy saved will be enough to meet the customer's debt obligation) provided that the price of energy does not go below a stipulated floor price (performance contracting is risk management, and dropping fuel prices—such as those experienced in North America in 1986—gave rise to this provision. We are indebted to Shirley Hansen for this clarification).[8] A variation on guaranteed savings contracts is pay-from-savings contracts, whereby the payment schedule is based on the level (percentage) of savings: the more the savings, the quicker the repayment.[13]

The guaranteed savings scheme is likely to function properly only in countries with an established banking structure, high degree of familiarity with project financing, and sufficient technical expertise, also within the banking sector, to understand energy-efficiency projects (e.g., in the United Kingdom; Austria; and, more recently, Hungary). The guaranteed savings concept is difficult to use in introducing the ESCO concept in developing markets because it requires customers to assume investment repayment risk. However, guaranteed savings foster long-term growth of ESCO and finance industries.[4] Newly-established ESCOs with no credit histories and limited resources would be unable to invest in the projects they recommend and might enter the market only if they guarantee the savings and the client secures the financing on its own.

In the United States, the guaranteed savings model evolved from the shared savings model in response to customers' desire to significantly reduce financing costs in exchange for accepting more risk due to their increased comfort with energy savings technologies. It also was initiated by smaller ESCOs and fostered by financial institutions to allow them to grow their respective industries. The primary benefit of this structure is that its reduced financing cost enables many more project investments to be made for the same debt service level. The public sector normally prefers this structure to maximize the amount of infrastructure investment made in its facilities from an EPC.

Conversely, under a shared savings model, the ESCO assumes both performance and credit risk. This is why a shared savings contract is more likely to be linked with TPF; ESCO financing; or a mixed scheme, with financing coming from the client and the ESCO whereby the ESCO repays the loan and takes over the credit risk. The ESCO therefore assumes both performance and the underlying customer credit risk; if the customer goes out of business, the revenue stream from the project will stop, putting the ESCO at risk.[13] Unfortunately, such a contractual arrangement may create leveraging and increased capital requirement problems for ESCOs because ESCOs become too indebted, and at some point financial institutions may refuse lending to an ESCO due to a high debt-to-equity ratio (experience in the United States shows that lenders tend to require a variety of credit enhancements for this type of financing, such as bonding or insurance[13]). In effect, the ESCO collateralizes the loan with anticipated savings payments from the customer based on a share of the energy cost savings. The financing in this case goes off the customer's balance sheet (under off-balance-sheet financing, also called nonappropriation financing, financiers hold title to equipment during the term of the agreement. Furthermore, to avoid the risk of energy price changes, it is possible to stipulate in the contract a single energy price. In this situation, the customer and the ESCO agree on the value of the service up front, and neither side gains from changes in energy prices. If the actual prices are lower than the stipulated floor value, the consumer has a windfall profit, which compensates the lower return of the project; conversely, if the actual prices are higher than the stipulated ceiling, the return on the project is higher than projected, but the consumer pays no more for the project. In effect, this variation sets performance in physical terms with fixed energy prices, which makes the approach resemble guaranteed savings[11]). A situation where savings exceed expectations should be taken into account in a shared savings contract. This setting may create an adversarial relationship between the ESCO and the customer[7] whereby the ESCO may attempt to lowball the savings estimate and then receive more from the excess savings (deliberate estimation of the lower value of savings is not restricted to the shared savings model; it is a standard practice for the ESCO to secure itself for the guaranteed performance with some buffer. The real questions are how big this buffer/cushion is and how the "excess" savings above the estimated ones are split between the client and the ESCO).[11]

The shared savings concept is a good introductory model in developing markets because customers assume no financial risk (the customers may have different reasons to be reluctant to assume financing, even if the cost of capital is higher for ESCOs than for customers. Among the reasons are adversity to assuming debt, borrowing limits, and budgetary restraints[11]). From the ESCO's perspective, the shared savings approach has the added value of the financing service.[11] However, this model tends to create barriers for small companies; small ESCOs that implement projects based on shared savings rapidly become too highly leveraged and unable to contract further debt for subsequent projects.[8,11] Shared savings concepts therefore may limit long-term market growth and competition between ESCOs and between FIs. For instance, small or new ESCOs with no previous experience in borrowing and with few resources are unlikely to enter the market if such agreements dominate.[3,4] It focuses the attention on projects with short payback times ("cream skimming"). Table 1 summarizes the features of the guaranteed and shared savings models.

Table 1 Guaranteed savings and shared savings: a comparison

Guaranteed savings	Shared savings
Performance related to level of energy saved	Performance related to cost of energy saved
Value of energy saved is guaranteed to meet debt service obligations down to a floor price	Value of payments to energy service companies (ESCO) is linked to energy price
Energy service companies carries performance risk energy user/customer carries credit risk	Energy service companies carries performance and credit risk as it typically carries out the financing
If the energy user/customer borrows, then debt appears on its balance sheet	Usually off the balance sheet of energy user/customer
Requires creditworthy customer	Can serve customers that do not have access to financing, but still requires a creditworthy customer
Extensive measurement and verification (M&V)	Extensive M&V
Energy service companies can do more projects without getting highly leveraged	Favors large ESCOs; small ESCOs become too leveraged to do more projects
More comprehensive project scope due to lower financing costs	Favors projects with short payback ('cream skimming') due to higher financing costs

Source: From Refs. 4,7,8 and 11.

Other Contracting Models

While there are numerous ways to structure a contract—hence, any attempt to be comprehensive in describing contracting variations is doomed—other contractual arrangements deserve some attention. Here, we describe the chauffage contract, the first-out contract, the build-own-operate-transfer (BOOT) contract, and the leasing contract.

A very frequently used type of contract in Europe is the chauffage contract, in which an ESPC or an ESCO takes over complete responsibility for the provision to the client of an agreed set of energy services (e.g., space heat, lighting, motive power). This arrangement is a type of supply-and-demand contract, and in effect it is an extreme form of energy management outsourcing. Where the energy supply market is competitive, the ESCO in a chauffage arrangement also takes over full responsibility for fuel/electricity purchasing. The fee paid by the client under a chauffage arrangement is calculated on the basis of its existing energy bill minus a percentage saving (often in the range of 5%–10%), or a fee may be charged per square meter of conditioned space. Thus, the client is guaranteed an immediate saving relative to its current bill. The ESCO takes on the responsibility of providing the improved level of energy service for a reduced bill. The more efficiently and cheaply it can do this, the greater its earnings. Chauffage contracts give the strongest incentive to ESPCs or ESCOs to provide services in an efficient way.

Chauffage contracts are typically very long (20–30 years), and the ESCO provides all the associated maintenance and operation during the contract. Chauffage contracts are very useful where the customer wants to outsource facility services and investment.[13] Such contracts may have an element of shared savings in addition to the guaranteed savings element to provide incentives for the customer. For instance, all savings up to an agreed figure would go to the ESCO to repay project costs and return on capital; above this, savings will be shared between the ESCO and the customer.

Another variation is the first-out approach, whereby the ESCO is paid 100% of the energy savings until the project costs—including the ESCO profit—are fully paid. The exact duration of the contract will actually depend on the level of savings achieved: the greater the savings, the shorter the contract.[5]

A BOOT model may involve an ESCO designing, building, financing, owning, and operating the equipment for a defined period of time and then transferring this ownership across to the client. This model resembles a special-purpose enterprise created for a particular project. Clients enter into long-term supply contracts with the BOOT operator and are charged accordingly for the service delivered. The service charge includes capital and operating-cost recovery and project profit. BOOT schemes are becoming an increasingly popular means of financing CHP projects in Europe.

Leasing can be an attractive alternative to borrowing because lease payments tend to be lower than loan payments. This method is commonly used for industrial equipment. The client (lessee) makes payments of principal and interest, and the frequency of the payments depends on the contract. The stream of income from the cost savings covers the lease payment. The ESCO can bid out and arrange an equipment lease-purchase agreement with a FI. If the ESCO is not affiliated with an equipment manufacturer or supplier, it can bid out, make suppliers' competitive analysis, and arrange the equipment.

There are two major types of leases: capital and operating. Capital leases are installment purchases of equipment. In a capital lease, the lessee owns and depreciates the equipment and may benefit from associated tax benefits. A capital asset and associated liability appears on the balance sheet. In an operating lease, the owner of the asset (lessor—the ESCO) owns the equipment and essentially rents it to the lessee for a fixed monthly fee. This is an off-balance-sheet financing source. It shifts the risk from the lessee to the lessor but tends to be more expensive for the lessor. Unlike in capital leases, the lessor claims any tax benefits associated with the depreciation of the equipment. The nonappropriation clause means that the financing is not seen as debt.

CONCLUSION

This entry has provided a concise overview of the key terminology related to energy service provision in Europe. It is the belief of the authors that the existence of standard, undisputed, and commonly used terms will facilitate the demand for, and ultimately the deployment of, more energy services.

An important step to securing the long-term credibility of energy efficiency is the ability to verify reduced consumption. To help end users and the financial community better understand EPC and gain confidence in the return on investment, it would be extremely beneficial to standardize savings M&V procedures. While the development of standard M&V has been an elusive task in Europe, as various companies consider their approaches unique and proprietary rather than developing a single standard, energy-service agreement efforts may be channeled toward agreeing upon a standard language for a set of key contract provisions, such as insurance, equipment ownership, and purchase options, which will allow standard contract forms to be built up gradually.

Due to space limitations, this entry has presented a fraction of the findings of the ongoing survey of ESCOs in Europe. Further information—including a concise review of the current status of the ESCO industry in Europe—on the project specifics of the most common types of activities and of the features of the ESCO industry in selected EU member states is available, together with an outline of the key factors of success of national ESCO industries and a list of suggested strategic actions needed to increase the deployment of ESCOs in Europe.[1]

ACKNOWLEDGMENTS

The authors would like to acknowledge the contributions toward working out often dubiously interpreted ESCO terminology for the "ESCOs in Europe" status report 2005 of Shirley Hansen, Thomas Dreessen, Pierre Langlois, and Anees Iqbal. The authors would like to thank all national and international experts who provided input to the survey and responded to our questions—and, of course, all ESCOs that provided information that was used for the analysis in the "ESCOs in Europe" report.

Energy Star® Portfolio Manager and Building Labeling Program

Bill Allemon
North American Energy Efficiency, Ford land, Dearborn, Michigan, U.S.A.

Abstract
This entry on the ENERGY STAR Portfolio Manager and building-labeling program acts as a single resource for first-time users of this energy benchmarking application from the U.S. Environmental Protection Agency's ENERGY STAR program. The entry provides background on the need for energy benchmarking, development of the Portfolio Manager application, and typical uses. Details regarding applicability of the tool, benchmarking requirements, and energy data normalization are included. The entry reviews the ENERGY STAR building-labeling program and requirements to apply for the building label. Last, additional uses of the application's results and additional related ENERGY STAR tools are included.

INTRODUCTION

Demand for accurate energy efficiency benchmarking increases as energy, labor, and other facility costs continue to rise. A number of benchmarking tools exist to access the energy efficiency of select facilities, but few are as comprehensive and widely adopted as Portfolio Manager, available from the U.S. Environmental Protection Agency (EPA)'s ENERGY STAR program.

This entry provides a general overview of the uses and applicability of Portfolio Manager. It is not intended to be a comprehensive user's guide explaining each individual data input screen or to be a technical narrative of the tool's statistical analysis method; neither does it attempt to act as a replacement for the extensive support and resources available through ENERGY STAR. It provides the user a solid understanding of the uses and benefits of the tool, offers tips on how to get started, and acts as a guide through the vast library of support materials and documents available at the ENERGY STAR web site. If there is one area of weakness in Portfolio Manager, it is the lack of a single, comprehensive user's manual.

BACKGROUND

ENERGY STAR is a program funded by the U.S. government and administered by the EPA, in partnership with the U.S. Department of Energy (DOE), to reduce the nation's consumption of energy by facilities and industrial processes. The program's main goal is to lower significantly the emission of greenhouse gases—specifically carbon dioxide (CO_2)—by reducing energy consumption. ENERGY STAR provides tools, resources, and support to a wide variety of markets, including residential, commercial, retail, industrial, and many others. ENERGY STAR is the leading contributor to the development and establishment of energy efficiency standards for home appliances; most U.S. consumers recognize the ENERGY STAR logo from retail shopping. The ENERGY STAR program facilitates a number of industry focus groups, in which manufacturers can come together in a noncompetitive environment to improve the energy efficiency of their industrial sector. The success of these focus groups is evidenced by the number of industry-specific tools and best practices generated by these sessions. More information on industry-specific groups can be found on the ENERGY STAR Web site.

The Need for Energy Benchmarking

Rising energy costs and increased competition are driving facility and property managers to evaluate every aspect of fixed and variable costs. Having a common measure of efficiency is essential so that all users within an industry are using the same standard of measure. Benchmarking tools must be accurate, recognized, and accepted by each industry, and must use a common industry baseline. The means and methods used in normalizing and analyzing data must also be standardized; otherwise, each user will have an inaccurate representation of his or her facility's efficiency relative to the industry as a whole.

Obtaining accurate competitive data can be extremely difficult, as is finding applicable energy modeling methods. Even if the user can gain access to competitive data, several methods exist to analyze facility data and normalize variances. A variety of methods exist to filter out the effect of significant influencers, such as weather, high-intensity

Keywords: ENERGY STAR; Building; Label; Certification; Benchmarking; EPA; Portfolio manager; Commercial.

loads, and facility use. When comparing one facility with others, it's important to use consistent analysis methodology to ensure predictable and accurate results. Each statistical model has its own limitations and caveats. An excellent technical reference regarding energy modeling is Measuring Plant-Wide Energy Savings, by Dr Kelly Kissock and Carl Edgar of the University of Dayton.[1]

After the issue of benchmarking accuracy is addressed, its applicability and many uses can be discussed. Benchmarking can identify whether energy is being wasted and, if so, how much. Quantifying the amount of energy waste provides a valuable number to the facility manager; it tells the manager up front how much load must be removed for the building to reach an identified level of efficiency. Without this value, a facility manager must find the value through trial and error, reducing consumption wherever he or she can, while waiting until a new set of energy data is collected and the results are analyzed.

Buildings can also be benchmarked against themselves to identify whether efficiency is improving, staying within limits, or getting worse. This method can also identify whether an energy reduction project has indeed met its goal and then quantify the actual savings. This feature is helpful for validating the effectiveness of energy performance contract projects.

Last, most companies and organizations do not have the level of in-house expertise required to model energy consumption accurately. Portfolio Manager is easy enough for a nontechnical manager to use without needing the engineering and statistical knowledge required to build a predictive model from scratch.

In summary, facility managers need a standardized and industry-accepted tool to enable the accurate identification of facility energy efficiency compared with that of similar buildings across the United States. The ENERGY STAR Portfolio Manager application addresses this need.

PORTFOLIO MANAGER OVERVIEW

Portfolio Manager is an online software application that benchmarks the energy use of a facility against a national database of similar buildings. In use since 1999, Portfolio Manager is an industry-accepted energy use model that was developed exclusively for ENERGY STAR by the University of Dayton. More than 26,000 buildings and more than 4 trillion square feet have been evaluated using Portfolio Manager, with more than 2500 buildings obtaining the ENERGY STAR label. The Portfolio Manager database continues to grow in size and accuracy as registered partners enter consumption data and analyze facilities, and usage continues to increase. Within the past 3 years, the number of architectural engineering firms using Portfolio Manager has increased by a factor of four.[2]

A variety of building types is included in the national database, representing more than 50% of the office space located within the United States.[3] Those building types include

- General office buildings
- Financial centers
- Bank branches
- Courthouses
- K-12 schools
- Hospitals
- Hotels and motels
- Supermarkets
- Residence halls/dormitories
- Warehouses

As Portfolio Manager analyzes the energy use of a subject facility, it adjusts or normalizes certain factors to compare facilities accurately. Adjustments can compensate for building size, geographic location, year-to-year weather variances, and other parameters.

Output from the model is expressed as a 0–100 percentile ranking, in which 50% identifies average energy efficiency (as compared with the national database) and 75% or higher identifies an energy-efficient facility. Data and results from a particular facility or group of buildings can be shared in a controlled fashion with other users. A number of energy efficiency statistics are generated by the tool, including overall energy intensity, the facility's Energy Performance Rating (0–100 percentile ranking), and effective CO_2 emissions. These results can be generated for one facility or a group of buildings.

Output from the model can be used to determine whether additional investment in the facility's infrastructure and systems is worthwhile or whether investment dollars should be spent at another location. Building ranking can also be used to quantify the improvement in efficiency and cost after energy-saving projects have been installed. Lastly, output from Portfolio Manager may be used to apply for the ENERGY STAR building label, if the facility has achieved a score of 75 or higher. Buildings that meet or exceed this level of efficiency, and that meet other requirements for indoor comfort and safety, will receive an ENERGY STAR plaque to display within or to affix to the benchmarked facility. This indicates to all that the facility resides within the top 25% of energy-efficient facilities within the United States.

USING PORTFOLIO MANAGER

Getting Started

ENERGY STAR provides new users a variety of ways to become familiar with Portfolio Manager. These include a self-guided online tour, regularly scheduled Web-based conferences, and a large collection of support documentation. These resources help the user understand how to apply the tool and the resultant output, and what the input data requirements are for specific facility types. This section will guide the user through the process of determining whether a specific facility can be benchmarked using the tool, identify necessary input data, review weather normalization methodology, and explain additional requirements of specific facility types.

Eligibility Requirements

For Portfolio Manager results to be valid, specific requirements have been established to ensure that the facility being benchmarked is similar to those contained within the tool's nationwide database. These requirements are called Eligibility Rulesets. Definitions exist for each facility and space type.

These requirements call for at least 50% of a facility's square-footage floor space to match the rulesets for each space type and for at least 11 months of energy use data to be entered. These requirements and links to others can be found on the online page Eligibility Requirements for Use of the National Energy Performance Rating System, located on the ENERGY STAR web site.[4]

Following is an overview of the general requirements of each ruleset. Before applying for the ENERGY STAR building label, the user should review the current rulesets and definitions at the ENERGY STAR web site.

- *General office buildings*. The building is used for administrative, professional, or general office purposes. Supporting functions—conference rooms, lobbies, stairways, etc.—should be included in the total. The building must operate at least 35 h/week and cannot contain more than 25,000 occupants. The total building size must be at least 5000 ft^2.
- *Financial centers*. The facility is used as a bank headquarters or as a securities or brokerage firm. The total building size must be at least 20,000 ft^2.
- *Bank branches*. The facility is used for bank-branch-office purposes. The total building size must be at least 1000 ft^2.
- *Courthouses*. The facility is used for federal, state, or local courts and associated office space. The total building size must be at least 5000 ft^2.
- *K-12 schools*. School buildings for kindergarten through 12th grade. The total building size must be at least 5000 ft^2.
- *Hospitals*. The facility must have at least 50% of its total square-footage floor space dedicated to acute care. These are facilities that typically provide a variety of services within the same building or among multiple buildings on a campus, including emergency medical care, physician's-office care, diagnostic care, ambulatory care, and surgical care. The facility must contain at least 16 licensed beds and may not exceed 1510 licensed beds. The building cannot exceed 40 floors. The total building size must be at least 20,000 ft^2 but not more than 5 million ft^2. Children's hospitals can also be benchmarked using the tool.
- *Hotels and motels*. Facilities that rent overnight accommodations with a bath/shower and other facilities in most guest rooms. Floor area for all supporting functions such as food facilities, laundry facilities, and exercise rooms should be in the total. Hotel/motel categories currently eligible for benchmarking include economy, midscale, upscale, and upper upscale. Resort and extended-stay categories are not eligible for benchmarking at this time. Total building size must be at least 5000 ft^2.
- *Supermarkets*. Facilities used for the retail sale of food and beverage products. Entire floor space—including warehouse, office, break room, and storage areas—should be included. Total building size must be at least 5000 ft^2.
- *Residence halls/dormitories*. Buildings that offer multiple accommodations for long-term residents associated with educational institutions or military facilities. Floor area for all supporting functions—food facilities, laundry facilities, exercise rooms, health club/spas, and others—should be included. Total building size must be at least 5000 ft^2.
- *Warehouses*. Facility space used to store goods, manufactured products, merchandise, or raw materials in a refrigerated or nonrefrigerated building. Refrigerated warehouses are those facilities designed to store perishable goods or merchandise at temperatures below 50°F. Nonrefrigerated warehouse is space designed to store nonperishable goods and merchandise. The total building size must be at least 5000 ft^2.

In addition to the primary spaces noted above, secondary space uses can be analyzed by Portfolio Manager. For each of these secondary space types, weekly hours of operation and gross square footage must be defined. Typically, the aggregate of the secondary space types cannot represent more than 50% of the total square footage of a building, and a facility cannot be comprised solely of secondary space types.

A few examples of secondary space types and their specific requirements are given below. Additional information regarding secondary space types can be found at the online page Eligibility Requirements for Use of the National Energy Performance Rating System, located on the ENERGY STAR web site.[4]

- *Ambulatory surgical centers*. These facilities are categorized by size and weekly hours. This space cannot be more than 50% of the facility's total floor area. The gross floor square footage cannot exceed 1 million square feet.
- *Computer data centers*. These facilities are designed and equipped to meet the needs of computer equipment

that must reside in areas with independently controlled temperature and humidity. Usually, the air conditioning system for this type of area is separate from the equipment used to control the space temperature of the general building. The total area of all computer data center spaces cannot exceed 10% of the total building space.

- *Garages and parking lots*. Enclosed or open parking facilities that operate from the same energy use meter as the primary building. Garages are categorized as either above ground or below ground. Below-ground garages are assumed to have mechanical ventilation. All parking facilities are assumed to have some kind of lighting. Garage space cannot account for more than 50% of the total building area.

As with any requirements and definitions, the user should first obtain the complete and most recent rulesets by visiting the ENERGY STAR web site.

Information Required for Data Input

Two levels of input data are required for facilities benchmarked by Portfolio Manager: facility summary data and facility space information. When the user creates a new building file, the application will ask for basic information, such as the building address, space use, energy use, and baseline/target usage.

Depending on the type of building being evaluated, Portfolio Manager will require specific input parameters to be identified. These include floor area, the number of personal computers, occupancy levels, and operating hours. Specific facility types will require additional information to benchmark the facility accurately. K-12 schools, for example, are required to supply the following additional information: the percentage of floor space that is heated, the percentage of floor space that is air conditioned, the square footage of the cooking area, the months that the school is in operation, the number of students, and whether the building has mechanical ventilation. Each of these parameters has been identified as a significant influence on the energy use profile of K-12 schools. Other facility types require specific input data relative to their particular drivers of energy consumption.

WEATHER NORMALIZATION

As can be expected, the geographic location of a facility greatly affects its energy consumption. A refrigerated warehouse designed to maintain an internal temperature of 45°F, for example, will have significantly different energy usage in Minnesota, Nevada, or California. When the need to control and maintain humidity levels is added, energy usage varies even more greatly. One additional factor includes severe weather variations at a specific location.

The statistical model used within Portfolio Manager normalizes changes in both historical temperature variances and year over year severe or mild temperature changes. Publicly available weather data are used to make these adjustments. Heating-degree-day (HDD) and cooling-degree-day (CDD) values are indices used to represent the energy demand placed on building heating and cooling equipment. The values are calculated from individual daily temperatures for a specific region or U.S. postal code.[5]

The statistical model used by Portfolio Manager is based on the E-Tracker software model developed by Dr Kelly Kissock of the University of Dayton. Additional technical information and an outline of the weather normalization methodology used by this statistical model can be found in the document Weather Normalization Description, located on the ENERGY STAR web site.[5]

THE ENERGY STAR BUILDING LABEL

Overview

Buildings with a Portfolio Manager score of 75 or higher that meet specific indoor air quality standards verified by a licensed professional engineer are eligible to apply for the ENERGY STAR building label. The label signifies the relative energy efficiency of the facility compared with Portfolio Manager's national building database. The user is required to generate a Statement of Energy Performance (SEP) using Portfolio Manager indicating a score of 75 or higher, have the input data and other requirements validated by a licensed professional engineer (PE), and submit a letter of agreement and the SEP (complete with PE stamp) to the EPA for review.

Statement of Energy Performance

The SEP validates the energy efficiency of a building. Facility managers can leverage the information in this document in a number of ways. Proof of superior energy efficiency can be beneficial during the sale or lease of a facility, confirming that facility improvements have been made. The document can also be used to demonstrate the value of an organization's energy efficiency program.

In addition to the energy performance rating of the facility, information in the SEP includes the year the facility was built, gross square footage, ownership and contact information, energy use summaries, and intensities with CO_2-emissions equivalents. The SEP has an area to hold a PE stamp authenticating the information in the document.

Professional Engineer Review and Validation

ENERGY STAR requires that a licensed PE verify that the data entered into Portfolio Manager identifying the building energy consumption and physical parameters are accurate. The engineer must visit the building and verify that it conforms to current industry standards for indoor environment, as referenced by ENERGY STAR in the Professional Engineer's Guide.[6] These standards address indoor air quality, illumination, and occupant comfort, as identified by the American Society of Heating, Refrigerating, and Air-Conditioning Engineer's (ASHRAE).

ENERGY STAR relies on the professionalism of the PE industry to provide an unbiased, trained, and accurate review of the building performance data. Because PEs are legally bound to uphold their standard of ethics, the PE stamp brings a mark of credibility and accuracy to the SEP. The PE stamp makes the SEP valid and official, whether the SEP is being used to apply for a building label or for any other purpose.

The Professional Engineer's Guide to the ENERGY STAR Label for Buildings is the technical reference used by PEs when validating data.[6] The guide has a chapter dedicated to each category or performance characteristic. Each chapter is clearly written in an outline format, identifying its purpose, identifying any reference standards, and defining acceptable conditions. Each chapter also outlines expectations of the PE, provides hints and tips, and concludes with a section on commonly asked questions and related answers. Overall, the guide is a statement of work identifying the responsibilities and expectations of the PE.

Indoor Air Quality Requirements

One common method used to improve energy efficiency, especially in commercial buildings, is reducing the quantity of airflow generated by heating and ventilating (H&V) equipment. Many commercial buildings are indeed overventilated due to poor commissioning, lack of maintenance, or conservative system design. However, lowering air flow reduces the volume of fresh outdoor air brought into a facility, thereby reducing indoor air exchanges—the number of times a facility's indoor air is replaced. Failure to properly exhaust used indoor air and its contaminants (including CO_2, mold, mildew, and microbes) can result in a number of health complaints and issues. To ensure that energy efficiency isn't being achieved at the expense of indoor air quality (IAQ), ENERGY STAR has identified a list of requirements to balance the goal of improving efficiency while maintaining a safe and healthy work environment.

An IAQ assessment is to be performed by the PE during the on-site building evaluation. The engineer is required to conduct a point-in-time assessment of the building's IAQ against four industry accepted standards, including:

- ASHRAE Standard 62-1999—Ventilation for Acceptable Indoor Air Quality
- ASHRAE Standard 55-2004—Thermal Environmental Conditions for Human Occupancy
- ASHRAE Standard 52.1-1992—Gravimetric and Dust Spot Procedures for Testing Air Cleaning Devices Used in General Ventilation for Removing Particulate Matter
- 9th Edition of the Illuminating Engineering Society of North America Lighting Handbook

Applying for the Building Label

Prior to applying for the ENERGY STAR building label, the user should review the Eligibility Rulesets for the building being benchmarked and use Portfolio Manager to identify an Energy Performance Rating for the facility.[7] If the rating is 75 or higher, the following additional requirements must be met.

Using the Professional Engineer's Guide, a licensed PE must verify that the building meets industry standards for occupant comfort and IAQ.[6] The PE must be licensed in the state where the building resides and will be required to stamp and sign the SEP. The facility manager should also read and understand the ENERGY STAR Identity Guidelines.[8] This booklet identifies usage requirements for the ENERGY STAR logo and brand name.

Finally, a signed letter of agreement is required. This document is also generated through Portfolio Manager. Mail the signed letter of agreement and the signed/stamped SEP to ENERGY STAR within 120 days of the energy consumption data's period ending date. Visit the ENERGY STAR Web site to verify the correct mailing address for the ENERGY STAR Label for Buildings program.

After final review of submitted forms and data, the ENERGY STAR program will award the facility a building plaque to display in a prominent area of the building.

ADDITIONAL PORTFOLIO MANAGER TOOLS

Target Finder

Target Finder is a Web-based software tool that generates a predictive Portfolio Manager score for a facility during its design stage. Using this tool, engineers and architects can establish an energy use target for the facility, enter estimated annual energy use, and then compare the building profile against the same database used by Portfolio Manager. Similar to Portfolio Manager, the tool will adjust estimated energy consumption based on space type and geographic location. The tool will not only generate an energy performance rating based on inputs, but also generate predictive energy use values for a target performance rating. Using this feature, the designer can not only forecast a performance rating, but perform a gap analysis to identify the quantity and type of fuel to be reduced in order to achieve the target score.

Delta Score Estimator

Similar to Target Finder but much less extensive, this tool quickly and easily quantifies the reduction in energy consumption necessary to improve a facility's Portfolio Manager score above the 75% level. The tool can also be used to identify a projected score, given a proposed reduction in consumption. Use this tool when analyzing existing facilities that do not generate an energy performance rating high enough to apply for a ENERGY STAR building label.

Tracking Water Consumption

In 2006, Portfolio Manager was enhanced to permit tracking of facility water consumption. Because commercial buildings consume almost 20% of U.S. drinking-water supplies, a reduction of only 10% would equate to the conservation of more than 2 trillion gal of water each year. Portfolio Manager now allows the facility to track water consumption in four major categories: Indoor Use, Outdoor Use, Combined Indoor/Outdoor Use, and Wastewater.[9] The new feature permits benchmarking water consumption over time and enables relationships between energy use and water consumption to be identified.

ENERGY STAR plans to expand this feature further by enabling Portfolio Manager to quantify water consumption per occupant and develop a percentile ranking system for water consumption.

WHERE TO GO FROM HERE

A key component of the ENERGY STAR program is the act of sharing best practices and lessons learned with others. This interaction is the primary element that sustains and strengthens the program over time, while the number of users and registered partners continues to grow. ENERGY STAR has a number of programs that users can employ to share experiences and expand their own knowledge base. A few are highlighted below.

Building Profiles

ENERGY STAR Building Profiles are case studies outlining the steps taken by an organization to improve the energy efficiency of a subject facility during its path toward obtaining a building label. Building Profiles are created within Portfolio Manager and submitted to ENERGY STAR for review from within the tool. After final review and approval by an EPA committee, the Building Profile is made available to all via the ENERGY STAR Registry of Labeled Buildings. First-time users may find it helpful to review the existing Building Profiles of similar facilities before attempting to achieve a Portfolio Manager score and embarking on making costly facility upgrades.

Industry-Specific Energy Performance Indicators

ENERGY STAR champions a number of industry-specific focus groups to give large companies the opportunity to improve the environment while sharing best practices. One of the outcomes of these sessions is the Energy Performance Indicator (EPI). Initially generated for the automotive industry, this successful tool is being replicated for other industries, including cement manufacturing, wet-corn milling, glass manufacturing, and food processing plants. Similar to the Portfolio Manager tool, the EPI benchmarks energy consumption for a specific industrial facility against similar facilities across the United States while normalizing energy consumption against statistically significant influencers. The automotive EPI, for example, normalizes motor-vehicle assembly plant consumption against variations in weather, production volume, conveyor line speed, vehicle wheelbase, and plant air tempering. For more information on industrial EPI tools, visit the Industries in Focus page on the ENERGY STAR web site.[10]

ACKNOWLEDGMENTS

The author would like to thank the ENERGY STAR staff at the EPA, the DOE, and the ENERGY STAR team of consultants and contractors for their assistance in teaching, applying, and supporting Portfolio Manager and its related tools. Without the extensive support system and network of registered ENERGY STAR partners, the tools outlined in this entry would significantly lose their impact and usefulness.

Energy Use: U.S. Overview

Dwight K. French
Energy Consumption Division, Energy Information Administration, U.S. Department of Energy, Washington, D.C., U.S.A.

Abstract
Virtually all of the myriad economic and social activities of United States society involve inputs of energy. Our high activity levels have propelled the United States to the forefront of energy consumers among nations. Our almost 100 quadrillion (100 followed by 15 zeroes) British thermal units (Btu) of energy consumed annually is more than twice as much as that of any other nation. However, relative to our population and economic activity, the U.S. is comparable to, and even below, other nations in energy use. A key to understanding the demand for energy in the United States is comprehending the vast scope of activity to which we intensively devote ourselves. This article attempts to capture that scope by providing an overview of energy use in the several major sectors of U.S. society—housing, commerce and institutions, industry, transport, and even energy transformation—in terms of the types of energy used and the purposes for which it is used.

INTRODUCTION

Any characterization of United States society and its people would have to include the descriptor "active." The great majority of people, businesses, and institutions of this country are about "doing," filling our time with an enormous variety of activities and responsibilities. People's personal, social, and professional reputations are very much built on what we "do." Even much of our "leisure" time is devoted to the quest to keep us entertained, informed, and otherwise occupied.

Virtually all of this activity involves inputs of energy—not just human energy, but outside energy sources as well. Over the past 150 years, outside energy inputs have mushroomed in importance, becoming an indispensable part of our social and economic structure. Our high activity levels have propelled the United States to the forefront of energy consumers among nations. Our almost 1002 quadrillion (100 followed by 15 zeroes) British thermal units (Btu)[1] of energy consumed annually is more than twice as much as that of any other nation, though relative to our population and economic activity, the United States is comparable to, and even below, some other nations in energy use.[2] Only three other nations—China, Russia, and Japan—use more than 20 "quads" of energy in total.

A key to understanding the demand for energy in the United States is comprehending the vast scope of activity to which we intensely devote ourselves. This article attempts to capture that scope by providing an overview of energy use in the several major sectors of U.S. society—housing, commerce and institutions, industry, transport, and electricity production and delivery—as well as the types of energy used. The article then presents a more detailed description of each sector in terms of major energy forms used, the uses of that energy, and the outputs and outcomes that result. Most of the information in this article comes from the Energy Information Administration (EIA), the informational organization within the U.S. Department of Energy.

U.S. ENERGY USE ACROSS THE MAJOR SECTORS

One common initial way to partition U.S. energy use is to allocate it to five major activity groups (hereafter referred to as sectors): electricity generation, residential, commercial, industrial, and transportation. Electricity generation is often thought of as a transformation process that results in energy available for the other sectors rather than an end use of energy (that is, a use in which the outputs are nonenergy products or services). Residential use is, of course, energy use associated with housing units. Commercial use, as defined here, includes not only traditional economic commerce, but also use by other organizations and institutions, including civilian government—broadly, the service sector. Industrial use encompasses goods/products output: Manufacturing, agriculture, forestry, fisheries, mining, and construction. Transportation use encompasses all movement of people and goods, and thus is associated with the activity of all other sectors.

United States energy use can be partitioned by sector in three different ways, each with its own interpretation. First, the energy value of the electricity, along with all energy used up in its generation, transmission, and

Keywords: Commercial; Electricity generation; End use sectors; Energy consumption; Industrial; Residential; Transportation.

Table 1 Three approaches to distributing energy use by sector: United States, 2003 (quadrillion Btu)

Sector	All energy associated with generation	Usable electricity associated with end use	All energy associated with end use
All sectors	98.2	98.2	98.2
Generation	38.2	26.3	0.0
Residential	7.2	11.6	21.2
Commercial	4.2	8.4	17.5
Industrial	21.7	25.1	32.5
Transportation	26.8	26.8	26.9

Note: Components may not sum to totals because of independent rounding.
Source: From Energy Information Administration, Annual Energy Review, 2003.

distribution, can be allocated to the generation sector. This approach essentially treats electricity delivered to the other (so called "end use") sectors as a non-energy input. Second, the heat and power value of the electricity delivered to the end use sectors, rated at a standard 3412 Btu per kilowatt-hour (kWh),[3] can be allocated to those sectors, leaving the energy dissipated in the generation and distribution processes allocated to the generation sector. This approach treats the end use sectors as accountable for the use of outside-generated electricity as it reaches them and keeps the energy used up in generating and delivering electricity associated with the generation sector. Third, the total energy requirements for generating and delivering electricity can be allocated to the end use sectors, with no energy allocated to the generation sector. This approach treats the end use sectors, the ultimate energy consuming entities, as responsible for all of the energy embodied in the electricity they use, and not just the useful energy as it arrives at their doorsteps.

Table 1 shows that these three approaches paint much different pictures of relative energy requirements among the various sectors. Taking approach 1, the total energy requirements embodied in electricity generation in the United States far exceeds the energy requirements of any other sector; transportation is the largest consumer of the end use sectors; and the residential and commercial sectors combined account for only about one-ninth of energy use. Using approach 2, the generation, industrial, and transportation sectors account for almost equal shares (note that transportation uses very small amounts of electricity), and the residential and commercial sectors, the largest electricity users, represent 20% of energy use. Under approach 3, the generation sector disappears and the energy distribution among the four end use sectors is much more balanced, with industrial now accounting for the largest share of energy use.

This final approach clearly shows an underlying reason for U.S. predominance in energy use. We use large amounts of energy in all of our sectors. With electricity requirements allocated to the four major end use sectors, each of them alone would rank the United States no lower than fourth in energy use relative to the total energy use of other nations.

U.S. ENERGY USE BY TYPE OF ENERGY

Energy use in the United States is dominated by fossil fuel consumption. Fig. 1 shows that the three major fossil fuels, coal, natural gas, and petroleum, account for about 86% of the country's energy use. In terms of physical quantities, petroleum use is about 20 million 42-gallon barrels per day (enough to cover a regulation football field over 2000 ft deep), natural gas use is about 60 billion cubic feet per day (equivalent to a cubic mile of gas about every two and one-half days), and coal use, now almost exclusively for electricity generation, is about 2.7 million tons per day (enough to fill a train of standard 100-ton coal cars[4] over 300 miles long). Nuclear energy, used solely for electricity generation, accounts for another 8%, and a variety of renewable sources, primarily hydropower and biomass, comprise the remainder.

Solar, wind, and geothermal energy, renewable energy forms commonly considered to be the most environmentally appealing, together account for only about one-half of 1% of U.S. energy use at this time. The rate of increase in their use is much larger than the more conventional energy types, but they are starting from such a small base that many more years of rapid growth are required in order for them to become even a moderately important contributor to the U.S. energy mix.

ENERGY USE WITHIN SECTORS

Electricity Generation

Electricity generation is a huge enterprise in the United States. The amount of energy used just to generate our electricity ranks the United States a close second to the total energy use of China, and far ahead of the total energy

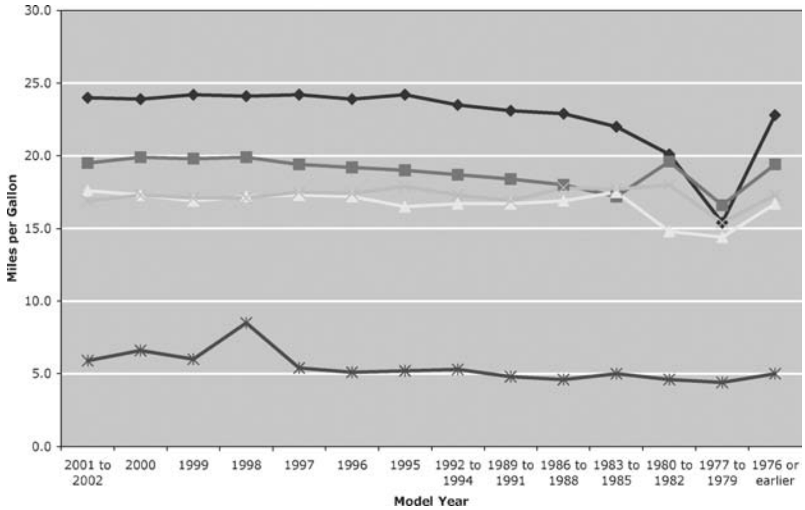

Fig. 1 Household vehicle fuel economy by vehicle type and model year. U.S., 2001.

requirements of any other country.[1,3,5] For many decades, virtually all electricity produced in the United States was generated within the traditional, vertically integrated electric utility, responsible for the entire process from initial generation to delivery to the final consumers. Over the past 30 years, various laws and regulations[6] have been put into place that encourage decentralized electricity production, and in some cases force the utilities to divest themselves of the generation process in order to deregulate the industry. As a result, the electric power industry looks much different than it did 30 years ago, or even a decade ago, in some ways.

Table 2 shows the distribution of electricity generated in the United States by type of generation facility and type of energy used in generation for the years 1993 and 2003. In 1993, electric utility generation accounted for the vast majority, 90.2%, of total generation, independent power producers accounted for 1.7%, and other generation, primarily commercial and industrial cogeneration, provided the remaining 8.1%. By 2003, the balance had notably shifted, with independent power producers claiming 27.4% share, carved out of the utility share. Much of this shift was due to divestiture of generating facilities by utilities as required by electricity deregulation, rather than closing of old facilities and construction of new ones. Thus, the distribution of generation by type of input energy would be expected to change much less dramatically than the distribution by type of facility, since ownership change by itself does not affect a facility's energy inputs.

And in fact, this was the case. Natural gas, the fuel of choice for a large part of new generation in the past decade, has made some limited inroads into generation share. However, the fundamental reliance on coal for electricity generation remains in place, use of nuclear energy has also grown, and hydro is in the same place as it was a decade earlier. This stability reflects a fundamental truth about U.S. energy use, both in this sector and, to a greater or lesser degree, across sectors: The country's energy demand infrastructure, built up over a century or more, will not change dramatically in the short term. Any significant technology-driven change in the country's energy consumption patterns will occur as the result of incremental changes that accumulate over a long time.

Table 2 Electricity generation by class of generator and input energy: United States, 1993 and 2003 (million mWh)

Generator class and input energy	1993	2003
Total generation	3197	3883
Class of generator		
Electric utility	2883	2462
Independent power producer	53	1063
Electric utility CHP[a]	108	196
Commercial/industrial CHP[a]	153	162
Input energy		
Coal	1690	1974
Petroleum	113	119
Natural gas	415	650
Nuclear energy	610	763
Hydro (net of pumped storage)	276	267
All other energy	93	109

Note: Components may not sum to total because of independent rounding.
[a]CHP: Combined Heat and Power.

Residential

The stock of housing units and their occupants currently account for about one-fifth of U.S. energy demand, including electricity requirements (Table 1). The Energy Information Administration's (EIA) Residential Energy Consumption Survey (RECS), which assesses energy use in the nation's occupied, year-round housing units, indicates that total residential energy use has remained remarkably stable over the past two-plus decades, even decreasing a bit, despite a 40% increase in housing units from 1978 to 2001 and increases in home floorspace, air conditioning, and appliances in those units.[7–11] Technological improvements in home construction and improvements in the efficiency of major energy systems (heating, air conditioning, and water heating), lighting products, and individual appliances (from refrigerators to computers) have helped to offset the increased demand for residential energy services. Also, the housing unit population grew most rapidly in the warmer South and West regions.

In recent years, space heating, the largest single home energy requirement, has migrated somewhat out of oil and into electricity. Natural gas retains its majority status for home heating; about 55% of homes used natural gas as their main space heating fuel in both 1980 and 2001. Similarly, liquefied petroleum gas (LPG) keeps its 4%–5% share in both years. But in 1980, electricity was neck and neck with oil as a main heating fuel (an estimated 18.5 and 17.4% of households, respectively, used them for main space heat). By 2001, electricity was the main space heating fuel in almost 30% of housing units, and oil provided the main space heat for only 8.3% of units. This shift reflects the migration of the population and the booming construction in the South and West regions of the country, where lesser heating requirements make electric heat more economically feasible, and the substantial additional entry of natural gas into the Northeast, formerly an area much more dependent on fuel oil for heating.[12,13]

Electric air conditioning is commonly thought to be a major contributor to household energy use, but its importance is not as great as one might expect. In 2001, an estimated 16% of electricity use was devoted to air conditioning, whereas four times as much household electricity use goes to lighting and appliances.[14] On the surface, this result may seem rather surprising. However, appliance use occurs in virtually all homes, whereas air conditioning is absent from almost one-fourth of households, and appliances are used year round, whereas air conditioning is only a few-month activity in many parts of the country.

Given the proliferation of appliances in homes in recent years, it may also seem surprising that appliance electricity use has not gained significant share over the years. However, some newer appliances are specialty gadgets that use relatively little energy, and others are somewhat redundant (the third and fourth televisions), so that use of each individual appliance goes down.

Commercial

The large majority of energy use in commercial, or service, facilities takes place in commercial buildings, defined here as structures totally enclosed by walls from the foundation to the roofline, intended for human occupancy, with a majority of floorspace devoted to commercial/service activity. A wide and interesting variety of service activity is associated with nonbuilding facilities, such as open parking garages, transmission towers, drawbridges, billboards, lumber yards, street lights, parks, open amphitheatres, outdoor sports facilities, and docks and piers. However, all this activity comprises a relatively small share of total commercial energy demand, based on comparisons between EIA's supply side data programs, which account for demand by all commercial customers, and its consumer survey, the Commercial Buildings Energy Consumption Survey (CBECS).[15–17] It should be noted that no known national survey of nonbuilding commercial facilities has ever been undertaken.

Latest building data from the CBECS, for 2003, indicates that there were slightly fewer than 5 million commercial buildings in the United States of 1000 ft^2 or larger. The building stock encloses about 71 billion square feet (more than 2500 mi^2) of floorspace, an area almost as large as the combined land area of Rhode Island and Delaware. Four types of buildings dominate the stock: education, mercantile (sales), office, and warehouse/storage. Together, these four types comprise about one-half of all commercial buildings and 60% of the floorspace. Additional major classes of activity in commercial buildings include assembly (e.g., auditoriums, theatres, civic and convention centers), health care, food sales, food service, religious worship, and several others.[18]

However, space dominance does not necessarily translate into energy dominance. Fig. 2 shows the shares of building stock, floorspace, and major energy consumption in 1999 for selected major building activities identified in the CBECS. Notable variations among the shares include the much larger shares of energy use than floorspace associated with three very energy-intensive types of buildings: health care (especially hospitals), food service (restaurants/cafeterias), and food sales (grocery stores). Each of these activities has its own set of reasons for its high energy requirements: health care due to space conditioning, water heating, and its sophisticated equipment; food service due largely to cooking and water heating, as well as refrigeration of stored food; and food sales due to space conditioning and refrigeration requirements.[19]

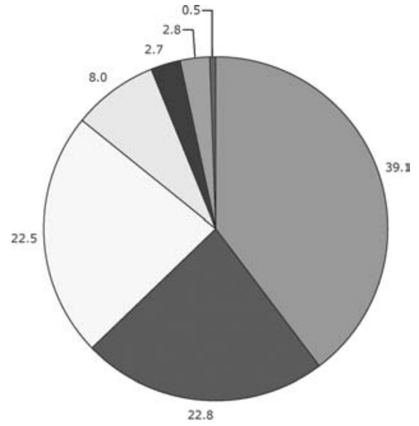

Fig. 2 Distriution of energy use by type of energy: United States, 2003.

Industrial

Of the major industrial activities mentioned earlier, only manufacturing is covered by an EIA consumer-based survey, the Manufacturing Energy Consumption Survey (MECS). Manufacturing has historically accounted for the great majority of industrial energy use, based on comparison with EIA supplier survey information.[20,21] Although much has been made recently of the departure of substantial amounts of manufacturing from the United States, the energy use, including energy embodied in electricity, associated with our manufacturing alone is still enough to rank the United States second in total energy use among the world's other nations, behind only China.[1,20]

Manufacturing is an especially interesting sector in which to examine energy use, because the throughput of energy at manufacturing plants is much more complex than it is in most other parts of the economy. Most other energy users obtain outside energy sources and use them to provide heat and power, with no further energy accounting required. Manufacturers obtain large quantities of outside energy sources, but sometimes also produce their own energy from sources such as hydro, onsite mines, and wells. However the energy arrives, much of it is used for heat and power, but some applications use energy sources for their chemical or physical content, as so-called feedstocks or raw material inputs to manufacturing processes that result in nonenergy products. One prominent example is the use of natural gas in producing ammonia and fertilizers. Another is the enormous petroleum inputs used to produce product outputs not subsequently treated as energy: asphalt and road oil, lubricating oils, wax and grease, and certain petrochemical feedstocks. Also, manufacturing processes produce byproduct streams, such as blast furnace gas at steel mills, still gas at petroleum refineries, wood residue at pulp and paper mills and plant residues at food processing plants—all can be reclaimed to provide heat or power. Manufacturers routinely transform energy inputs onsite, whether traditional or byproduct, into different forms, primarily electricity, steam, and hot and chilled water, for later use in manufacturing or managing the facility environment.[22]

In 2002, the latest year for which detailed MECS data are available, total manufacturing energy use for all purposes, with electricity counted at its site energy value, was 22.7 quads. Of this, 12.0 quads, or 53%, were accounted for by traditional energy inputs obtained from offsite and used for heat and power requirements. The remainder was onsite, byproduct, and waste product energy, and energy used as feedstock. Fig. 3 shows that 6 of the 21 major manufacturing industry groups account for 88% of total manufacturing energy use: food, paper, petroleum and coal products, chemicals, nonmetallic minerals (stone/clay/glass), and primary metals. These industries involve complex processes that require enormous amounts of heat and power to break down and reform primary materials, and substantial use of energy as raw material inputs. Other later-stage industries, such as assembly of vehicles, computers, clothing, appliances, and furniture, are much more intricate and are certainly valuable in their contribution to the country's economic output, but their energy requirements are much smaller than those of the dominant industries. A large portion of the energy inputs in manufacturing go into boilers for producing heat and electricity, power machinery, and direct process heat applications, such as kilns, heat treaters, and furnaces.[23]

Direct data on energy use for the other industrial applications—agriculture, forestry, fisheries, mining, and construction—are much more scattered, and in some cases not available. The EIA assembles energy use data for nonmanufacturing industries as part of its efforts to model future energy use. Data from this effort, assembled from the

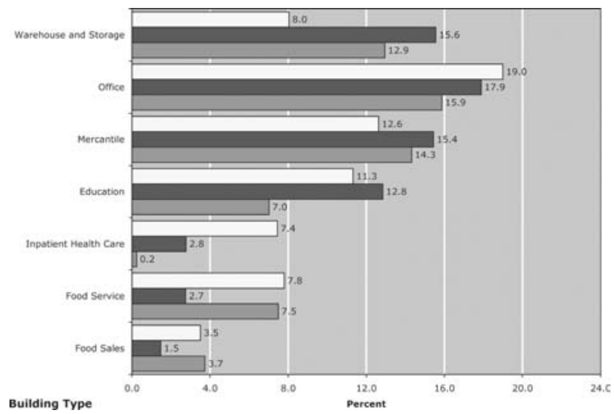

Fig. 3 Percent of commercial building stock, floorspace, and energy use for selected building tyes: U.S., 1999.
Source: From Energy Information Administration (see Ref. 16).

Census Bureau's Economic Censuses and other data sources, has agricultural energy use at about 1.2 quads in 2002, mining use at about 2.5 quads, and construction use at about 0.9 quads.[24]

Transportation

The movement of people and goods is a vital part of the U.S. economy and society. Transportation accounts for about one-fourth of U.S. energy use, but it is an enormously important fourth, because it is virtually all petroleum.[25] In fact, transportation accounts for about two-thirds of petroleum use in the United States. The sector consists of highway vehicles, including cars, trucks, motorcycles, buses, and other specialty vehicles; rail transport, both local and intercity/long distance; aircraft; marine craft, such as ships, smaller boats, and barges; and pipelines carrying a variety of commodities. These classes of vehicles use various grades of petroleum products: gasoline, light diesel, heavier diesel, jet fuel, and heavier, residual type bunker oil (for ships). The largest share of non-petroleum energy used for transportation is for natural gas pipeline transport.[26]

Transportation can be a difficult sector to categorize and study. It is enmeshed with all the other end use sectors, because they all use transportation or transportation services to carry out their roles. There are firms dedicated to transportation service (i.e., movers and other for-hire shipping companies, taxi companies, rental car companies, airports, cruise and ferry lines, towing services, etc.) whose holdings include buildings that are categorized as commercial, but whose vehicles are unquestionably characterized as transportation. Firms and organizations whose primary activities are not transportation service use vehicles for pizza delivery, landscaping service, funeral transport, transportation to school, traffic or weather observation, crop dusting, and so on, in vast array, in the course of carrying out their primary function.

Vehicle use can thus be split into terms of residential vs nonresidential, passenger vs freight, highway vs nonhighway, and by type of vehicle or transport medium. And to add more confusion, some vehicle use is commonly thought of as non-transport! For the purposes of categorizing energy use, some vehicles are commonly considered part of the sectoral activity they are supporting, rather than part of a separate transportation activity. Examples include forklifts at the local furniture store, hardware store, or warehouse; bulldozers and earthmovers at construction sites; captive vehicles used at commercial or industrial sites, but not registered for on-road use; vehicle rides at commercial theme parks and amusement parks; farm implements; and our riding lawn tractors at home.

The primary vehicles in our society are our household vehicles, which enable us to lead our lives in a way that could not even have been imagined a century ago. These

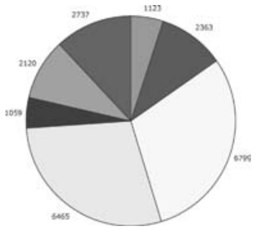

Fig. 4 Distribution of energy use by major manufacturing industry groups: United States, 2002 (Trillion Btu).
Source: From Energy Information Administration, 2002 Manufacturing Energy Consumption Survey. Table 1.2 at http://www.eia.doe.gov/emeu/mecs/mecs2002/sheltables.html (accessed May 2005).

vehicles, about 190 million of them, account for slightly over one-half of all transportation energy use, and about 35% of total U.S. petroleum use. Household vehicles used to be primarily automobiles, with a relative scattering of pickup trucks and "Jeeps." However, since 1980, pickup trucks have proliferated, Jeeps have evolved into our present large class of Sport Utility Vehicles (SUVs), and a new class of household vehicle, the minivan, has evolved from the old business van. As a result, over 50% of current household vehicle sales are one of these non-automobile categories, which now make up about 40% of the household vehicle stock.[27]

Pickup trucks, vans, and SUVs generally have somewhat lower fuel economy than their automobile counterparts. Therefore, their increasing presence in the vehicle stock has been one of the factors (along with increased horsepower and vehicle weight) offsetting engine, equipment, and vehicle design technology, all of which tend to increase fuel economy. As a result, the fuel economy of new vehicles has been relatively constant since the late 1980s (Fig. 4), though the overall fuel economy of the vehicle stock continued to rise for years after that as newer, better-mileage vehicles augmented the stock and replaced the vast majority of older, less technologically advanced vehicles.

CONCLUSION

Obviously, the workings of the U.S. economy, and indeed our entire society, are linked inextricably to energy consumption. Our geographical size, wide variety of climate, large population relative to that of most other nations, economic wealth, and high levels of personal and organizational activity combine to create enormous demands for energy. These demands continue to exert pressure on energy supplies and the infrastructure for energy delivery. The United States already makes use of a wide variety of energy forms to meet its needs. It is likely that, in the future, we will have to increase our use of unconventional energy that currently accounts for only a small part of our consumption, and bring new types of energy online in order to continue to meet the country's energy requirements reliably and at reasonable cost.

Additional information about energy throughput in the United States can be accessed through the Web site of the EIA at http://www.eia.doe.gov. More details on EIA's consumer surveys and the relationship between consumer characteristics and energy use can be accessed through the Energy Consumption page, http://www.eia.doe.gov/emeu/consumption/.

A British thermal unit is the amount of energy required to raise the temperature of one pound of water from 39 to 40 degrees F, about the amount of energy provided by a kitchen match. A gallon of motor gasoline contains about 125,000 Btu of thermal energy, and a typical home natural gas furnace is rated at 100,000 Btu used per hour of operation. A quadrillion Btu is a billion million Btu, enough energy to run that natural gas furnace continuously for more than a million years, or to drive around the World 6.4 million times in a 20 mile-per-gallon vehicle.

Energy Use: U.S. Transportation

Kevin C. Coates
Transportation & Energy Policy, Coates Consult, Bethesda, Maryland, U.S.A.

Abstract
Oil, gas, and electricity prices are spiking, America's highways and airports are overcrowded, suburbia has morphed into urbania, and suburban sprawl has led to exurban sprawl. As political and industry leaders continue to apply old solutions to solve the problems of rapid growth, they are discovering that those old solutions do not work in the face of exponential growth. The nearly simultaneous convergence of exponential growth factors in the demand for energy and transportation will eventually force America to reassess its present land development policies and find ways to link this new policy with more sustainable energy and transportation solutions. This paper not only looks at the root causes behind America's most pressing national issue, but also offers some workable and sustainable solutions for reversing what is most certainly a worsening situation for most American citizens.

Oil prices continue to climb and continue to reach new heights with each passing year. These increased prices impact the price and availability of chemical products where oil is the feedstock, as well as the cost and availability of oil-dependent transportation fuels, and they will increase the price of most other goods and services.

Soaring U.S. and world demand for oil has another consequence. Highway and road transportation systems are grinding to a halt under the crush of peak-time travelers, with average trip times taking ever longer in most U.S. cities.[1] In addition, airports suffer from "winglock," which leaves fuel-hungry jets idling on tarmacs while they wait for a gate or a runway while arriving flights are forced to slow down to avoid energy-wasteful holding patterns.

There are far deeper issues involved here than simply too many cars or planes in the same place at the same time or the price of a gallon of gasoline. The country's overburdened transportation system is really symptomatic of a more deeply rooted psychological malady—America's energy attitude. It could be that higher energy prices will provide the wake-up call America needs to change its profligate energy ways—not the least of which is the inefficient Helter-Skelter development of cheap land farther and farther from urban centers.

Weaned on the habit of cheap and widely available energy, generations of Americans have been seduced by the idea that they can build or travel wherever, whenever, and however they desire. Indeed, Americans have even come to equate mobility with their sense of liberty.

The real question is, is America truly free if it continues to build and attempt to maintain an entire societal infrastructure built upon the premise of endless supplies of cheap energy, especially when (1) 96.9% of its transportation system is dependent on oil for its fuel derivatives,[2] (2) these oil-based fuels rapidly rise in price and are extremely price volatile, and (3) two-thirds of the oil used to fuel the U.S. transportation system is dependent on foreign nations?

Few Americans know or care how much energy it takes to propel a single driver in a car at 60 mph. Slick advertising campaigns lure customers into buying 265-horsepower machines to roar down empty asphalt tracks in a powerful pursuit of freedom. Few people consider how much energy it takes to build each vehicle or to clear, construct, pave, and endlessly repave hundreds of thousands of miles of oil-based asphalt (Fig. 1).

America's ground transportation and energy problems are the direct result of failed land development policies. Where buildings are constructed directly impacts the development of road networks, influences the energy consumption levels of road trips, and dictates traffic patterns. As automobile ownership soared in the mid-20th century, America became less concerned with building lasting structures and communities scaled to human-powered transportation or activities, and focused more on quick construction and building an infrastructure that focused instead on accommodating its transportation machines. Think about how long it takes to walk between distant gates at Chicago's O'Hare airport vs the compact layout of a big-city train station. Not only does this overriding focus on meeting the needs of machines consume vast quantities of energy, but it also creates environments hostile to pedestrians—that's you and me when not traveling in machines.

The fact that America has three separate and distinct federal departments for housing, transportation, and energy reveals a lack of appreciation for the increasing importance of the energy correlation. In Germany, for

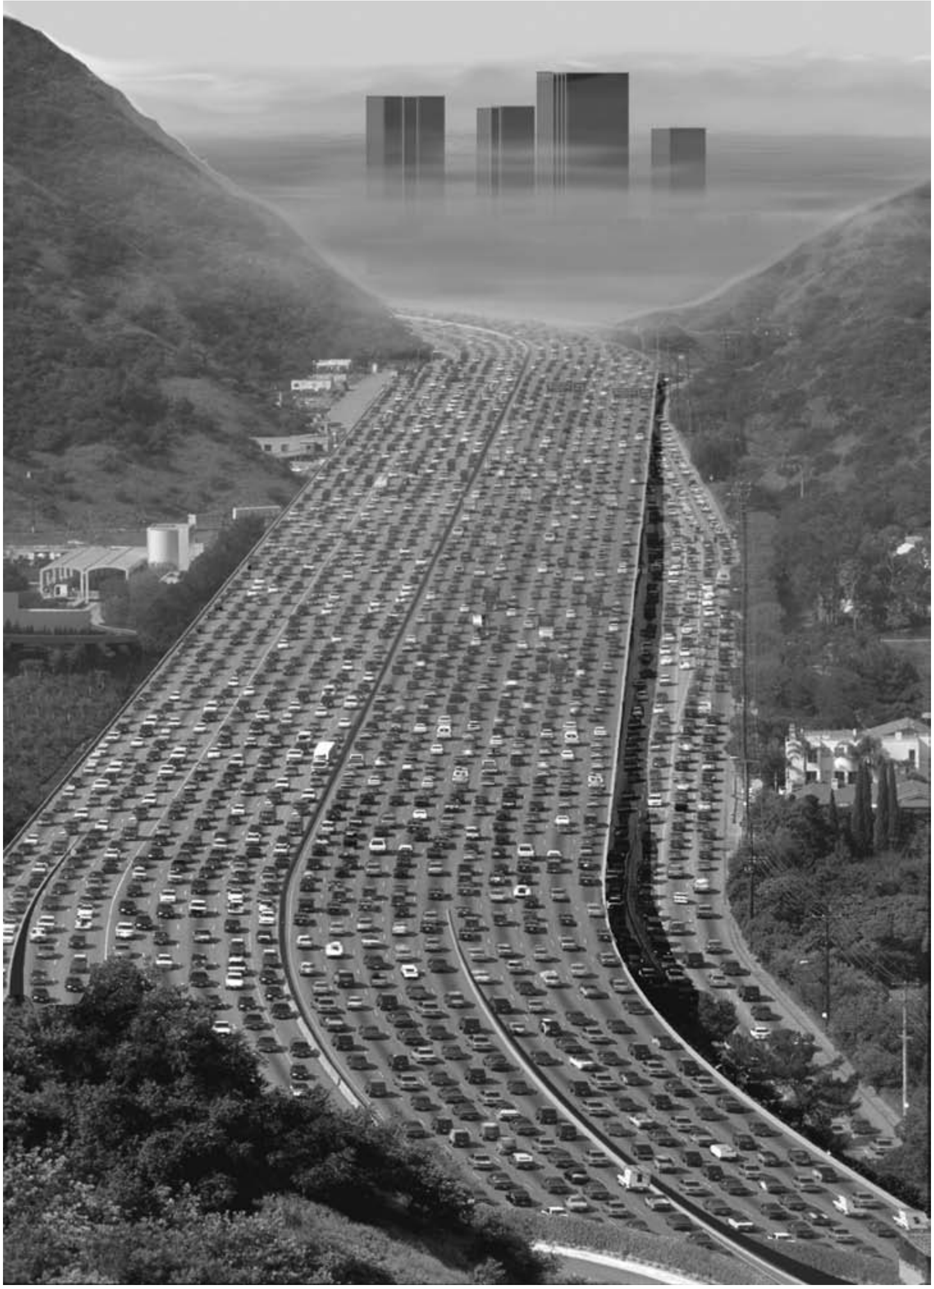

Fig. 1 Is this the future we want? Computer generated view of the 405 north of Los Angeles, courtesy of Phil Shisbey, Lake Elsinore, CA (www.transfuture.net). Note the Getty Museum trams on the left and the smog in the San Fernando Valley.

instance, housing and transportation are combined into one federal ministry, the Bundesministerium für Verkehr, Bauwesen, und Wohnungswesen (Federal Ministry of Transport, Building, and Housing). Japan has its Ministry of Land, Infrastructure, and Transport because land is limited, natural energy resources are scarce, and the efficient movement of people and goods between population centers keeps energy transportation costs low.

Industrialized countries around the world were forced years ago to recognize the "capacity limitations" of their infrastructure and domestic resources, especially their potential domestic sources of energy. In contrast, America's infrastructure was built upon the premise of widely available cheap land, endless supplies of cheap domestic energy, and relatively cheap personal transportation—a system that has nurtured an economic belief in growth without limits. Well, there are limits to exponential growth, and the negative effects are now becoming evident.

The power of an exponential equation is illustrated in the old fable about a ruler in ancient Persia who wanted to reward a subject for having created the game of chess. Rather than requesting gold or jewels, the clever inventor asked instead for one grain of wheat placed on the first of the 64 squares on the chessboard. For each successive square, he asked that the amount of wheat be doubled. Not being a mathematician, the perplexed ruler agreed. Unfortunately, long before reaching the 64th square, all of the wheat in the kingdom had been exhausted. Indeed, there is not enough wheat in the world today to satisfy this formula—nor is there enough oil (Fig 2).

Approximately 65% of American oil consumption is for transportation. The country's two primary transportation modes, road and air travel, are entirely oil dependent. These modes served America well enough (albeit with high pollution levels) when fuel was relatively cheap and the country's population rate of growth was slow, but as already mentioned, the price of all hydrocarbon fuels is rising, driven by a burgeoning worldwide consumer population.

What Americans are beginning to experience is the convergence of higher energy costs and the almost exponential increase of the number of vehicles on its capacity-limited highways. Indeed, the instant replacement of all of America's internal combustion powered vehicles with hybrid or electric cars would not solve its traffic congestion problems. The problem with relying almost exclusively on highways and roads for transportation is that they are inherently "capacity inflexible," meaning that massive amounts of new construction are needed to accommodate each successive doubling of the road-traveling population.[2] What used to be horrendous unidirectional rush hour traffic in the mornings and evenings has now extended into most of the day in both directions throughout most of the country.

As the periods shorten between the doubling of road populations, no amount of road construction will be able to

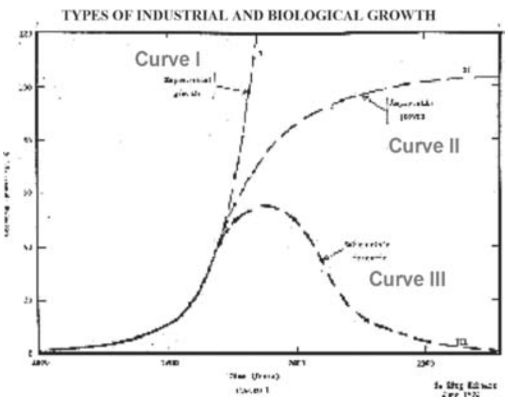

Fig. 2 Types of industrial and biological growth. This is a chart with three types of growth curves. Curve I is for exponential growth. Notice the similarity that Curve I has with the curves in the following two graphs. Curve II reflects growth that plateaus to a sustainable level (not applicable to a finite resource being depleted). This chart was shown during a 1974 Congressional subcommittee hearing on energy as part of M. King Hubbert's testimony; the geophysicist who predicted correctly in 1956 that U.S. oil production would peak in 1970 and then begin to decline (as modeled by Curve III). Hubbert's prediction proved remarkably accurate.

keep up with such demand. Despite ample evidence that proves this strategy is not working, federal, state, and local governments persist in allowing the building of houses farther and farther from urban centers, and hence force all taxpayers to subsidize exurban development by picking up the tab for the new road infrastructure.

The rapidly increasing need for new transportation construction combined with the costly issue of maintaining the vast infrastructure already in place is the major reason so many state highway budgets are in the red. Just to keep pace with the highway construction-intensive transportation system, the American Society of Civil Engineers and the House and Senate transportation subcommittees recommended in 2003 that funding levels for a new federal transportation bill be approximately 70% higher than the $218 billion authorized in the 1998 six-year TEA-21 bill,[3] which itself was 44% higher than the previous Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA).[4] The White House insisted that the two houses of Congress submit a bill to the president that was well below $300 billion or face a veto. For its part, the White House supported a $256 billion, six-year bill that was only $45 billion above the 1998 six-year TEA-21 bill, or only a 21% increase. Clearly, there is a disconnect here between reality and policy, given the exponential growth and demand on the system.

The transportation bill's various critics in the media blamed "pork barrel politics" for the steep funding requests. The reality is that most of the increases are more the direct result of exponential housing growth farther and farther from downtowns and the need for necessary repairs of an aging and overused highway, road, bridge, and tunnel infrastructure. Developer sprawl bleeds funding from existing transportation infrastructure maintenance to feed new road construction, thus creating a funding crisis in some states and forcing some governors and state legislatures to seriously consider increasing state gasoline taxes in spite of the threat of political suicide. Despite these realities, the 2005 transportation bill passed by Congress and signed by the president was predominantly a highway bill, and as a result, it represents another missed opportunity to pursue more workable and sustainable transportation solutions.

Conversely, transit system operators need only to add more cars to trains and run trains more frequently to accommodate periodic bursts in ridership and to avoid disrupting passenger flow. Furthermore, rail- or guideway-based transit infrastructure with dedicated right of ways (ROWs) can sustain longer periods of steady ridership growth (capacity flexible) before new infrastructure construction is deemed necessary.

Unfortunately for today's Americans, when U.S. leaders decided in the mid-1950s that rail travel was old fashioned and of low value, unprecedented levels of federal tax dollars were spent for airport expansion and launched the massive infrastructure development projects that became the present interstate highway system. This 1950s policy decision locked American transportation into today's oil dependence.[5] Massive federal funding for roads and airports not only eroded the many private rail operators' passenger base, but also eliminated rail as a viable alternative mode of transportation for taking ridership pressure off the other two modes. Entire rail networks have disappeared, such as the 1600-mile Pacific Electric Railway system that provided an efficient and affordable mass transit system in the first half of the 20th century for Los Angeles area residents—an area now all too frequently stuck in highway gridlock. With so many of America's roads and highways now suffering the same fate, the oil-dependent transportation policy born in the 1950s is proving to be shortsighted.

Besides being more capacity flexible, rail or guideway-based systems can also more easily use electricity for power because they operate "within and along an electricity corridor or grid." This also means they are not reliant on any one prime energy source and they do not introduce air pollution along their routes. Not only are these systems energy efficient, but they also are more cost effective because their energy costs are mitigated by the several primary energy sources that comprise electricity generation, which is usually attracted to the lowest-cost production methods. In addition, these transportation systems allow for the seamless introduction and integration of clean renewable energy sources at no additional cost. In other words, as new energy sources harnessed from the wind, the waves, the sun, and geothermal sources come online, they can seamlessly be injected into the existing power mix that is propelling 60 or 300-mph transit vehicles across the landscape. All the technology necessary to make this a reality is now available and in operation in various locations around the globe (Fig. 3).

By meshing the electricity industry's new power technologies into a cohesive network that is combined with a new transportation paradigm of high- and low-speed transit, such as magnetic levitation (maglev) systems, the country can create an extremely robust "electricity transportation grid" that not only upgrades America's aging electricity grid, but also revitalizes its overburdened transportation system. The combined result would introduce higher levels of reliability for both systems and improve trip times, reliability, safety, and comfort for intercity travel, while enabling and facilitating the wholesale transmission and distribution of electricity on a national scale (something for which the present grid was never designed). This combined approach would also cost less than pursuing either system upgrade independently because both would share the same ROW acquisition costs. Indeed, it is the difficulty of securing new ROWs for electricity transmission that has significantly hampered expansion and the reliability of America's power grid. By enclosing new transmission cables in conduits along a maglev ROW, not only would the site of transmission towers and power lines be eliminated, but also, disruption to electrical power flow resulting from inclement weather would be drastically reduced, resulting in higher electric transmission reliability, improved power flow capacity, and lower overall maintenance costs, which in turn should keep electricity rates low and stable.

One example of a capacity limit that is impacting the price of fuel in America is the international demand for oil tankers, which in late October 2004 exceeded the number of available ships. The countries that build oil tankers, such as Japan and Korea, are at capacity and building them

Fig. 3 Elevated 267 mph Shanghai Maglev is on time 99.9% of the time and places a minimal footprint on the landscape and does not cut communities in half or obstruct their existing road networks. Photo courtesy of Transrapid International.

as fast as they can. Additionally, it takes four years from the time an oil tanker is ordered until it is delivered into service, and the number of new tankers coming online in 2005 is not likely to keep pace with the projected increase in world demand. Exacerbating this already dicey shipping supply situation was an international maritime agreement that mandated the scrapping of all tankers built before 1982 by May 2005 and the scrapping of all non-double-hulled tankers by 2010. In October 2004, shipping rates for a load of crude jumped from $35,000 per day to $135,000 because of the shipping shortage, meaning that the cost of a typical 40-day cruise jumped $4 million.[6] This translated into a gasoline price increase of about a nickel per gallon for motorists and a further reduction of discretionary spending for other goods and services. Limited world refinery capacity is another choke point that is further constricted by temporary scheduled and unscheduled maintenance shutdowns and by permanent shutdowns caused by political pressures to lower pollution levels.

As the price of oil crept over the $50-per-barrel mark in early March 2005 and as traffic congestion continued unabated, there was little media attention. When the price hit $55 per barrel by midmonth and kept going, the media and the public finally took notice. Make no mistake about it—this is a serious omen for America. The problem is not that the world is running out of oil anytime soon, but that demand is exceeding the capacity limits of infrastructure to deliver and refine the oil being extracted from wells. Compounding America's energy problem is the fact that Asians hold over $2 trillion worth of its debt and are making noises about divesting themselves of dollars in exchange for euros or yen.[7] If oil exporting nations begin trading oil for euros instead of dollars, such a move would make oil even more expensive for Americans or even result in denied access to some oil supplies, thus setting up shortage scenarios or even oil wars.

Remedying these capacity limitations will cost billions of dollars and take years to implement. So why didn't all of the industries associated with the oil industry, such as shippers, refiners, and economic analysts, anticipate the rapid increase in oil demand years ago?

The main cause for seemingly sudden capacity problems is that most government and private-sector energy and economic experts miscalculated the precise impact that China's and India's rapid economic growth would have—not only on the world's supply of oil, but also on all commodities and available shipping. For instance, the Energy Information Agency (EIA) predicted in its May 2003 International World Outlook Report a world increase of 3.1% per year until 2025—far above the long-term annual trend rate of 1.4% that occurred through 1989–1999.[8] These EIA predictions were widely reported, especially the part that world oil prices would remain around $25 per barrel until a production peak of 120 million barrels per day (Mbd) was reached in 2020, even with a projected 60% increase in global energy demand and steady economic growth in developing nations.[9] How could they have been so far off? (Fig. 4)

One reason for confusion among experts is that China's political and economic system is not transparent, making accurate predictions of the demand for oil and other commodities impossible.[10] Further exacerbating the world oil economics prediction game is the lack of transparent data from the world's leading oil exporting countries for evaluating their maximum oil production capabilities.[11] This "oil reserve uncertainty" amounts to a huge accountability crisis for world economies and has the potential for causing a worldwide depression. Without knowing the actual maximum rate of oil production, governments, energy companies, financial markets, and other professionals have had no accurate way to evaluate the breadth and depth of supply. In spite of uncertainty in both supply and demand, demand remains high. Demand will remain high and even go higher until distribution bottlenecks force higher prices for oil and gasoline, eventually leading to a stifling of world economies until some sort of balance is restored between supply and demand.

Besides conventional oil supplies being severely restricted, oil production is now extremely vulnerable to a single contingency disruption. The world derives fully 20% of its oil from the 14 largest fields, each with an average age of 40-plus years.[11] Hundreds of medium-size and thousands of small fields produce the world's balance. It is well known in the oil industry that the largest oil fields have a tendency to be discovered first. And whatever an oil field's size, once tapped, it will run its production course and inevitably peak, as have the supergiant Prudhoe Bay, North Sea, and Texas oil fields. History has also demonstrated that once a field peaks, its production falls off sharply. Saudi Arabia's Ghawar oil field, by far the world's largest, might produce oil for another hundred

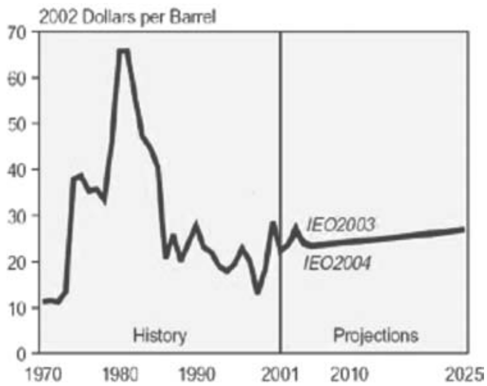

Fig. 4 Comparison of 2003 and 2004 World Oil Price projection, 1970–2025, The now infamously inaccurate 2002 EIA projections for world oil prices to steadily rise to $28 per barrel by 2025.

years, but with unknown and almost certainly lower flow rates. It may have peaked already, but no one knows for sure because the data is not publicly available. And because governments can use oil reserve estimates to secure large international bank loans, the temptation for some governments to inflate their reserve estimates is often too great to resist. Such vagaries make open accounting from the Middle East improbable at best (Fig. 5).

Oil-economy optimists tend to be economists, not geologists. Proponents of maintaining an oil-based economy are fond of trumpeting how advances in technology have enabled better yields from existing wells where perhaps as much as 70% of oil once remained underground and unrecoverable. To be sure, those percentages have improved to about 50% with today's technology. However, new technologies and more intensive extraction efforts can also lead to higher production costs. What the optimists studiously avoid mentioning is that new conventional oil field discoveries are averaging much lower yields. In 2003, Matthew Simmons, president of the energy industry's largest investment banking firm, Simmons & Company International, noted that "it could require more than 3000 new oilfields to be found and developed over the next ten years, compared to slightly more than 400 named new oilfields that were discovered in the 1990's—only 2.5% of which had yields in excess of 100,000 barrels per day."[11]

In other words, as world demand continues to increase, newly discovered sources of supply are smaller, more difficult to reach, have higher production costs, and are just barely keeping up with declines in production of existing fields, and not keeping up with increased world demand.

An alarming and related development on January 9, 2004, was the report that Shell Oil had revised its estimates of known reserves downward by 20%. On February 24, 2004, a Center for Strategic and International Studies (CSIS) forum in Washington, District of Columbia. exposed some professional doubts as to the ability of Saudi Arabia to meet future increases in demand. Attending oil executives and government officials from the United States and Saudi Arabia admitted that Saudi capacity would probably stall near current levels and potentially create a significant gap in the global energy supply[12]—a gap with enormous consequences for world transportation systems.

Simmons, who also presented at this CSIS forum, stated that "we need to begin creating a new form of energy to replace some portion of oil and gas use" and that "getting to this new era could take a long time, it all may not work, and the time to begin is today."[13] He went on to point out that Canadian and U.S. natural gas production has peaked, yet "nobody is talking about it." Well, people are starting to take notice since natural gas prices rose to over $14 per million Btu after Hurricane Katrina hit the Gulf Coast.

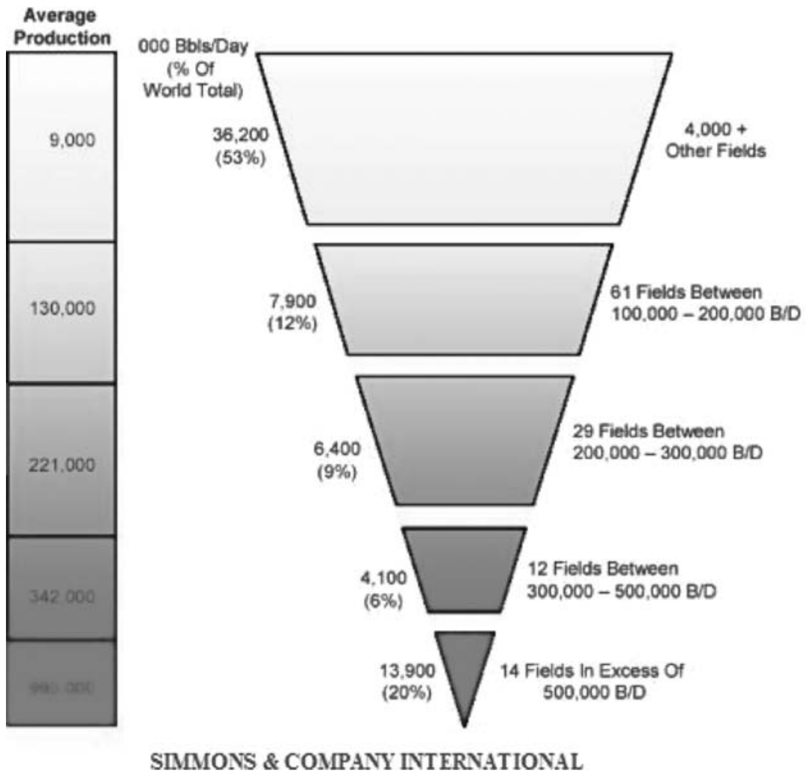

Fig. 5 The oil pyramid.

It just so happens that America's neighbor to the north has tar sand deposits with enough oil trapped in the sands to exceed the known reserves in the Saudi peninsula, albeit not as easy, clean, or cheap to recover. Syncrude, a consortium of eight U.S. and Canadian oil companies, has been actively improving methods for extracting crude from these sands since 1978. In 2003, Shell and Chevron Texaco jointly opened the $5.7 billion Athabasca Oil Sands Project in Alberta (about 250 miles north of Edmonton), which pumps out about 155,000 barrels per day. With oil prices well above the $50-per-barrel level, tar sand extraction can remain profitable and may justify further expansion.

In a well timed report and accompanying press release, Cambridge Energy Research Associates (CERA) stated that as a result of new recovery methods, tar sands represented a vast new oil reserve for the United States.[14] Maybe so, but this oil locked up in tar sands is a mixed blessing for both Canadians and Americans; America can continue its oil addiction, and Canada will be forced to deal with limiting the large amounts of carbon dioxide, sulfur dioxide, and other toxic emissions created from tar sand production.

However, from an energy expenditure standpoint, extracting oil from tar sands may end up not making very much sense, even if it does make monetary sense presently. The Canadian environmentalist Gary Gallon wrote in *The Gallon Environmental Newsletter* in October 2002, "Much of the energy used to extract tar sands oil comes from using natural gas. The natural gas price is closely tied to the price of conventional oil, on a British thermal unit basis. So when the price of oil zooms up, the price of natural gas rises accordingly. In fact, today, it is possible that the price of natural gas could increase more than conventional oil due to its environmental benefits over burning coal for generating electricity. This would leave tar sands production in an even worse economic situation."

Geologist Colin Campbell has pointed out that the Athabasca tar sands oil production uses "stranded gas"—natural gas from nearby fields that is of insufficient quantity to justify an interconnection with the North American gas pipeline grid. Stranded gas is cheap because there are no other customers for it beside the oil sand production companies. "It is running out fast," says Campbell, "and no one is going to use ordinary oil and gas to produce from the tar sands because they are too valuable." If Campbell is right, and tar sands end up being processed with commercially priced natural gas, when all the accumulated energy is tabulated for the creation of a barrel of tar sand oil, the net gain will be minimal, perhaps even a net negative. When the financial and health impacts of the resulting pollutants are factored in, the wisdom of pursuing this energy source becomes highly questionable.

The scenic region where Utah, Wyoming, and Colorado come together is known as the Green River Basin. It is also the site of the largest oil shale deposit in North America, containing more oil than all the known world reserves of conventional crude. Oil shale is supposedly another huge untapped energy source. Oil shale is neither oil nor shale. It is "source rock" that never reached the depths of the "oil window"—the depths between 7500 and 15,000 ft where organic material is transformed into oil. By exposing this source rock to high temperatures, however, the organic material contained within can be "cracked" to form oil.[15] To create the heat to crack oil takes a lot of energy; therefore, oil extracted this way comes at a cost higher than oil extracted via present conventional oil extraction methods or extraction from tar sands. Additionally, once these source rocks are heated, and the organic material contained within is converted into oil and removed, the source rock increases to about double its original volume, making tailings disposal a real financial, physical, and environmental challenge. Besides the expense and technical difficulty of extracting this oil, the damage that would be done to the land could well be far beyond what society is willing to pay for maintaining its car culture. Then again, maybe not…

These oil energy uncertainties not only portend extreme price volatility, but also raise the specter of an overly oil-dependent America once again having to come to grips with shortages. This time, however, any shortages will not be the result of a politically motivated embargo, as in the 1970s, but the result of physical limitations in oil production and distribution capacity. When and how long these periods of shortages occur depends more on what America does nationally to reduce its oil consumption levels significantly (demand) than on what the oil industry does to increase its production or distribution capacity (supply).

The 1970s oil shortages were a warning that the Nixon, Ford, and Carter administrations clearly understood and attempted to act upon with conservation measures. However, the majority of the American people did not want to hear about behaving in an energy-responsible manner. In 1980, Ronald Reagan was elected over Jimmy Carter in no small part because of his platform boasting that there was plenty of oil left in the world and that the conservationist measures of the Carter administration were another example of big government intruding on people's lives. The great disservice done to the American people by this unfounded political optimism was that it spurred increased housing development farther from city centers, put greater demands on highway and road infrastructure, and encouraged the sale of sport-utility vehicles (SUVs) with more powerful, fuel-hungry engines. The Reagan supporters discredited and ridiculed the notions of environmentalists and conservationists, and embraced the idea that increased oil consumption was a sign of American prosperity. This was a policy tailored for big business.

Unfortunately for Americans, conservationist measures are at complete odds with the economic goals of any profit-driven energy provider corporation; the production goals of any major manufacturer of internal combustion engine vehicles; the advertising industry, which thrives on producing automobile television commercials; and the political powers in Washington who have no trouble accepting political campaign contributions from all those who, understandably, do not want to get off the "gravy train." Ironically, even those who profit from the status quo are stuck in the same box as everyone else.

Ultimately, however, future generations will come to view the present extraordinary search for fossil fuels in much the same way that we now view our ancient ancestors' single-minded quest for wood—a quest that led, and is still leading, to the destruction of forests and denuded landscapes. With some enlightened conservationist measures, those forest resources could have been preserved and their use prolonged. If America cut back on government subsidies for oil exploration/production and highway and airport construction, and began instead to subsidize heavily the development of alternative energy regimes and electric-powered transportation systems, larger amounts of precious oil resources could be preserved for future generations. Oil is also the feedstock for plastics and other products, and its fuel derivatives are used in those applications that must have a compact, portable power source: aircraft, emergency vehicles, farm and construction equipment, and assorted military machines.

Long the world's largest consumer of oil, America presently consumes over 20 Mbd, 12 of which is imported and, at $55 per barrel, bleeds $240.9 billion from the U.S. economy per year (data as of late 2005). The next-largest oil consumer and fastest-growth market is China, which averaged 6.5 Mbd in 2004[16] and was hitting peaks of 8.6 Mbd by late 2005. This is out of a world total at the end of 2005 of 83.6 Mbd (1.5 Mbd more than predicted a year earlier).[17] This reveals a staggering rate of growth in world demand that presents enormous logistical challenges for expanding the existing oil extraction, delivery, and refining infrastructure. And it is this rapid worldwide demand that is driving up oil and gasoline prices in America (Fig. 6).

Rising oil and gas prices inevitably result in a plea for politicians to do something. So both sides of the aisle respond by demanding investigations. In mid-2005, many Democrats naïvely asked that President Bush stop refilling the country's strategic oil reserve to provide a short-term reduction in price pressures for something that is really a systemic long-term problem. And for their part, some Republicans used rising oil prices to gain support for opening the Arctic National Wildlife Reserve (ANWR) to oil and gas exploration, while they also quietly opened up nearly 45 million acres of previously protected federal lands in 12 Western states. At $50 per barrel or higher, even a small oil field deposit can be a profitable venture.

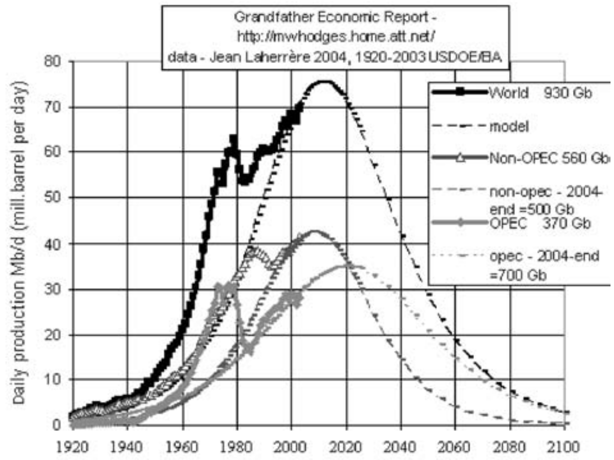

Fig. 6 World conventional crude oil production and forecast for an ultimate of 2.1 Tb (no demand constraint).

Unfortunately, the Republican attempt to drill the country's way out of its energy fix is also naïve because oil supplies can never hope to satisfy what is really a long-term worldwide demand situation.

What is surprising about the ANWR controversy is the lack of any national discussion about who should profit, and by how much, from its oil. After all, the resources to be extracted from ANWR—or any federal land, for that matter—technically belong to the people of the United States. Or do they? According to the General Accounting Office, oil exploration and production (E&P) companies pay either $12\frac{1}{2}\%$ or $16\frac{2}{3}\%$ royalties (a gentler term than taxes) for every barrel produced, depending on whether the oil field is onshore or offshore, respectively.

Practically every other oil-producing nation in the world has pried loose the financial grip of the international oil companies from their natural gas and oil resources: Mexico, Venezuela, Kuwait, Saudi Arabia, Iran, Libya, etc. For years, the oil companies gave these countries a small percentage of the revenue stream until their political leaders caught wise. One by one, these countries began to demand a greater share of the oil profits until they either took complete control of operations or allowed a joint operation partnership that left the oil companies a profit of about 20% or less. The oil companies stayed, figuring that 20% of something was better than 100% of nothing.

To be absolutely clear about what is at stake with ANWR—besides the possible trashing of a small bit of land that few people will ever see—what is at stake is an estimated 10 billion barrels of recoverable oil. At $70 dollars per barrel, that's about $700 billion. Let's just say that by the time this oil comes online in ten years, prices are $100 per barrel. That's over $1 trillion worth of oil. But how will the revenue be divided? According to present law, the government will get only 12.5% of the royalty. But which government gets the royalty? Under the provisions of the

Alaska Statehood Act of 1959, the federal government would receive only 10% of that royalty percentage (only 1.25% of total revenue), with Alaska receiving the other 90%. One has to believe that the majority of Americans would find this outrageous, especially because all Alaskans already receive yearly $2000 royalty checks and don't pay any state income tax. It is no coincidence that Alaskans and Saudi Arabians have similar attitudes toward energy resource ownership and management.

As oil is an internationally traded commodity, oil prices are determined by world markets. The best way for ANWR's oil reserves to help the American people significantly is for the government to take 80% of the revenue at the wellhead. At a production rate of 1 Mbd, this would increase yearly U.S. Treasury revenue from $456 million per year under current rules to $29.2 billion per year for the next 30 years. If Congress doesn't change the royalty system, the American people will get stuck with the triple whammy of basically giving away the oil to E&P companies, paying ever-rising prices to fill their tanks, and then being taxed for fuel at the pump. This is not a Republican vs Democrat issue or an environmentalist vs polluter issue—this is about capturing maximum revenues for the U.S. Treasury to fund properly the rebuilding of America's national transportation infrastructure to be non-oil-reliant for younger and future generations. And most important, it is about doing the right thing.

Given America's mammoth debt and pressing financial needs for Social Security, Medicare, Medicaid, clean and safe shelter for the mentally ill, electricity infrastructure development, and building new alternative electric-powered transportation networks, why is the United States not already charging 80% royalties for the oil under all federal land to fund national necessities? In fiscal 2003, the federal government collected $5.6 billion in royalties from oil and gas production on federal lands, whereas the oil companies presumably collected somewhere around $40 billion. Should the bulk of this money derived from public lands help the oil business earn record profits or should the ratios be reversed, and should the bulk of the money end up in the U.S. Treasury? Maybe this issue should be put in front of the American public as a national referendum.

If every other oil-producing country in the world took back control of its national resources and oil revenue, why doesn't America? Few Americans oppose the idea of a fair profit for E&P companies or allowing them to recoup their admittedly hefty expenses. E&P companies already receive tax breaks and subsidies for their operations, such as deductions for oil transport expenses. And with advances in seismic 3-D modeling for identifying oil deposits and directional drilling technology that allows access into many oil fields from one wellhead, costs have been dramatically lowered, and the likelihood of hitting "wet holes" has increased.

Both parties have declared their desire to lower America's reliance on foreign oil. But the truth is, oil is an internationally traded commodity that is sold to the highest bidder. In spite of laws to the contrary, it is highly conceivable that when ANWR oil production comes online, rather than just transporting it to America, oil companies will also be shipping it to Asia—just as they did with oil from Prudhoe Bay. It is simply too difficult to monitor and trace oil shipments. Regardless of ANWR, Americans will still be using and relying on foreign oil and paying the world's going rate.

America's problem is not reliance on foreign oil, but reliance on oil itself—period—regardless of the source. Because of the very real capacity limitations of world oil production, inevitable shortages will arise in the face of soaring worldwide demand. It is simply a matter of time. The price of oil will rise to unimagined levels as worldwide demand is not met. Then, as demand falls off due to oil no longer being affordable for increasing segments of consumers, prices will recede somewhat and then continue their inexorable upward climb until oil is no longer the predominant and common source of energy for general mass transportation. This price volatility cycle will eventually become a constant companion to all oil-based economies and could also be a major destabilizing ingredient for world democracies. The ramifications are huge.

On March 6, 2005, OPEC's acting secretary general, Adnan Shihab-Eldin, stated that he thought the price would reach $80 per barrel within two years. In a March 2004 interview with geologist Dr Kenneth Deffeyes, he intimated that conventional oil production would peak by November 2005 and that oil could easily hit $80 per barrel not long after. Picking who is right is irrelevant. The point is that America's transportation system simply cannot react fast enough to deflect the negative impacts of such a dramatic upward shift in the pricing levels of its primary transportation fuel (Fig. 7).

In spite of the imminent threat of dramatically rising oil prices and worsening traffic congestion, America's 2005 energy bill fails miserably to address this looming crisis; worse, it lacks any sense of urgency. In an amazing display of industry arrogance and lobbying power, the bill provided huge incentives for increased oil and gas production in spite of the industry's record profits as a result of unprecedented energy pricing levels.

In February 2004, Dr. Deffeyes stated, "Because the government has no 'Plan B,' they are essentially gambling that Hubbert and others are wrong, and their inaction will have catastrophic consequences." (M. King Hubbert was the geophysicist who accurately predicted in 1956 that 1970 would be the peak year for U.S. oil production and decline thereafter, and that the same would happen to world production soon after 2000.) Practically every other industrialized nation has attempted to insulate itself from the negative impacts of rising oil prices by employing

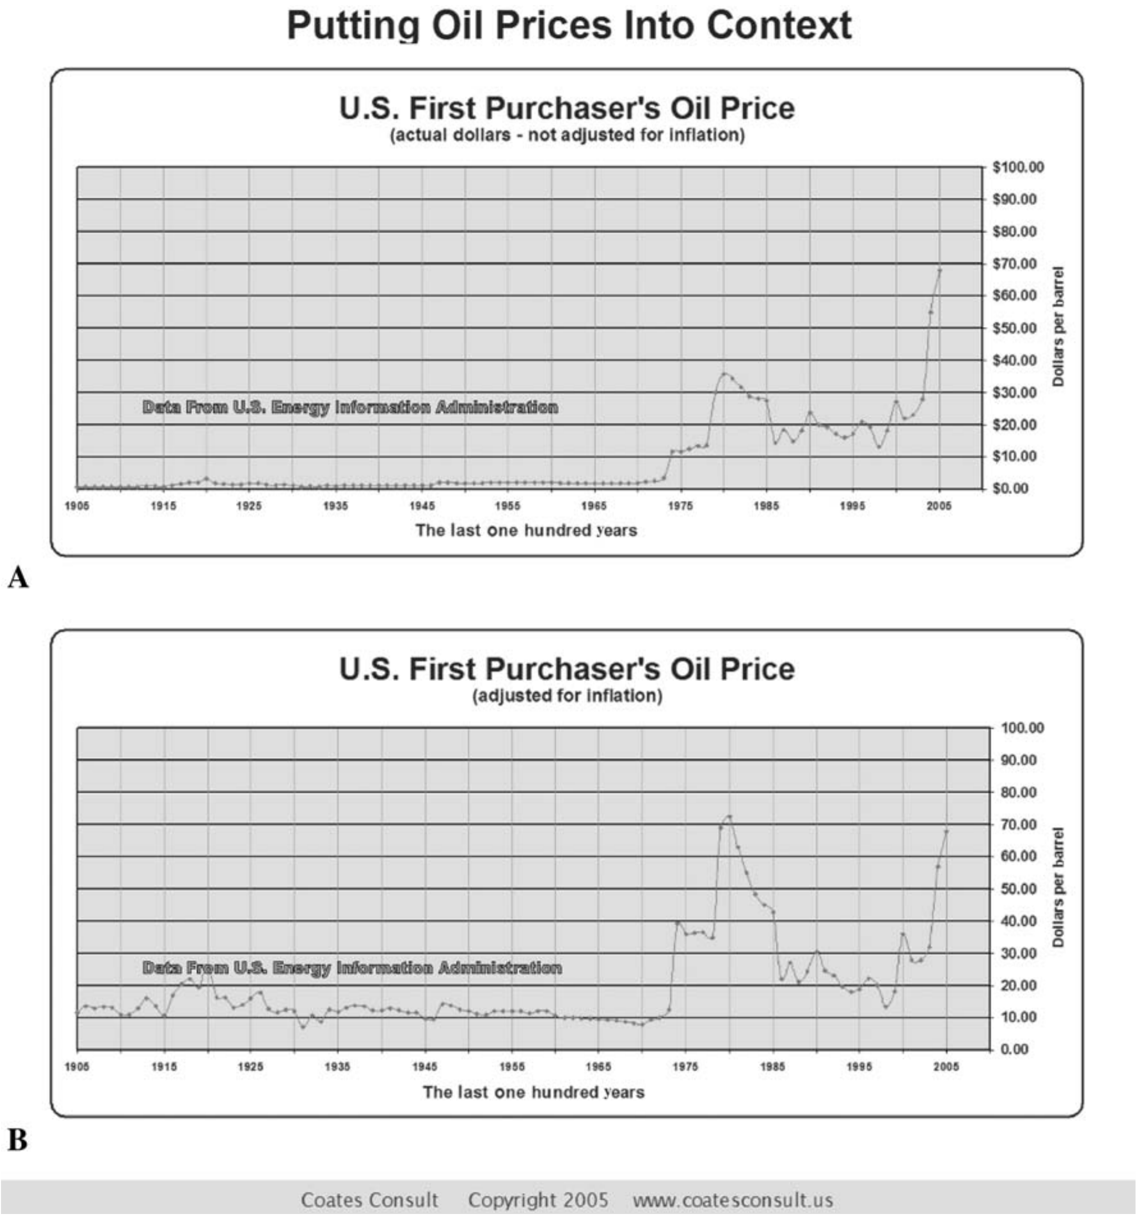

Fig. 7 Putting oil prices into context. (A) These two charts show the difference between real and inflation adjusted oil prices over the last 100 years. There are three outstanding episodes depicted in both charts: a long 65 year period of relative price stablity, followed by two major price spikes. In spite of two world wars and the Korean and Vietnam conflicts, the only significant difference is the dollar valuation in the 1970's. (B) The oil price spike in 1973, due to the first Arab oil the first Arab oil embargo, is obvious. What is not obvious, is that oil production in the United States peaked in 1970, making the country increasingly more dependent on foreign supplies and more vulnerable to volatile world oil markets. The oil embargos of the 1970's were a time of artificial, politically induced shortages. What is occurring in the early 21st century is the beginning of a period of soaring world demand in the face of a constricted oil supply infrastructure. This is a real long term problem and is not artificial. In spite of some claims to the contrary, strong conservation measures are needed.

meaningful energy conservation measures and by extensively deploying electric-powered intercity and intracity transit systems that are not oil reliant.

In light of evolving world events such as China's and India's dramatic economic growth, the world's burgeoning population, the present capacity limits of existing world oil production, the growing concern over the environmental impacts of burning hydrocarbons, and the ominous prospect of terrorist attacks[18] or natural disasters disrupting the flow of oil or natural gas, America needs a strong energy-efficiency program that proactively curtails oil demand and simultaneously supports the alternative development of an extensive electric-powered ground transportation network.

If America's leaders continue to ignore these problems, the country will be left in the weak position of constantly reacting to an increasingly volatile world energy market. The days immediately after the September 11, 2001, attacks exposed the weaknesses in the American transportation system when no practical rail transportation was available for many stranded travelers, and what rail systems were available were overwhelmed until commercial flights resumed several days later.

In spite of this collision course between energy and transportation, America persists in converting vast tracts of productive farmland into distant housing developments because farmland is cheaper than the land nearer to city centers. However, these housing "cost savings" are shifted to the energy and transportation sectors. This "distant affordable housing" and the lack of planned development that encourages energy transportation efficiency add ever more cars to highways that are already filled to capacity and increases the per capita miles driven in America, now double the amount of just 30 years ago.[1] It is this decades-long, automobile-dependent land development policy, combined with the SUV exemption from Corporate Average Fuel Economy (CAFE),[19] that is driving America's astronomical and ever-rising oil use.

Regardless of the many problems facing the nation, the first step is to understand the issues. One single thread running through all of America's more pressing national challenges seems to be a lack of a concerted vision for moving America forward on the eve of significant world change. This change is being spurred by exponential growth in world population and the concomitant growth of energy use in emerging economies. As the world begins to grapple with the impacts of these changes—not only on energy use but also on the quality of the environment—societies will be forced to transition from the previous oil-powered century into a new electric-powered century (Fig 8).[20]

How America generates and transmits its electricity is the pre-eminent challenge of the 21st century. Few Americans think about where their electricity comes from and would likely be astounded to learn that the majority of America's electricity, 51.8%, comes from burning coal.[21] To put things into a human-energy perspective, if a person were to pedal a stationary bicycle attached to a generator that powered a light bulb, the average, reasonably fit adult would be able to light a 100-watt light bulb for about a half hour before exhausting himself or herself. On average, burning 1 lb of coal is enough energy to light ten 100-watt light bulbs for 1 h. An average American's electricity usage consumes 20 lb of coal per day (incidentally, there is about 38% more energy in 1 lb of gasoline, or approximately 1 pint), and an average city with about 1 million people consumes more than 20,000 ton of coal daily—equal to the capacity of 200 railroad coal cars.[22] While tremendous progress has been made to keep emissions low in new coal-fired power plants, coal is still a dirtier hydrocarbon than oil or natural gas. Furthermore, it is also a labor-reliant fuel source with a history of work stoppages that have disrupted the flow of energy to society. It is also reliant on a rail transportation infrastructure that is running at near capacity.

According to a recent Massachusetts Institute of Technology team study,[23] it is likely that nuclear power

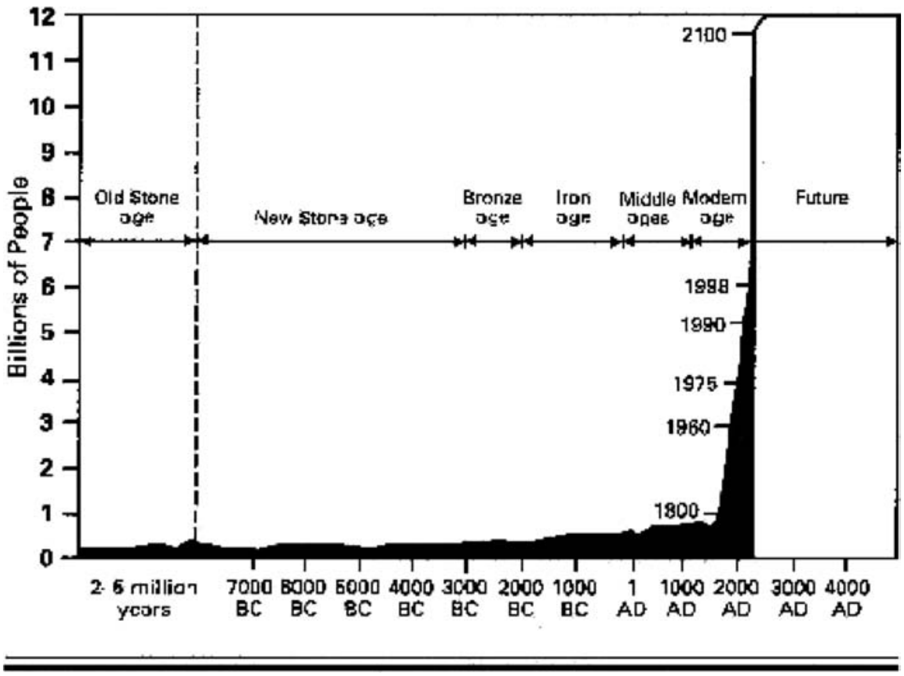

Fig. 8 World population growth history. (World population was estimated at 6.3 billion in 2004 and it is still climbing).

will be the only workable solution to meet our prodigious short-term energy needs while preventing greenhouse-gas emissions before cleaner "alternative" or "renewable" energy sources can be developed in sufficient quantities to meet our energy needs. Yet regardless of the source of power used to generate future electricity, there are serious infrastructure problems facing America's method of delivering that electric power. The same problem the oil industry faces with capacity limitations and bottlenecks also plagues the present electricity transmission grid. Transmission in America has been in dire need of massive investment for more than 25 years.

In its present state, the transmission power grid would not be able to accept the prodigious energy demands of converting large segments of America's transportation system to electric power, even if sufficient electricity generation capacity were available. Estimates are that generation capacity would need to triple or even quadruple to convert America's present transportation energy use to electricity. In other words, the grid must be expanded.[24] New transmission technologies such as superconductors and composite core transmission lines will no doubt play a major upgrading role for increasing the existing grid's capacity.

However, regardless of the source of electricity generation, reducing energy usage is the fastest, easiest, and most workable solution. This would necessarily require a renewed focus on better utilization of already available energy. Of course, the objective and the trick are to do this without sacrificing anyone's standard of living or requiring Americans to suffer physical deprivation or any real loss of freedom. Implementing a strategy that demands greater energy efficiency from all sectors of the economy, especially in regard to how and where real estate is developed, will solve many of the country's energy and transportation problems and would likely lead to a higher quality of life for more Americans.

America could implement stricter energy-efficiency requirements and create new employment opportunities by building homes, workplaces, and entertainment centers near interconnected transit hubs (known as Transit-Oriented Development, or TOD). Improved methods for insulating buildings, covering large building surfaces with photovoltaic cells to capture solar energy, and increasing the use of geothermal energy for space heating and cooling rather than burning hydrocarbons makes perfect sense.

For improved transportation efficiency, America can encourage the development and convenient use of reliable, electric-powered, quiet, efficient, and low-maintenance transit for short- and medium-distance travel, such as completely automated maglev systems. For example, the new 267-mph maglev airport connector in Shanghai, China, has been in commercial operation for over a year and is averaging an extraordinary 99.92% on-time-to-the-second schedule for arrivals and departures.[25] The low-speed (60 mph) maglev deployed in Nagoya, Japan, in March 2005 is achieving an astounding 99.97% level of reliability. With extensive electric-powered transit networks in place all along the grid, use of electric-powered cars for short local "last mile" trips would be more convenient and feasible. While rural state residents would not benefit directly from transit development for America's urban areas, their political support for urban transit could reduce overall national oil demand and thus lower the pressure on rising gasoline and oil prices, which are now hurting the agricultural sector. The list of constructive things to be done is almost endless, but by doing nothing new or by simply maintaining the status quo, America is only inviting ever-higher energy prices to force the issue, albeit painfully.

Rather than stubbornly chasing the single-minded obsession with finding cheap oil and internal combustion transportation solutions, it is critical for our federal, state, and local governments to reject their Kmart mentality of pursuing the cheapest infrastructure options and instead to focus on providing the highest-value solutions for present and future generations. And only by adopting a coherent and unified national policy that fully addresses the mutual impacts of energy, transportation, and human settlement patterns will America be able to orchestrate an effective strategy for proactively meeting its future civilian and military energy demands. However, such tectonic shifts in policy will require informed, engaged, and gutsy political leadership.

Access to cheap oil in the 20th century was the key element in America's economic development. Cheap oil was also instrumental in enabling America's successful projection of military might and preserving national security. By aggressively pursuing energy conservation simultaneously with the development of the renewable energy industry, by pursuing land development that is constructed more on the human-powered transportation scale (walking, cycling, and transit), and by converting our oil-reliant transportation system to electricity, America can regain its energy independence, achieve greater national security, create a more stable economy, and make a high quality of life for average citizens more easily attainable and sustainable.

America has the technology and financial capacity to physically transform its infrastructure systems into being more energy efficient. The country has a choice: change its energy attitudes and regain control over the quality of people's lives, or simply remain energy victims, constantly reacting to rising energy prices in a hostile world. It really boils down to choosing and electing politicians who will re-educate themselves on the energy issues, show the courage to speak the truth, and then demonstrate the political will to lead the country in the right direction.

Energy: Global and Historical Background

Milivoje M. Kostic
Department of Mechanical Engineering, Northern Illinois University, DeKalb, Illinois, U.S.A.

Abstract
The global and historical overview of energy use is presented with emphasis on energy diversity but also universality. Starting from ancient civilization a chronology of selected energy-related events is presented. It starts from the prehistoric age, when humans relied on their muscular power to survive; then they learned how to control and use fire, and to domesticate and use animal power, and slowly evolved from hunters and food-gatherers to developers of early agriculture. The use of water and wind power (waterwheels and windmills) expanded human activities and mobility. Further developments included smelting copper and iron ores; using charcoal; and developing different tools, gunpowder, and sailing ships. The use of coal in the mid-1700s and the development of steam engines set off fast growth of cities, population, and further inventions, including internal-combustion engines and the discovery and use of oil, natural gas, and electricity. This accelerated growth period, known as the Industrial Revolution, matured by the end of the 19th century with significant use of fossil fuels and further electrification, and resulted in almost-exponential growth of population and energy use. After the development of nuclear energy and the realization that the abundance of inexpensive fossil fuels will come to an end, along with concern about global environmental pollution, a modern era, with computerization and global Information Revolution, has been taking place. After all developments, life may be happier in the post-fossil fuel era, which represents only a bleep on the human-history radar screen.

INTRODUCTION AND GLOBAL OVERVIEW: ENERGY DIVERSITY AND UNIVERSALITY

The historical overview of energy intrinsically includes geological and societal (human) chronological developments. Energy is more than universal currency. The world view from inside to outside is possible, figuratively and literally, only through the energy prism. From shining stars to rotating planets; to global water, atmospheric, and life cycles; to the evolution, industrialization, and modernization of civilization, energy is the cause and measure of all that there has been, is, and will be.

Each and every material system in nature possesses energy. The structure of any matter and field is energetic, meaning active—i.e., photon waves are traveling in space; electrons are orbiting an atom nucleus or flowing through a conductor; and atoms and molecules are in constant interactions, vibrations, or random thermal motions. Energy is a fundamental property of material systems and refers to the system's potential to influence changes to another system by imparting work (forced directional displacement) or heat (forced chaotic displacement/motion of a system microstructure). Energy exists in many forms: electromagnetic, electrical, magnetic, nuclear, chemical, thermal, and mechanical. Electromechanical energy may be kinetic or potential, whereas thermal energy represents overall chaotic motion energy of molecules and related microstructures. Energy is the cause of all processes across all space and time scales, including global and historical changes. Actually, energy is "the building block" and fundamental property of matter and space; thus, it is a fundamental property of existence, as elaborated in the "Physics of Energy" article in this encyclopedia and elsewhere.[1,2] Energy is both the cause and the consequence of formation and transformation within the universe (everything we are capable of observing or comprehending) at the grand scale, down to the smallest subnanostructures within an atom nucleus and electromagnetic radiation.

Energy warms our planet Earth and keeps it alive. It moves cars and trains, and boats and planes. Energy bakes foods and keeps them frozen for storage. It lights our homes and plays our music. Energy makes our bodies grow and live and allows our minds to think. Through the centuries people have learned how to harvest and use energy in different forms to do work more easily and live more comfortably. No wonder that energy is often defined as ability to perform work—i.e., as a potential for energy transfer in a specific direction (displacement in force direction), thus achieving a purposeful process, as opposed to dissipative (less-purposeful) energy transfer in the form of heat.

Zooming in space and history from the formation of our planet Earth some 4.5 billion years ago, it is observed that our planet has been changing ever since due to energy

Keywords: Energy; Power; Fire; Fossil fuels; Steam and heat engines; Industrial revolution; Electrification; Nuclear energy; Solar energy; Computerization and information revolution; Global environmental pollution.

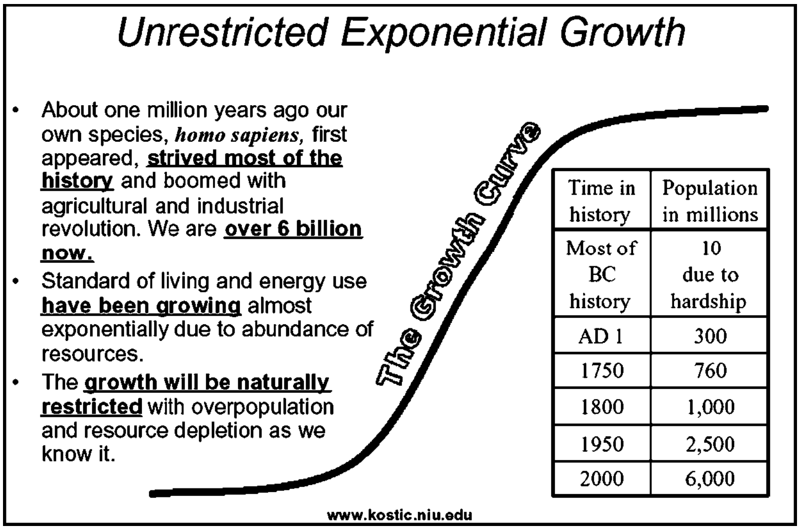

Fig. 1 Population historical growth caused by energy use.

exchanges or "energy flows" in different astrophysical, geological, chemical, biological, and intellectual processes. Hundreds of millions of years ago, life emerged from the oceans and transformed the landscape. Just a few million years ago, the first human species evolved and began its own process of interaction with its environment: the planet Earth. About 1 million years ago our own species, *Homo sapiens*, first appeared, then strived most of the history, and boomed with agricultural and the Industrial Revolution (see Fig. 1).

The current world population is about 6.3 billion. Standards of living and energy use have been growing almost exponentially due to an abundance of resources (see Fig. 2).[3] Today we humans have become sufficiently numerous and technologically active that we may be having a global impact on our planet Earth's environment.[4–6] Growth as we know it, however, will be naturally restricted by overpopulation and resource depletion (see Fig. 1). Two things are certain: in the not-too-distant future (1) the world population and its living-standard expectations will increase substantially, and (2) economical reserves of fossil fuels, particularly oil and natural gas, will decrease substantially. The difficulties that will face every nation and the world in meeting energy needs over the next several decades will be more challenging than what we anticipate now. The traditional solutions and approaches will not solve the global energy problem. New knowledge, new technology, and new living habits and expectations must be developed, both to address the quantity of energy needed to increase the standard of living worldwide and to preserve and enhance the quality of our environment.

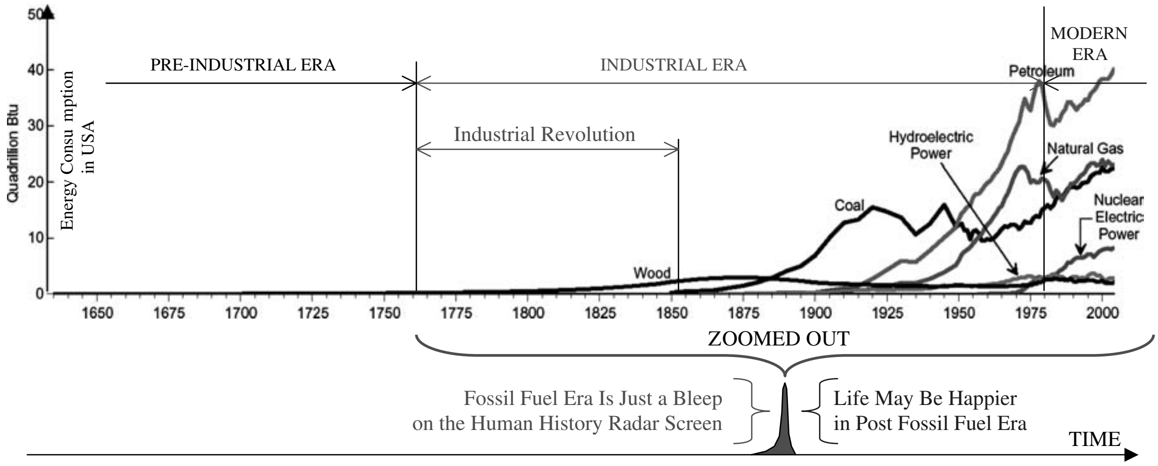

Fig. 2 Energy in history: PreIndustrial era encompasses human evolutionary survival and development of agriculture. Industrial era starts with Industrial Revolution and use of fossil fuels (just a bleep on the human history radar screen). Modern era start with human awareness of fossil fuel depletion and environmental pollution concerns.

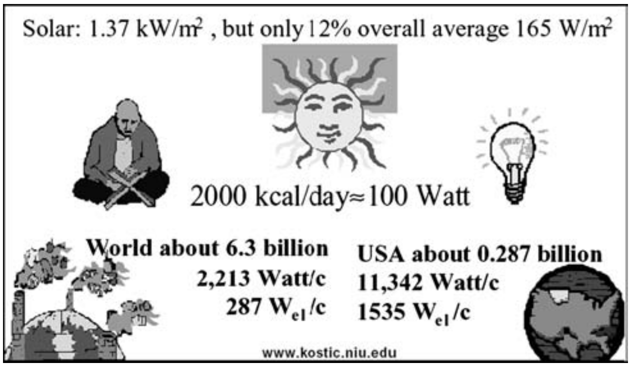

Fig. 3 Energy data: solar energy; dietary metabolic energy; and world and USA energy consumption per capita (per Person).

The human metabolism needed to maintain life is approximately equal to the dietary energy reference value of 2000 kcal/day, which is equivalent to 97 W or 331 Btu/h. Human sustained working power is about 75 W, or one-tenth of 1 hp. Human muscular power bursts may be a hundred times greater than basal metabolic or sustained power. By comparison, the world's population is about 6.3 billion, with total energy consumption about 7550 Btu/h or 2.21 kW per capita (or 11.34 kW per capita for a population of about 0.3 billion in the United States). The total energy rate in kW is often scaled by the typical 33% of thermal-to-electrical conversion efficiency to be compared qualitatively with the electrical energy rate in kW, and vice versa. The corresponding per-capita electricity consumption rate is 0.287 kW and 1.535 kW in the world and the United States, respectively (see Fig. 3).

The total energy coming to the Earth's surface is 99.98% solar, 0.02% geothermal, and 0.002% tidal/gravitational. Currently, about 14 TW (Terawatt, or 2.2 kW/capita [per person]) of the world's energy consumption rate represents only a tiny fraction—0.008%—of the solar energy striking Earth and is about six times smaller than global photosynthesis (all life). Global photosynthesis is only 0.05% of total solar energy, whereas global atmospheric water and wind are about 1% of solar energy. Note that the energy rate or power of 1 TW$=10^{12}$ W$=$29.9 QBtu/year$=$5.89 bbl/year (billion barrels of oil per year) and 1 Quad (QBtu)$=10^{15}$ BTU$=1.055\times10^{18}$ Joule$=$1.055 EJ (Exa-Joule). For energy-unit conversion and fuel, and other energy equivalents, see below and Table 1.

As an ultimate energy source for virtually all natural processes, the solar energy is available for direct "harvest" if needed and is absorbed by vegetation and water surfaces on Earth, thus being the driving force for natural photosynthesis and, in turn, for biosynthesis processes, as well as the natural water cycle and all atmospheric processes. (See the solar-related renewable energy sources in Table 2.) The solar-radiation power density incident to Earth's atmosphere, known as the Solar Constant, is 2 cal/min/cm^2 or about 1.4 kW/m^2—which, after taking into account average day/night time (50%), varying incident angle (50%), and atmospheric/cloud scatter and absorption (53%), reduces to only $0.5\cdot0.5\cdot0.47=11.7\%$ of the Solar Constant, or about 165 W/m^2 at the Earth's surface, as the all-time average (see Fig. 3).

Table 1 Energy units with conversion factors and energy equivalents

Energy units	**J**	**KWh**	**Btu**
1 Joule (J)	1	2.78×10^{-7}	9.49×10^{-4}
1 Kilowatt hour (kWh)	3.6×10^{6}	1	3.412×10^{3}

Table 2 Primary energy sources and conversion to work

Primary energy source	Conversion
Non-renewable	
Fossil fuels	
Coal	Combustion (heat and heat-engine H/HE/W[a])
Peat	
Oil/crude petroleum	
Natural gas	
Nuclear	
Uranium	Fission (H/HE/W)
Thorium	
Deuterium	Fusion[b] (H/HE/W)
Renewable[c]	
Geothermal[d]	
Hot steam/water	H/HE/W
Ground soil/rock heat	
Volcanic, etc.[b]	
Ocean-gravitational	
Tidal-ocean wave	Direct to work
Solar-related	
Ocean	
Ocean thermal	H/HE/W
Ocean currents	Direct to work
Ocean wave	
Biomass	
Wood	Combustion (H/HE/W)
Vegetation, etc.[e]	
Direct solar	
Solar-thermal	H/HE/W
Photoelectric	Direct to work
Photochemical	
Electrostatic	
Lightning, etc.[b]	
Wind	
Wind–air streams	
Hydro	
River/accumulation	
Muscular	
Human and animals	

Note: Secondary energy sources (electrical, synthetic fuels, hydrogen, etc.), with energy storage and distribution complete the energy supply domain, which with energy needs, consumption and efficiency complete the global energy realm.

Energy related processes: electromagnetic radiation; photosynthesis cycle in nature; biosyntheses cycle in nature; electrical processes: electro-dynamic, electro-magnetic, electro-chemical; nuclear reactions: fission, fusion, radioactive radiation; chemical reactions: combustion, oxidation, etc.; heat transfer and frictional dissipative processes; thermo-mechanical expansion and compression; natural air streams driven by solar dissipation and gravitational buoyancy (wind); natural water cycle driven by solar dissipation, gravitation and buoyancy (evaporation, precipitations, water streams); natural water streams (rivers and ocean streams); mechanical expansion and compression.

[a]H/HE/W, conversion to Heat and via Heat-Engine to Work.

[b]Not commercialized yet.

[c]All renewables, except tidal and geothermal, are due to solar radiation.

[d]Usually renewable, but may be non-renewable.

[e]Includes many types, as well as waste/garbage.

Source: From Elsevier Inc. (see Ref. 1).

Energy, Work and Heat Units, and Energy Equivalents

Energy is manifested via work and heat transfer, with a corresponding Force × Length dimension for work (N m, kg_f m, and lb_f ft, in SI, metric, and English system of units, respectively); and the caloric units, in kilocalorie (kcal) or British thermal unit (Btu), the last two defined as heat needed to increase a unit mass of water (at specified pressure and temperature) for 1 degree of temperature in their respective units. Therefore, the water-specific heat is 1 kcal/(kg °C) = 1 Btu/(lb °F) by definition, in metric and English system of units, respectively. It was demonstrated by Joule that 4187 N m of work, when dissipated in heat, is equivalent to 1 kcal. In his honor, 1 N m of work is named after him as 1 Joule, or 1 J, the SI energy unit, also equal to electrical work of 1 W s = 1 V A s. The SI unit for power, or work rate, is watt—i.e., 1 J/s = 1 W—and also corresponding units in other system of units, such as Btu/h. Horsepower is defined as 1 hp = 550 lb_f ft/s = 745.7 W. Other common units for energy, work and heat, and energy equivalents for typical fuels and processes are given in Table 1.

Energy Sources

Energy is provided from different sources—i.e., those systems (substances or natural phenomena) that allow for abundant, convenient, efficient, and thus economical conversion of their energy into useful energy forms (for consumption needs). This form usually is thermal for heating, and mechanical and electrical for work, with the latter being also very convenient for transmission and very efficient for conversion into any other useful energy forms. Because energy consumption needs are time and location dependent, energy conversion rate, energy density (per unit mass, volume, area, etc.), transportation (transmission), and storage are important.

There are many sources of energy (see Table 2) that provide for the diverse needs of human activities and society in general. Energy consumption may be classified in four general sectors: (1) residential, for appliances and lighting, space heating, water heating, air-conditioning, etc.; (2) commercial, for lighting, space heating, office equipment, water heating, air-conditioning, ventilation, refrigeration, etc.; (3) industrial, for water and steam boilers, direct-process energy, machine drive, etc.; and (4) transportation, for personal automobiles, light and heavy trucks, air-, water-, pipe-, and rail-transport, etc., see Fig. 4.[7] In all four sectors, in addition to primary energy sources, electrical energy, as a secondary energy source produced from primary energy sources, is used extensively, as presented elsewhere. Conversion efficiencies from different energy sources to useful mechanical or electrical work are given in Table 3.

Chronology of Events

A chronology of selected energy-related events is presented in Table A1 in the appendix.[8–10] It starts from the prehistoric age, when humans relied on their muscular power to survive; then they learned how to control and use fire, and how to domesticate and use animal power, and slowly evolved from hunters and food gatherers to cultivators of crops and developers of early agriculture. The use of water and wind power (waterwheels and windmills) enabled humans to expand their activities and mobility. Further developments included smelting of copper and iron ores, using wood and charcoal, and developing different tools, gunpowder, and sailing ships. The use of coal in the mid-1700s and the development of steam engines set off fast growth of cities, population, and further inventions, including internal-combustion engines and the discovery and use of oil, natural gas, and electricity. This accelerated growth period, known as the Industrial Revolution, matured by the end of the 19th century with significant use of fossil fuels and further developments in electricity, resulting in almost-exponential growth of population and energy use. After the development of nuclear energy and realization that the abundance of inexpensive fossil fuels will come to an end, along with concerns for global pollutions, a modern era, with computerization and global Information Revolution, has been taking place.

Regardless of the depletion of fossil-fuel resources, however, the outlook for future energy needs is encouraging. There are many diverse and abundant energy sources with promising potential, so mankind should be able to enhance its activities, standard of living, and quality of life by diversifying energy sources and by improving energy conversion and utilization efficiencies while increasing safety and reducing environmental pollution.

PREINDUSTRIAL ERA: SURVIVAL AND AGRICULTURAL DEVELOPMENT

In contrast to today's mostly sedentary lifestyle, our ancestors spent most of their existence as hunters and food gatherers, with strong physical and mental challenges to succeed in survival. Those challenges and longtime adaptations ultimately evolved in the complexities of today's societies. It took about 1 million years for our own species, *Homo sapiens*, to survive, literally in hardship, and in most of BC history, the world population was below 10 million. Except for very few early communities living in "favorable" localities, most of our ancestors were surviving on grasslands and forests with population densities comparable to their roaming foragers. Development of traditional agriculture was followed by a rise in population; further cultivation of

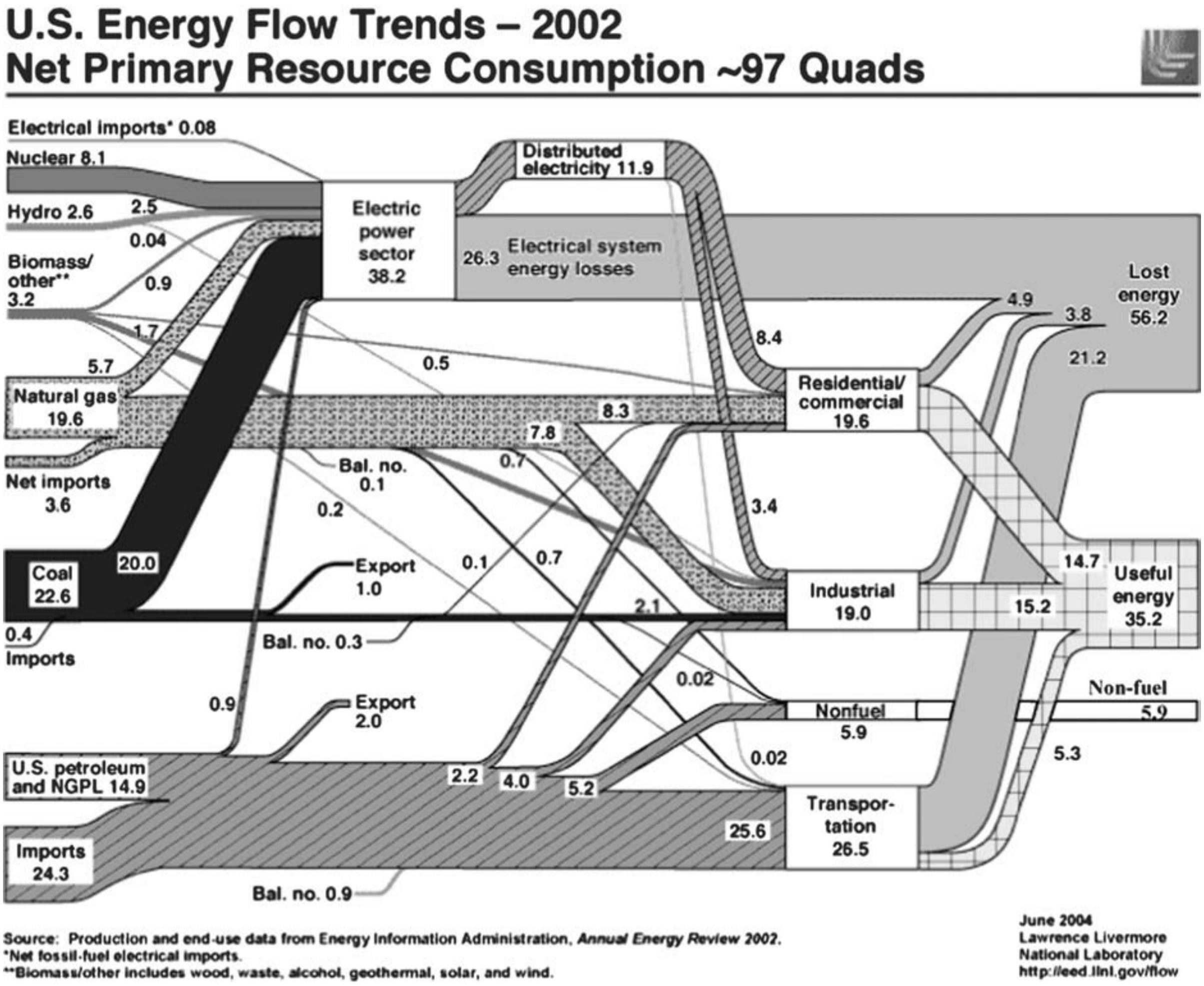

Fig. 4 Energy input–output cross-paths from primary sources to consumption sectors and energy losses. [Note that total energy is close to 100 QBtu, thus numbers are close to %].
Source: From Lawrence Livermore National Laboratory (see Ref. 7).

crops; and domestication of animals, including horses. Many cattle breeds provided draft and power, as well as milk. Virtually all fuel in preindustrial societies came from straw, wood, and charcoal. The latter was critical for smelting and processing, first metals (copper, iron, and steel) and then firing bricks. The power was provided by the muscular labor of people and animals. Even today, in undeveloped rural areas of Asia, Africa, and Latin America, most of the work is provided by human and animal labor.

Smelting metal ores required large quantities of wood and charcoal, as well as skills to sustain high temperatures in metallurgical pits and furnaces. In turn, improved tools and utilities were made of metals, leading to the development of waterwheels and windmills, as well as wheeled carts and sailing ships (see Table A1).[8,9] Increased mobility on land and sea helped in exchange of goods and skills from one area to another, which in turn helped the development of better goods, new materials and tools, and ultimately the rise of population.

INDUSTRIAL ERA: THE FOSSIL FUELS' BLEEP ON THE CIVILIZATION RADAR SCREEN

Development of prime movers using heat from fuels—the heat engines—was a critical historical event, because stored high-density energy in fuels like wood, and particularly coal and oil, could provide energy at any time and in any place. The abundance of fossil fuels (coal, oil, and natural gas) and energy independence from locality and seasonal natural phenomena, such as waterfalls and wind, opened many opportunities for unforeseen development. Invention of the first practical steam engine by Newcomen and Savery in 1712 and improvements by James Watt in 1765 started intensive development and utilization of fossil fuels—still the most dominant energy source, with an 85% share of the total energy use of modern society. The so-called Industrial Revolution was set in motion, with unprecedented developments, including internal-combustion engines; electrification and electrical motors; new devices, materials, and chemicals;

Table 3 Energy conversion efficiencies

Engine/process	Efficiency %
Otto (gasoline) engine	20–30
Diesel engine	30–40
Gas turbine	30–40
Steam turbine	35–45
Nuclear, steam turbine	30–40
Combined gas/steam turbines	40–60+
Fuel cell (hydrogen, etc.)	40–60+
Photovoltaic cell	10–25
Geothermal plant	5–15
Windmill	30–40 (59% limit)
Hydro turbine	80–85
Electro-mechanical motor/ generator	70–98

Note: Thermal-to-mechanical work conversion is limited by stochiometric combustion temperature and the Carnot cycle efficiency. Fuel cell efficiency is limited by Gibbs free energy values for process reactants and products, and may be close to 100%. Due to material property limitations and process irreversibilities (dissipation of energy), practical efficiencies are much lower and there is room for substantial improvements. For example, existing hybrid cars have 80% improved efficiency (and mileage) over the same classical cars, from 25 to 45%, by using electro/mechanical engines/storage hybrid systems.

and other inventions (see Table A1). The birth and intense development of the new energy science, thermodynamics, was taking place, along with the discovery of the fundamental laws of nature and many other discoveries in chemistry and physics. One invention was fueling another invention, and so on. The use of new heat engines and the need for more fuels were propelling discovery of many coal mines and oilfields. In return, available energy sources were enabling an intense rise in human activities, skills, and knowledge, as well as the growth of civilization, reaching 1 billion people by the end of the 18th century (see Fig. 1). The Industrial Revolution matured and continued with the Industrial Era and ultimately evolved into the modern era of societal development.

MODERN ERA: SOPHISTICATION, CONSERVATION, AND DIVERSIFICATION

The Modern Era in societal development represents a continuation of the Industrial Era, with development of new technologies (including nuclear energy, space exploration, computerization, and information technologies) as well as the realization that the abundance of inexpensive fossil fuels will come to an end, along with concern about global environmental pollution.

The primary energy sources for the world in 2003 and the United States in 2004 are presented in Table 4, and the primary sources for the production of electricity are presented in Table 5.[3,4] In addition, the U.S. energy supply by consumption sector, including electricity production, is given in Table 6. The world and U.S. populations, energy production, and consumption also are summarized in Table 4. Total energy production—including losses, import, and export—is available as energy supply for consumption and storage. Also, most of the world's electricity (about 65%, and about 71% in the United States) is produced from fossil fuels, with overall conversion efficiency of only about 33%. Conversion

Table 4 World and U.S. total energy supply by source (in QBtu)

Source	World, 2003		U.S., 2004	
Coal	99.69	23.9%	22.528	22.6%
Petroleum	159.17	38.2%	40.130	40.2%

Table 5 World and U.S. electric energy supply by source (in Billion kWh)

Source	World, 2003		U.S., 2004	
Coal			1,976.3	50.0%
Petroleum			117.6	3.0%
Natural Gas			714.6	18.1%
Fossil Fuels	10,364.8	65.4%	2,808.5	71.0%
Nuclear Electric	2,523.1	15.9%	788.6	19.9%
Hydro-electric	2,645.8	16.7%	269.6	6.8%
Renewables/Others	241.9	1.5%	89.2	2.3%
Total	15,843.9	100%	3,955.9	100%

Note: Energy in Billion kWh or %; 1 kWh(electric) equivalent to 10580 Btu(thermal) at 33% efficiency, however 1 kWh = 3412 Btu (as unit conversion).
Source: From U.S. Department of Energy (see Refs. 3 and 4).

efficiency is similar in nuclear power plants, which contribute to about 16% of world and about 20% of U.S. electricity production. When the global energy supply is given together with fossil fuels and expressed in British thermal units (Btu), all electrical energy (including hydro and wind) is given in equivalent Btu thermal units, accounting for the conversion efficiency (typically, 33%). When electrical energy is accounted separately, the actual electrical output is given in kilowatt hours (kWh), as shown in Table 5. Due to different forms and conversion efficiencies of primary energy sources, and due to the complexities of energy production and losses, transportation and storage, import, and export, it is virtually impossible to account correctly for all energy paths and forms in the same units; therefore, the total figures (and percentages) usually do not add up exactly (see Fig. 4 and Table 6 for examples).

Fossil fuels account for more than 85% of total world and U.S. energy consumption (see Table 4). Almost 40% of total world and U.S. primary energy is used for electricity production (see Tables 4–6), mainly in thermal and nuclear power plants (more than 80% in the world and more than 90% in the United States), using heat engines undergoing thermomechanical conversion processes with relatively low conversion efficiencies (see Table 3). The overall conversion efficiency from chemical or nuclear fuel energy to thermal energy of combustion gases or steam, to mechanical and electrical energy, is only about 30%–35%.

FUTURE ENERGY OUTLOOK: LIFE MAY BE HAPPIER AFTER FOSSIL FUELS

At present, most of the world's energy consumption is supplied by fossil fuels (about 85%). The proven fossil-fuel reserves are limited, however, and if they continue to be used at the present rates, it is estimated that coal (as used under current conditions) will be depleted in about 250 years; oil, in 60 years; and natural gas, in about 80 years. We have to keep in perspective that "proven reserves" refers to the customary and economical mining and utilization of fuels, but new reserves and more efficient technologies are being discovered, making new fuel reserves economical. At present, a substantial amount of the world's electricity is obtained from nuclear and hydro energy (about 16 and 17%, respectively), and the use of other renewable energy resources is increasing—namely, geothermal, wind, biomass, and solar. In addition, alternative synthetic fuels, including hydrogen, are being developed. It is worth noting that some countries (including Norway, Brazil, New Zealand, Austria, and Switzerland) produce almost all or most of their electricity from hydro energy, and France produces most of its electricity (more than 75%) from nuclear. Reserves of nuclear fuel are orders of magnitude higher than reserves of fossil fuels, and nuclear fuel does not contribute to CO_2 and greenhouse pollution.

Table 6 U.S. energy consumption by sector in 2004 (in QBtu)

Sector	Primary		Electric		Total	
Residential	7,022	7.1%	14,154	36.43%	21,176	21.2%
Commercial	4,072	4.3%	13,443	34.60	17,515	17.6%
Industrial	22,076	22.3%	11,171	28.75%	33,247	33.3%
Transportation	27,709	27.6%	84	0.22%	27,793	27.9%
Electric	38,850	38.7%				
Total	99,729	100.0%	38,852	100%	99,740	100%

Source: From U.S. Department of Energy (see Ref. 3).

Furthermore, advances in energy conversion and utilization technologies, and increases in efficiency, including computerized control and management, contribute to energy conservation, an increase in safety, and a reduction of related environmental pollution. Actually, per-capita energy use in the United States and other developed countries has been reduced in recent years. The increase of the world's population, however, and the development of many underdeveloped and very populated countries (China, India and others) will influence continuous increase of the world's energy consumption.

Fig. 5 gives one of the most recent projections of the world's energy consumption, by region, until 2025.[5] The Mature Market Economies region (15% of the 2005 world population) represents North America, Western Europe, and Mature Market Asia (Japan, Australia, and New Zealand). The Transitional Economies region (6% of the 2005 world population) represents Eastern Europe (EE) and the former Soviet Union (FSU). The rest is the Emerging Economies region (78% of the 2005 world population), consisting of emerging Asia (53% of the 2005 world population), the Middle East (4% of the 2005 world population), Africa (14% of the 2005 world population), and Central and South America (7% of the 2005 world population).

World energy consumption is projected to increase by 57% from 2002 to 2025. Much of the growth in worldwide energy use is expected in the Emerging Economies countries. The increase is projected on average to be 2.0% per year over the 23-year forecast (from 2002 to 2025)—somewhat lower than the 2.2% average annual growth rate from 1970 to 2002. Worldwide, total energy use is projected to grow from 412 QBtu (quadrillion British thermal units) in 2002 to 553 QBtu in 2015 and 645 QBtu in 2025 (see Fig. 5).[5] Emerging Economies will account for much of the projected growth in energy consumption over the next two decades, with energy use in the group more than doubling by 2025 due to strong projected economic growth in the region. The world population is expected to grow on average by 1% per year (0.4, −0.2, and 1.2% in the Mature, Transitional, and Emerging regions, respectively) and to reach 7.85 billion by 2025. The gross domestic product (GDP) is expected to increase by 3.9% per year on average: 5.1% per year in the Emerging Economies countries, compared with 2.5% per year in the Mature Market Economies countries and 4.4% per year in the Transitional Economies countries of Eastern Europe and the former Soviet Union (EE/FSU). The long-term projections are more uncertain because future development may turn in many different, even unexpected, directions.

Fig. 5 World energy history and projection consumption by region.
Source: From U.S. Department of Energy (see Ref. 5).

As already stated, two things are certain: In the not-too-distant future (1) the world population and its living-standard expectations will increase substantially, and (2) economical reserves of fossil fuels, particularly oil and natural gas, will decrease substantially. The difficulties that will face every nation and the world in meeting energy needs over the next several decades will be more challenging than what we anticipate now. The traditional solutions and approaches will not solve the global energy problem. New knowledge, new technology, and new living habits and expectations must be developed, both to address the quantity of energy needed to increase the standard of living worldwide and to preserve and enhance the quality of our environment.

A probable scenario, in the wake of a short history of fossil fuels' abundance and use (a bleep on the human-history radar screen), the following energy future is anticipated:

1. Creative adaptation and innovations, with change of societal and human habits and expectations (life could be happier after the fossil-fuels era).
2. Intelligent, high-tech local and global energy management in a wide sense (to reduce waste, improve efficiency, and improve the quality of the environment and life).
3. Unforeseen large (higher order of magnitude) potential for energy conservation and regeneration in industry, transportation, and the commercial and residential sectors.
4. Nuclear energy and re-electrification for most stationary energy needs.
5. Cogeneration and integration of power generation and new industry on a global scale (to close the cycles at sources, thus protecting the environment and increasing efficiency).

6. Renewable biomass and synthetic hydrocarbons for fossil-fuel replacement (mobile energy, transportation, and chemicals).
7. Advanced energy storage (synthetic fuels, advanced batteries, hydrogen, etc.).
8. Redistributed solar-related and other renewable energies (to fill in the gap).

In conclusion, life may be happier after the fossil fuel era, which represents only a bleep on the human-history radar screen. With increased population and technological developments, and sophistication in many areas of complex societies, there will be many unforeseen opportunities to enhance efficiencies of energy production and utilization. Therefore, the outlook for energy needs is encouraging. There are many diverse and abundant energy sources with promising potential, so the mankind should be able to enhance its activities, standard of living, and quality of life by diversifying energy sources and by improving energy conversion and utilization efficiencies, while at the same time increasing safety and reducing environmental pollution.

APPENDIX A

Table A.1 Chronology of selected energy-related events in history

Year	Event in energy history
500,000+ or BC	Middle Pleistocene humans control fire (burning wood). Direct evidence was found outside a cave at Chou k'ou-tien, China, where charcoal was found along with traces of a stone tool
10,000+	Paleo-Indians used hot springs in North America for cooking, and for refuge and respite
6,000+	The earliest known use of ships comes from Egyptian rock drawing dating from 6,000 BC
4,500+	Egyptians mine copper ores and smelt them
4,000+	Horses are ridden in what is now the Ukraine
3,500+	Wheeled vehicles are used in Mesopotamia as seen in a pictograph found in Uruk
1,000+	Coal from the Fu-shun mine in northeastern China may have been used to smelt copper
900+	The use of natural gas was mentioned in writings from China
480+	The Persians used incendiary arrows wrapped in oil-soaked fibers at the siege of Athens
400+	Greek philosopher Democritus theorized that matter consists of tiny particles called atomos, that could not be divided
250+	Archimedes invents a number of items including the Archimedian screw—a helix-shaped screw in a tube for lifting water. He is also credited with having discovered the principles of the lever
211+	It was in China that the first known well was drilled for natural gas to reported depths of 150 m (500 ft)
100+ BC or +	In Illyria (ex-Yugoslavia and Albania), and probably in western Anatolia (Turkey), water-powered mills are used for grinding grain
100 AD	Hero of Alexandria invents the first steam engine called the aeolipile. It consisted of a spherical vessel fitted with two jets pointing in opposite directions. Hero also invented a wind device
300	Chinese learn to use coal instead of wood as fuel in making cast iron
300	Water mills appear in Roman Empire
300	First known references to a perpetual motion machine appears in a Sanskrit manuscript. It describes a wheel with sealed cavities in which mercury would flow in such a fashion that one half of the wheel would always be heavier, providing continuous spinning
600	The earliest known references to wind-driven grain mills, found in Arabic writings
1100	As a result of the Arab invasion of Spain, the industrial art of distillation of petroleum products into illuminants became available in western Europe by the 12th century
1200	The first documented proof that coal was mined in Europe, provided by the monk Reinier of Liège
1200	Alcohol is first distilled in Europe from grains
1221	Chinese use bombs and other uses of gunpowder, leading eventually to development of rockets
1500	Leonardo da Vinci invents many devices including a glider, parachute and a helicopter type of device
1570	William Gilbert studies magnetism and the corresponding attraction of rubbed amber and various rubbed jewels
1603	Hugh Platt discovers coke, a charcoal-like substance produced by heating coal
1609	The first attempt is made to harness ocean energy in the Bay of Fundy

(Continued)

Table A.1 (*Continued*)

1612	A primitive thermometer invented by Galileo
1650	Otto van Guericke develops a way to charge a ball of sulfur with static electricity. He also observed light produced by electricity. The term electricity is coined to describe the force that is found when amber is rubbed with silk (static electricity)
1659	Natural gas is discovered in England; the first time in Europe
1660	Robert Boyle presented a law (Boyle's law), which states that pressure varies inversely with volume at constant temperature, paving the way for the ideal gas law
1670	Christian Huygens builds a motor driven by explosions of gunpowder
1680	Sir Isaac Newton proposes that a jet of steam could be used (like a rocket) to power a carriage, an idea now considered to be a precursor to development of the jet engine
1680	The match is first discovered by Robert Boyle who rubbed phosphorus and sulfur together
1687	In famous Principia, one of the most important and influential works on physics of all times, Isaac Newton presents the universal law of gravitation and the three fundamental laws of motion
1690	The recycled paper manufacturing process is introduced. The Rittenhouse Mill near Philadelphia made paper from fiber derived from recycled cotton and linen rags
1698	Dennis Papin describes an apparatus (called the Papin Cylinder in which the condensation of steam in a cylinder creates a vacuum. He later in 1698 develops the first piston that is moved by the pressure of steam rather than atmospheric pressure
1709	Sir Issac Newton builds an electric generator consisting of a rotating glass sphere
1712	Thomas Newcomen in collaboration with Thomas Savery build the first practical steam engine to use a piston and cylinder
1738	Daniel Bernoulli published the conservation of live forces in hydraulics (now known as Bernoulli equation) and the kinetic molecular theory of gasses
1747	Benjamin Franklin describes in a letter his discovery that a pointed conductor (Franklin's lightning rod) can draw electric charge from a charged body
1755	Leonhard Euler equations for the motion of inviscid incompressible fluid and contributions in mathematics, optics, mechanics, electricity, and magnetism
1765–1776	The steam engine is perfected by James Watt with condenser that is separated from the cylinder
1766	The element hydrogen (symbol is H) is discovered by Henry Cavendish (1731–1810), an English physicist and chemist
1774	Joseph Priestley and Karl Scheele independently discover the element oxygen (symbol is O)
1775	Allesandro Volta describes his electrofore perpetuo (electrophorus), a device for producing and storing a charge of static electricity, replacing the Leiden jar and eventually leads to modern condensers
1777	The first buildings in France since Roman times are heated by warm water central heating systems
1779	The first versions of the bicycle appear in Paris
1783	Montgolfier brothers of France create the first hot air balloons using flame fires
1787	First steamboat in America is demonstrated on the Delware River in Philadelphia, Pennsilvania
1789	The element Uranium (symbol is U) is discovered by Martin Klaproth, a German chemist
1789	Antoine Lavoisier presented a unified view of new theories of chemistry, contained a clear statement of the law of mass conservation, and denied the existence of phlogiston. He lists elements, or substances that could not be broken down further, which included oxygen, nitrogen, hydrogen, phosphorus, mercury, zinc, and sulfur. His list, also included light, and caloric (heat fluid), which he believed to be material substances. He underscored the observational basis as opposed to reasoning
1799	Alessandro Volta creates the first electric battery called the Voltaic pile
1804	Richard Trevithick develops a steam locomotive that runs on iron rails
1816	Robert Stirling invents a power cycle with heated air that operates without a high-pressure boiler
1821	Michael Faraday reports his discovery of electromagnetic rotation. He creates the first electrical "motors," although his rotating needle is not a real motor because it cannot power anything
1821	Johann Seebeck observes that two different metals joined at two different places kept at two different temperatures will produce an electric current. This is called thermoelectricity and the Seebeck effect will later be used in the development of the semiconductor

(Continued)

Table A.1 (*Continued*)

1823	Methyl alcohol was first discovered by condensing gases from burning wood into a liquid. It is used as a solvent and a chemical building block to make consumer products as plastics, plywood and paint
1824	In "On the motive power of fire," Sadi Carnot shows that work is done as heat passes from a high to a low temperature. He defines work and hints at the second law of thermodynamics
1827	George Ohm writes "The galvanic circuit investigated mathematically," which contains the first statement of the Ohm's law, that the electrical current is equal to the ratio of the voltage to the resistance
1830	The first locomotive in the U.S. to carry 26 passengers 13 miles over the tracks of the Baltimore and Ohio Railroad. George Stephenson's steam locomotive was chosen over three competitors to open the Liverpool to Manchester railway in England. This is considered the start of the railroad boom
1831	Michael Faraday independently discovers that electricity can be induced by changes in an electromagnetic field. Though Henry found it earlier, but didn't publish it, so Faraday is credited with the discovery
1832	Joseph Henry discovers self-induction, or inductance, the second current in a coil through which one current is passing that is induced by the first current
1838	The steamship Sirius is the first ship to cross the Atlantic on steam power alone, taking 18 days and very nearly running out of coal before reaching New York
1839	The first work done with photovoltaics was performed by Edmond Becquerel
1839	William Grove develops the first fuel cell, a device that produces electrical energy by combining hydrogen and oxygen
1841	Frederick de Moleyns obtains the first patent for an incandescent lamp, an evacuated glass containing powdered charcoal that bridges a gap between two platinum filaments
1842	Julius Robert Mayer is the first to state the law of conservation of energy (known as the first law of Thermodynamics), noting that heat and mechanical energy are two aspects of the same thing
1943	Joule experimentally measure the "heat equivalent of work," also known as "mechanical equivalent of heat," thus discrediting the caloric theory
1948	William Thomson (i.e. Lord Kelvin) proposed an absolute scale of temperature. It was based on theory proposed by Sadi Carnot and later developed by Clapeyron
1850	Rudolf Clausius and later Rankine formulate the first law of energy conservation, which starts new science "Thermodynamics." The first statement of the second law of thermodynamics was enhanced by Clausius in 1865 as "entropy always increases in a closed system." In other words, other energies in an isolated (i.e., closed) system will change toward heat and disorder
1851	William Thomson (i.e. Lord Kelvin) describes heat pump, a device where heat is absorbed by the expansion of a working gas and given off at a higher temperature in a condenser
1853	William Rankine, proposed a thermodynamic theory with Kelvin based on the primacy of the energy concept. He stated the Law of Conservation of Energy as "all different kinds of physical energy in the universe are mutually convertible." He also invented an absolute temperature based on the interval of one degree Fahrenheit termed the Rankine temperature scale
1853	Kerosene is extracted from petroleum for the first time
1855	Henry Bessemer introduces the Bessemer process for producing inexpensive steel in a blast furnace
1859	Gaston Plante in Paris invents the first lead-acid storage battery, which produces electricity from a chemical reaction and can be recharged again and again
1865	Natural gas first found near Stockton, California when workmen drilling for water found natural gas at 1,800 feet. It supplied gas for lighting the courthouse as well as warm water for nearby swimming baths
1867	Nicholaus Otto developed an internal combustion engine that is an improved version of Lenoir's engine
1870	Heinrich Hertz used Edmond Becquerel's discoveries that certain materials, such as selenium, produced small amounts of electric current when exposed to light. Not long after that, selenium photovoltaic cells were converting light to electricity at 1–2% efficiency
1875	Alfred Nobel accidentally discovered that nitroglycerine retain its explosive properties when absorbed by diatomaceous earth, calling it "dynamite." He left his estate to establish famous "Nobel Prizes."
1882	Joseph Fourier developed a mathematical theory of heat in terms of differential equations
1877	Nikolaus Otto develops the four-cycle internal combustion engine, similar to what we use today
1879	Thomas Alva Edison invented the first electric incandescent lamp of practical value

(Continued)

Table A.1 (*Continued*)

1880	Pierre Curie discovers the piezoelectric effect that certain substances produce electric current under pressure
1882	The first electric central station to supply light and power was the Edison Electric Illuminating Company of New York City. It had one generator which produced power for 800 electric light bulbs. Within 14 months, the service had 508 subscribers and 12,732 bulbs
1884	Nikola Tesla invents the electric alternator, an electric generator that produces alternative current
1885	James Prescott Joule builds an internal combustion engine that is the precursor to the diesel engine
1886	Henry Ford builds his first automobile in Michigan
1888	Heinrich Hertz detects and produces radio waves for the first time. Radio waves are called Hertzian waves until renamed by Guglielmo Marconi, who calls them radiotelegraphy waves
1890	Clement Ader's Eole is the first full-size aircraft to leave the ground under its own power, carrying its inventor as a pilot. The plane crashed on landing, so the invention was not credited to Ader
1891	Nikola Tesla invents the Tesla coil, which produces high voltage at high frequency
1893	Rudolf Diesel describes an internal combustion engines that will be named after him. The ignition of the injected fuel in the cylinder is self-ignited due to high temperature of the compressed air
1895	On the Willamette River at Oregon City, Oregon, the first dam is specifically built to drive a hydroelectric power plant
1897	Joseph Thomson discovers the electron, the particle that makes electric current and the first known particle that is smaller than an atom
1900	The first offshore oil wells are drilled
1901	Guglielmo Marconi transmits first long distance communication using electromagnetic or radio waves
1902	America's first moving-picture theater opens in Los Angeles, charging 10 cents for a one hour show
1902	Maie and Pierre Curie discover the atomic weight of radium
1902	Willis H. Carrier invents the first air conditioner, although his name is first used in 1906 to describe a different device
1905	Albert Einstein published his paper on the photoemissive photoelectric effect, along with a paper on his theory of relativity. The paper describes light for the first time as being both a wave and a particle. He later wins Nobel Prize in 1921
1908	Polish scientist Czochralski developed a way to grow single-crystal silicon, a necessary step for computer industry and solar cells
1919	British airship R-34 is the first airship to cross the Atlantic Ocean
1921	A German scientist, Friedrich Bergius succeeds in liquefying coal into oil in Stuttgart
1927	First successful long-distance television transmission was demonstrated, from President Hoover's office in Washington, DC, to the Bell Laboratories in New York
1929	The first "talking" movie filmed entirely in color was released
1929	Felix Wankel patents a rotary engine, but the engine is not practical until the 1950s
1929	Georges Claude develops the first electrical power plant to use the difference in temperature between the upper and lower layers of ocean
1937	Frank Whittle and A.A. Griffitsh build the first working jet engine in England. Independently in Germany, von Ohain and M. Muller develop a similar engine
1942	The first self-sustaining nuclear chain reaction was demonstrated by Enrico Fermi and his staff at the University of Chicago, making possible the development of the atomic bomb
1945	U.S. explodes the first nuclear weapon at Alamogordo, N.M, a different type of atomic bomb is dropped on the Japanese city of Hiroshima, followed by another nuclear bomb on Nagasaki on August 9, 1945
1946	The ENIAC computer is demonstrated to scientists and industrialists; even though it was used during W.W.II. It multiplies 360 ten-digit numbers and extracts a square root "in a single second."
1946	First Soviet nuclear reactor goes into operation
1947	The first peacetime nuclear reactor in the U.S. starts construction at Brookhaven, NY
1947	Andrei Sakharov and F.C. Frank propose the use of negative muons to produce fusion reactions in a mixture of deuterium and hydrogen. This possibility is rediscovered in 1957 by Luis Alvarez

(Continued)

Table A.1 (*Continued*)

1947	The first airplane to break the speed of sound, the Bell X-1, is flown by Chuck Yeager
1948	The first transistor, invented by Drs. John Bardeen and Walter Houser Brittain, was demonstrated. The essential element of the device was a tiny wafer of germanium, a semi-conductor
1948	Market acceptance of frozen orange concentrate leads to the expansion of the frozen foods industry, with associated increases in packaging
1951	An announcement was made of a battery that converts nuclear energy to electrical energy. Philip Edwin Ohmart of Cincinatti, Ohio, invented the radioactive cell
1952	Westinghouse Electric Corporation builds the first breeder reactor at the U.S. Atomic Energy Commission's laboratories in Arco, Idaho. It produces more plutonium than the uranium it burns, promising an era of cheap nuclear energy
1954	Bell Lab's Chapin, Fuller, Pearson: AT&T, patent "Solar Energy Converting Apparatus," submitted to U.S. patent office
1957	The Soviet Union launches the world's first artificial satellite, Sputnick 1. Another satelite Sputnick 2 carried a live dog Laika into space, but the dog did not return to earth
1958	Integrated circuits produced by Texas Instruments
1959	Francis Bacon builds a fuel cell in which hydrogen and oxygen react in a mixture of potassium hydroxide in water to produce electricity
1961	Yuri Gagarin becomes the first human in space making a single orbit of the planet in 1 h 48 min
1962	Telstar satellite launched; the first commercial telecommunication satellite; project of Bell Telephone Laboratories, proposed in 1955 by John R. Pierce
1969	Humans first steps on the Moon. Neil Armstrong and Michael Collins and Edwin Aldrin on the Apollo 11
1969	Geologists discover oil in Alaska's north slope
1971	Silicone chips are produced by Intel and Texas Instruments
1972	The first electric power using municipal refuse as a boiler fuel was generated by the Union Electric Company's Meramec Plant in St. Louis, Missouri
1973	The polyethylene terephthalate plastic bottle is patented by chemist Nathaniel Wyeth which soon began to replace glass bottles. The recycling of the plastic soon followed
1976	Unmanned US Voyager spacecraft lands on Mars
1977	Trans-Alaska oil pipeline opens
1980s	Personal computers take off
1982	CD players produced by Philips and Sony
1983	Specially built 1-kW, PV-powered car, the Solar Trek, drives across Australia, covering 4000 km in less than 20 days. The maximum speed was 72 kph, with an average speed for the trip of 24 kph
1984	A 20-MW geothermal plant opened at Utah's Roosevelt Hot Springs
1985	Martin Green team, University of New South Wales, Australia, breaks the 20-percent efficiency barrier for silicon solar cells under "1-sun" conditions
1986	Chernobyl nuclear reactor number 4 near Kiev in ex-Soviet Union explodes leading to a catastrophic release of radioactivity
1986	The world's largest 14,000 MW Itaipu Dam, along the border of Brazil and Paraguay, is opened
1986	NOVA, an experimental laser fusion device at the Lawrence Livermore National Laboratory create the first laser fusion reaction. Fusion, however, remains elusive through the end of the century
1989	Exxon Valdez, a 1,260,000 barrels-of-oil tanker strikes a reef in Alaska's Prince William Sound, spilling an estimated 240,000 barrels of crude oil
1992	The biggest array of 9600 thin film photovoltaic modules ever assembled starts operation in Davis, California, delivering up to 479 kW, enough for over 100 homes
2000s	Computerization with Internet information exchange, sophistication and globalization (see Energy Future Outlook section above)

Note: All early dates are approximate and other dates may differ due to reference to either conception, patenting, publication, or first application, in different sources[8–10] or elsewhere.

Glossary

Energy: It is a fundamental property of a physical system and refers to its potential to maintain a system identity or structure and to influence changes with other systems (via forced–displacement interactions) by imparting work (forced directional displacement) or heat (forced chaotic displacement/motion of a system's molecular or related structures). Energy exists in many forms: electromagnetic (including light), electrical, magnetic, nuclear, chemical, thermal, and mechanical (including kinetic, elastic, gravitational, and sound).

Energy Conservation: It may refer to the fundamental law of nature that energy and mass are conserved—i.e., cannot be created or destroyed, but only transferred from one form or one system to another. Another meaning of energy conservation is improvement of efficiency of energy processes so that they could be accomplished with minimal use of energy sources and minimal impact on the environment.

Energy Conversion: A process of transformation of one form of energy to another, such as conversion of chemical to thermal energy during combustion of fuels, or thermal to mechanical energy using heat engines, etc.

Energy Efficiency: Ratio between useful (or minimally necessary) energy to complete a process and the actual energy used to accomplish that process. Efficiency may also be defined as the ratio between energy used in an ideal energy-consuming process vs energy used in the corresponding real process, or vice versa for an energy-producing process. Energy, as per the conservation law, cannot be lost (destroyed), but the part of energy input that is not converted into useful energy is customarily referred to as energy loss.

Industrial Revolution: Controversial term referring to the development of heat engines and use of fossil fuels, first in Britain and later in other countries, from 1760 to 1850.

Nonrenewable Energy Sources: The energy sources (such as fossil and nuclear fuels) created and accumulated over a very long period in the past, for which the creation rate is many orders of magnitude smaller than the consumption rate, so that they will be depleted in a finite time period at the current rate of consumption.

Renewable Energy Sources: The continuously or frequently available (renewed daily or at least annually) energy sources—solar energy, wind, water flows, ocean and tidal waves, biomass, and so on—that, for all practical purposes, are expected to be available forever.

Enterprise Energy Management Systems

Gregory Cmar
Bill Gnerre
Kevin Fuller
Interval Data Systems, Inc., Watertown, Massachusetts, U.S.A.

Abstract
Building automation systems and metering systems are an enormous source of valuable operational data. However, it is rarely put to use, as facilities professionals do not have adequate means to collect and manage the data. The information is lost and decisions are made without solid operational facts, resulting in underperforming buildings and physical plants. An Enterprise Energy Management System (EEMS) addresses this by collecting all of the operational data from building systems, organizing it, and providing users with highly interactive access to the infomation contained within the raw data.

This article highlights the key functional requirements of an EEMS, and focuses on the complexities of collecting data from the many disparate sources and making it a highly valuable information source for operators, engineers, technicians, and management.

INTRODUCTION

It is all about the data. Current building automation systems (BAS) and metering systems produce huge amounts of valuable data—most of which is thrown away. Facilities staff and engineers typically use as little as 1% of the available data for making decisions about operations, building and plant optimization, commissioning, design engineering, performance contracting, automated diagnostics, and other related tasks. This is the fundamental role of an enterprise energy management system (EEMS)—to collect all of the available data related to energy consumption and costs, organize it, and provide users with access to the engineering facts that live within the data.

Unlike control systems and diagnostic tools, an EEMS provides a complete view of an entire facility's operations, not just component parts. This level of insight is the only way to achieve all of the business benefits possible, including lower energy consumption, improved space comfort, extended equipment life, better use of staff, energy purchase savings, demand reduction, better engineering designs, lower construction costs, and much more.

This entry highlights the key functional requirements of an EEMS and focuses on the complexities of collecting data from the many disparate sources, making it a highly valuable information source for operators, engineers, technicians, and management.

Keywords: Energy management; Facilities operations; Chiller plant; Boiler plant; Optimization; HVAC; Interval data; Utility billing.

EEMS Defined

An EEMS consolidates energy-related data (sources, costs, and control and monitoring points) into a data warehouse and provides a platform for tools to access the data easily and obtain actionable information.

The EEMS makes data-driven information available so that the end user is able to perform in-depth diagnostics, engineering analysis, and monitoring in a small fraction of the time it took with earlier methods. By publishing information for consumption outside the traditional facilities management area, an EEMS supplies critical information to department heads, financial staff, and executive management as well.

Five simple but crucial principles form the basis of an ideal EEMS:

1. All energy-related data is consolidated into a centralized data warehouse.
2. The collected data is "normalized" and structured.
3. Access to data is interactive to facilitate distillation of actionable information.
4. The system makes it easy to measure and verify results.
5. The system provides a platform that embraces industry standards for data collection, management, analysis, and publication.[1]

It is worth noting what an EEMS is not: it is not a control system, and it should not be confused with a BAS. An EEMS is much broader in scope. It provides a platform for data collection, data access, diagnostic and monitoring capabilities, a historical data warehouse, and a lot more, as detailed throughout this entry. Similarly, an EEMS is not a utility billing system. It encompasses billing and meter data but extends beyond by connecting billing information directly to the related operational data.

EEMS PRINCIPLE 1: CONSOLIDATE ALL ENERGY-RELATED DATA INTO A DATA WAREHOUSE

Energy-related data comes from purchased utilities, generated utilities, BAS, metering systems (both advanced and manually read), weather, computerized maintenance management systems (CMMS), and space planning systems. Additionally, an EEMS manages rate and billing data, users, and organizational information.

To be able to utilize energy data, the first step is to identify and collect the right data into a data warehouse so that accurate and actionable information can be available. The EEMS needs to collect all data, as one cannot optimize the whole system by optimizing each component.

This section identifies the different data sources and attributes that define an EEMS and populate its data warehouse.

Purchased Utilities

Most facilities purchase electricity, fuel (usually natural gas or oil), and water. Some also buy chilled water and steam. An EEMS manages both consumption and billing information, and presents this data in an intelligible, clear, and actionable format. Fig. 1 is a simplified view of the issues related to collecting utility data.

Consumption information is typically time based, regardless of the type of utility. For example, electric utilities commonly use 15-min intervals; natural-gas utilities use daily intervals; and water uses monthly or quarterly intervals. Eventually, these different time series need to be "normalized" so that information can be presented in consistent intervals.

Billing information is equally complex. Large facilities often have multiple vendors for each utility type, each with differing rates, billing cycles, and pricing structures, resulting in a significant amount of billing data to collect and manage. For example, a university may have 1000–10,000 utility bills per year.

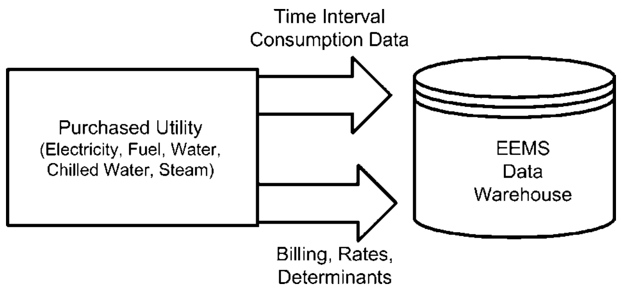

Fig. 1 Billing and consumption data should be collected in tandem.

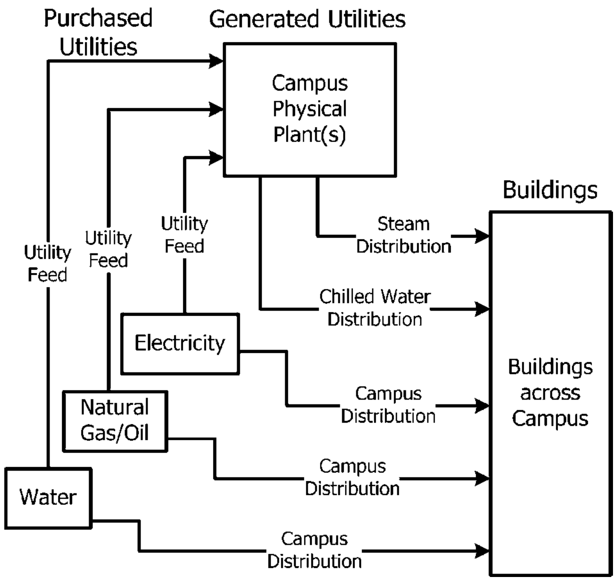

Fig. 2 Institutions typically deliver purchased and generated utilities to the facility.

Generated Utilities

Most large facilities have their own physical plants that generate and distribute chilled water and steam. An EEMS collects data from the control system(s) of the plant, as well as from the distribution network and buildings (Fig. 2).

The EEMS also collects billing information, just as it does for purchased utilities. Facilities that generate their own chilled water, steam, or even electricity will have their own rate structures and determinants, and they will bill internally based on consumption.

Building Automation Systems

Many institutions operate more than one BAS, so an EEMS provides a complete, holistic view by collecting data from all systems and overcoming the limitations of relying on the BAS for data. It is this systemwide view that enables organizations to diagnose operations and energy usage more quickly and effectively (Fig. 3).

Extracting Data from the BAS

To provide a comprehensive picture, an EEMS requires data from all control and monitoring points. Gathering data only from monitoring points (without control data) means that while you may identify something to improve,

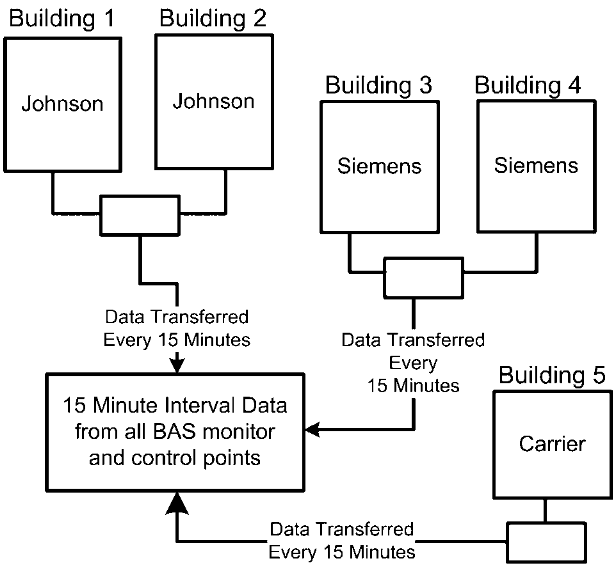

Fig. 3 Energy management system (EEMS) collecting data from multiple building automation systems (BAS).

it is unlikely that you'll gather sufficient information to know with certainty how to improve it (Fig. 4). (This is what happens when one installs advanced metering systems instead of an EEMS.)

At large facilities, it is not unusual to have 30,000–130,000 points (or more), each generating one value every 15 min. For every 30,000 points, there are over a billion data intervals per year. Without an EEMS, much, if not all, of this information is thrown away (Fig. 5).

Meters and Metering Systems

Meters and metering systems are typically located at buildings and throughout the distribution system to measure the use of electricity, steam, chilled water, fuel, etc. (Fig. 6).

For electricity, access to metering data via the metering database is a relatively straightforward process, but for those utilities that do not leverage advanced metering systems, data can be obtained through the BAS (Fig. 7).

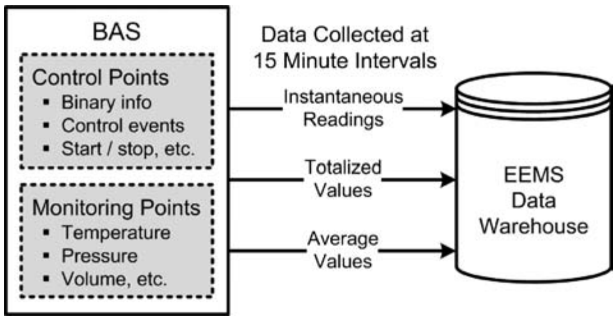

Fig. 4 The energy management system (EEMS) collects various kinds of data from control and monitoring points every 15 min.

In addition to the automated data collection described above, an EEMS will incorporate manually collected data.

Other Data Sources

Weather has a large impact on energy consumption and forecasting. For the most accurate results, an EEMS includes official weather data from a local airport, in addition to local sensors that may be inaccurate for various reasons, such as being located too close to a building, in the sun, broken, etc. (Fig. 8).

Space planning data is used by an EEMS to identify energy costs at the space level. Space planning systems contain information concerning the use and allocation of all areas within a facility. They map the hierarchy of the facility and understand the relationships between space and cost centers.

Market and pricing data affects the ability to purchase energy at favorable rates. Prices, pricing structures, and regulations constantly change. The role of the EEMS in purchasing energy is threefold:

- To display past and future energy usage patterns
- To convert and present utility billing and consumption usage into an equivalent real-time price
- To present real-time pricing information.

Easy access to actual and predicted usage patterns enables the organization to make more-informed utility purchasing decisions than ever before.

Do Not Throw Data Away

Large organizations spend millions of dollars annually on energy, millions on systems like BAS, and tens of millions for heating, ventilation, and air conditioning equipment, yet they throw away most of the data these systems generate, largely because there is so much data, and they are difficult to access, manipulate, and interpret.

An EEMS captures these data and leverages them to provide a complete picture of utility consumption and an organization's energy infrastructure over time so that the most expeditious analysis can take place to reduce the total cost of ownership and operation.

EEMS PRINCIPLE 2: NORMALIZE AND STRUCTURE DATA

Energy management system (EEMS) Principle 1 focuses on the importance and requirements of getting data into the system. Principle 2 addresses constructing a data warehouse based upon the data least common denominator: a standard time interval.

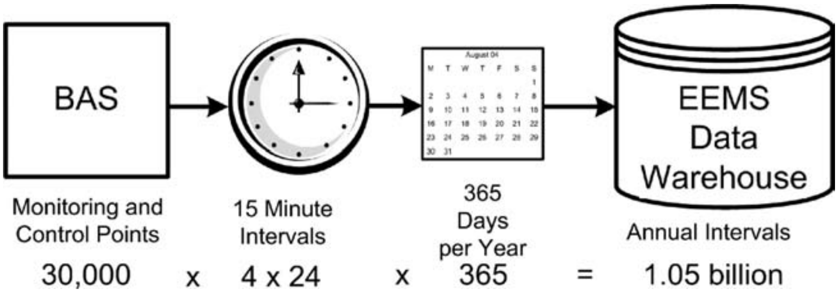

Fig. 5 The ability of an energy management system (EEMS) to store, manipulate, and display very large volumes of data in an efficient manner is mission critical.

Optimal Time Interval

An EEMS uses a standard time series interval, selected to ensure sufficient data to identify transitions. This means that there should be enough data points gathered to discern performance fluctuations across transition time periods (between day and night, office hours and nonworking hours, etc.) so that behavior patterns and problems become apparent quickly.

For this reason, and because electricity is frequently metered within the same time interval, 15 minutes is an appropriate time for EEMS normalization. Longer intervals do not provide sufficient data granularity to show all behavioral changes. Shorter intervals can be used, but one has to manage the trade-off between more data and more information. You also need to consider how long data will be kept—ideally, for the lifetime of a piece of equipment (20 years or more).

Normalized Interval Data

Normalizing means that data from all sources is stored in the warehouse in the same time interval. Not all data sources provide data in the same interval, so the EEMS reconciles these differences.

Interval data inconsistencies are a fact that must be acknowledged and addressed. A well-implemented EEMS accepts these inconsistencies and fills the gaps with estimates that, when totaled, account for the total energy consumed and represent the pattern of that energy usage in a precise and accurate manner. For meter data, the relevant utilities' processes for validating, editing, and estimating (VEE) should be followed.

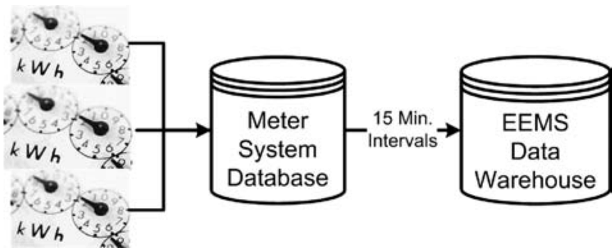

Fig. 6 A connection between the metering databases and energy management system (EEMS) must exist to synchronize data views of meter and building automation systems (BAS) data.

Data Warehouse Structure and Hierarchy

To derive value from such a large amount of data, a defined structure and hierarchy must exist to make the data readily consumable. The EEMS data structure requires flexibility too, because physical configurations are constantly changing—buildings are added, equipment fails unexpectedly, organizational changes lead to space modification, etc.

Warehouse Objects

The data structures in an EEMS parallel the physical facility, allowing it to be easily used to focus on an individual building or piece of equipment.

An EEMS warehouse supports logical objects—sets of information and relationship hierarchies—that allow for this structure. Table 1 shows six such warehouse objects and the hierarchy that exists within them. The warehouse structure also supports the way different elements within the object inter-relate—for example, the way meter interval data connect to billing rate data and physical building data.

EEMS PRINCIPLE 3: PROVIDE INTERACTIVE ACCESS TO ACTIONABLE INFORMATION

Defining Interactive and Actionable

Interactive access allows the users to work with the data in a dynamic fashion, moving seamlessly through the data with tools that provide near-instantaneous response. This allows users to "work the way they think" rather than being limited to a series of static queries and reports.

Actionable information is usable as the basis and rationale for effective decision-making. To create

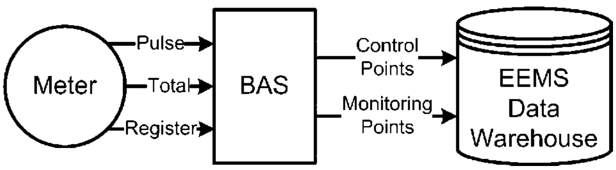

Fig. 7 Data can be obtained and transferred through a building automation systems (BAS).

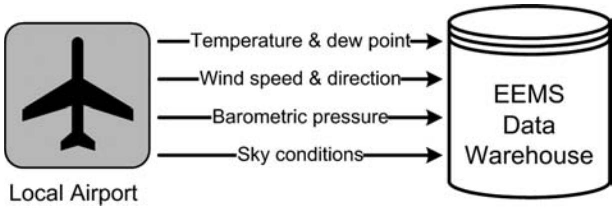

Fig. 8 METAR weather data should be used within an energy management system (EEMS).

actionable data, the EEMS should collect both monitoring and control points. With monitoring data alone (without control information), it is difficult to verify or quantify the savings opportunity.

Time and Usability Matters

With gigabytes or even terabytes of data to manage, the use and operation of an EEMS cannot be an arduous and time-consuming task. An EEMS accesses and presents data to users at the "speed of thought," enabling users to view information created from hundreds of thousands of data intervals in a few minutes. If users have to wait for this information, their thoughts will wander. If they continually have to wait, and if they are not constantly engaged, their reaction will be that the EEMS is wasting their time.

Currently, most facility personnel waste an enormous amount of time collecting and distributing data. This wasted time is culturally accepted as part of the job, when in fact, instead of spending days manually gathering and piecing together data, a well-implemented EEMS can deliver it in seconds. With immediate access to the data and information, staff frees up time to devote to the real engineering work of diagnostics, analysis, and planning.

The time required to gain insight is directly related to the usability of the system. It is essential that data can be assembled dynamically by the user via a simple, intuitive interface. The elements of the interface include the data organization and visualization, and the program interface itself. A well-integrated EEMS supports other aspects of the facility staff's workflow, such as tracking identified issues or interacting with external analysis tools.

Data Organization and Presentation

An EEMS categorizes data in meaningful ways, such as organizing within the facility hierarchy (zones, buildings, floors, rooms), organization (departments, rooms), or systems (chiller system, air handling system). In most cases, data access occurs through multiple views so that, for example, a building manager can examine the building information while a plant engineer can look at chiller operations facility-wide. Users can "drive through the facility" from their desktops by viewing the information. An EEMS also provides a method for users to define their own organized views.

The Importance of Trend Data

Trend data is the foundation of diagnostics, monitoring, measurement, and verification, and building a historical record of facility operations. While BAS typically contain a function called trend logs, they are a poor mechanism to collect trend data for the EEMS due to a variety of limitations. Trend lines from the EEMS interval data provide a data visualization and interaction paradigm that does not suffer these same limitations (see Table 2). The differences elevate, by orders of magnitude, the

Table 2 Some of the uses, users, and differences between building automation systems (BAS) trend logs and energy management system (EEMS) trend lines

Application of BAS trend logs and EEMS trend lines

Criteria	**BAS trend logs**	**EEMS trend lines**
When to use		
Diagnosing operations	After problem has been identified as under the control of the BAS and further data is needed for final diagnosis	Always—superior tool for nearly all diagnostics and all cases where historical data or data outside the BAS must be considered
Monitoring operations	When real-time data for a small number of BAS points needs to be watched	Always—provides the ability to monitor hundreds of trends in minutes, combining data from any and all sources
Typically used by	BAS control engineers and technicians	BAS control engineers and technicians, energy engineers, area mechanics, facility managers, performance monitoring contractors, commissioning agents, HVAC design engineers
Technology perspective		
Data storage	Stores point data for trends defined	Stores data for all points from all systems
Data availability	Only those points explicitly trended, with the total number of trends extremely limited (a few points)	Historical trend data always available for every point in the system (many thousands) without affecting control system performance
Time interval of data	Captures data in increments from milliseconds to minutes	Captures data from all systems at regular intervals (e.g., 15 min)
Displays data from	Native BAS	Multiple BASs, metering systems, utilities, weather, billing
Display time period	Typically a few days or weeks	Between a day and a year, with historical data going back years
Data storage	Up to a few months and data is discarded	Up to 20 years

effectiveness of an EEMS for diagnostics, monitoring, and other applications, which results in actionable information.

Building automation systems trend logs do have their place in providing needed information—where their ability to collect real-time data is useful—as shown in Table 2.

Calculated Data: Providing Actionable Information

The efficiency gains in having commonly desired calculations available for monitoring and diagnostics are tremendous, and they have a dramatic impact on usability. A visual display of an ongoing trend built on a calculation can provide insight instantly that would otherwise take hours of analysis in Microsoft Excel.

More complicated calculations can provide users an overall operational efficiency rating, the power consumptions, and the energy cost for each 15-min period. Calculations of this complexity rely on the EEMS's ability to integrate fully data from all sources and present them in a normalized fashion as actionable information.

A sample of calculations includes

- Balance equations
- Chiller efficiency
- Chiller total cost
- Chiller plant total hourly cost of operations
- Cooling tower cost and efficiency
- Cooling tower makeup water cost and efficiency
- Delta T
- Pump brake horsepower
- Pump efficiency
- Pump kW
- Theoretical water loss
- Tons output.

Application Interface

All the usability factors mentioned must come together in the software user interface. It is how end users interact with the data—through mouse clicks, menu selections, expandable data trees, contextual menus, dragging and dropping, etc.

The EEMS allows users to take an iterative approach with each action, building on the last for diagnostic purposes. Monitoring is fast and efficient, allowing users to cycle quickly through hundreds of trend lines in minutes. Ultimately, it is the combination of information display (trend lines, calculations, etc.), user interface, and system performance of the EEMS that allows the user to work at the speed of thought and to improve the quantity and quality of decisions made.

Present User-Specific Information

An EEMS supports a variety of energy-related applications and users, including energy engineers, HVAC design engineers, technicians, area/building mechanics, facilities engineers and managers, commissioning agents, energy purchasers, and performance contractors.

An EEMS provides a variety of output options that enable everything from detailed reports with data tables and charts of multiple trend lines to summary reports that roll up information into cost breakdowns and overall operating-efficiency ratings.

Users of information from an EEMS extend well beyond facilities and maintenance staff to building managers, department heads, finance personnel, executives, and managers—anyone who has occasional needs for some facilities information. These "tier two" users typically do not need interactive access to the data at the individual point level and are well served by predefined reports focused on business issues, not engineering details. Enterprise-level energy and operational data published to meet their specific needs and interests will help realize the many business benefits listed later in this entry.

EEMS PRINCIPLE 4: MEASURE AND VERIFY RESULTS

All too often, performance measurement and verification (M&V) ends up neither measuring nor verifying performance. It is a simple case of not having access to the data to do M&V properly—a problem an EEMS solves. Without an EEMS, verifying and measuring results of optimization efforts are largely left to engineering estimates and educated guesswork. At the very least, it is an extremely time-consuming process to gather thorough operational data. The ability to quantify improvements accurately and monitor their persistence gives facility directors the tools to hold contractors and their own staff accountable, and these tools can help directors increase their credibility with upper management.

In measuring and verifying results, it is important to define terms often used to justify and quantify the impact of investments in utility operations.

Energy Savings vs Dollar Savings

An EEMS accounts for both energy savings and cost savings (actual dollars). Just because the utility bill dropped does not necessarily indicate that money/energy has been saved; rather, it confirms only that less money was spent. It verifies nothing about reduced energy consumption.

Factors like price, weather, new construction coming online, and consumption rates are required to understand whether actual energy savings have occurred. To realize true energy savings, which in turn lead to dollar savings, consumption must be reduced independent of these factors, and this can be achieved only when energy usage is being controlled more efficiently.

Stipulated Savings vs Real Savings

Stipulated savings typically are savings amounts specified and agreed to up front with an entity assisting with funding energy efficiency improvements—for example, a performance contract for retrofitting lighting that uses 25% fewer watts or replacing an older chiller with a newer, more efficient model. Stipulated savings often do not translate into real savings because more variables than just the efficiency of the equipment come into play.

The stipulated amount will not take into account issues such as the percentage of lighting fixtures that aren't working prior to the retrofit, or behavioral changes in hours the new lighting is in use or the percentage of lights turned on, and often, this amount will not consider the additional heating energy required during winter months because of the lower wattages. This isn't to say that the efficiency gains promised don't exist, but that one may not see the expected consumption reductions in utility bills. An EEMS allows one to view both the data for the electricity consumed by equipment type and for the utility consumed to heat (or cool) the area, all within the context of a specific space, allowing a real savings assessment to be made.

Use Life-Cycle Costing

An important concept to adopt is life-cycle costing. It is the most appropriate way to assess equipment and building costs. The initial purchase of HVAC equipment is a significant capital investment, but its true costs lie in this number plus the cost of its operation, service, maintenance, and total life span.

EEMS PRINCIPLE 5: A PLATFORM THAT EMBRACES INDUSTRY STANDARDS

Using industry standards and an open architecture is the right way to build any enterprise-class application. This has been proved repeatedly at all levels of technology and business, where broad support and interoperability are significant benefits. A platform architecture and the use of standards protect the organization by minimizing dependency on any single vendor, even allowing functionality to be added outside the vendor's development cycle.

There are standards in several areas that an EEMS should adhere to.

Operating system. There are three platforms, sufficiently open and standardized, that an EEMS could run on. The first, and by far the most popular, is Microsoft Windows. It offers the greatest availability of tools and options, and is already installed and supported nearly everywhere. The Microsoft.NET platform is excellent for developing and integrating application components. Other options include Linux, which has strong server support and tools such as J2EE but is a limited end-user platform, and a Web-based solution, which involves Windows or Linux servers using Web browsers for the application front end (which instills limitations on the user interface).

Database management. Data storage for an EEMS should be open, accessible, and interoperable with other systems using a standard relational database (e.g., SQL Server, Oracle, etc.). Proprietary data managers will handcuff users to rely on the vendor for everything.

Data collection. As discussed earlier, data are the lifeblood of an EEMS, and access to these data is a complex and arduous task. Standards such as OLE for process control (OPC), BACnet, and LonWorks enable cost-efficient solutions for data collection.

Analysis. Data analysis tools range from the most general and broadly available (Excel) to highly specialized analytics. Ideally, the EEMS will provide direct support for Excel, allowing users to take advantage of analysis routines already developed. Minimally, the EEMS will provide data export into any analysis program.

Space planning and classification. For colleges and universities, the EEMS should support higher education general information survey (HEGIS) groups and classifications for space planning. It should also interface with market-leading space planning systems.

Publishing. Making information available throughout the organization requires a standard format, such as HTML. For long or data-intensive publishing, other formats may be appropriate, such as PDF, XML, or Microsoft Office.

Geographically Dispersed Enterprises

Not all enterprises are located in a single building or campus. When implementing an EEMS across a series of locations, it is preferable to collect data locally at each facility, primarily to minimize the number of possible points of failure that could interrupt data collection. A well-architected EEMS will allow centralized users to view and combine data from the individual locations, thereby still realizing the full benefits of an enterprisewide understanding of operations.

The size of the individual facilities may influence the local/central decision. For example, a school district may choose to deploy an EEMS centrally because the engineering and operations staff may be a single, district-wide group. However, local technicians and mechanical staff should have access to the data pertaining to their school.

BUSINESS APPLICATIONS OF AN EEMS

The EEMS has many business applications, each with different benefits to the facility. Some of these applications deliver benefits that are operational savings (reduced energy consumption); some enhance the infrastructure; and others address the business of facilities operations. The most common applications of an EEMS are:

- Operational diagnostics and monitoring
- Efficient building control strategies
- Building and physical plant commissioning (existing buildings and new construction)
- Validating engineering design/redesign and construction
- Chiller plant efficiency calculations
- Controlling building comfort
- Enhanced customer service
- Accurate energy cost allocation
- Capital-request justification
- Information publishing
- More accurate budgeting and forecasting
- Increased accountability and credibility
- Purchased utility accounting
- Vastly improved performance M&V.[2]

Financial Benefits of EEMS

It is clear that an EEMS is able to provide the infrastructure to support many different business purposes. It is important that these applications of EEMS technology are also able to deliver a rapid return on investment in a number of areas, including:

- Lower operational costs
- Positive cash flow
- More effective staff deployment
- Greater indirect cost recovery
- Reduction in equipment maintenance costs and increased equipment life
- Improved efficiency of energy purchasing.

CONCLUSIONS

This entry provides the reader a definition, a functional description, and insight into the complexities of an EEMS. For readers considering an EEMS purchase, this entry does not address in detail issues such as the functionality/value/cost relationships. Larger facilities—those with a million square feet of space or more—should look for an EEMS that is complete and meets the ideal criteria. At this writing (2006), these systems have not scaled down in size sufficiently to necessarily be cost effective for smaller facilities. This will happen over time, especially as BAS vendors make data more easily available.

An ideal EEMS will adhere to the following criteria:

- It collects data from all monitoring and control points from all sources, gathering consumption data, control settings, and billing and rate information to provide a holistic view.
- It normalizes and structures the data within a data warehouse, providing flexibility to handle complex relationships, hierarchies, calculations, and adjustments to meet evolving requirements.
- It presents actionable information through trend lines and other reporting/graphical formats. Performance and user interface must combine to provide interactive access to the data.
- It delivers value and savings that can be measured and verified.
- It is more than an application—it is a platform for energy management and other facilities operations that is expandable and conforms to open standards.

An effectively implemented EEMS provides unparalleled insight into facility operations. It nearly eliminates the time wasted by staff gathering needed data. It provides individuals the ability to find and address inefficiencies rapidly (fixing the root cause, not just treating symptoms) that can result in immediate cost savings and an ongoing financial return—often when these problems have gone undetected for many months or even years.

An EEMS presents the opportunity to span all existing BAS and energy-related data so that assessments can be made in the context of the whole facility, environment, and billing climate. Complete information leads to better decisions—decisions that address building comfort, energy consumption, operational costs, capital investments, and stewardship of the assets.

Environmental Policy

Sanford V. Berg
Director of Water Studies, Public Utility Research Center, University of Florida, Gainesville, Florida, U.S.A.

Abstract
Environmental policy is designed to reduce the negative impacts of economic activity on water, air, and other natural resources. It is difficult to identify and quantify the damage caused by pollution on human health or inflicted upon sensitive ecosystems, so determining the benefits and costs of remediation policies is often extremely difficult. Policy-makers respond to domestic political pressures by devising institutions and instruments to address pollution and environmental sustainability. Cost-benefit analysis (CBA) and cost-effective analysis provide frameworks for systematically identifying and evaluating abatement strategies that avoid potential inefficiencies or inequities.

INTRODUCTION

When economic activity leads to pollution and over-use of common property resources, government intervention can improve social welfare. Pollution involves a market failure in which damages caused by a producer or consumer are imposed on third parties. These damages can involve personal health, the physical deterioration of buildings, and foregone options for the future. Of course, if transaction costs are low, those that are causing pollution damage can be taken to court if the liability rules are clear. Destruction of common property resources such as losing unique ecological habitats, endangering particular species, or destroying valued scenic vistas is another form of market failure affecting the environment. Because there may not be clear property rights to such elements of the environment, these common property resources can be overutilized. Given the lack of well-defined property rights, government enacts environmental laws to address these market failures. However, identifying and quantifying the damage caused by pollution sources or inflicted upon sensitive ecosystems can be difficult, making any determination of the benefits and costs a contentious exercise. Consequently, choosing policies that define the extent of the environmental protection can be both contentious and problematic.

The next section describes the multidisciplinary inputs that are incorporated into environmental policy analysis, selection, and implementation. Other topics addressed here include policy impacts, the burden of proof, economic evaluation, and the strengths and limitations of policy options.

Keywords: Environmental impacts; Regulation; Cost-benefit analysis; Cost-effective analysis.

MULTIDISCIPLINARY APPROACH TO DEVELOPING ENVIRONMENTAL POLICY

Environmental economics is the study of how economic and environmental issues interact. Issues addressed by environmental economists include but are not limited to evaluating ways to reduce pollution, analyzing the trade-offs between using renewable and nonrenewable resources, or estimating monetary values for ecosystems or habitat. While no single field of study contains all the insights needed to develop and implement sound environmental policies, the focus here will be on economics because it provides a system for incorporating many perspectives and it is the framework by which environmental policy is designed and evaluated. Depending on the burden of proof, the resulting policies might be excessively stringent (costly relative to their benefits) or inadequate for the protection and preservation of environmental features that affect human health and welfare and have intrinsic value.

We know from materials balance that human activity does not create matter but only changes its form, concentration, and location, thus there is a need for physical sciences such as chemistry, physics, and biology to help inform environmental policy. While all societies affect natural systems, the scale of potential impacts has grown with economic development. There is evidence that as incomes rise, citizens are willing to devote relatively more resources to controlling environmental impacts. Moreover, many citizens would like to see much more attention given to reducing current damages and limiting the risks for future harm, hence an understanding of societal and political dynamics is also important for informing environmental policy.

The development and implementation of sound environmental policy draws upon information and procedures from many fields of study. Here, economics is utilized as the framework for integrating the concepts, measurements, and values required for the steps:

1. Determine appropriate regulatory objectives (through citizen participation in political processes and community consensus-building).
2. Balance those objectives to determine regulatory priorities.
3. Identify and legislate oversight responsibilities for environmental agencies.
4. Develop (a) mechanisms for monitoring environmental impacts (such as ambient air and water quality) and (b) methodologies for integrating new scientific understandings of environmental impacts into the policy prioritization process.
5. Define the appropriate targets for different types of pollutants and the protection of biodiversity.
6. Determine (and then apply) the appropriate policies for meeting objectives.
7. Analyze environmental indictors on a regular basis, checking for noncompliance.
8. Evaluate the impacts, recognizing potential biases in the measures and the ways impacts are valued.
9. Establish an effective process for monitoring and reviewing the framework, including the penalties and sanctions applied when there is noncompliance.

These steps require input from a number of disciplines that shape the way we see things. Although technical training allows analysts to delve deeply into subjects in a consistent manner, awareness of other disciplines' perspectives can be important for constructive environmental policy-making, including:

- Engineers look to technology for solutions to environmental problems. They are able to incorporate new (often expensive) control technologies into energy extraction, production, consumption (energy efficiency), and pollutant disposal and storage (as with nuclear waste).
- Meteorologists and hydrologists analyze pollution transport in air and water systems. They have a deep understanding of the impacts of discharges under different conditions. In conjunction with demographers and epidemiologists, they can estimate the doses received by different population groups.
- Medical scientists and toxicologists analyze the dose-response relationships for citizen health, conducting exposure and risk assessments.
- Ecologists study the impacts of pollutants on the local and global environment, assess the value of ecosystem services, and track invasive species and biodiversity. Climate scientists help assess the causes and consequences of changes in local and global temperatures and other weather patterns.
- Materials scientists look at damages caused by air and water pollution. The associated impacts include cleaning and painting buildings, treatment costs, and shorter life spans for affected equipment.
- Political scientists focus on issues of power, legitimacy, social cohesion, and the roles of different stakeholder groups in influencing environmental policies. Consensus is critical because ultimately, in a democratic system, there needs to be widespread agreement on the desired outcomes if the system is to avoid instability.
- Economists emphasize the importance of efficiency in resource allocation. They apply benefit-cost analysis and tend to depend on price signals to provide incentives for the adoption of appropriate control technologies and conservation measures.
- Planners deal with land-use and zoning issues, given population growth projections. Planners integrate legal constraints with historical experience, bringing topological, aesthetic, and geographical elements to the analysis.
- Archeologists and anthropologists provide insights on the impacts of dams, mines, and their related economic activities on unique historical sites, local populations, and indigenous groups. Such impacts create difficult valuation issues.[1,2]
- Lawyers spotlight the institutions of policy implementation. For example, rules and regulations attempt to pay significant attention to procedural fairness. Due process contributes to the legitimacy of outcomes. If different parties perceive that there is no transparency and no opportunity for participation, environmental policy will be perceived as unreasonable and the laws will either be changed or they will be disobeyed in a variety of ways.
- Environmentalists advocate sustainability and environmental equity. The by-products of energy production affect public health and have environmental outcomes. Those impacts have economic value, but often that value is nonmonetary or difficult to quantify. For example, generation and transmission siting decisions incorporate impacts on biodiversity and sustainability.
- Ethicists help society understand personal values and notions of stewardship. Humans have a clear responsibility to leave future generations with a legacy of sound institutions and a clean environment, though the best means to this end are often not obvious.

Thus, physical, biological, and social scientists attempt to uncover patterns and identify lessons to help us improve policy. Given the complexity of environmental issues, most environmental problems are managed, not solved.

IMPACTS

Energy production and consumption impact people and the environment in a number of ways. For example, activities can damage ecosystems in the extraction phase (oil drilling or coal mining) or involve cross-media emissions in the consumption phase that can lead to further ecosystem damage. Emissions can be from a single point or a mobile source. In addition, they can be continuous or intermittent (with exposure and impacts depending on wind and other weather conditions or the presence of other chemicals). The transport mechanism can be complicated and involve multiple jurisdictions (as with SO_2 and NO_x—emissions lead to “acid rain” or ozone problems in downwind areas).

Air

Issues range from local concentrations of particulate matter in the atmosphere to concerns over anthropogenic climate change. Consequences for health, ecosystems, agriculture, coastal settlements, species survival, and other impacts make atmospheric change a serious policy issue. For example, long-range transport means pollutants cross national boundaries and require coordination. Other pollutants—such as greenhouse gas emissions of CO_2—require coordination not due to transport, but because the effects are global in nature regardless of where emissions occur.

Water

Effects of contaminants vary in surface waters and groundwater. The United States has primary standards to protect public health (with maximum contamination levels [MCLs] for toxic wastes). Secondary standards and associated MCLs are meant to protect public welfare (for example, ensuring that the taste, odor, and appearance of groundwater do not result in persons discontinuing water use). Other environmental issues include species loss and dealing with nonindigenous, invasive species.

Land Use

Siting is an issue for electricity generators, transmission lines, and distribution systems (other aspects of land use include urban sprawl and availability of land for agriculture. The focus here is on the environmental impact of energy systems. For example, social investments in mass transit affect emissions from mobile sources (autos). However, environmental policy addresses many other issues, such as the use of pesticides and fertilizers by agriculture or deforestation). The problem of not in my back yard (NIMBY) is universal: we like the convenience of electricity but do not want its production or transport to affect our own property. Surface coalmines are an eyesore, but restoration can be costly. Hydroelectric dams can affect fisheries, flood unique canyons (causing a loss of scenic vistas), damage ecosystems (as in the Amazon), or displace human populations (as with China’s Three Gorges Project). Solar collection stations and wind generators require space and have impacts on aesthetics. For some, viewing large windmills along the crest of a lovely mountain range is an eyesore. For others, the same scene is a symbol of hope.

Environmental policy-makers must be aware of the relationship between changes in impacts in one medium and changes in impacts in other media. For example, reducing airborne emissions of mercury will also lead to reduced mercury concentrations in rivers and lakes. However, it may also be the case that reducing ozone precursors from auto emissions by using methyl tert-butyl ether (MTBE) leads to increasing harm to bodies of water as the MTBE precipitates out in rain. Finally, there may be policy and impact trade-offs that must be evaluated with reducing CO_2 emissions through a greater use of nuclear energy. The policy reduces greenhouse gases but raises issues and associated risks of waste storage and protection. In all cases, the links between different environmental media and different environmental policy must be understood for society to properly evaluate the trade-offs.

BURDEN OF PROOF

Because environmental issues tend to be complex, delays in responding to citizen concerns and new scientific information can lead to negative impacts or a local crisis. What is more problematic: erring on the side of environmental protection or erring on the side of development? When science is unclear or when studies yield conflicting outcomes, the issue of burden of proof arises. Two types of errors are possible. In a Type I error, a hypothesis is rejected when it is in fact true (e.g., deciding that a pollutant causes no health damages when in fact it does). Rejecting the hypothesis of a health link would lead to more emissions (and citizen exposure) than otherwise would be the case.

A Type II error occurs when the decision maker fails to reject a hypothesis that is in fact false (e.g., not rejecting the hypothesis that low doses of a pollutant have no damaging side effects for certain types of citizens, such as asthmatics, who are viewed as potentially sensitive to a particular pollutant). If in fact at low doses the pollutant does not have negative health impacts, environmental regulators might have imposed standards that induced costly compliance strategies that were based on the Type II error. Dose-response models that do not reject linear functions when the actual relationships are non-linear would fall into this category.

Both types of errors have costs. However, the political implications may depend on the type of error, leading decision-makers to prefer making errors that are difficult to detect. Thus, it can be argued that environmental regulators will tend to avoid making Type I errors. When evidence accumulates and shows conclusively that a pollutant has health impacts, those responsible for environmental policy do not want to be blamed for acting too slowly. Furthermore, citizens might prefer excessive caution (labeled a "precautionary bias"). On the other hand, Type II errors can result in regulators imposing high abatement costs onto polluters (and those purchasing associated products) in a manner that is not cost effective.

A related issue is whether or not the environmental impact is irreversible. If it is not reversible, a case can be made that the burden of proof should be assigned to those who assert that relatively higher levels of pollution are not problematic. On the other hand, if abatement costs are systematically underestimated and the benefits of pollution reduction are overestimated, it is possible to devote excessive resources to limiting environmental impacts.

ECONOMIC FRAMEWORK

Economists are aware that it is difficult to place monetary values on many impacts of pollution but argue that environmental amenities must be balanced against other valued goods and services.[3] Some view economists as over-emphasizing the efficacy of market incentives to the exclusion of other instruments. However, because economics offers a consistent framework for integrating insights from other fields, it will be described here.

Cost-Benefit Analysis (CBA)

The most fundamental economic analysis looks at how pollution impacts (reflected in "external costs") cause excessive consumption of polluting goods in the absence of government intervention. These external costs are the negative spillover effects of production or consumption for which no compensation is paid (e.g., a polluted stream that damages the health of those living along the stream). Producers consider the environment to be a free input; hence they only minimize private costs. If these external costs are added to the private costs (reflected in the supply curve), this is the total social cost.

Fig. 1 shows how a competitive product market yields an equilibrium price ($4) and quantity (80 units per week). However, in the absence of public intervention, the price only reflects the private costs of production, not damages imposed on others (amounting to $2 when the 80th unit is produced, but this is assumed to be less if only 65 units of the good are produced. The external costs are higher at higher levels of output presumably because damages rise dramatically when there are very high concentrations of the pollutant in the atmosphere). Determining the extent of those damages requires some valuation metric.

For now, let us assume that the analysts "got it right" in estimating both benefits and costs. This is a strong assumption because environmental services are notoriously hard to price. This problem can limit the ultimate effectiveness of CBA because the abatement costs tend to be short-term and quantifiable, but the benefits (avoided damages) are often long-term and difficult to quantify. For now, consider the impacts of environmental regulation within the CBA framework. Regulation requires pollution abatement activity, raising production costs but reducing the pollution and associated damages (as shown in Fig. 2).

The imposition of environmental regulation raises production costs (shifting the supply curve up) and reduces equilibrium consumption of the polluting good (from 80 to 75 per week) because the price has risen (from $4.00 to $4.40). In addition, external costs are reduced (so the sum of private and external costs is now $5 when 75 units of the good are produced). Emissions are reduced (though this particular figure only indicates the reduction in damages, not the precise reduction in emissions).

The next question is how much pollution abatement makes economic sense, since control costs rise rapidly as emissions are cut back towards zero. Continuing with our illustrative example, Default three depicts the total benefits of abatement and the total cost of abatement. The latter depends on the abatement technology and input prices and the interdependencies among production processes (for retrofitting control technologies). It is relatively easy to compute abatement costs from engineering cost studies, although predicting future control costs is not easy because innovations will create new control technologies. The benefits from abatement (or the

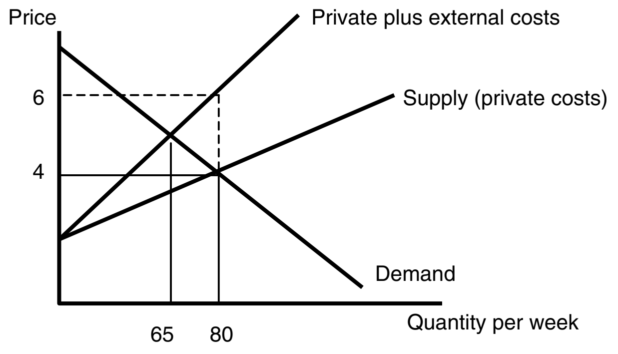

Fig. 1 Private costs and external costs.

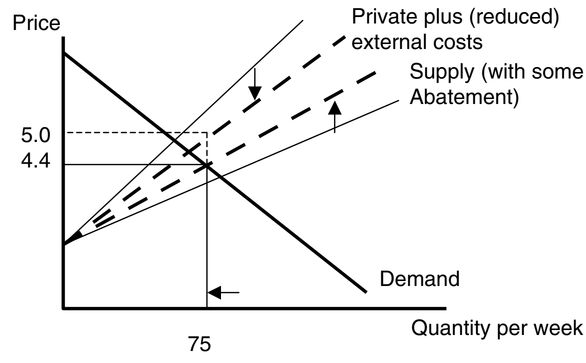

Fig. 2 Reducing external costs.

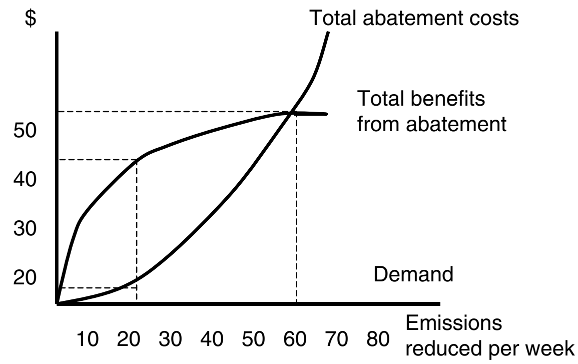

Fig. 3 Total benefits and total cost of abatement.

reduction of pollution damages—the cost of pollution) depend on the size of the affected population, incomes (indicating an ability to pay for environmental amenities), and citizen preferences (reflecting a willingness to pay). The benefits can be very difficult to estimate. Consider, for example, the health benefits of reduced particulates in the atmosphere, habitat values, and citizen valuations of maintaining a habitat for a particular species. Physical benefits can be found from dose-response studies. Various survey methods and market proxies for computing willingness to pay to avoid experiencing the impacts of pollution have methodological problems. However, if the dollar metric is to be used for determining the benefits of environmental improvements, techniques can at least establish rough benchmarks (as shown in Fig. 3) (Some argue strongly against the use of CBA.[4]).

The total benefits and costs to the marginal benefits and costs can be related because, for economists, the issue is not zero emissions versus unlimited emissions. In the former situation, if 80 units of the good results in 80 tn of emissions, then zero emissions reduced would be characterized as having no abatement costs (but also, no benefits from abatement). When the total benefits equal the total cost of abatement (at 65 tn of emissions reduced per week in Fig. 3), the last reductions in emissions were very costly and the additional benefits were fairly small. Zero

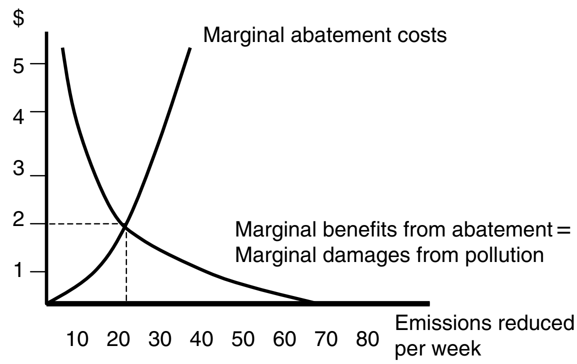

Fig. 4 Marginal benefits and marginal cost of abatement.

abatement activity would also be inefficient in this example because the marginal damages are very high and marginal abatement costs are quite low. Economics tries to determine the optimal amount of emissions. In the hypothetical example, the "optimal" quantity of reduced emissions is about 25, where the marginal abatement cost is just equal to the marginal benefits of $2. These are depicted in Fig. 4.

This outcome means that there are still 55 tn of emissions per week. If the estimated benefits and costs of pollution abatement are correct in this illustration, economic efficiency would be violated if additional resources were devoted to abatement activity. For example, if 50 tn of emissions were reduced (so only 30 tn of the pollutant are released), the marginal benefit would be about $1, but the marginal cost would be greater than $5. From the standpoint of economic efficiency, those resources could be used to create greater value in other activities.

Of course, the difficulty of obtaining a common dollar metric for all the impacts of different pollutants means that benefit-cost analysis must incorporate a range of values. The range could be incorporated in Fig. 4 as a band around the marginal benefit curve indicating one standard deviation from the calculated values. A conservative approach would recognize that the marginal benefit function could be above that depicted in Fig. 4, which would lead to optimal emission reduction of more than 25 tn per week (improving the ambient air quality).

Further complicating the analysis are production and exposure interdependencies. For example, the marginal cost of abatement associated with one type of emission may depend on the level of treatment (or abatement) for another contaminant. A joint optimization problem results, with the basic principles unchanged. Many investments in abatement equipment have this characteristic: once one set of contaminants is being reduced from a discharge flow and the cost of dealing with additional contaminants can be relatively low. For example, in the case of water discharges, if iron or manganese is removed via the precipitation method, total dissolved solids (TDS) is reduced and there may be an improvement in water clarity.

Interdependencies can also arise on the benefit side when the dose-response relationship for a particular contaminant is influenced by the presence of other contaminants. Again, in the case of secondary groundwater standards, perceptions of odor and color will be affected by whether or not they occur in combination. Such considerations must be factored into the analysis when comparing the benefits and costs of different treatment options.

Cost-Effective Analysis

Instead of trying to estimate the dollar benefits of saving a human life (or reducing the incidence of asthmatic attacks), one can compare the number of lives saved per dollar spent in abatement activity across programs. Thus, cost-effective analysis involves finding the least-cost method of achieving a given economic or social objective such as saving lives or retaining unique ecological settings. No dollar value (or explicit measure of avoided damages) is placed on that objective.[5] One advantage of this approach is that the focus is on minimizing the cost of meeting the (politically determined) target. It promotes consistency across a range of programs that might be designed to address a particular problem,whether that involves health impacts or a loss of habitat. Cost-effective analysis facilitates comparisons across programs, leading to reallocations of resources devoted to meeting such targets as new information is gathered over time.

POLICY INSTRUMENTS

Political systems have passed legislation and created agencies to apply laws to improve environmental performance. For example, in the United States, the Water Pollution Control Act of 1956 and the Clean Air Act of 1963 and subsequent amendments to both pieces of legislation have focused on achieving ambient standards. The U.S. Environmental Protection Agency is responsible for implementing these laws, and in other nations agencies have also been established to reduce emissions and improve environmental outcomes. A number of policy options can lead to emission reductions.[6,7] These instruments have different economic efficiency implications. In addition, some of these approaches are difficult to implement (due to being information-intensive), some are not cost effective (in that other approaches achieve the same outcome at lower cost), and the distributional implications can differ across these approaches (tax burdens differ or some groups obtain valuable assets).

Tax on the Polluting Good

An excise tax could be imposed on the good, cutting back consumption to 65 units per week (Fig. 1). Of course, the problem is not with the product but with the emissions associated with its production. Thus, this option does not provide incentives for developing new technologies that reduce abatement costs—it represents a static approach to the problem because it does not promote technological innovation.

Tax on Emissions

A penalty or charge for each ton of emissions would lead suppliers to cut back on emissions—to the extent that the abatement is less expensive than the tax. Thus, in Fig. 4, a tax of $2/tn would lead to the optimal reduction of pollutants. In addition, it provides incentives for innovation in the control technology industry. Firms will seek ways to reduce abatement costs, thus reducing their pollution taxes. This strategy is likely to be opposed by polluters who will be passing the taxes on to customers (where the ultimate incidence depends on supply and demand elasticities in the product market).

Tradable Emissions Permits

The same result (and incentive) is obtained if "allowances" of 25 tn are allocated to polluting firms, limiting emissions (the situation is not completely identical—a tax has certain costs to firms but yields uncertain overall abatement because regulators will not have precise estimates of abatement costs; the allowances have certainty in terms of overall abatement but uncertain cost. Of course, with monitoring, the tax can be varied over time to achieve a desired ambient condition). This approach provides an incentive for those with low abatement costs to reduce emissions and sell their permits (allowances) to others whose abatement costs would be very high. This places entrants at a disadvantage because incumbent firms are "given" these valuable allowances. The SO_2 regime in the United States has this feature. Of course, the initial allocations raise political issues (because permits represent wealth). In establishing a tradable permit regime, an environmental agency must determine the allowed level of emissions (here, 25 tn) and whether additional constraints might be applied to local areas with particular circumstances. In addition, the energy sector regulator has to make decisions regarding the treatment of cost savings from the regime. For example, savings might be passed on to consumers or retained by firms. The latter situation provides an incentive for utilities to participate in the emissions trade markets. A sharing plan can also be utilized so customers benefit as well.

Tighten Liability Rules

An alternative approach would utilize a court-based system, where fees would be assessed against those responsible for damaging the health of others, for reducing the economic value of assets, or for reducing the amenity values of ecosystems. Of course, this approach requires a well-specified set of property rights and clear causal links between specific emitters and affected parties. The transaction costs of such a system (resources devoted to negotiations and legal activity) could be prohibitive for many types of pollutants.

Emission Reduction Mandates (Quantity-Based Command-and-Control)

Although equal percentage cutbacks sound "fair," this strategy is not cost-effective because abatement costs can differ widely across pollution sources. If there are scale economies to emission reductions, it would be most efficient to have a few firms reduce emissions. The least-cost way to achieve a given overall reduction in emissions will involve differential cutbacks from different firms.

Mandate a Specific Control Technology (Technology-Based Command-and-Control)

This "command and control" strategy is not cost-effective because production conditions and retrofitting production processes differ across firms (based on the age of the plant and other factors). However, this policy option has been utilized in a number of situations as a "technology-forcing" strategy.

OTHER POLICY ISSUES

The above instruments have been utilized in different circumstances. Additional issues include intrinsic benefits, income distribution, sustainability, and renewable resources.

Intrinsic or Nonuse Benefits

Some people take a more expansive view of environmental amenities as they attempt to separate economic values from inherent values. However, this might be partly accounted for in terms of the perceived benefits to future generations. Intrinsic benefits from environmental programs include option values, existence values, and bequest values.[8] The first value represents a form of insurance so future access to a potential resource is not eliminated due to current consumption. The rationale behind option values is closely related to the "margin for error" argument noted earlier. Existence values reflect a willingness to pay for the knowledge that the amount of contaminant in the environment does not exceed particular levels or that a particular species (or level of biodiversity) is retained. The resource or ecological system is available for others. The bequest values can be interpreted as the willingness to pay for preserving a resource (or a geographic site) for future generations.

Redistributive Effects

It is important to note that citizens being harmed by emissions are not necessarily the same as those who are consuming the polluting good (such as electricity). Even if a particular program has positive net benefits, some parties are likely to be losers. They are seldom compensated and left better off, raising concerns about the distributional consequences of alternative policies. Furthermore, those harmed may have lower incomes (and thus, a lower willingness to pay to avoid damages due to the lower ability to pay). This point underscores the role of fairness as a factor that might outweigh efficiency considerations in some circumstances. Some agencies have been forbidden to use CBA on the grounds that the numbers are too speculative and that social concerns should be given priority. Intergenerational concerns can be interpreted as reflecting redistributive considerations.

Sustainable Development

Some of the issues associated with energy involve the use of nonrenewable resources (irreversibility). Some citizens argue that sustainability requires development that can be supported by the environment into the future. These people wish to ensure that resources are not depleted or permanently damaged. However, since sustainability depends on technology and innovations change resource constraints, defining the term with precision is quite difficult.

Renewable Energy Resources

Generating electricity without fossil fuels (e.g., hydro, wind, solar, biomass) is sometimes referred to as using green options. Green options are often limited in the amount (and reliability) of energy produced in a given time period. Utility applications for renewable resources include bulk electricity generation, on-site electricity generation, distributed electricity generation, and non-grid-connected generation. A number of regulatory commissions have required utilities to meet renewable portfolio standards. Such strategies reduce dependence on a particular energy source (to reduce the region's vulnerability to supply disruptions or rapid price run-ups). In addition, such requirements imply that managers are not making the most efficient investments in long-lived assets. Also, note that demand reduction through energy-efficient technologies is a substitute for energy, whatever the source.

CONCLUSIONS

The three main trends in environmental regulation in recent years have been shifting from command-and-control regulation towards a greater use of economic instruments (such as emissions trading), seeking more complete information on the monetary value of environmental costs and benefits, and a tendency for addressing environmental objectives in international meetings, as with the Kyoto Protocol.[9]

The interactions between economic and environmental regulation raise important policy issues. If energy sector regulation and environmental regulation remain separate, some means of harmonization may be necessary to promote improved performance. Collaboration would involve clarifying the economic duties of the environmental regulator and the environmental duties of the economic regulator. To avoid regulatory competition, agencies sometimes establish task forces or other mechanisms for identifying and resolving issues that might arise between jurisdictional boundaries (across states or between state and federal authorities). Such cooperation can serve to clarify the division of responsibilities and identify regulatory instruments that will most effectively meet economic and social objectives.

In summary, policy-makers respond to domestic political pressures by devising institutions and instruments to address pollution and environmental sustainability.[10] Although no single field of study contains all the tools necessary for sound policy formulation, economics does provide a comprehensive framework for evaluating the strengths and limitations of alternative policy options. Because of the pressures brought to bear by powerful stakeholders, adopted policies and mechanisms are not necessarily cost minimizing. The resulting inefficiencies may partly be due to considerations of fairness, which places constraints on whether, when, how, and where environmental impacts are addressed. As emphasized in this survey, citizens want to be good stewards of the land. We appreciate the adage: “The land was not given to us by our parents; it is on loan to us from our children.” How to be good stewards—through the development and implementation of sound environmental policies—has no simple answer given the complexity of the issues that need to be addressed.

Evaporative Cooling

David Bisbee
Customer Advanced Technologies Program, Sacramento Municipal Utility District (SMUD), Sacramento, California, U.S.A.

Abstract
This report discusses the principles of evaporative cooling and provides an overview of the different types of systems currently on the market. It includes diagrams, system comparisons and a discussion of market barriers for direct evaporative coolers, indirect–direct evaporative coolers (IDECs) and the Coolerado Cooler.

INTRODUCTION

It is another sizzling summer day in America. Radio and television news weather forecasters wearily predict high temperatures of over 100°F all week long. Electric utilities all across the nation urge people to conserve electricity. Electricity demand and prices soar as air conditioners struggle to keep people comfortable. Although the energy crisis of 2001 may be over, the need for high efficiency air conditioning systems remains stronger than ever. This report discusses the principles of evaporative cooling and provides an overview of the different types of systems currently on the market.

PRINCIPLES OF EVAPORATIVE COOLING

When air comes into contact with water, some of the water evaporates. This happens because the temperature and the vapor pressure of the water and the air attempt to equalize. As the water molecules become a gas (evaporate), they "absorb" heat from the surrounding air and lower its temperature. The heat is still present, however, it has just been "captured" in the form of water vapor within the air (humidity). This phenomena is known as *adiabatic cooling* and is found throughout Nature—lakes, rivers, oceans, and anywhere there is water. Today people use evaporative cooling systems for a wide variety of purposes—comfort cooling, manufacturing processes, and other applications.

Some cool terms

Dry-bulb temperature: Temperature of air independent of its moisture content. It may be measured by using common thermometers.

Wet-bulb temperature: The lowest theoretical temperature achievable by evaporating water in a quantity of air at a given dry bulb temperature and humidity level, using only the heat within the air. It is measured by placing a moist piece of fabric over the thermometer and blowing air across it. The air evaporates the water, lowering the temperature on the thermometer to the wet bulb temperature[1].

Absolute humidity: The amount of water vapor present in air.

Relative humidity: The amount of water vapor present in air compared to the maximum amount it could hold.

Direct evaporative cooler: System in which the air comes into direct contact with wetted pads before entering the conditioned space. Commonly called swamp coolers.

Indirect-direct evaporative cooler (IDEC): System that uses a combination of direct evaporative cooling and an indirect evaporative heat exchanger. Commonly called two-stage evaporative coolers.

The effectiveness of evaporative cooling depends greatly upon the humidity or amount of water vapor in the air. Simply put, the drier the air, the more effective evaporative cooling will be. Air conditioning technicians often use a special thermometer known as a sling psychrometer to determine how much water vapor is present in the air. Essentially, this measurement involves placing a wet cloth (wick) on a thermometer and spinning the psychrometer until the water has evaporated and recording the lowest temperature obtained. This measurement is known as the "wet-bulb" temperature. What is important to understand about wet bulb temperature is that it tells us what the theoretical lowest supply air temperature for direct evaporative coolers will be. For example, standard design conditions for sizing residential

cooling systems in Sacramento, California are:

- Outside air (a.k.a. "dry bulb") temperature: 100°F
- Wet bulb temperature: 70°F (relative humidity 23%)
- Desired indoor temperature: 78°F.

Under these conditions, the lowest theoretical supply air temperature that a standard evaporative cooler could provide would be 70°F. Realistically speaking, however, most direct evaporative cooling systems would only be able to achieve 78°F (Fig. 1). To put this into perspective, conventional refrigerant-based air conditioning systems are designed to deliver air at temperatures of about 55°F–65°F. At first glance, it appears that direct evaporative coolers would not work. After all, it is difficult to cool a home using 80°F air. To make matters worse, direct evaporative coolers increase the humidity within the house—making conditions even less comfortable. Fortunately, these shortcomings are somewhat mitigated by what is known as "effective temperature." Since evaporative coolers run at airflow rates that are 3–5 times higher than conventional air conditioning systems, they create a "cooling breeze" that makes the occupants of a room feel 4–6 degrees cooler than the actual temperature. For this reason, the effective temperature created by an evaporative cooler will feel 4–6 degrees cooler than the temperatures shown in the chart shown in Fig. 1. This chart also shows the dramatic effect that humidity has upon the performance of evaporative cooling systems. For this reason, direct evaporative cooling systems are limited to climates with low relative humidity levels. However, newer types of evaporative cooling systems, such as the OASys and the Coolerado Cooler may help somewhat overcome this limitation (more on this later).

Types of Evaporative Cooling Systems

There are three basic types of evaporative cooling systems: direct evaporative coolers (a.k.a. "swamp coolers"), indirect–direct evaporative coolers (IDECs), and the Coolerado Cooler.

Direct Evaporative Cooling Systems

In direct evaporative cooling systems, a.k.a. swamp coolers, the conditioned air comes into direct contact with the water used to produce the cooling effect. These systems are relatively simple and are widely used to provide comfort cooling for mobile homes, single-family housing, and industrial warehouses. Direct evaporative cooling systems generally cost about half as much to install as traditional vapor-compression systems and consume only about a fourth of the energy.[1] However, as discussed earlier, swamp coolers are limited to climates with dry air and produce high humidity levels within the conditioned space (Fig. 2). This is a considerable market

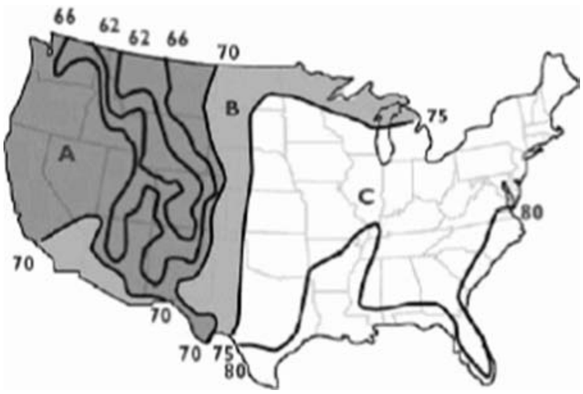

Fig. 2 Map showing climate zones suitable for direct evaporative coolers. Map is based upon wet bulb temperatures at 1% design conditions. Evaporative coolers would work best in the dry climates (areas marked A) may work somewhat in the areas marked B. However, in the eastern parts of the country, other types of air conditioners should be used.
Source: From U.S. Geological Survey (see Ref. 3).

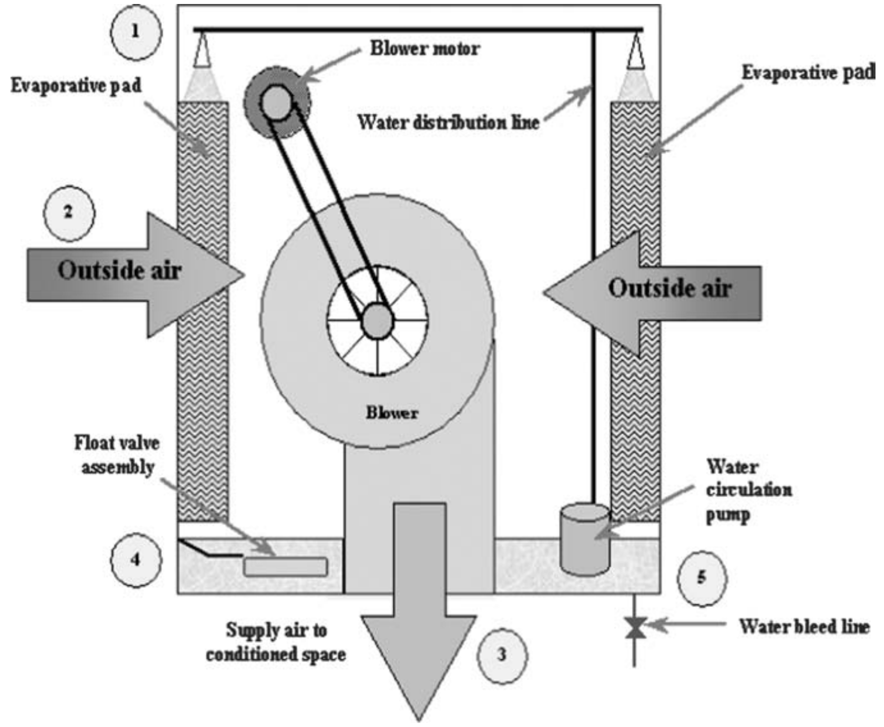

Fig. 3 Direct evaporative cooling system (fiber pad type).

barrier since studies conducted by American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) and others have consistently shown that most people prefer lower humidity levels.

Overview of Operation (Fig. 3)

1. Water is pumped from the basin (bottom of the unit) and distributed across the top of the evaporative cooling pads. These pads are usually made of wood shavings from aspen trees or other absorbent materials. Some of the water saturates the pads while the rest falls back down into the basin.
2. The blower draws outside air across the face of the evaporative cooling pads. When the air comes into contact with the wetted pads, some of the water evaporates and lowers the dry bulb temperature of the air.
3. The blower delivers cool moist air to the conditioned space. Since this air is very humid, it must ultimately be exhausted through open windows or relief dampers.
4. The evaporated water is replaced via a float valve assembly.
5. When water evaporates, minerals and other impurities are left behind. Eventually the water within the basin will become supersaturated with minerals and scale will begin to form on the surfaces of the cooler. To help address this issue, some water must be drained off (via the "bleed line") and replaced with fresh water. Modern systems accomplish this by periodically purging the basin water via a timer-controlled pump.

Not all Direct Evaporative Coolers are Created Equal

There two distinct types of direct evaporative coolers: fiber pad coolers and rigid sheet pad coolers.

1. *Fiber pad coolers*: (Fig. 4) the most commonly used evaporative cooling systems use pads that are made from shredded aspen wood fibers (a.k.a. excelsior) packed within a plastic net. Although synthetic fiber

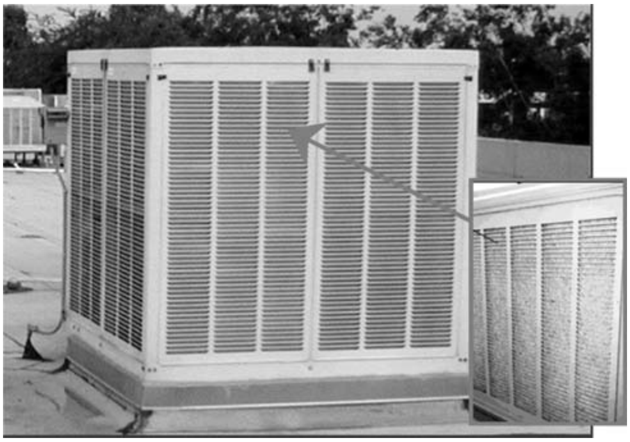

Fig. 4 Fiber pad evaporative cooler with aspen pads.

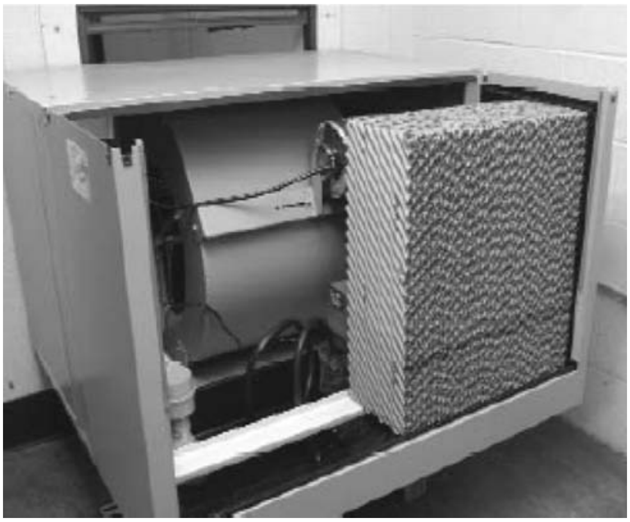

Fig. 5 Direct evaporative cooler with rigid sheet pads.
Source: From Pacific Gas & Electric Co. (see Ref. 5).

pads are available, they seldom perform as well as high-quality aspen pads. Fiber pads usually range from 1 to 2 in. in thickness. They are disposable and should be replaced every 1 or 2 years.[4]

2. *Rigid sheet pad coolers*: (Fig. 5) this type of cooler, also known as a "single-inlet cooler," used to be found only in large commercial applications, but is now becoming more common in residential applications as well. It uses rigid-sheet pads made from corrugated material that allows air to move through at higher velocities than is possible with aspen pads. Rigid sheet pads are usually 8 or 12 in. thick and have a corrugation pattern that forces water to flood the pad's air inlet side where most of the evaporation of water occurs. They can last for many years if water quality is properly maintained (Fig. 6).

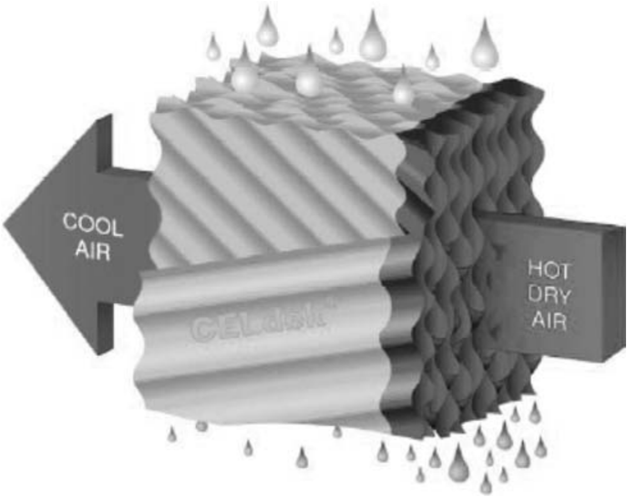

Fig. 6 Modern evaporative cooling media have to be efficient, which means that they must allow for as much cooling as temperature conditions allow while minimizing pressure drop, thereby saving fan power. Well-designed media filter the airstream but are also self cleaning in that the water dripping across the media to the sump below performs a cleaning function. Finally, the media should be durable and easy to replace at the end of their functional lifetime. Master Cool from Munters uses alternating corrugated layers to achieve these ends.
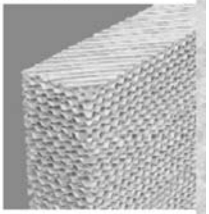
Source: From Munters Corporation (see Ref. 6).

Rigid sheet pad coolers are substantially more expensive than fiber pad coolers, but are much more energy efficient. According to a fact sheet published by Pacific Gas and Electric Company (PG&E), rigid sheet pad coolers can deliver air that is 5–10 degrees cooler than conventional aspen pad media coolers.[5] Both PG&E and Southern California Edison offered rebates to residential customers for qualifying "Energy Efficient Ducted Evaporative Coolers" (EEDEC) in 2005 (Fig. 7).

Finally, at least one prominent manufacturer, AdobeAir Inc., offers evaporative media (pads) that have been treated to resist microbial growth. This helps prevent the growth

Energy Efficient Ducted Evaporative Coolers (EEDEC)

EEDEC units are more efficient than conventional evaporative coolers because of the following advanced features:



Rigid Evaporative Media (typically 8-12" thick)

- Evaporative media which comes from manufacturers, and is certified with an 85% or higher evaporation efficiency delivers air that is 5 to 10 degrees cooler than the air delivered by a conventional aspen pad media evaporative cooler.
- Multi-function controls allow the EEDEC to also function as a whole house fan.
- Pressure relief dampers, if present, help in two ways; 1) they exhaust air to the outside typically through the attic keeping the attic cool which may reduce heat gain in the house, and 2) allow the system to operate when the house is not occupied.
- Special thermostatic controls remotely mounted to the wall and paired with pressure relief dampers allow for operation of the unit based on cooling requirements of the home.
- A water quality management pump eliminates old water from the system periodically and uses less water overall than continuous bleed systems.
- The EEDEC provides fresh air as it cools, using 100% outside air instead of re-circulating the existing indoor air as with conventional central air conditioning.

Fig. 7 Excerpt from a technical fact sheet produced by Pacific Gas & Electric Company (PG&E).
Source: From Pacific Gas & Electric Co. (see Ref. 5).

of microbes that can cause stains, odors, and product degradation.

Choosing the Right-sized Evaporative Cooler

Because direct evaporative coolers do not actually remove heat, they are rated by airflow instead of cooling capacity. According to PG&E, the following formulas may be used to determine the proper size cooler needed for residential applications[5]:

Hot dry climate: floor area (in square feet) × 4 CFM per square foot (based upon 30 air changes per hour and a ceiling height of 8 ft)

Average climate: floor area (in square feet) × 3 CFM per square foot (based upon 22.5 air changes per hour and a ceiling height of 8 ft)

Example: the size of an evaporative cooler needed for a 1500 square foot house in a hot dry climate would be: $1500\ ft^2 \times 4\ CFM/ft^2 = 6000$ cfm

Advantages of Direct Evaporative Cooling Systems

- Simple, proven technology: thousands of units have been sold and installed.
- Low first cost: generally cost less than half of conventional air conditioning systems.
- Energy efficient: 75% energy savings compared to conventional air conditioners.
- Easy to operate and service: units and replacement parts are widely available from multiple vendors, including many home improvement stores.
- Provides excellent ventilation: uses 100% outside air and may be used in a similar manner as a whole house fan (when operated in the fan only mode).

Disadvantages

- Manufacturers must overcome poor public perception caused by older, inferior equipment.
- Does not work well on humid days or in humid climates.
- Requires venting through open windows or relief dampers.
- Produces high humidity within conditioned space (most people prefer low humidity levels).
- Water quality has a major impact upon system performance and maintenance requirements. Hard water deposits (scale) may clog the media and reduce the airflow across the evaporative cooling pads (Fig. 8). Fortunately, new water quality management control strategies such as periodically purging the basin water have significantly reduced problems with scale.

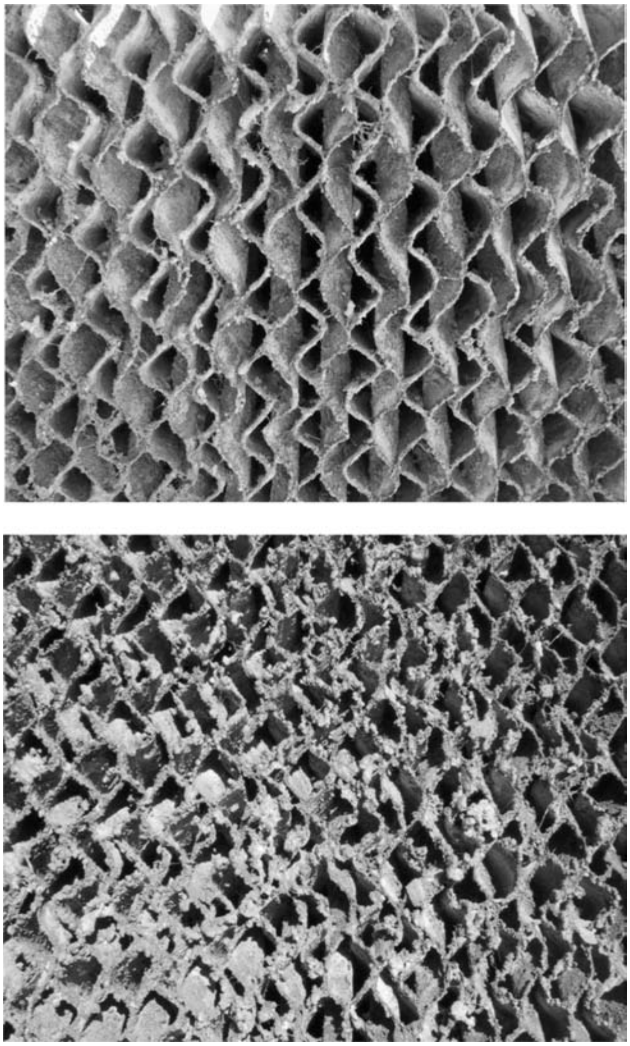


Fig. 8 Water quality has a major impact upon system performance and maintenance requirements. Note the hard-water deposits (scale) on the pads in the lower photo.

INDIRECT–DIRECT EVAPORATIVE COOLING SYSTEMS

As the name implies, IDEC or two-stage systems incorporate both direct evaporative cooling and an indirect evaporative heat exchanger. Unlike direct systems, the supply air within the heat exchanger does not come into direct contact with the water. Since this process reduces the amount of moisture added to the supply air, IDECs offer increased comfort over swamp coolers. Indirect–direct evaporative coolers cost about the same to install as conventional air conditioning systems, but are nearly four times more energy efficient.

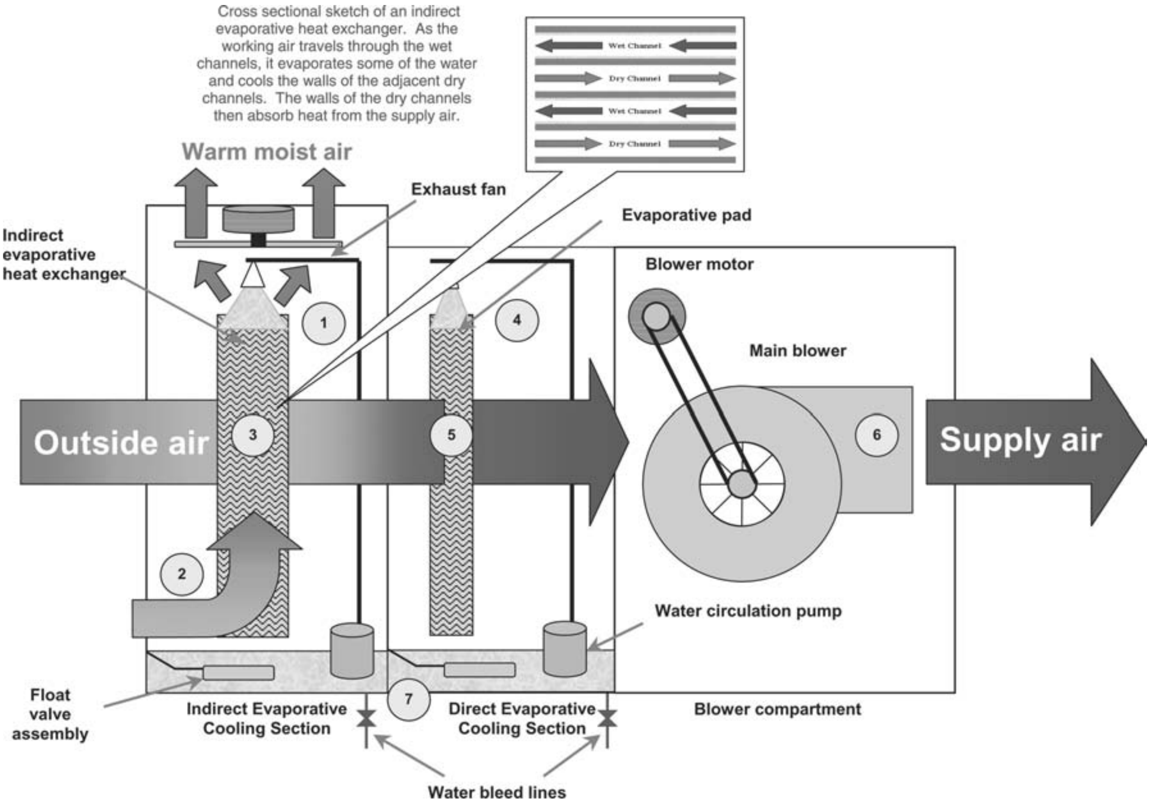

Fig. 9 Indirect–direct evaporative cooler (IDEC) system.

Overview of Operation (Fig. 9)

1. Water is pumped from the basin and distributed across the top of the indirect evaporative heat exchanger. The water clings to the surfaces within the wet channels of the heat exchanger as it travels back down into the basin.
2. The exhaust fan draws working air up through the wet channels. As the working air comes into contact with the water, some of the water evaporates and lowers the surface temperature of the heat exchanger. The warm moist working air is then exhausted through the top of the unit. The evaporated water is replaced via a float valve assembly.
3. The main blower draws outside air (supply air) across the face of the indirect evaporative heat exchanger. When the supply air comes into contact with the cool surface of the heat exchanger, some of its heat is transferred indirectly into the water via the heat exchanger. In other words, the supply air does not come into direct contact with the water. After the supply air passes through the indirect heat exchanger, it continues on to the direct evaporative cooling section.
4. Water is pumped from the basin and distributed across the top of the evaporative cooling pads. Some of the water saturates the pads while the rest falls back down into the basin of the unit.
5. The main blower draws the supply air across the face of the evaporative cooling pads. When the supply air comes into contact with the wetted pads, some of the water evaporates and lowers its dry bulb temperature.
6. Cool moist air is delivered into the conditioned space. Since this air is relatively humid, it must be exhausted through ducts or open windows.
7. The evaporated water is replaced via a float valve assembly. When the water evaporates, minerals and other impurities are left behind. Eventually the water within the basin will become super-saturated with minerals and scale will begin to form on the surfaces of the cooler. To help address this issue, some water must be drained off (via the bleed line) and replaced with fresh water. Modern systems accomplish this by periodically purging the basin water via a timer-controlled pump.

A Rough Beginning For IDECs

During the late 1990s, some early versions of IDECs were plagued with reliability and performance issues stemming

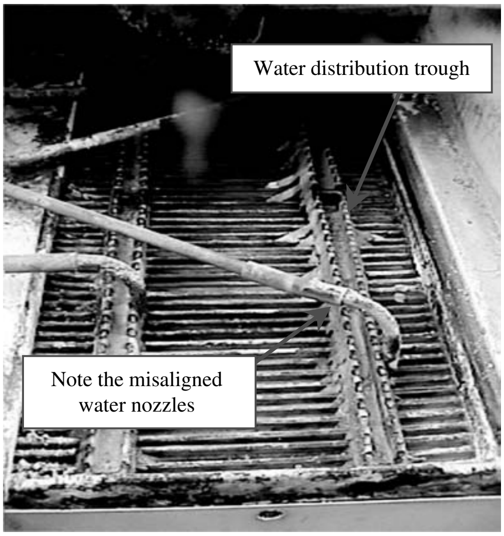

Fig. 10 The heat exchanger of this IDEC was rendered useless by misaligned water nozzles. Note also the presence of hard-water scale. This system was not equipped with a bleed line. Source: From Sacramento Municipal Utility District (see Ref. 7).

from a lack of understanding regarding proper system installation, misunderstood maintenance requirements and poorly designed systems.

Some examples:

1. *Reliability*: the water troughs of the indirect evaporative heat exchanger of the IDEC shown in Fig. 10 are designed to distribute water over the evaporative cooling media. Once the troughs are filled, the water is supposed to overflow across the top of the media. Unfortunately, this heat exchanger was rendered useless by misaligned water nozzles. This situation may have been easily avoided through the use of inexpensive hose clamps.
2. *Improper installation*: simply put, evaporative cooling systems require a lot of air—three to five times more than conventional vapor compression systems. Installers need to ensure that the ductwork is sized and installed correctly to ensure proper airflow is delivered to the conditioned space (Fig. 11).
3. *Poor engineering*: one particular IDEC system experienced severe reliablity problems due to faulty engineering. Periodically the water float valve would stick and cause the water within the basin to rise. Although there was an overflow drain to prevent the system from overflowing, the blower would draw water droplets into the motor and controls cabinet. Needless to say, water, motors and controls don't mix. Every time this occurred, it cost the owner about $500 to replace the motor and controls.

Fig. 11 A poorly installed IDEC system. The ductwork is far too restrictive to deliver the airflow needed to meet the cooling requirements of this classroom.
Source: From Sacramento Municipal Utility District (see Ref. 7).

Third Time a Charm?

The Davis Energy Group (DEG) and Speakman CRS have introduced a third generation IDEC known as the OASys that will hopefully overcome many of the problems of the past. The system was designed under a research grant provided by the California Energy Commission's Public Interest Energy Research (PIER) program. Additional tests were completed in 2005 in a field study sponsored by the Sacramento Municipal Utility District. According to the DEG, the OASys includes the following improvements (Fig. 12):

- Corrosion-proof, single-piece polyethylene cabinet ensures long life.
- Electronically commutated, variable-speed blower fan motor enhances efficiency and comfort during part-load conditions.
- Blower motor is located upstream of the evaporative cooling media—eliminates the chance of water droplets being drawn into the blower fan motor.
- Programmable thermostat that varies the speed of the blower motor in proportion to cooling load requirements.
- Water quality management controls (timed purge cycle).
- High performance evaporative cooling media and indirect heat exchanger enables OASys to cool

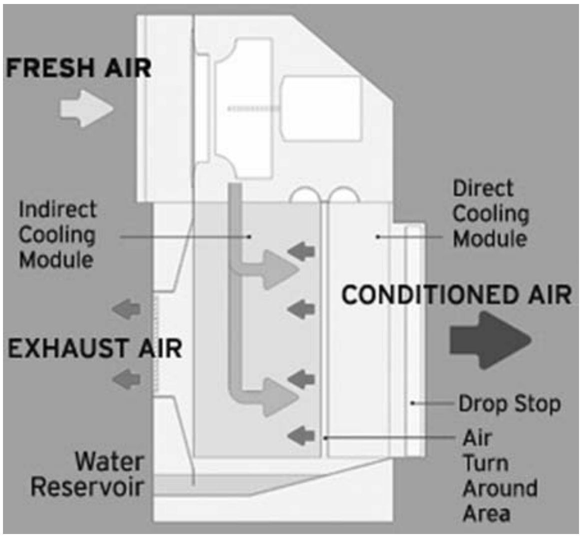

Fig. 12 Airflow diagram for the OASys.
Source: From Speakman CRS (see Ref. 10).

air *below* the ambient wet bulb temperatures (Fig. 13).

Advantages of IDECs

- Energy efficient—75% energy savings compared to conventional air conditioners.
- Offers increased comfort over swamp coolers (less moisture added to supply air).
- Provides excellent ventilation and may be used in a similar manner as a whole house fan (when operated in the fan only mode).

Disadvantages

- Does not work well in humid climates or on humid days.
- Units and replacement parts are not widely available.
- Requires venting through open windows or barometric relief dampers.
- Some previous IDECs have been known to have reliability problems.
- Adds some humidity to the conditioned space (most people prefer low humidity levels).
- Water quality has a major impact upon system performance and maintenance requirements. Hard water deposits (scale) may clog the media and reduce the airflow across the evaporative cooling pads. Fortunately, new water quality management control strategies such as periodically purging the basin water have significantly reduced problems with scale.

COOLERADO COOLER

A third type of evaporative cooling system was introduced in 2004—the Coolerado Cooler. This system utilizes a patented indirect evaporative heat exchanger that cools the air multiple times before it enters the

Fig. 13 Cooling performance for different types of evaporative cooling systems. Note that the dry-bulb temperatures of the air delivered by the OASys are lower than the wet-bulb temperatures of the outside air.
Source: From E-Source (see Ref. 1).

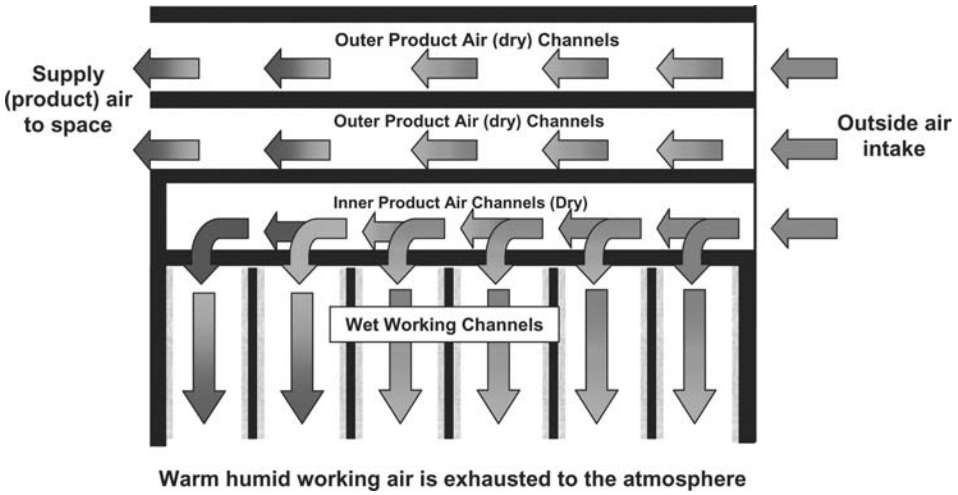

Fig. 14 The Maisotsenko cycle uses the same wet and dry channels as indirect evaporative coolers but with a much different geometry and airflow, creating a new thermodynamic cycle. It works by incrementally cooling and saturating working air and benefiting from that cooling on the next increment. This 2-D diagram of the Maisotsenko cycle shows how air is incrementally cooled by the continuous exhaust of heat followed by additional cooling. This cycle allows any fluid (gas or liquid) to be cooled below the wet-bulb temperature and within a few degrees of the dew-point temperature of the incoming working air. In addition, no moisture is added to the product airstream.
Source: From Idalex Technologies Inc. (see Ref. 8).

conditioned space. In essence this creates a "cascade" effect that enables the Coolerado Cooler to cool the air below the ambient air wet bulb temperature *without adding any moisture* to the supply air. The patented Coolerado heat and mass exchanger is designed to take advantage of the Maisotsenko Cycle (Fig. 14) and is constructed from cellulose fiber and ethyl vinyl acetate (EVA). The heat exchanger contains both wet and dry channels and separates incoming air into two air streams: Working Air and Product Air. The wet and dry air channels are separated via polyethylene coated sheets.

The Working Air is the air used to produce the cooling effect. As it travels through the wet channels of the heat exchanger, it comes into direct contact with wetted cellulose surfaces. When this happens, some of the water evaporates and absorbs heat (indirectly) from the Product Air stream (i.e., the air delivered to the conditioned space), which is traveling through the dry channel of the heat exchanger. This process is repeated several times within the heat exchanger.

Overview of Operation[9] (Fig 15)

1. Outside air is pushed into the Coolerado Cooler heat exchanger with a single fan.
2. Product air channels.
3. Working air channels.
4. Heat from the product air is transferred through the thin plastic and into the Wet Channels below.
5. Working air is blocked from entering the building.
6. The blocked working air is turned and passed through small holes into wet channels below the product air stream.

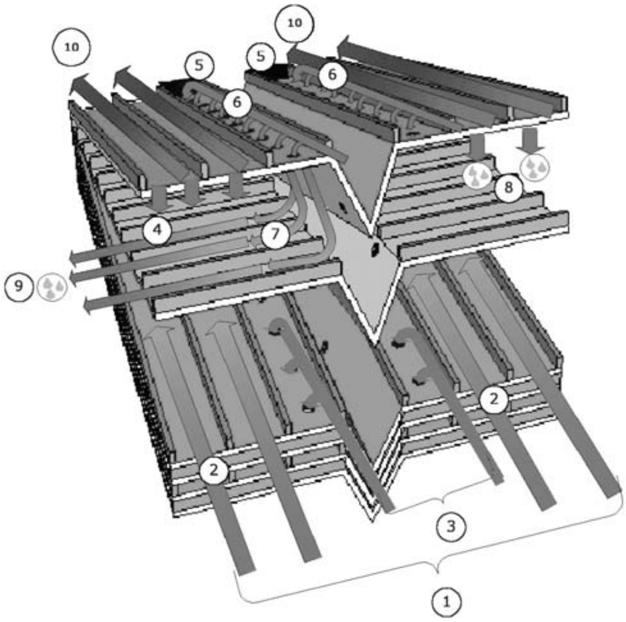

Fig. 15 Coolerado Cooler's patented heat-mass exchanger.
Source: From Idalex Technologies Inc. (see Ref. 9).

7. The working air is now moving through wet channels perpendicular or cross flow above and below the dry channels.
8. The heat that is passed from the dry channel is converted into water vapor.
9. Heat from the product air has been converted to water vapor and is now rejected as exhaust to the outside air.
10. The product air, which has now traveled the length of the heat exchanger, enters the conditioned space cold and dry.

Potential Applications

According to the manufacturer, the Coolerado Cooler may be used to provide residential and commercial comfort cooling or to pre-cool ventilation air for large conventional air conditioning systems in many areas of the United States. The map shown below is based upon the humidity within each climatic zone at the 1% design conditions (Fig. 16).

Advantages

- Energy efficient—75% energy savings compared to conventional air conditioners
- Does not add moisture to the conditioned air
- Able to cool near or below wet bulb temperature of the ambient air (Fig. 17).
- Provides excellent ventilation (Fig. 18).
- System has only two moving parts (supply fan and solenoid valve).

Disadvantages

- Units are not yet widely available.
- Requires venting through open windows or barometric relief dampers.

Fig. 16 Potential applications for the Coolerado Cooler in the continental United States.
Source: From Idalex Technologies Inc. (see Ref. 9).

	Outdoor design conditions (°F)			Temperature of air delivered by unit (°F)

Fig. 17 Cooling performance for different types of evaporative cooling systems. Note that the dry-bulb temperatures of the air delivered by the coolerado are very close to the wet-bulb temperatures of the outside air.
Source: From E-Source (see Ref. 1).

- Reliability is unknown: fewer than 200 units have been deployed.
- Water quality may impact system performance and maintenance requirements.

SYSTEM COMPARISON

Recall that evaporative cooling systems incorporate adiabatic cooling. In this process, the heat within the air stream is converted into water vapor—it is not actually removed. Because of this, there is currently no established industry metric for comparing the performance of evaporative cooling systems to conventional vapor-compression systems. However, in April of 2005, E Source, a well-respected research firm, published a report on evaporative cooling systems. The chart shown in Fig. 19 provides an excellent summary of the relative performance and costs for all three types of evaporative cooling systems.

CONCLUSION

Evaporative cooling systems offer an energy efficient alternative to vapor-compression air conditioning systems in areas with favorable climatic conditions. Indeed as energy prices continue to climb, consumer demand for ultra-high efficiency air conditioning systems will increase. Innovative systems such as the OASys and the Coolerado Cooler may help overcome market barriers associated with the high humidity conditions provided by traditional swamp coolers. However, these systems will have to prove to be reliable and cost effective in order to compete with well-established refrigerant-based air conditioning systems.

Exergy: Analysis

Marc A. Rosen
Faculty of Engineering and Applied Science, University of Ontario Institute of Technology, Oshawa, Ontario, Canada

Exer—Fed

Abstract
Exergy analysis is an assessment technique for systems and processes that is based on the second law of thermodynamics. Exergy analysis has been increasingly applied over the last several decades largely because of its advantages over energy analysis: more meaningful efficiencies are evaluated because exergy efficiencies are always a measure of the approach to the ideal and inefficiencies in a process are better pinpointed because exergy analysis quantifies the types, causes, and locations of losses. In this article, the role of exergy analysis in assessing and improving energy systems is examined. Also, exergy and its use as an analysis technique are briefly described, the range of energy systems that have been assessed with exergy analysis are surveyed, and several example applications of exergy analysis are presented, ranging from simple to complex.

INTRODUCTION

Energy analysis is based on the first law of thermodynamics, which embodies the principle of conservation of energy and is the traditional method used to assess the performance and efficiency of energy systems and processes.

Exergy analysis is a thermodynamic analysis technique for systems and processes that is based on the second law of thermodynamics. Exergy analysis has been increasingly applied over the last several decades, in large part because of its advantages over energy analysis:

- More meaningful efficiencies are evaluated with exergy analysis because exergy efficiencies are always a measure of the approach to the ideal.
- Inefficiencies in a process are better pinpointed with exergy analysis because the types, causes, and locations of the losses are identified and quantified.

In this article, the role of exergy analysis in the assessment and improvement of energy systems is examined. First, exergy and its use as an analysis technique are briefly described. Second, the ranges of energy systems that have been assessed with exergy analysis are surveyed. Third, several example applications of exergy analysis are presented, ranging from simple devices to large and complex systems.

Keywords: Exergy; Irreversibility; Efficiency; Second law of thermodynamics; Entropy; Environment; Economics; Design.

EXERGY

Exergy can be regarded as a measure of the usefulness or quality of energy. Technically, exergy is defined as the maximum amount of work that can be produced by a stream of energy or matter, or from a system, as it is brought into equilibrium with a reference environment. Unlike energy, exergy is consumed during real processes due to irreversibilities and conserved during ideal processes. Exergy and related concepts have been recognized for more than a century.[1]

Exergy analysis is a methodology that uses the first and second laws of thermodynamics for the analysis, design, and improvement of energy and other systems.[2–14] The exergy method is useful for improving the efficiency of energy-resource use, for it quantifies the locations, types, and magnitudes of wastes and losses. In general, more meaningful efficiencies are evaluated with exergy analysis rather than energy analysis because exergy efficiencies are always a measure of the approach to the ideal. Therefore, exergy analysis accurately identifies the margin available to design more efficient energy systems by reducing inefficiencies.

In evaluating exergy, the characteristics of the reference environment must be specified,[2–15] usually by specifying the temperature, pressure, and chemical composition of the reference environment. The results of exergy analyses, consequently, are relative to the specified reference environment, which in most applications is modeled after the actual local environment. The exergy of a system is zero when it is in equilibrium with the reference environment. The tie between exergy and the environment has implications regarding environmental impact.[7,8,16]

The theory and the applications of exergy have been described in specialized books, e.g.,[2–8] general thermodynamics texts, e.g.,[9,10] and journal articles e.g.[11–14] Many applications of exergy analysis have been reported in fields ranging from power generation[17,18] and cogeneration[9] to district energy,[19] thermal processes,[20,21] and thermal energy storage[22,23] and on to systems as large as countries.[24,25]

Exergy and the Reference Environment

Exergy quantities are evaluated with respect to a reference environment. The intensive properties of the reference environment in part determine the exergy of a stream or system. The reference environment is in stable equilibrium, with all parts at rest relative to one another and with no chemical reactions occurring between the environmental components. The reference environment acts as an infinite system and is a sink and source for heat and materials. It experiences only internally reversible processes in which its intensive state remains unaltered (i.e., its temperature T_0, pressure P_0, and the chemical potentials μ_{i00} for each of the i components present remain constant). The exergy of the reference environment is zero. More information on reference-environment models can be found in this encyclopedia in an article by the present author entitled "Exergy: Environmental Impact Assessment Applications."

Exergy Balances

Energy and exergy balances can be written for a general process or system.

Since energy is conserved, an energy balance for a system may be written as

$$\text{Energy input} - \text{Energy output} = \text{Energy accumulation} \quad (1)$$

Energy input and output refer respectively to energy entering and exiting through system boundaries. Energy accumulation refers to build-up (either positive or negative) of the quantity within the system.

By contrast, an exergy balance can written as

$$\text{Exergy input} - \text{Exergy output} - \text{Exergy consumption} = \text{Exergy accumulation} \quad (2)$$

This expression can be obtained by combining the principles of energy conservation and entropy nonconservation, the latter of which states that entropy is created during a process due to irreversibilities. Exergy is consumed due to irreversibilities, with exergy consumption proportional to entropy creation.

Eqs. 1 and 2 demonstrate an important difference between energy and exergy—energy is conserved while exergy, a measure of energy quality or work potential, can be consumed.

Definitions

It is helpful to define some terms related to exergy for readers. The following are exergy quantities:

Exergy: A general term for the maximum work potential of a system, a stream of matter, or a heat interaction in relation to the reference environment (see definition below) as the datum state; or the maximum amount of shaft work obtainable when a steady stream of matter is brought from its initial state to the dead state (see definition below) by means of processes involving interactions only with the reference environment.

Physical exergy: The maximum amount of shaft work obtainable from a substance when it is brought from its initial state to the environmental state (see definition below) by means of physical processes involving interaction only with the environment.

Chemical exergy: The maximum work obtainable from a substance when it is brought from the environmental state to the dead state by means of processes involving interaction only with the environment.

Thermal exergy: The maximum amount of shaft work obtainable from a given heat interaction using the environment as a thermal energy reservoir.

Exergy consumption: The exergy consumed during a process due to irreversibilities within the system boundaries.

The following terms relate to the reference environment and its state:

Reference environment: An idealization of the natural environment, which is characterized by a perfect state of equilibrium, i.e., absence of any gradients or differences involving pressure, temperature, chemical potential, kinetic energy, and potential energy. The reference environment constitutes a natural reference medium with respect to which the exergy of different systems is evaluated.

Dead state: The state of a system when it is in thermal, mechanical, and chemical equilibrium with a conceptual reference environment, which is characterized by a fixed pressure, temperature, and chemical potential for each of the reference substances in their respective dead states.

Environmental state: The state of a system when it is in thermal and mechanical equilibrium with the reference environment, i.e., at the pressure and temperature of the reference environment.

Reference state: A state with respect to which values of exergy are evaluated. Several reference states are used, including environmental state, dead state, standard environmental state, and standard dead state.

EXERGY ANALYSIS

Exergy analysis involves the application of exergy concepts, balances, and efficiencies to evaluate and improve energy and other systems. Many engineers and scientists suggest that devices are best evaluated and improved upon using exergy analysis in addition to or in place of energy analysis.

A journal devoted to exergy matters entitled *The International Journal of Exergy* has recently been established by Inderscience. Some extensive bibliographies have been compiled, including one by Goran Wall (see the Web site http://exergy.se).

A simple procedure for performing energy and exergy analyses involves the following steps:

- Subdivide the process under consideration into as many sections as desired, depending on the depth of detail and the understanding desired from the analysis.
- Perform conventional mass and energy balances on the process and determine all basic quantities (e.g., work, heat) and properties (e.g., temperature, pressure).
- Based on the nature of the process, the acceptable degree of analysis complexity and accuracy, and the questions for which answers are sought, select a reference-environment model.
- Evaluate energy and exergy values relative to the selected reference-environment model.
- Perform exergy balances, including the determination of exergy consumptions.
- Select efficiency definitions depending on the measures of merit desired and evaluate the efficiencies.
- Interpret the results and draw appropriate conclusions and recommendations relating to such issues as design changes, retrofit plant modifications, etc.

EXERGY ANALYSIS AND EFFICIENCY

Increases in efficiency are subject to two constraints, which are often poorly understood:

- Theoretical limitations, which establish the maximum efficiency theoretically attainable for a process by virtue of the laws of thermodynamics
- Practical limitations, which further limit increases in efficiency

First, consider practical limitations on efficiency. In practice, the goal when selecting energy sources and utilization processes is not to achieve maximum efficiency, but rather to achieve an optimal trade-off between efficiency and such factors as economics, sustainability, environmental impact, safety, and societal and political acceptability. This optimum is dependent on many factors controllable by society. Furthermore, these factors can be altered to favor increased efficiency (e.g., governments can offer financial incentives that render high-efficiency technologies economically attractive or provide disincentives for low-efficiency alternatives through special taxes and regulations).

Next, consider theoretical limitations on efficiency, which must be clearly understood to assess the potential for increased efficiency. Lack of clarity on this issue in the past has often led to confusion, in part because energy efficiencies generally are not measures of how nearly the performance of a process or device approaches the theoretical ideal. The consequences of such confusion can be significant. For example, extensive resources have at times been directed towards increasing the energy efficiencies of devices that in reality were efficient and had little potential for improvement. Conversely, devices at other times have not been targeted for improved efficiency even though the difference between the actual and maximum theoretical efficiencies, which represents the potential for improvement, has been large.

The difficulties inherent in energy analysis are also attributed to the fact that it only considers quantities of energy and ignores energy quality, which is continually degraded during real processes. Exergy analysis overcomes many of the problems associated with energy analysis.

OVERVIEW OF EXERGY ANALYSIS APPLICATIONS

Exergy analysis has been applied to a wide range of processes and systems, including those that are mechanical, thermal, electrical, and chemical. The types of applications of exergy methods that have been reported over the last several decades include:

- Electricity generation using both conventional devices such as fossil and nuclear power plants as well as alternative devices such as fuel cells and solar energy systems.
- Energy storage systems such as batteries, pumped storages, and thermal energy storages.
- Combustion technologies and systems and engines of various types.
- Transportation systems for land, air, and water transport.
- Heating and cooling systems for building systems and industrial applications.
- Cogeneration systems for producing heating and electrical needs simultaneously.
- Chemical processes such as sulphuric acid production, distillation, and water desalination, as well as petrochemical processing and synthetic fuels production.
- Metallurgical processes such as lead smelting.

EXAMPLES OF EXERGY ANALYSIS APPLICATIONS

Three examples of differing complexity of applications of exergy analysis are presented:

- An electrical resistance space heater (a simple component)
- A thermal energy storage system (a simple system containing a number of components)
- A coal-fired electrical generating station (a complex system)

Electrical Resistance Space Heater

An electrical resistance space heater converts electricity to heat at a temperature suitable for room comfort, and is illustrated in Fig. 1 (Part A).

The energy efficiency of electric resistance space heating often exceeds 99%, implying that the maximum possible energy efficiency for electric resistance heating is 100%, corresponding to the most efficient device possible.

This understanding is erroneous; however, energy analysis ignores the fact that in this process, high-quality energy (electricity) is used to produce a relatively low-quality product (warm air). Exergy analysis recognizes this difference in energy qualities and indicates the exergy of the heat delivered to the room to be about 5% of the exergy entering the heater. Thus, the exergy efficiency of electric resistance space heating is about 5%.

The exergy results are useful. Since thermodynamically ideal space heating has an exergy efficiency of 100%, the same space heating can in theory be achieved using as little as 5% of the electricity used in conventional electric resistance space heating. In practical terms, one can achieve space heating with a greatly reduced electricity input using an electric heat pump (see Part B of Fig. 1), using 15% of the electricity that electric resistance heating would require, for a heat pump with a "coefficient of performance" of 7.

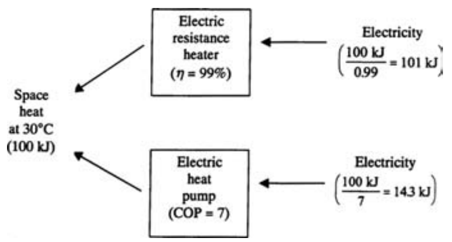

Fig. 1 Comparison of the quantity of electricity required to provide 100 kJ of space heat using two different heating devices: (a) an electric resistance heater and (b) an electric heat pump. Here, η denotes energy efficiency and COP coefficient of performance.

Thermal Storage System

A thermal energy storage system receives thermal energy and holds it until it is required. Thermal storages can store energy at temperatures above or below the environment temperature, and they come in many types (e.g., tanks, aquifers, ponds, caverns).

The evaluation of a thermal energy storage system requires a measure of performance which is rational, meaningful, and practical. The conventional energy storage efficiency is inadequate. A more perceptive basis is needed if the true usefulness of thermal storages is to be assessed and their economic benefit optimized, and exergy efficiencies provide such performance measures.

The notion that energy efficiency is an inappropriate measure of thermal storage performance can be illustrated. Consider a perfectly insulated thermal storage containing 1000 kg of water, initially at 40°C. The ambient temperature is 20°C and the specific heat of water is taken to be constant at 4.2 kJ/kg K. A quantity of 4200 kJ of heat is transferred to the storage through a heat exchanger from an external body of 100 kg of water cooling from 100 to 90°C. This heat addition raises the storage temperature 1.0°C to a value of 41°C. After a period of storage, 4200 kJ of heat are recovered from the storage through a heat exchanger, which delivers it to an external body of 100 kg of water, raising the temperature of that water from 20 to 30°C. The storage is returned to its initial state at 40°C.

For this storage cycle, the energy efficiency—the ratio of heat recovered from the storage to heat injected—is 4200/4200 kJ = 1, or 100%. But the recovered heat is at only 30°C and is of little use, having been degraded even though the storage energy efficiency was 100%. The exergy recovered in this example is 70 kJ and the exergy supplied 856 kJ. Thus the exergy efficiency, the ratio of the thermal exergy recovered from storage to that injected, is 70/856 = 0.082 or 8.2%, a much more meaningful expression of the achieved performance.

Consequently, a device which appears to be ideal on an energy basis is correctly shown to be far from ideal on an exergy basis, clearly demonstrating the benefits of using exergy analysis for evaluating thermal storage.

Coal-Fired Electrical Generating Station

Energy and exergy analyses are applied to the Nanticoke coal-fired electrical generating station in Ontario, Canada, which has a net unit electrical output of approximately 500 MWe and is operated by the provincial electrical utility, Ontario Power Generation (formerly Ontario Hydro). This example illustrates how exergy analysis allows process inefficiencies to be better pinpointed than an energy analysis does and how efficiencies are to be more rationally evaluated.

A detailed flow diagram for a single unit of the station is shown in Fig. 2. The symbols identifying the streams are described in Table 1a–c for material, thermal, and electrical flows, respectively, with corresponding data. Fig. 2 has four main sections:

- *Steam Generation*. Eight pulverized-coal-fired natural circulation steam generators each produce 453.6 kg/s steam at 16.89 MPa and 538°C and 411.3 kg/s of reheat steam at 4.00 MPa and 538°C. Air is supplied to the furnace by two 1080 kW 600-rpm motor-driven forced draft fans. Regenerative air preheaters are used. The flue gas passes through an electrostatic precipitator rated at 99.5% collection efficiency and exits the plant through two multiflued, 198 m high chimneys.
- *Power Production*: The steam passes through a series of turbine generators linked to a transformer. Extraction steam from several points on the turbines preheats feedwater in several low- and high-pressure heat exchangers and one spray-type open deaerating heat exchanger. The low-pressure turbines exhaust to the condenser at 5 kPa. Each station unit has a 3600-rpm, tandem-compound, impulse-reaction turbine generator containing one single-flow high-pressure cylinder, one double-flow intermediate-pressure cylinder, and two double-flow low-pressure cylinders. Steam exhausted from the high-pressure cylinder is reheated in the combustor.
- *Condensation*: Cooling water from Lake Erie condenses the steam exhausted from the turbines. The cooling-water flow rate is adjusted to achieve a specified cooling-water temperature rise across the condenser.
- *Preheating*: The temperature and pressure of the feedwater are increased in a series of pumps and feedwater-heater heat exchangers.

The reference-environment model used here has a temperature of 15°C (the approximate mean temperature of the lake cooling water), a pressure of 1 atm, and a chemical composition consisting of air saturated with water vapor, and the following condensed phases at 15°C and 1 atm: water (H_2O), gypsum ($CaSO_4 \cdot 2H_2O$), and limestone ($CaCO_3$). For simplicity, heat losses from external surfaces are assumed to occur at the reference-environment temperature of 15°C.

Energy and exergy values for the streams identified in Fig. 2 are summarized in Table 1. Exergy-consumption values for the devices are listed, according to process

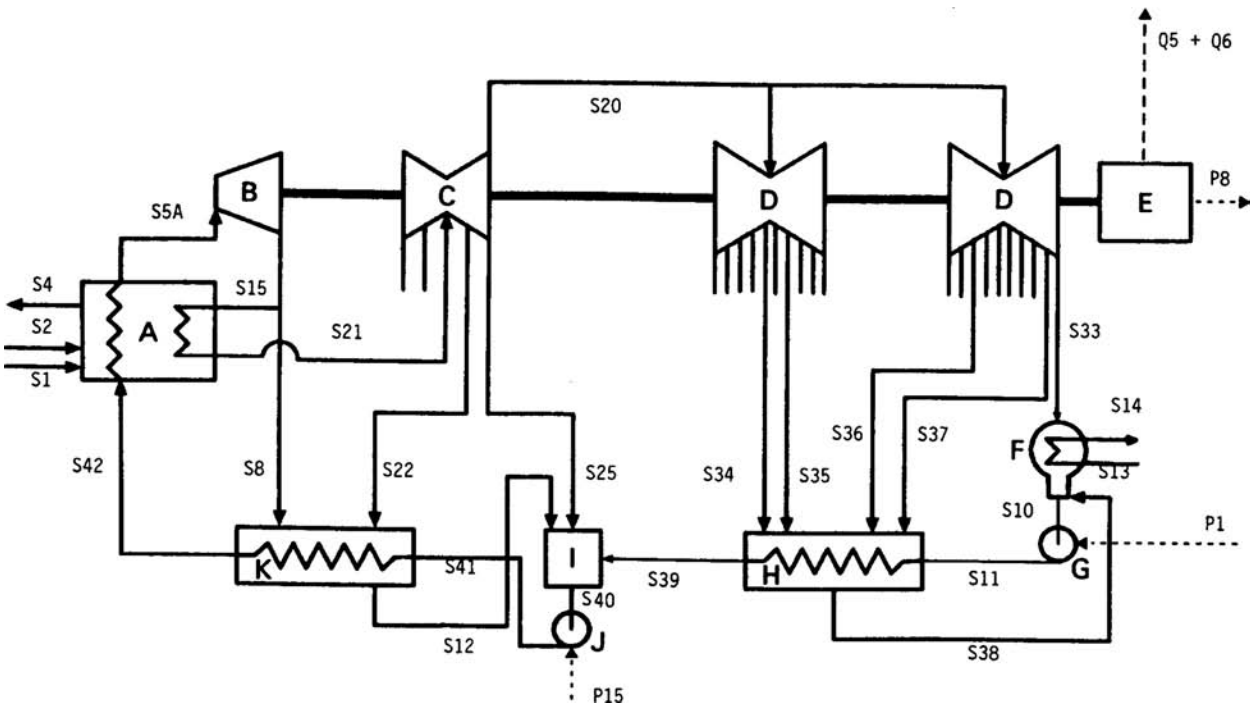

Fig. 2 A unit of the coal-fired electrical generating station. Lines exiting the turbines represent extraction steam. The station has four main sections: *Steam Generation* (Device A), *Power Production* (B–E), *Condensation* (F), and *Preheating* (G–K). The external inputs for Device A are coal and air, and the output is stack gas and solid waste. The external outputs for Device E are electricity and waste heat. Electricity is input to Device G and Device J and cooling water enters and exits Device F. A: steam generator and reheater, B: high-pressure turbine, C: intermediate-pressure turbine, D: low-pressure turbines, E: generator and transformer, F: condenser, G: hot well pump, H: low-pressure heat exchangers, I: open deaerating heat exchanger, J: boiler feed pump, K: high-pressure heat exchangers.

[a]The composition of all streams is 100% H_2O, except that, on a volume basis, the composition of S1 is 100% carbon, of S2 is 79% N_2 and 21% O_2, and of both S3 and S4 is 79% N_2, 6% O_2, and 15% CO_2.
[b]Vapor fraction is listed as 0.0 for liquids and 1.0 for superheated vapors.
[c]Stream S3 (not shown in Fig. 2) represents the hot product gases for adiabatic combustion.

section, in Table 2. Fig. 3a and b illustrate the net energy and exergy flows and exergy consumptions for the four main process sections.

Overall energy and exergy efficiencies are evaluated as

Energy efficiency

$$= (\text{Net energy output with electricity})/(\text{Energy input}) \quad (3)$$

and

Exergy efficiency

$$= (\text{Net exergy output with electricity})/(\text{Exergy input}) \quad (4)$$

Coal is the only input source of energy or exergy and the energy and exergy efficiencies are 37 and 36%,

Total		844.0

respectively. The small difference in the efficiencies is due to the fact that the specific chemical exergy of coal is slightly greater than its energy. Although the station energy and exergy efficiencies are similar, these efficiencies differ markedly for many station sections.

In the *Steam Generation* section, exergy consumptions are substantial, accounting for 659 MW (or 72%) of the 916 MW station exergy loss. Of this 659, 444 MW is consumed with combustion and 215 MW with heat transfer. The energy and exergy efficiencies for the *Steam Generation* section, considering the increase in energy or exergy of the water as the product, are 95 and 49%, respectively. The *Steam Generation* section thus appears significantly more efficient on an energy basis than on an exergy basis. Physically, this discrepancy implies that although 95% of the input energy is transferred to the preheated water, the energy is degraded as it is transferred. Exergy analysis highlights this degradation.

In the condensers, a large quantity of energy enters (775 MW for each unit), of which close to 100% is rejected, while a small quantity of exergy enters (54 MW for each unit), of which about 25% is rejected and 75% is internally consumed. Thus, energy analysis leads to the erroneous conclusion that almost all losses in electricity-generation potential for the station are associated with the heat rejected by the condensers, while exergy analysis demonstrates quantitatively and directly that the condensers are responsible for little of these losses (see Fig. 3b). This discrepancy arises because heat is rejected by the condensers at a temperature very near that of the environment.

In the *Power Production* and *Preheating* sections, energy losses are small (less than 10 MW) and exergy losses moderately small (118 MW in *Power Production* and 23 MW in *Preheating*). The exergy losses are almost completely associated with internal consumptions.

In assessing the thermodynamic characteristics of a coal-fired electrical generating station, several illuminating insights into performance are acquired:

- Although energy and exergy efficiencies are similar for the station, energy analysis does not identify the location and cause of process inefficiencies, while exergy analysis does. Energy losses are associated with emissions (mainly heat rejected by condensers) and exergy losses are primarily associated with consumptions (mainly in the combustors).
- Because devices with the largest thermodynamic losses have the largest margins for efficiency improvement, efforts to increase the efficiencies of coal-fired electrical generating stations should focus on the combustors. For instance, technologies capable of producing electricity without combustion (e.g., fuel cells) or utilizing heat at high temperatures could increase efficiencies significantly. This suggestion is, of course, overly simplistic, as such decisions must also account for other technical and economic factors.
- The use of heat rejected by condensers only increases the exergy efficiencies by a few percent.

APPLICATIONS BEYOND THERMODYNAMICS

Exergy concepts can be applied beyond thermodynamics in such fields as environmental impact assessment,[7,8,16] economics,[5,17,20,26] and policy.[27]

Exergy and Environment

Many suggest that the impact of energy utilization on the environment is best addressed by considering exergy. Although the exergy of an energy form or a substance is a measure of its usefulness, exergy is also a measure of its potential to cause change. The latter point suggests that exergy may be or may provide the basis for an effective

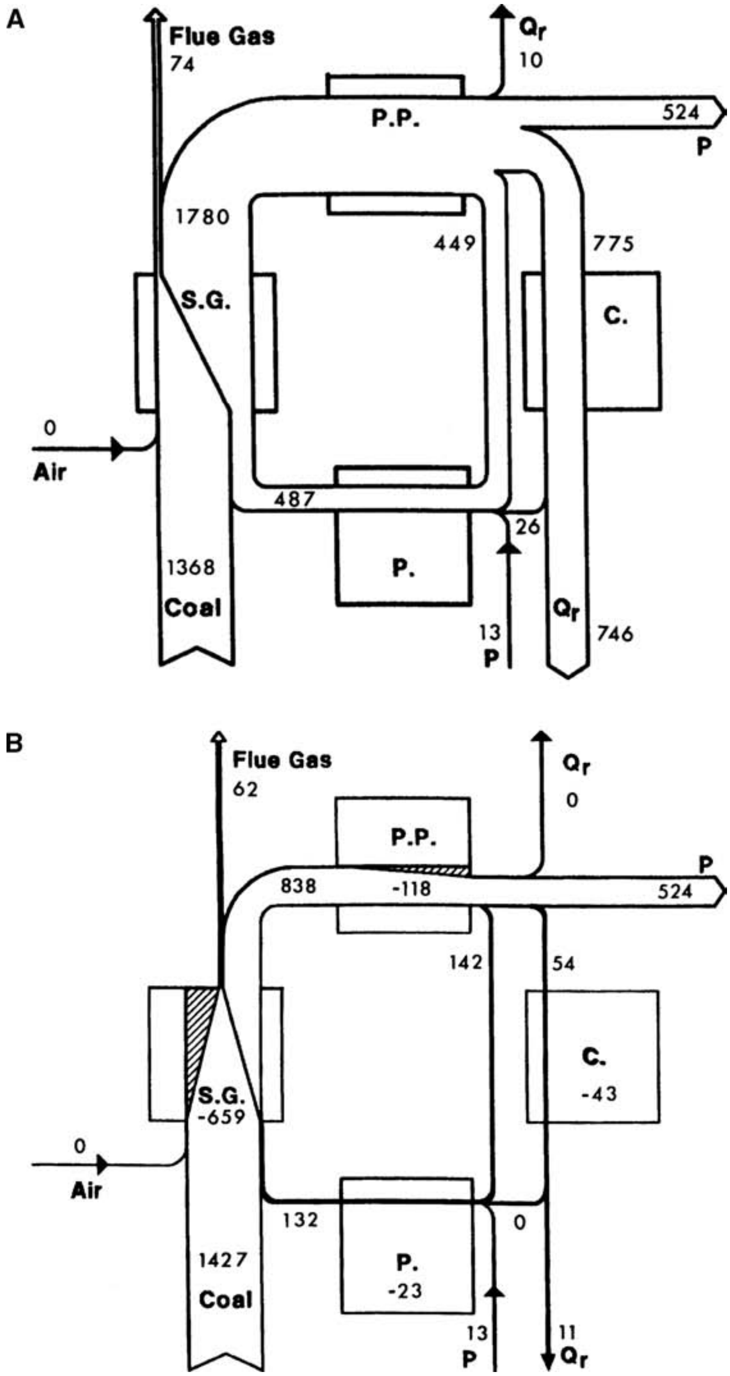

Fig. 3 (A) Diagram for a coal-fired electrical generating station unit indicating net energy flow rates (MW) for streams. Stream widths are proportional to energy flow rates. Station sections shown are *Steam Generation* (S.G.), *Power Production* (P.P.), *Condensation* (C.) and *Preheating* (P.). Streams shown are electrical power (P), heat input (Q), and heat rejected (Q_r). Stream widths are proportional to exergy flow rates and shaded regions to exergy consumption rates. Other details are as in (A).

measure of the potential of a substance or energy form to impact the environment. The relation between exergy and the environment is discussed in this encyclopedia in an article entitled "Exergy: Environmental Impact Assessment Applications."

Exergy and Economics

Another area in which applications of exergy are increasing is that of economics. In the analysis and design of energy systems, techniques are often used that combine scientific disciplines like thermodynamics with economics to achieve optimum designs. For energy systems, costs are conventionally based on energy. Many researchers, however, have recommended that costs are better distributed among outputs based on exergy. Methods of performing exergy-based economic analyses have evolved (e.g., thermoeconomics, second-law costing, and exergoeconomics). These analysis techniques recognize that exergy, not energy, is the commodity of value in a system, and assign costs and prices to exergy-related variables. These techniques usually help in appropriately allocating economic resources so as to optimize the design and operation of a system and its economic feasibility and profitability (by obtaining actual costs of products and their appropriate prices).

CONCLUSION

Exergy analysis provides information that influences design, improvement, and application decisions and it is likely to be increasingly applied. Exergy also provides insights into the "best" directions for research, where "best" is loosely considered most promising for significant efficiency gains. There are two main reasons for this conclusion:

- Unlike energy losses, exergy losses represent true losses of the potential to generate the desired product from the given driving input. Focusing on exergy losses permits research to aim at reducing the losses that degrade efficiency.
- Unlike energy efficiencies, exergy efficiencies always provide a measure of how closely the operation of a system approaches the ideal. By focusing research on plant sections or processes with the lowest exergy efficiencies, effort is directed to those areas that inherently have the largest margins for efficiency improvement. By focusing on energy efficiencies, on the other hand, research can inadvertently be expended on areas for which little margins for improvement exist, even theoretically.

Exergy analysis results typically suggest that improvement efforts should concentrate more on internal rather than external exergy losses based on thermodynamic considerations, with a higher priority for the processes that have larger exergy losses. Of course, effort should still be devoted to processes having low exergy losses when cost-effective ways to increase efficiency can be identified.

Energy-related decisions should not be based exclusively on the results of energy and exergy analyses even though these results provide useful information to assist in such decision making. Other factors must also be considered, such as economics, environmental impact, safety, and social and political implications.

Exergy: Environmental Impact Assessment Applications

Marc A. Rosen
Faculty of Engineering and Applied Science, University of Ontario Institute of Technology, Oshawa, Ontario, Canada

Exer–Fed

Abstract
Exergy can help to understand and mitigate environmental impact because exergy is a measure of the departure of a substance from equilibrium with a specified reference environment, which is often modeled as the actual environment. Furthermore, exergy is a measure of potential of a substance to cause change, so the exergy of an emission is a measure of the potential of the substance to change or impact the environment. Thus, exergy may be, or provide the basis for, an indicator of the potential of an emitted substance to impact the environment. This article describes exergy and its use via exergy analysis, the reference environment in exergy analysis, the relation between exergy and environmental impact, and how environmental impact assessment and reduction can be accomplished with exergy methods.

INTRODUCTION

Exergy analysis is a thermodynamic technique for assessing and improving systems and processes, which is similar but advantageous to energy analysis, in large part because it is based on the second law of thermodynamics. The exergy of an energy form or a substance is a measure of its usefulness.

Exergy can also be applied to understand and mitigate environmental impact because exergy is a measure of the departure of a substance from equilibrium with a specified reference environment, which is often modeled as the actual environment. Furthermore, exergy is a measure of potential of a substance to cause change. The exergy of an emission to the environment, therefore, is a type of measure of the potential of the substance to change or impact the environment. The greater the exergy of an emission, the greater is its departure from equilibrium with the environment, and the greater is its potential to change or impact the environment. The exergy of an emission is zero only when it is in equilibrium with the environment and thus benign. Consequently, exergy may be, or provide the basis for, an effective indicator of the potential of an emitted substance to impact the environment.

This article focuses on describing both the relations between exergy and environmental impact, and how environmental impact assessment can be accomplished with exergy methods. Such knowledge can permit the development of better understanding of, and more rational approaches to mitigating, the environmental impact associated with systems and processes. The scope of this article is as follows:

- Exergy and its use as an analysis technique via exergy analysis are briefly described, with particular attention on the role of the reference environment in exergy analysis.
- Relations between energy and the environment as well as exergy and the environment are discussed.
- Ways to reduce environmental impact with exergy are described.

Keywords: Exergy; Environmental impact; Emissions; Resource; Energy degradation.

EXERGY ANALYSIS

Exergy is defined as the maximum amount of work which can be produced by a flow of matter or energy as it comes to equilibrium with a reference environment. Exergy is a measure of the potential of a flow to cause change, as a consequence of being in disequilibrium with the reference environment.

The exergy Ex contained in a system may be written as

$$\text{Ex} = S(T - T_0) - V(p - p_0) + N_k(\mu_k - \mu_{k_0}) \qquad (1)$$

where the intensive properties are temperature, T, pressure, p, and chemical potential of substance k, μ_k; and the extensive properties are entropy, S, volume, V, and number of moles of substance k, N_k. The subscript "0" denotes conditions of the reference environment. It is evident from this expression that the exergy of a system is zero when it is in equilibrium with the reference environment (i.e., when $T = T_0$, $p = p_0$, and $\mu_k = \mu_{k_0}$ for all k). Clearly, evaluations of exergy require that the state of the reference environment, or the reference state, be specified, normally by its temperature, pressure, and chemical composition.

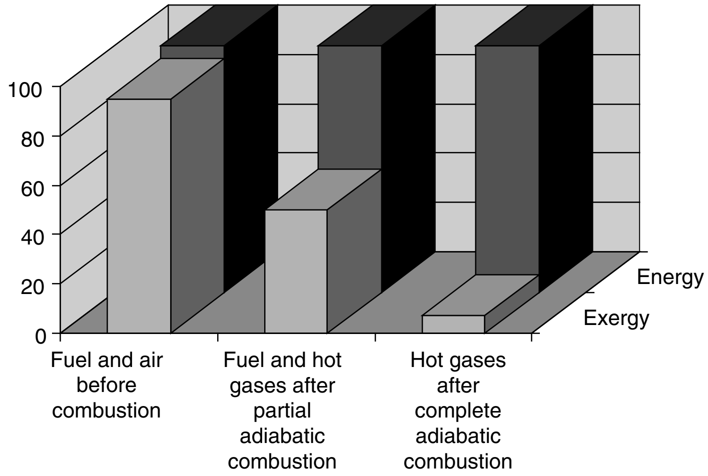

Fig. 1 Comparison of energy and exergy during combustion, for an input of 100 units of fuel energy.

Exergy analysis[1–7] uses the first and second laws of thermodynamics for the design and analysis of energy systems. Exergy is not subject to a conservation law, and is consumed due to the irreversibilities in any process. The exergy method is useful for attaining more efficient energy-resource use, for it enables the locations, types, and magnitudes of wastes and losses to be determined. Therefore, exergy analysis reveals by how much it is possible to design more efficient energy systems by reducing inefficiencies. Applications of exergy analysis occur in many areas and are increasing.

As a simple example, consider an adiabatic system containing fuel and air at ambient conditions. The fuel and air react to form a mixture of hot combustion gases. During the combustion process, the energy in the system remains fixed because it is adiabatic. But the exergy content declines as combustion proceeds due to the irreversibilities associated with the conversion of the high-quality energy of fuel to the lower quality energy of combustion gases. The different behaviors of energy and exergy during this process are illustrated qualitatively in Fig. 1.

More information on the fundamentals of exergy can be found in this encyclopedia in an article by the present author entitled "Exergy Analysis."

THE REFERENCE ENVIRONMENT IN EXERGY ANALYSIS

Exergy analysis requires a reference-environment model. Exergy is evaluated with respect to the reference-environment model, with the exergy of a flow and system being dependent on the intensive properties of the reference environment. The exergy of the reference environment is zero, and the exergy of a stream or system is zero when it is in equilibrium with the reference environment.

The reference environment has several theoretical characteristics. It is in stable equilibrium, and has all parts at rest relative to one another. In addition, the reference environment acts as an infinite system, is a sink and source for heat and materials, and experiences only internally reversible processes in which its intensive state remains unaltered (i.e., its temperature, pressure, and chemical potentials for each of the components present remain constant). No chemical reactions can occur between the reference-environment components.

The natural environment does not possess the theoretical characteristics of a reference environment, since it is not in equilibrium and its intensive properties vary spatially and temporally. Many chemical reactions in the natural environment are blocked because the transport mechanisms that are necessary to reach equilibrium are too slow at ambient conditions. Thus, the exergy of the natural environment is not zero, as work could be obtained if it were to come to equilibrium. In developing reference-environment models for exergy analysis, a compromise is made between the theoretical requirements of the reference environment and the behavior of the actual environment.

Several classes of reference-environment models are now described.

Natural-Environment-Subsystem Models

These models simulate subsystems of the natural environment. One such model consists of saturated moist air and liquid water in phase equilibrium.[8]

An extension of that model allows sulphur-containing materials to be analyzed.[9] The temperature and pressure of this reference environment (Table 1) are normally 25°C and 1 atm, respectively, and the chemical composition consists of air saturated with water vapor, and the following condensed phases at 25°C and 1 atm: water (H_2O), gypsum ($CaSO_4 \cdot 2H_2O$), and limestone ($CaCO_3$).

Table 1 A reference-environment model

Temperature, T_0	25°C
Pressure, P_0	1 atm
Composition	(i) Atmospheric air, saturated with H_2O at T_0 and P_0, having the following composition

Air constituents	Mole fraction
N_2	0.7567
O_2	0.2035
H_2O	0.0303
Ar	0.0091
CO_2	0.0003
H_2	0.0001

(ii) The following condensed phases at T_0 and P_0

Water (H_2O)

Limestone ($CaCO_3$)

Gypsum ($CaSO_4 \cdot 2H_2O$)

The stable configurations of C, O, and N, respectively, are taken to be those of CO_2, O_2, and N_2 as they exist in air saturated with liquid water at T_0 and P_0 (the temperature and pressure for the reference environment); of hydrogen is taken to be in the liquid phase of water saturated with air at T_0 and P_0; and of S and Ca, respectively, are taken to be those of $CaSO_4 \cdot 2H_2O$ and $CaCO_3$ at T_0 and P_0.

Reference-Substance Models

With this model, a "reference substance" is selected for every chemical element and assigned zero exergy. In one such model, the reference substances are selected as the most valueless substances found in abundance in the natural environment.[1,3] The criterion for selecting such reference substances is consistent with the notion of simulating the natural environment, but is primarily economic in nature, and is vague and arbitrary with respect to the selection of reference substances. Part of this environment is the composition of moist air, including N_2, O_2, CO_2, H_2O, and the noble gases; gypsum (for sulphur) and limestone (for calcium).

In a related model, reference substances are selected arbitrarily,[10] so the model does not resemble the natural environment. Absolute exergies evaluated with this model do not relate to the natural environment, and cannot be used rationally to evaluate efficiencies or environmental impact.

Equilibrium Models

In this model all the materials present in the atmosphere, oceans and a layer of the crust of the earth are pooled together and an equilibrium composition is calculated for a given temperature.[11] The selection of the thickness of crust considered is subjective and is intended to include all materials accessible to technical processes. Thicknesses varying from 1 to 1000 m, and a temperature of 25°C, have been considered. For all thicknesses, the model differs significantly from the natural environment. Exergy values obtained using these environments are significantly dependent on the thickness of crust considered, and represent the absolute maximum amount of work obtainable from a material. Since there is no technical process available which can obtain this work from materials, the equilibrium model does not give meaningful exergy values when applied to the analysis of real processes.

Constrained-Equilibrium Models

A modified version of the equilibrium environment model excludes in the equilibrium composition the possibility of the formation of nitric acid (HNO_3) and its compounds.[11] All chemical reactions in which these substances are formed are in constrained equilibrium, and all other reactions are in unconstrained equilibrium. When a thickness of crust of 1 m and temperature at 25°C are used, the model is similar to the natural environment.

Process-Dependent Models

This model contains only components that participate in the process being examined in a stable equilibrium composition at the temperature and pressure of the natural environment.[12] Being dependent on the process examined, the model is not general. Exergies evaluated for a specific process-dependent model are relevant only to the process, and cannot rationally be compared with the exergies evaluated for other process-dependent models or used in environmental assessments.

EXERGY, ENERGY AND THE ENVIRONMENT

Energy and the Environment

Energy production, transformation, transport, and end-use have significant impacts on the earth's environment. The present world distribution of per capita energy consumption suggests that a close correlation exists between a country's energy consumption and economic development. But, there does not appear to be a simple correlation between a country's energy consumption and the decay of its environment.

Exergy and the Environment

Some researchers suggest that exergy provides a less-subjective measure capable of providing greater insight into environmental impact.[13–19]

The exergy contents of waste emissions can be seen to be more meaningful than the corresponding energy contents as measures of potential for environmental impact. Material and energy flows only possess exergy when in disequilibrium with a reference environment. The exergy associated with waste emissions has the potential to cause environmental damage, particularly when released in an unconstrained manner into the environment. Many believe that by considering the exergy content of a waste emission, rational, and meaningful assessments can be made of the environmental impact potential of the emission.

Exergy losses, which consist of exergy destruction and waste exergy emissions, have a significant effect on environmental impact. Exergy destruction, in particular, is a significant criteria for assessing the depletion of natural resources. Exergy analysis can assist efforts to minimize the use of natural resources, as it indicates where the work potential of natural resources in relation to the surrounding environment is lost, i.e., where irreversibility, or exergy destruction, occurs.

A waste emission possesses exergy as a result of its being in a state of mechanical, thermal and/or chemical disequilibrium with the reference environment.[20,21] Exergy is often separated into two components: physical and chemical. From an environmental impact viewpoint, the exergy of an emission attributable to mechanical and thermal disequilibrium is not considered significant, as the potential impact on the environment of physical exergy is limited. That is, the pressure differences between an emission and the environment normally dissipate quickly and temperature differences are normally localized near the emission source (e.g., thermal pollution in the region of a lake near the cooling water discharge of a thermal power plant) and can be controlled. The exergy of an emission due to chemical disequilibrium (i.e., the chemical exergy), on the other hand, is often significant and not localized. The chemical exergy of emissions is normally a concern.

The exergy of a flow can only be entirely converted to products in a completely reversible process, since there are no exergy destructions within the system and no waste exergy emissions to the environment. In real-world processes, which are irreversible, both destruction of the exergy of resources and waste exergy emissions occur. Many efforts are being expended on reducing resource exergy destructions and eliminating waste exergy emissions—often by converting them into useful products. A reversible process represents a theoretical ideal which we can strive towards but never actually achieve.

REDUCING ENVIRONMENTAL IMPACT WITH EXERGY

Efforts to increase efficiency can reduce environmental impact by reducing exergy losses. Regional and national actions to improve exergy efficiency, in particular, can have major impacts on environmental protection. Work is being carried out on methods to reduce environmental impact with exergy methods. Some examples:

- Environomics is a methodology for analyzing and improving energy-related systems by simultaneously taking into account energy, exergy, economic, and environmental factors.[22] Exergy has also been integrated with life cycle analysis,[21,23] ecology and industrial ecology,[3,24–26] renewable concepts[27,28] and sustainability.[16,28–30]
- A recent study concluded that exergy analysis is a key tool for obtaining sustainable development. That study stated that, although energy can never be destroyed, exergy can be destroyed and this exergy destruction (irreversibility) must be appropriately minimized to obtain sustainable development. That study also showed that environmental effects associated with emissions and resource depletion can be expressed in terms of one indicator, which is based on physical principles.[17]
- The Consortium on Green Design and Manufacturing at the University of California-Berkeley is carrying out a project entitled "Exergy as an Environmental Indicator" to increase the practical application of exergy for rectifying problems associated with material and energy flows in industry.
- Several projects have recently been carried out at the Delft University of Technology and University of Twente to determine whether exergy analysis can be used in environmental policy development, especially for the comparison of alternative production chains. These studies are investigating if the linkages of exergy

with phenomena such as pollution and dispersion can be converted into a reliable tool on which policy decisions can be based, and are exploring how the environmental effects of processes can be linked to or expressed in terms of exergy changes.

Several researchers suggest the most appropriate way to link the second law and environmental impact is through exergy because it is a measure of the departure of the state of a system from that of the environment. The magnitude of the exergy of a system depends on the states of both the system and the environment. This departure is zero only when the system is in equilibrium with its environment. Tribus and McIrvine suggest that performing exergy analyses of the natural processes occurring on the earth could form a foundation for ecologically sound planning because it would indicate the disturbance caused by largescale changes.[18]

An understanding of the relations between exergy and the environment may reveal the fundamental patterns and forces affecting changes in the environment and help researchers deal better with environmental damage.

RELATIONS BETWEEN EXERGY AND ENVIRONMENTAL IMPACT

Three relations between exergy and environmental impact that help to explain patterns that underlie changes in the environment are now discussed.

Order Destruction and Chaos Creation

The destruction of order, or creation of chaos, is a form of environmental damage.

Fundamentally, entropy is a measure of chaos. A system of high entropy is more chaotic or disordered than one of low entropy. For example, a field with papers scattered about has a higher entropy than the field with the papers neatly piled. Conversely, exergy is a measure of order. Relative to the same environment, the exergy of an ordered system is greater than that of a chaotic one.

The difference between the exergy values of the two systems containing papers described above is a measure of the minimum work required to convert the chaotic system to the ordered one (i.e., in collecting the scattered papers). In reality, more than this minimum work, which only applies if a reversible clean-up process is employed, is required. The exergy destroyed when the wind scatters a stack of papers is a measure of the order destroyed during the process.

Resource Degradation

The degradation of resources found in nature is a form of environmental damage.

One definition of a resource is a material, found in nature or created artificially, in a state of disequilibrium with the environment. Resources have exergy as a consequence of this disequilibrium. For some resources (e.g., metal ores), it is their composition that is valued. For others (e.g., fuels), their reactivity is valued (i.e., their potential to cause change, or "drive" a task or process).

By preserving exergy through increased efficiency, i.e., degrading as little exergy as necessary for a process, environmental damage is reduced. Increased efficiency also has the effect of reducing exergy emissions.

The earth is an open system subject to a net influx of exergy from the sun. It is the exergy (or order states) delivered with solar radiation that is valued; all the energy received from the sun is ultimately radiated out to the universe. Environmental damage can be reduced by taking advantage of the openness of the earth and utilizing solar radiation, instead of degrading resources found in nature to supply exergy demands. This would not be possible if the earth was a closed system, for it would eventually become increasingly degraded, or "entropic."

Waste Exergy Emissions

The exergy associated with process wastes emitted to the environment can be viewed as a potential for environmental damage. (This should not be confused with exergy in the environment that is constrained and thus a resource, as shown in Fig. 2).

Typical process wastes have exergy, a potential to cause change, as a consequence of not being in stable equilibrium with the environment. When emitted to the environment, this exergy represents a potential to change the environment. In some cases, this exergy may cause a change perceived to be beneficial (e.g., the increased rate of growth of fish and plants near the cooling-water outlets from thermal power plants). More often, however, emitted exergy causes a change which is damaging to the

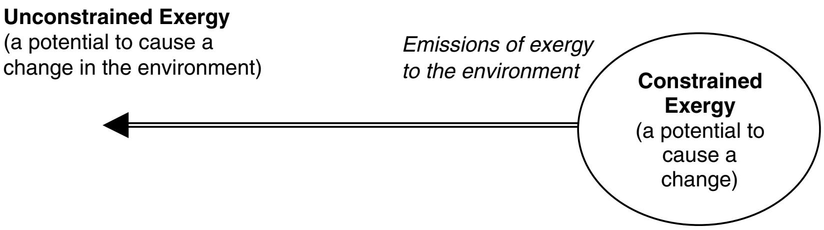

Fig. 2 Comparison of constrained and unconstrained exergy. Exergy constrained in a system represents a resource, while exergy emitted to the environment becomes unconstrained and represents a potential for environmental damage.

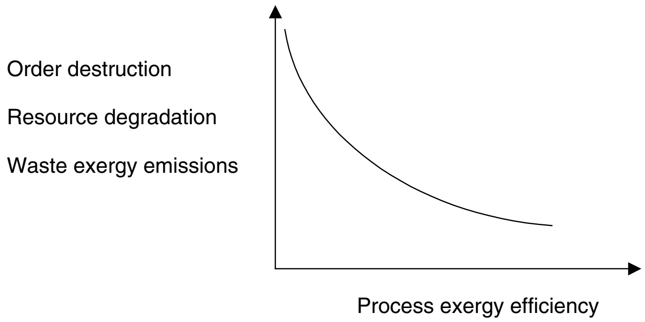

Fig. 3 Qualitative illustration of the relations between the exergy efficiency of a process and the associated environmental impact in terms of order destruction, resource degradation and waste exergy emissions.

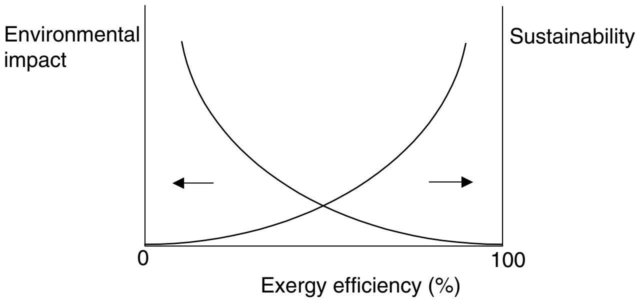

Fig. 4 Qualitative illustration of the relations between the environmental impact and sustainability of a process, and its exergy efficiency.

environment (e.g., the deaths of fish and plants in some lakes due to the release of specific substances in stack gases as they react and come to equilibrium with the environment).

Emissions of exergy to the environment can also interfere with the net input of exergy via solar radiation to the earth. Carbon dioxide emissions appear to be changing the atmospheric CO_2 concentration, affecting the receiving and re-radiating of solar radiation by the earth.

The relation between waste exergy emissions and environmental damage has been recognized by several researchers. By considering the economic value of exergy in fuels, one air-pollution rating estimates the air-pollution cost for a fuel as either the cost to remove the pollutant or the cost to society of the pollution (i.e., the tax which should be levied if pollutants are not removed from effluent streams).[2] Reistad claims the rating is preferable to mainly empirical ratings commonly used.

Discussion

The decrease in the environmental impact of a process, in terms of the three measures discussed in this section, as exergy efficiency increases for a process is illustrated in Fig. 3. Fig. 3 can be expanded as shown in Fig. 4 to illustrate the tie to sustainability. There sustainability is seen to increase and environmental impact to decrease as process exergy efficiency increases. Two limiting cases in Fig. 4 are significant:

- As exergy efficiency approaches 100%, environmental impact approaches zero, since exergy is converted from one form to another without loss (internal consumptions or waste emissions), and sustainability approaches infinity because the process approaches reversibility.
- As exergy efficiency approaches 0%, sustainability approaches zero because exergy-containing resources are used but nothing is accomplished, and environmental impact approaches infinity because to provide a fixed service, an ever-increasing quantity of resources must be used and a correspondingly increasing amount of exergy-containing wastes are emitted.

CONCLUSION

The relations between environmental impact and exergy could lead to simple, rational, and objective procedures for assessing the harmful effects on the environment and predicting the potential for environmental impact for a substance. This view is primarily based on the general premise that a substance has exergy due to its disequilibrium with respect to a reference environment, and therefore the exergy of unconstrained waste emissions has the potential to impact on the environment. The potential usefulness of exergy analysis in addressing and solving environmental problems is substantial, although further work is needed if utilizable exergy-based environmental-impact measures and methods are to be developed.

Facility Air Leakage

Wendell A. Porter
University of Florida, Gainesville, Florida, U.S.A.

Abstract
Building air leakage issues are described in detail in this entry. The advantages and disadvantages of the most popular techniques and materials used to reduce air leakage are discussed. Information concerning the most often missed avenues for air leakage through penetrations and air flow bypasses is also provided.

Each major building component that contributes to air leakage, such as floors, ceilings and walls, is described in detail. The proper application method for each technique used to reduce air leakage is explained in both the text and illustrations. Measurement techniques utilizing blower door technology are also introduced. These techniques have been used to measure the success of the goal of reducing unintended building air leakage.

INTRODUCTION

Air leakage is a major problem for both new and existing buildings, and it can:

- Contribute to over 30% of cooling and heating costs
- Create comfort and moisture problems
- Pull pollutants, such as radon and mold, into buildings
- Serve as easy access for insects and rodents

To effectively reduce air leakage requires a continuous air barrier system—a combination of materials linked together to create a tight building envelope (Fig. 1). An effective building envelope should form both a continuous air barrier and an insulation barrier. An air barrier minimizes air currents inside the cavities of the building envelope, which helps maintain insulation *R*-values.

The air barrier should seal all leaks through the building envelope—the boundary between the conditioned portion of the building and the unconditioned area. Most standard insulation products are not effective at sealing air leakage. The *R*-value for these products may drop if air leaks through the material.

The builder should work with his or her own crew and subcontractors to seal all penetrations through the envelope. Then, continuous material should be installed around the envelope. In the air sealing process, it is critical to use durable materials and install them properly.

INFILTRATION CONTROL

Vapor Retarders

An infiltration barrier shall provide a continuous air barrier from the foundation to the top plate of the ceiling and shall be sealed at the foundation, the top plate, at openings in the wall plane (windows, doors, etc.), and at the seams between sections of infiltration barrier material. When installed on the interior side of the walls, such as with insulated face panels with an infiltration barrier, the infiltration barrier should be sealed at the foundation or subfloor. This prevents wind from circulating air within the insulation. If properly sealed at the seams and ends, plywood and builder's felt will serve as an effective infiltration barrier, but not as a moisture retardant. A vapor retarder will essentially stop moisture transmission or diffusion. Common vapor retarders include 6-mil polyethylene sheet and aluminum foil-backed paper or boards. Contrary to northern construction practices, a vapor retarder, including vinyl wall coverings, installed next to the conditioned space is not recommended; during the summer, water may condense on the vapor retarder surface within the wall cavity when the inside temperature is below the outside dew point. This could wet and degrade insulation, deteriorate wall components, and contribute to mold and mildew. Vapor retarders are not recommended on the conditioned side of walls in Florida buildings. In fact, the ASHRAE 2001 Fundamentals Handbook does not recommend vapor retarders at all in hot, humid climates (on walls or ceilings). It should be noted that vinyl wallpaper acts like a vapor barrier. Placement on the conditioned side of the wall may cause moisture problems.

Air Barriers

Housewraps serve as exterior air barriers and help reduce air leakage through outside walls. Most products block only air leakage, not vapor diffusion, so they are not vapor retarders.

Typical products are rolled sheet materials that can be affixed and sealed to the wall between the sheathing and exterior finish material (Fig. 2). For best performance, a housewrap must be sealed with caulk or tape at the top and bottom of the wall and around any openings, such as

Keywords: Air leakage; Vapor barrier; Continuous air barrier; Insulation barrier; Infiltration.

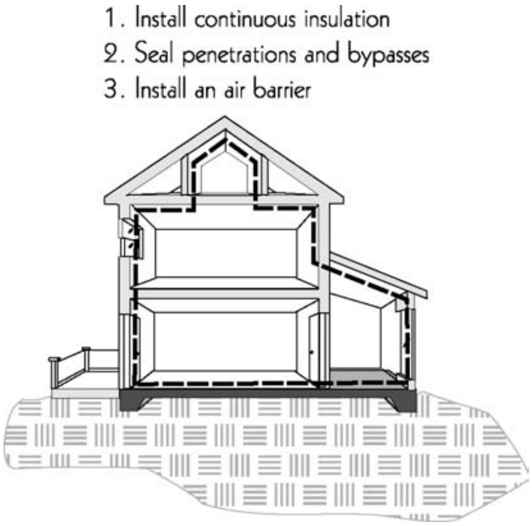

Fig. 1 Tight building envelope.

windows, doors, and utility penetrations, and be installed per manufacturer's specifications.

A housewrap can help reduce air leakage through exterior walls, but, by itself, is not a continuous air barrier for the entire envelope and, hence, is not a substitute for the airtight drywall approach. Housewraps are primarily recommended as further insurance against air leakage and, because they can block liquid water (bulk water) penetration, can help protect a building from moisture damage. In some instances, the exterior sheathing may be used as an outside air barrier (Fig. 3). Careful sealing of all seams and penetrations, including windows, is required (Fig. 4).

Materials

Most air barrier systems rely on a variety of caulks, gaskets, weatherstripping, and sheet materials such as plywood, drywall, and housewraps.

Use a combination of these different air sealing materials:

- Caulk—Use to seal gaps less than 1/4 in. Select the grade (interior, exterior, high temperature) based on application.
- Spray foam—Expands to fill large cracks and small holes. It can be messy; consider new, water-based foams. Not recommended near flammable applications (flue vents, etc.) and not permitted around PVC pipe. May be prohibited around windows by window manufacturers.
- Gaskets—Apply under the bottom plate before an exterior wall is raised or used to seal drywall to framing.
- Housewrap—Installed between the sheathing and exterior finish material. Must be sealed with tape or caulk to form an airtight seal. Resists liquid water and is not a vapor retarder.
- Sheet goods (plywood, drywall, rigid foam insulation)—These are the solid materials that form the building envelope. Air will only leak at the seams or through unsealed penetrations.
- Sheet metal—Used with high temperature caulk for sealing high temperature components, such as flues, to framing.
- Polyethylene plastic—Inexpensive material for air-sealing that also stops vapor diffusion. Must have all

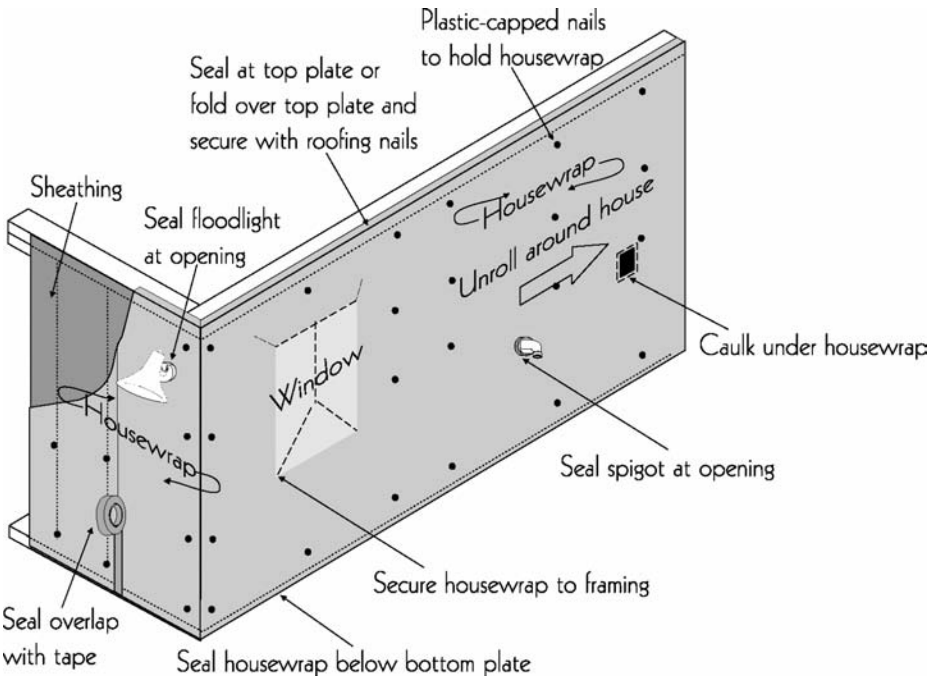

Fig. 2 Housewrap air barrier.

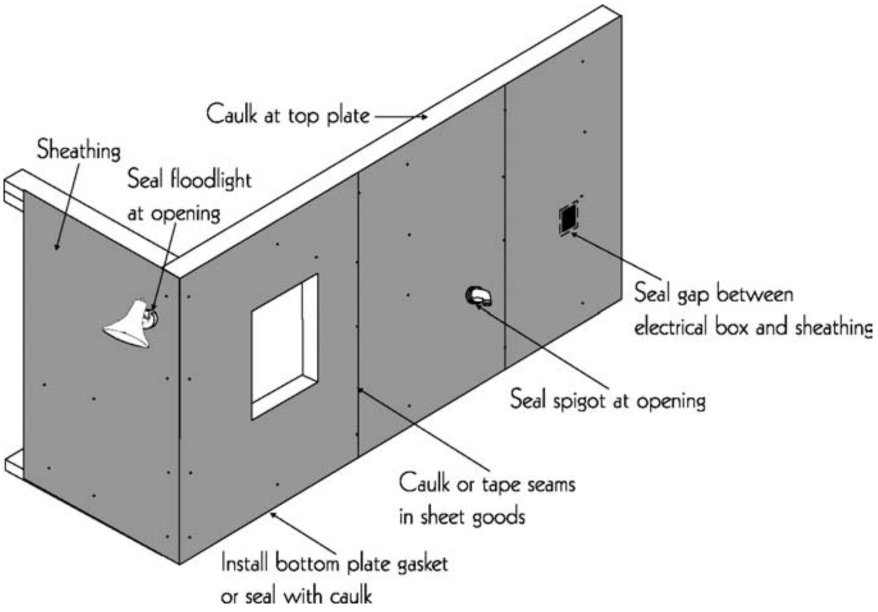

Fig. 3 Exterior sheathing air barrier.

edges and penetrations sealed to be effective air barriers. This material is recommended for use under slabs. Incorrect application in wall cavities can lead to mold and mildew problems.

- Weatherstripping—Used to seal moveable components, such as doors and windows.

Seal Penetrations and Bypasses

The first step in successfully creating an air barrier system is to seal all of the holes in the building envelope. Too often, builders concentrate on air leakage through windows, doors, and walls, and ignore areas of much greater importance. Many of the key sources of leakage—called bypasses (Fig. 5)—are hidden from view behind soffits for cabinets, bath fixtures, dropped ceilings, chases for flues and ductwork, recessed lighting fixtures, or insulation. Attic access openings and whole house fans are also common bypasses. Sealing these bypasses is crucial in reducing a building's air leakage and maintaining the performance of insulation materials. Table 1 provides examples of commonly used sealants for various types of leaks.

Air Leakage Details

The guidelines that follow in Fig. 6 show important areas that should be sealed to create an effective air barrier. The builder must clearly inform subcontractors and workers of these details to ensure that the task is accomplished successfully.

- Slab Floors—If a house is to be constructed on a concrete slab, a vapor retarder of plastic sheeting should be placed under the slab. Without a vapor retarder, moisture will migrate from the ground through the porous slab and into the house. If a house is to be built off-grade, a sheet of 6-mil polyethylene plastic should always be placed directly on the ground

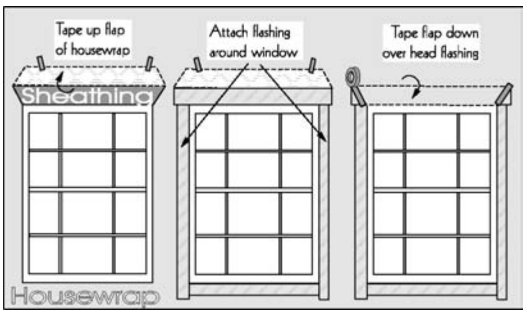

Fig. 4 Air barrier sealing around windows.

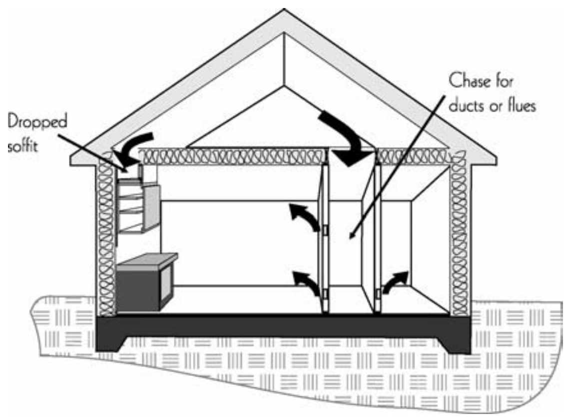

Fig. 5 Air leakage bypasses.

Table 1 Leaks and sealants

Type of leak	Commonly used sealants
Thin gaps between framing and wiring, pipes, or ducts through floors or walls	40-Year caulking; one-part polyurethane is recommended
Leaks into attics, cathedral ceilings, and wall cavities above first floor	Firestop caulking, foam sealant (latex or polyurethane)
Gaps, or cracks or holes over 1/8 in. in width that do not require firestop sealant	Gasket, foam sealant, or stuff with fiber glass or backer rod, and caulk on top
Open areas around flues, chases, plenums, plumbing traps, etc.	Attach and caulk a piece of plywood or foam sheathing material that covers the entire opening
	Seal penetrations
	If a flue requires a non-combustible clearance, use a noncombustible metal collar, sealed in place, to span the gap
Final air barrier material system	Install airtight drywall approach or other air barrier

under the house to prevent moisture from moving upward from the soil.

- Floor Joist—Seal sill plates in basements and unvented crawl spaces. Caulk or gasket rim or band joists between floors in multi-story construction.
- Bottom Plate—Use either caulk or gasket between the plate and subflooring.
- Electrical Wiring—Use wire-compatible caulk or spray foam to seal penetrations.
- Electrical Boxes—Use approved caulk to seal wiring on the outside of electrical boxes. Seal between the interior finish material and boxes.

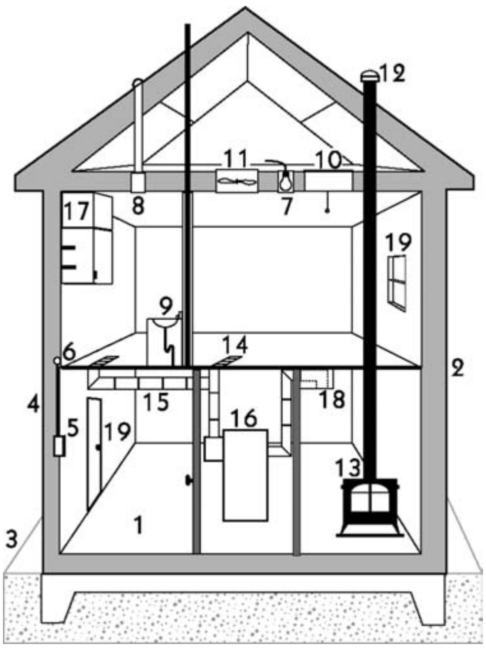

Fig. 6 Air leakage details.

- Electrical Box Gaskets—Caulk foam gaskets to all electrical boxes in exterior and interior walls before installing coverplates.
- Recessed Light Fixtures—Consider using surface-mounted light fixtures rather than recessed lights. When used, specify airtight models rated for insulation contact. Ensure fixtures meet appropriate fire codes.
- Exhaust Fans—Seal between the fan housing and the interior finish material. Choose products with tight-fitting backdraft dampers.
- Plumbing—Locate plumbing in interior walls, and minimize penetrations. Seal all penetrations with sealant or caulk.
- Attic Access in Conditioned Spaces—Weatherstrip attic access openings. For pull-down stairs, use latches to hold the door panel tightly against the weatherstripping. Cover the attic access opening with an insulated box.
- Whole House Fan—Use a panel made of rigid insulation or plastic to seal the interior louvers.
- Flue Stacks—Install a code-approved flue collar and seal with fire-rated caulk (Fig. 7).
- Combustion Appliances—Closely follow all codes for firestopping measures, which reduce air leakage as well as increase the safety of the appliance. Make certain all combustion appliances, such as stoves, inserts, and fireplaces, have an outside source of combustion air and tight-fitting dampers or doors.
- Return and Supply Registers—Seal all boots connected to registers or grilles to the interior finish material.
- Ductwork—Seal all joints in supply and return duct systems with mastic. Mechanically attach duct systems to prevent dislocation and massive leakage.
- Air Handling Unit (for heating and cooling system)—Seal all cracks and unnecessary openings with mastic. Seal service panels with UL 181 listed and labeled tape.

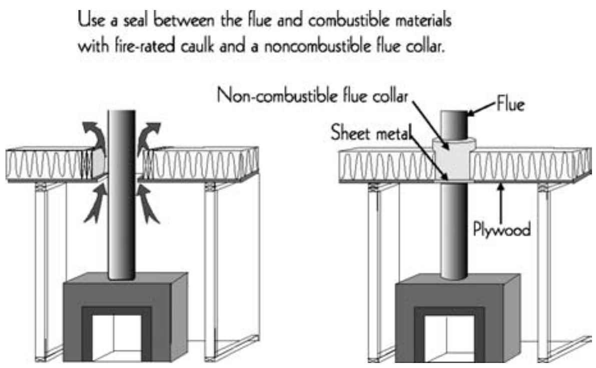

Fig. 7 Flue stacks air leakage details.

- Dropped Ceiling Soffit—Use sheet material and sealant to stop air leakage from attic into the soffit or wall framing, then insulate (see Figs. 4–8 for more details).
- Chases (for ductwork, flues, etc.)—Prevent air leakage through these bypasses with sheet materials and sealants (see Figs. 7 and 9 for more details).
- Windows and Doors—Must meet allowable air infiltration rates found in state building codes.

Air Leakage Driving Forces

Requirements for air leakage to occur:

- Holes—The larger the hole, the greater the air leakage. Large holes have higher priority for air sealing efforts.
- Driving Force—A pressure difference that forces air to flow through a hole. Holes that experience stronger and more continuous driving forces have higher priority.

The common driving forces are:

- Wind—Caused by weather conditions.
- Mechanical Blower—Induced pressure imbalances caused by the operation of fans and blowers.
- Stack Effect—Upward air pressure due to the buoyancy of air.

Wind is usually considered the primary driving force for air leakage. When the wind blows against a building, it creates a high pressure zone on the windward areas. Outdoor air from the windward side infiltrates into the building, while air exits on the leeward side. Wind acts to create areas of differential pressure, which cause both infiltration and exfiltration. The degree to which wind contributes to air leakage depends on its velocity and duration. In the following Figs. 10–12, a "Pascal" is the metric system unit of measure for stress or force per unit area.

Poorly designed and installed forced-air systems can create strong pressure imbalances inside buildings, which can triple air leakage whenever the heating and cooling system operates. In addition, unsealed ductwork located in attics and crawl spaces can draw pollutants and excess moisture into the building. Correcting duct leakage problems is critical when constructing an energy efficient building.

The temperature difference between inside and outside causes warm air inside the building to rise while cooler air falls, creating a driving force known as the stack effect. The stack effect is weak, but always present. Most buildings have large holes into the attic and crawl space. Because the stack effect is so prevalent and the holes through which it drives air are often so large, it is usually a major contributor to air leakage, moisture, and air quality problems.

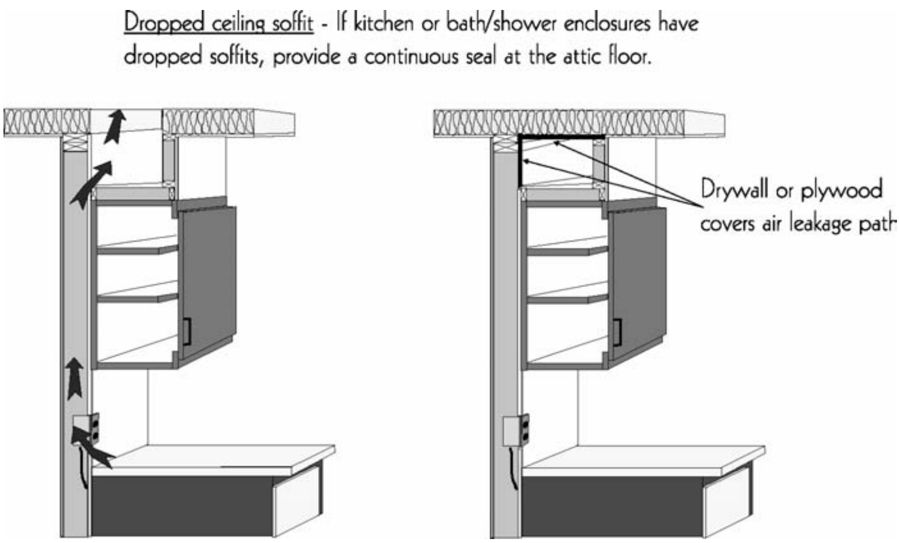

Fig. 8 Dropped ceiling soffit air leakage details.

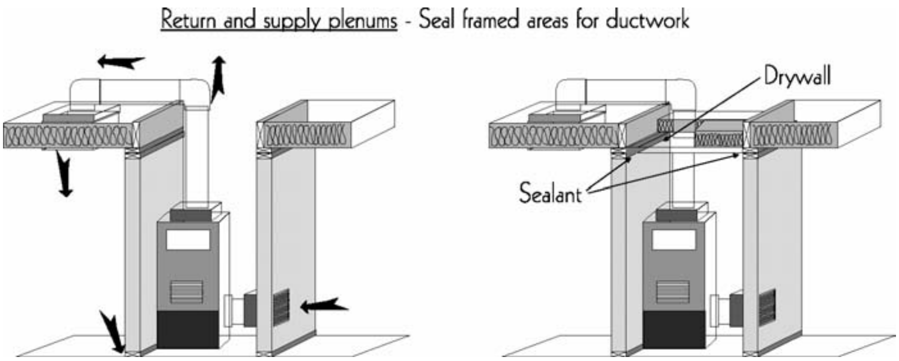

Fig. 9 Flue stacks air leakage details.

Airtight Drywall Approach

The airtight drywall approach is an air sealing system that connects the interior finish of drywall and other building materials together to form a continuous barrier (Fig. 13). The airtight drywall approach has been used on hundreds of houses and has proven to be an effective technique to reduce air leakage, as well as keep moisture, dust, and insects from entering the building.

In a typical drywall installation, most of the seams are sealed by tape and joint compound. However, air can leak in or out of the building in the following locations:

- Between the edges of the drywall and the top and bottom plates of exterior walls.
- From inside the attic down between the framing and drywall of partition walls.
- Between the window and door frames and drywall.
- Through openings in the drywall for utilities and other services.

The airtight drywall approach uses either caulk or gaskets to seal these areas and make the drywall a continuous air barrier system.

Advantages

- Effective—The airtight drywall approach has proven to be a reliable air barrier.
- Simple—Does not require specialized subcontractors or unusual construction techniques. If gasket materials are not available locally, they can be shipped easily.
- Does Not Cover Framing—The use of the airtight drywall approach does not prevent drywall from being glued to the framing.
- Scheduling—Gaskets can be installed anytime between when the house is "dried-in" and when the drywall is attached to framing.
- Adaptable—Builders can adapt airtight drywall approach principles to suit any design and varying construction schedules.
- Cost—Materials and labor for standard designs should only cost a few hundred dollars.

Disadvantages

- New—Although the airtight drywall approach is a proven technique, many building professionals and code officials are not familiar with its use.
- Requires Thought—While the airtight drywall approach is simple, new construction techniques require careful planning to ensure that the air barrier remains continuous. However, the airtight drywall approach is often the most error-free and reliable air barrier for unique designs.
- Requires Care—Gaskets and caulking can be damaged or removed by subcontractors when installing the drywall or utilities.

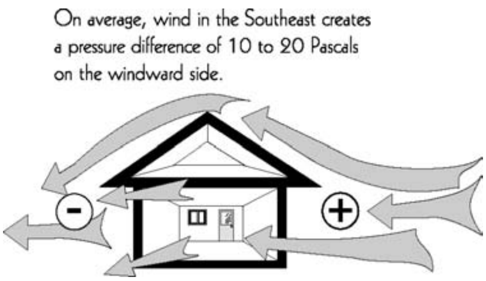

Fig. 10 Wind effect on houses.

Fig. 11 HVAC equipment effect on building pressure differences.

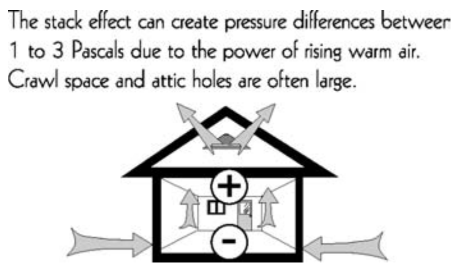

Fig. 12 Stack effect on building pressure differences.

Installation Techniques

Slab Floors

- Seal expansion joints and penetrations with a concrete sealant, such as one-part urethane caulk.

Exterior Framed Walls

- Seal between the bottom plate and subflooring with caulk or gaskets.
- Install gaskets or caulk along the face of the bottom plate so that when drywall is installed, it compresses the sealant to form an airtight seal against the framing. Some builders also caulk the drywall to the top plate to reduce leakage into the wall.
- Use drywall joint compound or caulk to seal the gap between drywall and electrical boxes. Install foam gaskets behind coverplates and caulk holes in boxes.
- Seal penetrations through the top and bottom plates for plumbing, wiring, and ducts. The code requires firestopping for leaks through top plates.

Partition Walls

- Seal the drywall to the top plate of partition walls with unconditioned space above.

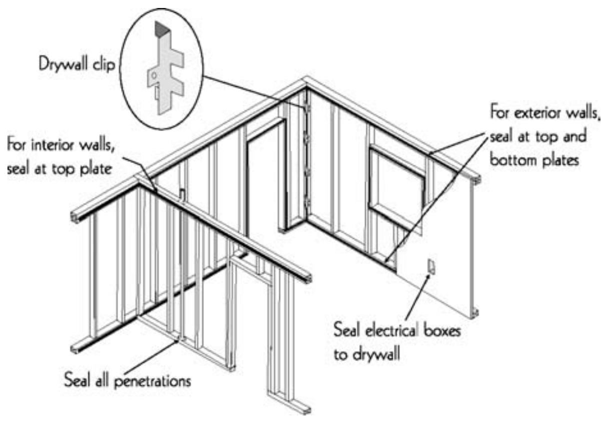

Fig. 13 Airtight drywall approach.

- Install gaskets or caulk on the face of the first stud in the partition wall. Sealant should extend from the bottom to the top of the stud to keep air in the outside wall from leaking inside.
- Seal the ductwork where it projects through partition walls.
- Seal penetrations through the top and bottom plates for plumbing, wiring, and ducts. Fire code requirements dictate how this should be accomplished.

Windows and Doors

- Seal drywall edges to either framing or jambs for windows and doors.
- Fill rough opening with spray foam sealant or suitable substitute.
- Caulk window and door trim to drywall with clear or paintable sealant.

Ceiling

- Follow standard finishing techniques to seal the junction between the ceiling and walls.
- When installing ceiling drywall, do not damage gaskets, especially in tight areas such as closets and hallways.
- Seal all penetrations in the ceiling for wiring, plumbing, ducts, attic access openings, and whole house fans.
- Seal all openings for chases and dropped soffits above kitchen cabinets and shower/tub enclosures.
- Avoid recessed lights; where used, install airtight, IC-rated fixtures and caulk between fixtures and drywall.

Wood Framed Floors

- Seal the rim joist to minimize air currents around floor insulation. Also, seal rim joists for multi-story construction (Fig. 14).
- For unvented crawl spaces or basements, seal beneath the sill plate.
- Seal the seams between pieces of subflooring with quality adhesive.

MEASURING AIRTIGHTNESS WITH A BLOWER DOOR

While there are many well-known sources of air leakage, virtually all buildings have unexpected air leakage sites called bypasses. These areas can be difficult to find and correct without the use of a blower door. This diagnostic equipment consists of a temporary door covering, which is installed in an outside doorway, and a fan that pressurizes

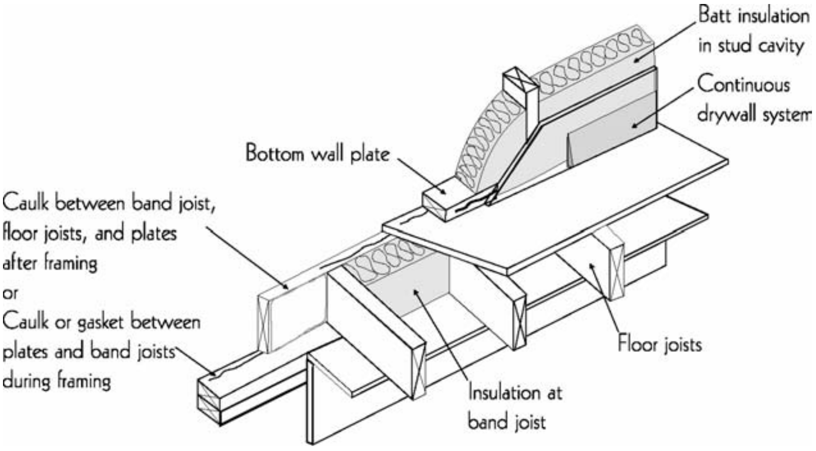

Fig. 14 Between-floor air barrier.

(forces air into) or depressurizes (forces air out of) the building. When the fan operates, it is easy to feel air leaking through cracks in the building envelope. Most blower doors have gauges which can measure the relative leakiness of a building (Fig. 15).

One measure of a building's leakage rate is air changes per hour (ACH), which estimates how many times in one hour the entire volume of air inside the building leaks to the outside. For example, a home that has 2000 square feet of living area and 8-foot ceilings has a volume of 16,000 cubic feet. If the blower door measures leakage of 80,000 cubic feet per hour, the home has an infiltration rate of 5 ACH. The leakier the house, the higher the number of air changes per hour, the higher the heating and cooling costs, and the greater the potential for moisture, comfort, and health problems (Table 2).

To determine the number of air changes per hour, many experts use the blower door to create a negative pressure of 50 Pascals. A Pascal is a small unit of pressure about equal to the pressure that a pat of butter exerts on a piece of toast—about 0.004 in. water gauge. Fifty Pascals is approximately equivalent to a 20 mile-per-hour wind blowing against all surfaces of the building. Energy efficient builders should strive for less than five air changes per hour at 50 Pascals pressure (ACH50). Given ACH50, a natural infiltration rate (resulting from wind and temperature effects) can be estimated. In hot, humid climates, ACH50 can be divided by 40 to yield an expected natural infiltration rate. For example, if ACH50 = 10, then the estimate for natural infiltration for hot, humid climate homes would be 10/40 = 0.25 ach. This means that under normal wind and temperature conditions, we would expect about 25% of the house air to be replaced with outdoor air each hour. Note that this is only an estimate of long-term average infiltration. Actual infiltration will vary considerably based on changes in wind, temperature, and time of day.

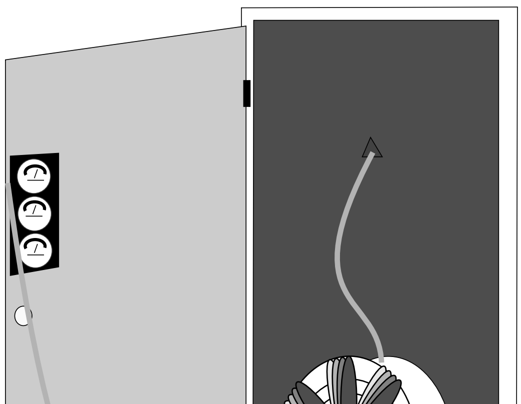

Fig. 15 Blower door test equipment.

CONCLUSION

Building air leakage or infiltration can be a significant contributor to increased energy costs, comfort issues, and unacceptable levels of indoor pollution. However, with the incorporation of proper materials and techniques,

Table 2 Typical infiltration rates for homes (in air changes per hour at 50 Pascals—ACH50)

New home with special airtight construction and a controlled ventilation system	1.5–2.5
Energy efficient home with continuous air barrier system	4.0–6.0
Standard new home	7.0–15.0
Standard existing home	10.0–25.0
Older, leaky home	20.0–50.0

problems associated with air leakage can be reduced. The reduction of a building's total air leakage requires an overall strategy coupled with an appreciation of the techniques and materials required. Proper implementation of these techniques can result in significant reduction in a building's energy consumption coupled with a positive economic picture.

Much attention has been given to the proper use of air infiltration barriers or housewraps and their success at reducing unwanted infiltration. More attention should be directed to building penetrations and airflow bypasses. Construction techniques need to be modified to reduce unintended air infiltration that occurs as a consequence of current construction practices.

The growing popularity of blower door technology has allowed the industry to track progress toward reducing building air leakage. Progress has been significant, even to the point of reducing infiltration below the amount needed for fresh air requirements. Reductions to this level allow mechanical systems designers to implement active ventilation schemes that both enhance healthy conditions and reduce energy consumption.

ACKNOWLEDGMENT

Many thanks to Kyle Allen, a mechanical engineering student at the University of Florida, because without his persistent efforts the publication of this article would not have been possible.

Abstract
This article examines the information and control technology used in new vehicles and points out the potential for using similar information and control technology in new buildings. The authors draw on their knowledge of new cars and new buildings to present a list of information and control functions together with the available sensors, computers, controls, and displays used in new cars that can provide significant opportunities for new buildings. Methods for integrating this new technology into new buildings are also discussed. The use of information and control technology in new cars should serve as a model for new building technology. This potential for new buildings should be recognized and similar technological improvements should be implemented.

INTRODUCTION

A great deal of new technology is available for buildings. The labels "Smart Buildings" and "Intelligent Buildings" have been around for years. Unfortunately, this wealth of new technology for buildings only exists in pieces and with products from many different companies—virtually no building constructed today utilizes a significant amount of this new technology. Most new buildings operate just like the buildings of the 1970s. Even though new materials, new design and construction methods, and new American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE) building codes have greatly improved new buildings, these buildings still look and function much as they did 20 years ago. While most new buildings do have new equipment and better insulation, there is little in the way of new controls and display technology for the building occupants to see and use. Individuals seldom have the ability to control personal comfort and preferences.

In contrast, every new automobile—regardless of its price—is filled with new technology compared to the automobile of the 1970s. A new car typically comes with about 50 separate computers or microprocessors, has around 40–50 sensors, and provides about 20 electronic display and control functions. It does this for as little as $20,000. These automotive information and control systems commonly require little or no maintenance or repair for a period of three to five years. The technology is often visible, it can be used by the driver and passengers, it is generally standard on all new cars, and it is inexpensive and reliable. There is much fancier technology available if one want to pay for it (Lincoln Navigators, 7-Series BMWs, and S-Class Mercedes have around 100 processors onboard), but the majority of new automotive technology is found on every new car. The authors bought a new Toyota Prius Hybrid in early 2006, and it is like driving a computer! It even has a computer display console as a major feature of the dashboard.

With all of this new technology, today's cars are much more reliable and have significantly reduced maintenance requirements. In the 1970s, an automobile needed a tune up every 10,000 miles. Today, a typical new car does not need a tune up for 100,000 miles. Older cars needed new brakes about every 20,000 miles and now it's every 50,000 miles. The authors bought a new minivan in 1998 and did not have to take it back to the dealer for service for 40,000 miles! The vehicle had several oil changes in that period, but it needed no mechanical or electrical work.

In comparison, buildings need maintenance people from the moment they are first used. This does not include janitorial work, but the maintenance of lights, air conditioners, switches, controls, doors, and windows. This is like in the old days with cars—when people started making lists of things to be fixed as soon as they drove the car off the dealer's lot. People are paying extra for building commissioning just to make sure everything in the building is operating correctly and that it is fixed if it is not. Why can't a new building operate for six months, a year, or even several years without needing any maintenance? Cars do.

Keywords: Car technology; Controls; Displays; Building control systems; Dashboards; Smart sensors; Control modules; Individual controls; Automotive controls and displays.

What is the potential for using reliable, comprehensive, integrated, and inexpensive components in new buildings to create a transparent and efficient information and control system? What should be done in terms of buying new buildings? Clearly, progress in adapting and implementing technology for new buildings has a long way to go. Nonetheless, societies should demand more technology—a lot more. Technological improvements should be standard features that come with every new building without question rather than being options that add significant cost to the building. The only question should be where does one draw the line between standard features and additional new technology that will cost more?

FEATURES OF AUTOMOBILES THAT COULD BE USED IN BUILDINGS

Individual Control Systems

One of the most noticeable features of new automobile technology is how it provides the driver and often the passengers with individual control systems. Compared to a building, a new car has far more sensors, controls, and displays in a much smaller space. There are individually controllable air supplies for the driver and for the front passenger. Large vehicles often have air controls for the rear seat passengers too. Temperature ranges for heating or air conditioning are individually controllable, often for the front passenger as well as the driver. The air velocity is controllable with a multispeed fan. The outlet vents are easily reached and can be moved to direct the airflow onto or away from the person. The amount of outside air can be controlled by selecting fresh air or recirculation. Some lights, such as headlights and interior dome lights, are activated by sensors. Other lights are individually controllable. The driver or the passenger can turn on selected interior lights, can often dim these lights, and can direct the light to the area where it is needed. The moon roof can be opened or closed by the driver or the front passenger. Both front seats are individually adjustable for horizontal position, height, tilt, and back support, and many are heated as well. In addition, in some cars, these individual settings or preferences for functions like heating, ventilation and air conditioning system (HVAC) and seat positions are provided through a memory setting tied to an electronic key and settings for more than one person can be stored in memory.

Compare this technology to the control systems currently available in a common new building. A typical room in a new building may have a thermostat with a control set point and a temperature display at that location. It also usually has an unseen variable air volume system (VAV) control function and in a few instances a humidistat with a set point control and a display of the relative humidity at that location. Lighting is controlled with a single light switch or possibly by a single occupancy sensor. Otherwise, the occupants usually have no other sensors, controls, or displays in that room.

An example of a new technology that is currently available and that achieves some of the goals of individual control over personal space within a building comes from Johnson Controls. Their Personal Environments system is an easy to use desktop control unit that gives each person the flexibility to adjust temperature, lighting, air flow, and acoustic characteristics as often as necessary to maintain personal comfort levels. Individuals can adjust the air temperature and control the amount and direction of air flow at their desktop. They have a heating panel under the desk to adjust the temperature to their legs and feet. The Personal Environments system also allows an individual to control task lighting and to mask background noise. The system has a sensor that turns off all functions when the workstation is unoccupied for more than 10–15 minutes. Although this system is being used by a number of companies, it is the exception rather than the rule.

Operational Controls

In addition to personal comfort controls, the new car also has a large number of automatic control systems to optimize and control its own operation. Engine control systems insure fuel efficiency and reduce air pollutants from the combustion process. Sensors for inlet air temperature and relative humidity allow optimum fuel flow control and optimum combustion. System computer modules also control the anti-lock braking system (ABS), transmission, cruise control, and body controller. These microprocessor systems are standard on new vehicles, but new buildings are not built the same way. Operational controls are available for new buildings but they require special design criteria. No one considers the possibility that they should be standard equipment.

Display Systems

New cars tell the owner about much of the maintenance and repair that needs to be done and they certainly notify the driver whenever one of the major systems is in need of attention. A new car has sensors that report tire pressure, unclosed doors, lights or other controls left on, unfastened seatbelts, brake fluid status, and many other operational features related to the safety of the car and the occupants. Most new cars are also giving drivers and occupants information about the operation of the car, including real time fuel economy as well as average fuel economy over a selected mileage. Even a cursory comparison shows that new buildings lag very far behind the present use of technology in new cars.

Much of the information on car maintenance and safety is aimed at the driver. What comparable information does a building operator get about the maintenance needs of the building or the various rooms in a building? Things that would be helpful to know include whether the air handling system filters are dirty, whether the refrigerant is at the proper level, whether sensors are working properly, whether lights are burned out, or whether the doors have been left open.

The present system in buildings is essentially a manual system. Filters are checked by maintenance personnel on a time schedule. Maintenance workers often depend on "human" sensors to notify them of burned out lights, improperly functioning photo sensors, or temperature problems in individual rooms.

Options

New cars have options and new buildings have options, but these mean very different things. An option for a new car is an item or function that is already available and can be installed on the car at extra cost. For a building, an option is an item or function that an owner wants to add at extra cost, but expensive additional design, engineering integration, and testing work must usually be performed before it can be installed and operated.

HOW DID THE AUTOMOTIVE INDUSTRY DO THIS?

It is important to understand how new automobiles can have so much new technology at such a low cost and why they are so reliable in order to know how to utilize similar innovations in the building industry.

Engineering Analysis and Design

A significant amount of engineering analysis and design goes into both the structural and operational features of a new car. In addition, significant engineering analysis and design also go into the manufacturing and production processes for assembling the new cars. A major benefit of this approach is that the car's entire system and subsystems, as well as each of the car's components, are carefully engineered. For example, the electrical power consumption of the components and systems in a new car are carefully analyzed—built and selected to make sure that the total power demand is not greater than the capacity of the electrical power supply system, i.e., the 12-volt battery. Thus, with cars, the need for energy efficient electrical systems is built in from the start.

When a building is designed, the electrical load is specified first, and then a power supply system that is big enough to handle the load of the building is specified. Little or no thought is given to minimizing the electrical load itself because there are generally no constraints on the amount of power a utility will supply to the building.

Overall Quality Control Programs

A new car is reliable because a significant amount of engineering goes into both the car design and its manufacturing process. Quality and quality control start with the engineering design and are strongly emphasized throughout the manufacturing and assembly of the car. Individual components are designed and made with quality and reliability as major goals. Subsystems and final systems—including the entire car—are similarly produced. Ordinary and accelerated life testing are conducted on the car's components, subsystems, and systems. These extensive tests include the effects of temperature, moisture, mechanical and thermal stress, and other factors. As a result, most of the car's components and systems will last at least three years or for 36,000 miles. Warranties on some new cars are now available for seven years or 70,000 miles.

Quality control and warranties in building design and construction are very different. The auto manufacturer provides the warranty for the entire vehicle (with the possible exception of the tires); the systems in new buildings are likely to be under several different warranties. The HVAC manufacturer covers the HVAC system, the flooring manufacturer guarantees the carpet/flooring, the plumbing manufacturer guarantees the plumbing fixtures, etc. There is usually no centralized quality control or warranty for a new building as with cars.

Widespread Use of Microprocessors and Computers

Much of the technology and operational features of new cars comes from the use of microprocessors and microcomputers. A new car may have as many as 50 separate microprocessors and 11 major computer-based systems. Some new luxury cars have up to 90 microprocessors. It is often said that a new car has more computer power in it than the first manned space capsule did. Computer-based systems are found in the system modules for new cars and they account for much of the engine performance, reduced emissions, sophisticated diagnostics, and many comfort and convenience features. The Engine Control Unit (ECU) is the most powerful computer in the car and it has the demanding job of controlling fuel economy, controlling emissions from the engine and the catalytic converter, and determining optimum ignition timing and fuel injection parameters. These computers, microprocessors, and system modules greatly simplify the diagnostic job of finding problems with the car and provide information on what kind of repair or replacement work is needed.

While a large new building with a sophisticated building automation system (BAS) may well contain 50 or more microprocessors, this does not match the new car in terms of having equal computing power per room or per group of rooms with two to four occupants. The rooms and offices in buildings do not have monitoring and self-diagnostic features. They could—the technology, equipment, and systems exist—but they are not supplied as a standard item and they are not available in the same way that options available on new cars are.

System Modules

As discussed above, the system modules are where the computer-based systems reside in new cars. These system modules are highly complex and highly important systems in new cars. Many highly desirable performance and comfort features are provided by system modules. Typical system modules in a new car are the Engine Control Unit, the instrument panel module, the climate control module, the transmission control module, the power distribution box module, the airbag module, the driver's door module, the ABS module, the body controller module, and the cruise control module. These are the system modules found on every basic car. Additional system modules are options for lower priced cars or standard features for higher priced cars. These include navigation control modules, entertainment system modules, advanced comfort control modules, and communication control modules for computers, cell phones, and Internet access.

Communications Buses

Using standardized communications buses with these system modules makes both designing and building new cars much easier than it was in the old days. Two major services must be accessible to every area of a new car—electric power and the communications bus. All of a car's system modules must be able to communicate with each other, receive signals from most of the sensors in the car, and send signals to the control components, systems, and actuators. Using a communications bus greatly simplifies the wiring, reduces the number of data sensors, and implements additional features at very little additional cost. Without the communications bus, the job of wiring up a car during the assembly operation would simply be too labor intensive and time consuming for a reasonable-cost product. Also, the speed of communications is so important now that only a digital bus has the speed and capacity to handle the data collection and data transfer load for a new car.

The communications bus and the system modules work together to make the design and building of the car much easier. Information is sent over the communications bus in a standard communications protocol—usually the SAE J1850 standard or the Controller-Area Network (CAN) standard, although some manufacturers are using FlexRay, which is a faster and more sophisticated communications bus. Data is sent in packets with a standard structure—a label and some data. For example, an information packet with Speed for the label and 52.5 for the speed data in MPH is picked up by the instrument control module, which refreshes the indication on the speedometer with this new data. The standard communications bus makes the design of the various system modules much more straightforward. In addition, the sensors in the car only need to send packets of data to the communications bus; therefore, the car maker does not have to deal with the problem of a particular sensor putting out a strange voltage or a current signal that must be converted somewhere into a true physical parameter of the car's operation. In this example, the alternative is to tell the instrument panel module maker that the signal for speed was going to be a 4–20 mA current loop value and that 10 mA was equivalent to 40 MPH.

The use of the standardized communications bus also makes it easy to use outside suppliers and sources for many of the components and systems in a new car. The carmakers do not have to worry about how a specific sensor or module works internally, they only need to know that the data will be transmitted in a known, standardized manner, and that it will have a known, standardized structure. Much of the success with using modern technology in cars and much of the reliability of that technology comes from using the simplified approach of a standardized communications bus.

This same type of technology is essentially available for new buildings. BACnet, LONWorks, and TCP/IP are the most common standard communication protocols. TCP/IP may be the ultimate answer, but another level of standardization is also needed to insure the data that comes across TCP/IP means the same thing to each different piece of equipment in a facility. Most buildings are being wired for a Local Area Network (LAN) using either coaxial cable or fiber optic cable. Thus, the hardware and software are available, but there is no organization responsible for requiring or enforcing the standardized interconnection of all of the building components, subsystems, and systems, like the automakers have. Without a standardized communications bus running through the entire facility, together with accessible electric power, buildings will never have the kind of technology that cars have and will never have the cost benefit or the reliability that this kind of technology can bring to buildings.

Smart Sensors

Most of the basic automobile sensors that were used in the past to read continuous physical parameters such as temperatures, pressures, flows, and levels operated on the principle of producing a voltage or current output proportional to the real value of the parameter. The output of these sensors was almost always nonlinear and also varied with the temperature or other physical parameters. This resulted in poor measurements or required the use of more equipment and processing power to correct the sensor reading for the nonlinearity and to provide temperature compensation curves to get accurate readings. Today, smart sensors are used to provide these functions and to output data to a microprocessor or system module. The sensor output is input to the microprocessor and the sensor reading is digitized, corrected, temperature compensated, and sent out over the standardized communications bus.

These smart sensors interface directly to the communications bus and provide fast and accurate measurements. Because the sensor package contains a microprocessor, much of the load is removed from the system module that the smart sensor is supporting. Designed and built as an integrated package, the smart sensor fulfills its mission reliably with a low initial cost.

The sensors for buildings are expensive and many of them are not very reliable. They are certainly not reliable in comparison to sensors in cars. In particular, the relative humidity (RH) sensors and CO_2 sensors are notoriously unreliable and require frequent cleaning, calibration, and general maintenance. That level of performance would be unacceptable for these sensors in a car. Why shouldn't the sensors in buildings work reliably for a period of three to five years before they need any significant attention?

Wiring Harnesses and Standard Connectors

The use of preassembled wiring harnesses and standard connectors has made the task of wiring up a new car much easier. It is important to use stranded, not solid, wire cable. Each length of stranded wire consists of a twisted bundle of very thin thread-like wires. Solid wire, on the other hand, is a single thick wire segment. The advantage of stranded wire is that it is much more flexible than solid wire and it also less susceptible to breakage. One thread of a stranded wire can break without affecting the performance of the connection, but if a solid wire breaks the connection is lost. Also, if there is one weak link in the reliable performance of any electrical or electronic system, it is the connectors. With this in mind, the importance of carefully and correctly built standardized connectors cannot be overemphasized.

Use of Skilled Assembly Workers

The auto industry has a large supply of skilled workers for its design, engineering, and assembly operations. These skilled workers receive training in their specific jobs as well as training in quality control and process improvement techniques. Many of the manufacturing and design improvements in new cars have come from the production workers themselves. In addition, skilled workers have made a great improvement in the overall reliability and quality of the new cars. Autoworkers are usually paid more than those working in other industries or services.

Problems with the construction of new buildings often come from the use of workers with minimal or insufficient skills for the job. Finding skilled workers may be difficult, and is certainly expensive. The nature of building construction often impedes the retention of skilled workers. As a result, there may not be a large pool of highly qualified building construction workers available when a particular building is being built.

One of the most common problems in building structures is the roofing, which is the subject of the greatest number of lawsuits in building construction. Most roofs leak, and they leak from the day the building is first occupied. Roof leaks are the result of poor installation and construction rather than problems with roofing technology and materials. When a roof leaks, water leaks into the walls and may not be noticed until mildew and rot are visible. By then, the building may be significantly damaged. Mold, mildew, and indoor air quality (IAQ) problems in the building will require more time and money to fix. Using sensors in new buildings to identify roof and wall leaks when they occur is a critical application of automotive-type technology in new buildings. New cars use infrared reflectance sensors to identify rainfall on windshields and they automatically start up the windshield wipers. These sensors, or other types of moisture sensors, if installed throughout new buildings, would quickly identify leaks and moisture buildup and alert building operational people to this serious problem.

Poor workmanship can cause many other problems in buildings. Even the HVAC system can be affected because random testing has shown that many air conditioning systems are installed with an improper charge of refrigerant. In economic terms, the problem of workers with insufficient skills and workers who have had poor quality training results in the need to commission buildings to check and see if the building components and systems work as they should. (See the discussion on Commissioning below.) This expense is clearly attributable to a lack of adequate engineering, a lack of quality control measures, and especially a lack of highly trained workers.

WHY DOESN'T NEW BUILDING CONSTRUCTION INCLUDE MORE NEW TECHNOLOGY AS STANDARD EQUIPMENT AND SYSTEMS?

Automobiles are built according to a standard plan; building architects, on the other hand, reinvent the wheel each time they design another building. This lack of standardization in buildings impedes the introduction of new technology in new building construction. Other factors also influence this difference in approach.

Unlike new cars, most new buildings are site-built, and are built to "cookie cutter" specifications that emphasize the lowest first cost of construction. Even "custom built" buildings are held hostage to the lowest first cost syndrome. Thousands of different construction companies build residential and commercial buildings. Hundreds of different companies build fairly large commercial buildings. These companies range in size from small businesses to major architectural and engineering firms and major construction firms. It is extremely difficult to implement standards of technology when this many individual companies are involved.

The fact that most buildings are site-built impedes the assembly line and systems approach to installing new technology used in the auto business. One area of building construction that is immediately amenable to the assembly line approach of the carmakers is the construction of prefabricated or modular buildings. This manufacturing sector could easily incorporate the knowledge from the automotive assembly sector to produce buildings with the same level of technology and reliability as new cars. The engineering and quality control functions are much more cost effective in this sector. This sector could easily use more computers, more microprocessors, more system modules, more smart sensors, and a standardized communications bus.

Cars are Constructed in a Factory Assembly Line and Moved to Their Ultimate Market and User

The factory environment makes it easier to train workers to install the equipment in new cars as well as training them in quality control procedures. Buildings, however, are constructed at the point of use. Construction workers may work for a long time on a single building doing all types of work. Their training is not likely to be technology specific. Auto assembly workers typically specialize in some part of the assembly process and therefore can be trained on this more limited work task. In addition, they become quite knowledgeable on this part of the assembly operation and soon become able to add value to the company by suggesting improved methods of designing and constructing components and systems that they assemble. Quality control is more easily stressed in this environment and many of the workers actually see the final result of their work drive off the assembly line, which serves to positively reinforce the need for a high skill level and the need to perform high quality work. In fact, these workers often own and drive cars produced by the company they work for. They are more likely to reject poor quality parts, components, systems, and assembly procedures.

More new cars are sold each year than new buildings, so there is a larger market for the technology and the price can be reduced due to bulk purchase of the equipment. This is certainly true at face value, but when the scale of use of technology for buildings is considered, the numerical superiority of the cars goes away. If one considers that the unit of interest in buildings is rooms and that the interest is in having the same technology level in each room that is in cars, the perspective is now very different. There may very well be more rooms than cars built each year. Thus, the comparison of a room to the car rather than a building to a car will lead to a much greater economy of scale for new building construction and should provide a strong economic incentive to move in this direction for buildings.

Cars have a shorter lifetime than buildings, so new technology can be introduced faster and the customers can develop a faster appreciation for what it does. Cars do have a shorter lifetime than buildings, but most buildings end up being refurbished or having the equipment and systems retrofitted, so there is still a lot of opportunity to use new technology in older buildings. Sensors, controls, system modules, and many of the other features of new car technology can be added to older buildings when they are needed. In general, the most cost effective way to build an energy-efficient and functionally superior building is to do it right the first time rather than retrofit it later. However, new equipment (especially new information technology) can be added to rooms and to the entire building. It would have been easier and cheaper to install coaxial or fiber optic cable in a building when it was built, but people still have managed to find a way to get the LAN cable and connections into rooms and offices so PCs can be networked.

Purchasers of new cars are influenced by features they have seen on other cars. Therefore, consumer demand is important in increasing the marketability of new technology options. This is one reason it is necessary to start installing some of this new technology in buildings. Once building owners, managers, and occupants start seeing what has been done in other buildings and how much more enjoyable and productive it is to work in buildings with this advanced technology, they will start to demand more technology as a result. It is somewhat amazing that the people who drive cars with all this new technology will go happily to work in buildings that do not come close to providing similar comfort and operational features of automobile technology!

Cars are Designed for Use by Individuals; Buildings are Designed for Use by Companies

The motivation of the designers and the manufacturers of cars is frequently different from that of people who design and build buildings. Car manufacturers build a car to attract a buyer—they add bells and whistles to make their car different. They encourage innovation and thinking outside the box. Architects and construction companies are building a box, so their thinking often stays in the box. They may work on the exterior design or they may make the interior appearance pleasing, but they do not think very hard about what goes on inside the box and they don’t consider the needs of the individuals living and working in the box. A car designer should consider safety when drawing up plans for a new car. Beyond putting in emergency exits and sprinkler systems, a building designer may not think about how to make the building safer because that is not part of the job. Among the questions that building designers should be asking are: "How can this building be made more comfortable, safer, and more user-friendly?" "How can occupants interact with this building to increase their comfort and safety levels?" "How can we make this a building of the future?" With a little imagination and an increased use of information and controls technology, building designers can make significant changes in the comfort level of the occupants.

WHAT DOES THE BUILDING CONSTRUCTION INDUSTRY NEED TO DO?

Establish an Integrated Design-and-Build Engineering and Management Structure

The amount of engineering work that goes into a new building must increase significantly. The building structure should be designed with high technology use in mind and it should utilize new technology to deliver the performance and comfort features that are desired in new buildings. In addition, quality control and reliability should be designed and engineered into the building from the start of the project. Then, quality management techniques should be employed so that the building is actually constructed to provide the quality and reliability features that are expected.

Use Equipment and System Modules in New Buildings

This approach has facilitated the use of most new technology in new cars at a reasonable cost and with extremely good reliability. However, the standardized communications bus has made the most dramatic difference. By using a standardized communications bus and system modules, car technology could be transferred to buildings relatively easily. Individual HVAC modules for occupants, individual lighting modules, other comfort modules (such as for seating), and building operation and maintenance modules could all be used to greatly increase the performance and reliability of new buildings and yet allow them to be built at reasonable costs. Certain sectors such as the residential manufactured housing sector and the hotel/motel sector as well as many office buildings could easily adopt this approach.

Even site-built homes could incorporate some of these features. Residences are often prewired for intercoms, telephones, security systems, cable, and high-speed internet connections. Designing a central integrated system for monitoring and controlling the performance and comfort of a home and prewiring the house for such a system is well within the realm of feasibility. It is possible to envision a home with a central control panel that is accessible from the Internet. Homeowners could monitor their homes from work. They could receive security or fire alarms. They could make changes to thermostat settings if they knew they were going to be early or late getting home. They could receive alarms if there was a water leak or if the refrigerator stopped running.

Build More Modular Buildings

The solutions for providing greater use of technology in new buildings and for providing quality and reliable buildings are much easier for modular buildings with significant presite construction performed in a factory or controlled environment. High-tech components and equipment can be installed more easily in prefabricated and modular buildings within a controlled environment with highly skilled and quality control trained workers.

Impose Standards on Equipment and System Suppliers

Most major construction companies are already in a position to do this—they have the financial leverage to specify the components and equipment that meet their exact requirements. The residential manufactured housing sector in particular could do this quite easily. The federal sector, states, and large companies also have excellent opportunities to set these standards. One of the most important standards is to require a standardized communications bus in a building with all sensors and controls interfacing directly with that communications bus.

Support Codes, Standards, or Legislation to Increase the Use of New Technology in Buildings

Building codes and standards have been responsible for many of the improvements in standard buildings. With minimum equipment efficiencies, minimum thermal transfer levels, and minimum structural standards in place, companies that construct buildings must meet these minimum standards regardless of whether it increases the first cost of the building. Without minimum standards such as the ASHRAE 90.1 standard, many buildings would still have inferior equipment and poor insulation because it was cheaper to put in initially. Other programs like Leadership in Energy and Environmental Design (LEED) and EnergyStar could incorporate requirements for adding new comfort and control technology in buildings. The standards for utilizing new technology could be set voluntarily by large companies and big purchasers of buildings like the federal sector, states, schools, and the hotel/ motel sector. The auto industry has certainly incorporated many of the new technological features without needing government intervention.

Integrate New Building Technology with the Desktop Computers and Building Automation System that are Already Being Installed in New Buildings

The types of smart sensors, system modules, and standardized communications buses that the authors have been recommending for use in new buildings should be considered an integral part of the overall Building Automation System. All of the components, systems, and equipment must work together seamlessly to provide the expected level of performance and comfort and all the desktop computers should be tied into these systems through a Local Area Network.

The desktop computer could be the equivalent of the car dashboard or instrument panel, and it should be the personal interface to an expanded building automation system (BAS). It could tell what the space temperature is and how much ventilation is being provided. It should allow occupants to set their personal preferences for lighting levels, seat positions, window or skylight openings, etc. It should also let them enter new desired values of these space parameters.

BENEFITS OF STANDARDIZED COMMISSIONING OF BUILDINGS

Commissioning a building is defined in ASHRAE Guideline 1 (1996) as the processes of ensuring that building systems are designed, installed, functionally tested over a full range, and capable of being operated and maintained to perform in conformity with the design intent (meaning the design requirements of the building). Commissioning starts with planning and includes design, construction, start-up, acceptance, and training, and it can be applied throughout the life of the building.

Commissioning a building involves inspection, testing, measurement, and verification of all building functions and operations. It is expensive and time consuming, but it is necessary to insure that all building systems and functions operate according to the original design intent of the building. Commissioning studies on new buildings routinely find problems such as control switches wired backwards, valves installed backwards, control set points incorrectly entered, time schedules entered incorrectly, bypass valves permanently open, ventilation fans wired permanently on, simultaneous heating and cooling occurring, building pressurization actually negative, incorrect lighting ballasts installed, pumps running backwards, variable speed drives bypassed, hot and cold water lines connected backwards, and control dampers permanently fully open. And this is only a short list!

The process of commissioning a building constructed like a new car and using the new car-type technology would be far quicker and simpler as well as much less expensive. The use of standardized components, subsystems, and systems could actually eliminate the need to check and test these items each time they are used in a new building. In a factory or laboratory, standardized commissioning tests could well determine their acceptability with a one-time procedure. The use of a standardized communications bus would dramatically shorten the time and effort of on-site testing of the building components, subsystems, and systems. Data from all sensors and controls would be accessible on the communications bus and would allow a significant amount of automated testing of basic functions and complex control actions and responses in the building. A commissioning module could also be added to the building systems, and this would even further automate and speed up the commissioning process. This commissioning module would remain as a permanent building system and it would not only aid in the initial commissioning process but also the recommissioning process and the continuous commissioning process.

Presently, the cost of commissioning a new building is around two to five percent of the original cost of construction. The use of standardized commissioning tests and the use of a commissioning module would greatly reduce this cost. Although commissioning is a cost effective process—usually having a payback time of one to two years—many building owners do not want to spend the additional money for the commissioning effort. A prevailing attitude is "I have already paid to have the job done correctly. Why should I have to be the one to pay to check to see that it has actually been done correctly?" This is a difficult attitude to overcome, and it is often a hard sell to convince new building owners that they will actually come out ahead by paying to verify that their building does work as it was designed to work.

One final note on commissioning is from one of the author's energy audit experience. Many problems found when conducting audits of existing buildings are clearly problems that have been there since the building was constructed. For example, in the audit of a newspaper publishing company, it was found that the cost of air conditioning was excessive. Further checking showed that the heating coil and the cooling coil of the major air handling unit were both active during the hottest part of the summer. The control specifications specifically called for simultaneous heating and then cooling! Once that original problem was corrected, not only did the air conditioning bill go down dramatically, but the building occupants reported that they thought the air conditioning system was working much better because they were much more comfortable.

DO NEW BUILDINGS NEED "DASHBOARDS"?

The dashboard and instrument panel is the heart of the driver-car interface. Status information on the car's operation is presented there in easily understood form. A similar feature in a new building would make sense—not the complex human-machine interface (HMI) or graphical user interface (GUI) from a BAS, but a simplified display for average building occupants and maybe even one for the building engineer or maintenance supervisor. Each floor of a building could have a "dashboard" display. It could be located in a visible place and occupants could see the status of energy use in terms of peak cost or off-peak cost, daily use of kWh, and therms of gas. They could also see temperature and RH conditions at a glance and they could get red light/green light indicators for energy use and maintenance actions. Several of these "dashboards" could be provided to the operation and maintenance staff. These simplified "dashboard" displays could also be available on the PCs of the occupants and operating personnel. Cars provide a powerful model to use in many building technology applications.

CONCLUSION

New buildings have not kept up with technological advances, especially when compared to automobiles. All one needs to do is make one trip in a typical new car and then make one visit to a typical new building to see this themselves. Comfort levels, safety levels, reliability levels, quality control levels, and automation levels are all much higher in new cars than in buildings. The imagination and creativity that goes into new car technology and manufacture should be harnessed for new buildings as well. It is necessary to start building new buildings in the same way new cars are built.

Abstract

When you do an energy audit, you must have a good understanding of how the energy is used by a facility to make sure that your energy efficiency recommendations are accurate and appropriate. You must know what equipment uses energy, how much energy it uses and how much energy it uses as a proportion of the total energy used at the facility. You can do this by monitoring the energy use of all the major pieces of equipment, but this is quite expensive and time-consuming. In this article, Part I, we discuss an alternative way for you to estimate the energy use by developing an "Energy Balance." This method is particularly helpful if you have limited time to gather the energy use data.

At the University of Florida Industrial Assessment Center (UF IAC) we devised the energy balance method of energy analysis because we realized that we had sometimes overestimated the energy savings available to a facility. This happened when we did not have a clear idea of how much energy was used by each group of equipment such as motors, lighting, air compressors, air conditioning, etc. Therefore, we developed a spreadsheet where we entered the energy use data gathered at the facility and compared it to the actual energy use as shown in the utility bills.

We then refined our assumptions with respect to load factors and hours of usage if our preliminary results were out of line with the actual total energy use by the facility. Our result is an approximation of the energy used by the major electric equipment systems in the facility. We perform separate energy balances for each type of energy source (electric, natural gas, propane, etc.).

Performing an energy balance gives you several benefits. You can see which equipment systems contribute the most to the energy costs and can spend your time analyzing recommendations for those systems. Since the equipment data is already available in the energy balance spreadsheet, you can easily export portions of the data to the recommendation analysis spreadsheets to calculate energy cost savings. You can check the credibility of your energy savings recommendations by making sure that the recommendation does not save more energy than a given equipment system uses.

Finally, you can show the facility how its energy use and energy dollars are apportioned among the various systems.

In this article, we describe the spreadsheet we developed to estimate an energy balance along with several sample energy balances. We explain how to reconcile the preliminary results to achieve a reasonably realistic energy balance. We also provide examples of recommendations that we had to reanalyze and basic assumptions that we needed to revise for consistency with the energy balance.

INTRODUCTION

To improve the efficiency of energy use at a facility, the analyst must have a good understanding of what that energy use is. Energy use data can be gathered by metering and monitoring equipment, but this method is expensive and time-consuming. Often, the energy analyst can spend only a day gathering data, and this sometimes makes getting an accurate picture of the facility's energy use difficult.

At the UF IAC, we were faced with the task of gathering sufficient data in a 1-day plant visit, to analyze the existing energy use and make recommendations for changes. We developed an energy balance approach to simulating facility energy use to help with our analysis.

This article will demonstrate the usefulness of constructing an energy balance as an alternative to more

costly methods of measuring energy use. We will detail the major steps of creating and using an energy balance. We start with data collection, explain the method used to reconcile the simulated use with the historical use patterns, and discuss use of the energy balance for making recommendations.

WHAT IS AN ENERGY BALANCE?

We modeled our energy balance after the traditional mass and heat balance approach of physics and thermodynamics. We realized that it was not sufficient to look at each energy use system at a facility in isolation because we sometimes found situations where the whole did not equal the sum of its parts. That is, the total metered kWh (and/or kW) use was lower (or higher) than the sum of the estimated uses by each system within the facility. Therefore, we developed a model for estimating the energy uses of each system as a part of the whole system, and we call our model the energy balance.[1]

CONSTRUCTING A DETAILED ENERGY BALANCE SPREADSHEET

Before visiting the facility site, you must gather the historical energy use data either from the facility or from the utility supplying the energy. This data must be collected both to prepare for an audit and to start understanding the energy use of a facility. At the facility site visit, you should collect data on all energy-consuming equipment (electricity, gas, or any other form of energy). The equipment-energy use data should be entered in the energy balance spreadsheet. Next, you calculate demand and energy use for the facility based on that data, and adjust the equipment energy use parameters until the predicted use matches the historical use within a given tolerance factor. Only then should you start the data analysis, necessary to make energy efficiency recommendations.

Collecting Historical Energy Use Data

To analyze a facility's historical energy use, gather atleast 12 months of energy bills. For each type of energy source, find the average demand and energy uses and charges for the past year or business cycle. Do not forget to factor in the various taxes and tariffs. For electricity, demand charges are based on the peak recorded each month, while the energy charge is typically based on the number of kilowatt-hours used each month.

At the UF IAC, we used an excel spreadsheet for organizing monthly use and costs. Once the data has been entered, you can quickly produce useful bar graphs of demand and energy use as well as costs trended by the month. These graphs give a quick picture of historical energy use.

For example, you may find a bi-level peak pattern that may indicate a business with different seasonal usages, or you may see a continually increasing pattern. This type of picture will help the auditor understand the processes and business of the client and may prompt questions that plant personnel can answer during the plant visit.

For example, can a bi-level pattern of demand and energy be explained by different operating schedules during different seasons? Or, why is the use continually increasing? Perhaps increased production accounts for the increase, but maybe it is poor maintenance practices and aging equipment.

In addition to the bar graphs, we used pie charts to illustrate the relative energy use between different energy sources. For example, if a plant uses both natural gas and electric energy, then a pie chart makes it easy to see the relative usage between gas and electricity. If the analysis shows insignificant gas use (less than 10% or so), then you know that you should focus your major analytical efforts on the electrical equipment. You will also use this historical use data with your energy balance calculations in order to validate your data collection and assumptions.

Collecting Equipment Energy Use Data

We utilized the following basic method to collect data:

- Meet with plant personnel, someone like the plant manager, to discuss the processes at the plant as well as major energy-consuming equipment and safety concerns. We placed an emphasis on the plant process, since these processes are how the plant makes money. Any energy savings recommendation that causes the plant to lose money in other areas is sure to be rejected.
- Conduct a plant walk-through with plant personnel, again focusing on processes with the emphasis on major energy-consuming equipment and safety concerns. We generally followed the path that the raw material would take as the plant transforms it to a completed product.
- Perform a detailed data collection of energy-consuming equipment. If plant maintenance personnel will help with this task, their services are invaluable.

You will need the following basic data from all types of energy-consuming equipment to compile the energy balance:

- From the discussion with plant personnel, climate conditions, and personal observation, you can estimate the annual use in hours per year (h/yr) and assign a utilization factor for each piece of equipment. We chose the number of hours a year that a piece of equipment should be available for operation as the annual use number. For example, we often used the operating hours for the facility for the annual use hours. Then we modified this annual use number with a utilization factor (uf) to account for the actual time of use of that equipment. For equipment in constant use, the utilization factor could be 0.9 to account for 10% downtime due to maintenance. The utilization factor for equipment in less than constant use is assigned a value according to the percent of use time estimated by plant personnel. This parameter can be adjusted, if necessary, when refining the energy balance.

- From the name plate of the equipment, you should collect and record the following data if available:
  - The power rating in kilowatts (kW), horsepower (hp), tons, or similar information. For example, if neither kW nor hp is available, collect the amperage, voltage, power type, and power factor. By power type, we mean alternating current (a.c.) single-phase or three-phase, or direct current (d.c.) With this additional information, you can estimate the power rating.
  - Any efficiency values that may be available. For cooling equipment, you should record the energy efficiency ratio (EER) or coefficient of performance (COP). Motor efficiency values can be found on the nameplate or from tables in the DOE MotorMaster program.[2]
  - If no data are available, try to get the manufacturer's name, model and serial numbers, and contact the manufacturer for data.
- Since a motor rarely runs at its rated power level, you need to determine the motor load factor (lf) to calculate the actual power used. You can take a current measurement or a speed measurement of a major motor to get an approximate load factor. You could use a clamp-on ammeter or a tachometer and compare the measurement to the amperage rating or the speed drop characteristics curve to estimate its load factor. However, you must remember even this type of measurement is just a one time sample. The only way to get an accurate measure would be to measure load over a relatively long period. To get this accurate measurement, you could use a strip chart recorder, a monitor connected to a computer, a data logger, or part of an energy management system. If you have not measured the load factor, you will have to estimate one. We have found that typical motor load factors are between 0.35 and 0.60. However, some motors such as fans and air compressors generally have higher load factors of 0.8–0.9.
- To adjust the total power use, we also assign a diversity factor (df) to each piece of equipment. We use this to account for similar pieces of equipment that are not run concurrently. For example, if the plant has two condensate pumps but only one can be run at any given time and the second is used in a backup mode, you should account for this fact with a diversity factor of 0.5. Most equipment that operates a large number of hours during the plant's peak use shift will have a diversity factor of 1. (For a more complete explanation of load factor and diversity factor, see Capehart[1,3]).

It is not feasible to collect data on every piece of equipment at a facility. However, you should try to collect detailed information on the larger pieces of equipment that use 90% of the energy. We used a miscellaneous category to account for the last 10% of energy use by the large number of small energy users.

You should collect data on the following pieces of equipment:

- *Motors*. These are the largest single energy consumer category in most manufacturing facilities. Generally, you should concentrate on motors over 5 hp. However, depending on the size and type of facility, you may want to increase or decrease this threshold. Furthermore, you may want to treat a large number of similar small-size motors as a group. For example, some facilities may have a large number of conveyor belt motors of similar size and with similar usage patterns. See the motor section of Fig. 1: Energy Balance—Electrical Equipment.
- *Heating, ventilating, and air conditioning* (*HVAC*). Locate all the heating, cooling and ventilating equipment. Exhaust fans should be included in the motor list. Sizes of equipment (in kW, tons or other units) together with EERs or COPs must be found and recorded. From this EER or COP data, we can find the kW/ton power consumption and the total kW by knowing the size in tons of each unit. The energy consumption is then found by multiplying the full-load kW by a factor called the Full Load Equivalent Operating Hours (FLEOH) of the compressor unit. The FLEOH is dependent on the geographical area where the facility is located, and can usually be found from the local utility or from the State Energy Office for the area. (Note: you need to use the compressor operating hours, not the hours that the facility is air-conditioned, for your air conditioning equipment operating hours.) See the HVAC section of Fig. 1: Energy Balance—Electrical Equipment.
- *Air Compressors*. We placed air compressors in a separate category from other motors because the efficiency recommendations are often quite different and we wanted to isolate the air compressor system's energy use. The hp size of each compressor should be recorded. When you examine the air compressor system, also look for auxiliary equipment, such as air dryers. See the air compressor section of Fig. 1: Energy Balance—Electrical Equipment.
- *Lights*. Note the usage patterns of the lights as well as the usage patterns of the lighted areas. Then find the total wattage of the facility's lighting system. Purely resistive lighting loads, such as incandescent lights, will have a ballast-energy use factor of one. You will

Fig. 1 (*Continued*)

have to take into account the ballast factor for fluorescent lights and HID lamps. If you cannot obtain information that is more accurate, you can estimate the ballast-energy use factor to be 1.15–1.20, meaning that the ballast consumes 15%–20% energy in addition to the rated power of the lamp. See the lighting section of Fig. 1: Energy Balance—Electrical Equipment.

- *Specific process equipment*. Sometimes the facility process will have specialized equipment that should be examined carefully to make sure all energy data is gathered. For example, a plastic-products facility may have injection molding machines. These machines will have motors, which should be included in the motor section with appropriate load factors. They will generally have heaters that heat the plastic before it enters the injection process, and they may have some type of chilling (typically chilled water) to cool the final product. All these energy-using components of the injection molding process must be recorded in the data collection process. They can be entered in a separate injection molding process equipment section of the energy balance if desired.
- *Gas and oil powered equipment*. Nameplate ratings in British thermal unit per hour, efficiencies, and load factors must be obtained. You should also verify the maintenance schedule for possible tuning opportunities.
- *Miscellaneous equipment*. You will not need to collect detailed data on small energy consumers such as office equipment or other plug loads at a manufacturing facility. We typically consider the miscellaneous uses to account for 10% of the actual kW and kWh use in a facility. That number goes into our energy balance as part of the total facility energy use. However, in a commercial facility or office building, the computers, fax, and copy machines may account for a substantial energy use, and do need to be recorded.

Data Compilation

After collecting the data for the energy-using equipment, you need to record and organize the data and simulate the operations of this equipment to develop an estimated energy use to compare to the historical energy use. At the UF IAC, we used an excel spreadsheet to organize the data in preparation for data analysis. We started with a spreadsheet template that already contained the basic layout and equations. To prevent inadvertent altering of the equations, we locked the fields containing equations.

We typically organized the data in one of four ways:

- By type of equipment;
- By building or location;
- By process;
- By utility meter or other energy use measuring device.

These different organizational methods are not mutually exclusive. Often, we used a combination of these methods to help us focus on the energy-using equipment. For example, if we organized by building, we would have a sub-organization by type of equipment. We might also organize by utility meters where the facility had more than 1 m, then by equipment on that meter. No matter how you decide to organize your data, you should sub-total the energy use, demand, and cost of each area. You will find these sub-totals useful in latter analysis. Fig. 1: Energy Balance—Electrical Equipment contains the formulas used in each section of the energy balance and shows a sample layout of the sections of an energy balance.

By Equipment

Our fundamental organization is always by type of equipment. For example, we typically start by listing lighting, process motors, heating ventilation and air-conditioning equipment, air compressors, and specialized process equipment. We list any non-electric power equipment, such as natural gas or oil-fired boilers, separately. (Natural gas-fired equipment will also be separated by meter.) Then, we assign the power ratings, hours of use, and initial load, utilization, and diversity factors to each piece or group of equipment. Fig. 1 illustrates this basic layout for the electric portion of an energy balance.

By Building or Location

You may also find it useful to further separate the equipment by building or location. One obvious example would be to separate lighting by office, parking lot, and manufacturing area because the lighting is used differently in each area. The office may only be operated from 8 to 5, while the manufacturing area operates 24 h/day. The parking lot lighting should only operate at night. We found that this type of separation can help identify energy-saving opportunities. For example, if the parking lot lights were operating more than the nighttime hours, then it might be profitable to install photo-sensors. The lighting section of Fig. 1 illustrates the office and a saw mill.

By Process

For a facility that has multiple processes or multiple lines performing similar processes, you may find it useful to further separate equipment by process. Different processes may have different operation schedules, and their separation makes it easier to understand how energy is used in each. For example, a lumberyard may cut lumber 8 h a day, but it may take 60 days to dry the lumber, and the drying processes may operate 24 h/day. Once the data is organized in this manner, opportunities for improvement may become obvious. Does the lumberyard need a better method for drying wood to keep up with the cutting operations? In another example, we visited a plant that had multiple lines performing similar processes. After we had organized the equipment by lines and analyzed the diversity factor, we found that their peak load could be lowered by managing the maintenance and line change-over schedule.

It is very helpful to consider the whole process when you are checking to see if your equipment list is complete. For example, if the facility spray-painted items that went on a conveyor line and through a drying oven, you would check to see if you had recorded an air compressor (for spray painting), conveyor motors, and heating elements.

By Meter

The more meters a facility has, the more accurately you can simulate the energy use at that facility. If a facility has multiple meters, develop a separate energy balance for each meter. Then, at the end, aggregate the values to get the total facility usage. For example, the office areas may have a different electric meter from the manufacturing plant. You may find it useful to first separate by meter, since each meter will have a different bill. Of course, you must separate gas-metered equipment from electric-metered equipment in any case. In addition, you will find it necessary to separate equipment related to each different type of energy sources: oil, coal, wood, propane, etc. Fig. 1 shows only the electric use section of the energy balance. We use the same energy balance template for other meters or energy types by using a similar section with the appropriate equations and units for that energy source and that equipment.

VALIDATING ENERGY BALANCE WITH HISTORICAL USAGE PATTERNS

Once you have collected and organized the data and entered it into the energy balance spreadsheet, start by totaling the demand and energy use from each equipment sector to get a total for the facility. Then you must compare it to the historical totals. If you have separated the equipment by meters, you should perform this balance for each meter and then aggregate each part at the end.

If your data collection and utility measurements are accurate, you should have a reasonably good estimate of the energy use by equipment sector. If the energy balance values are fairly close to the historical usage, you can fine-tune the energy balance values using the steps described below (see Fine-tuning the Energy Balance). However, if the values are more than a few percentage points apart, you should check the following areas before you start trying to adjust the energy balance.

- Was equipment missed during the site visit?
- Did you fully understand how the equipment is used?
- Did you fully understand equipment diversity?
- Did you fully understand the motor load factors?
- Did you fully understand the utility bills? Did you record them correctly?
- Was the energy demand and use metered correctly by the utility?

Comparing Energy Balance to Historical Energy Bills

The past use of energy and power is a good indicator of how a plant may be currently using their energy-consuming equipment. However, you must be aware of any changes in operation between the past and present. For example, you must consider if the plant has added any equipment or changed production schedules when you use the historical energy bills. Again, the goal is to specifically account for 90% of the historical energy use, and a demand between the actual minimum and maximum demand values achieved during the last business cycle. If a large piece of equipment has been added or removed during the period for which you are analyzing the bills, you must adjust the hours of use for that equipment for the appropriate period.

Sources of Problems with Reconciling the Energy Balance to Historical Energy Bills

You will find that at times you have trouble reconciling your predicted use with the historical use. In these cases, we have found a number of reasons for this inability to satisfactorily complete the energy balance. An advantage of performing the energy balance in the manner we describe is that this process may uncover a problem either of your understanding how a plant uses energy or a problem that must be addressed by the plant or the utility company.

Missing Equipment from the Plant Audit

Perhaps during the plant visit, you missed collecting data on some large energy-consuming equipment. The best way to approach this issue is to verify with plant personnel that you covered all primary and secondary processes at the plant. Sometimes it is easy to miss some of the less significant processes at a plant. The plant may produce a by-product from its processes that are almost an afterthought for plant personnel. For example, they may not have realized that processing scrap requires energy use at the plant. Equipment required for processing scrap may include shredders, compactors, cyclone separators, etc. Maybe you made the plant visit in the winter and the company uses portable coolers or a large number of personal fans in the summer for employee comfort.

Faulty Understanding of Equipment Usage

Possibly, during the plant visit, you did not properly find out how or when equipment is used because plant personnel may not understand its use. Equipment run primarily during off peak business hours may be a prime suspect. For example, plant personnel may give you faulty information about how personnel on shifts, other than his shift, actually use the energy-consuming equipment. Maybe, plant personnel who are on site during the day do not know when outdoor lights are used. To approach this issue, you could interview plant personnel or make follow-up visits during various times to get a better understanding how the equipment operates. For example, we came across one plant that we estimated a higher energy use than the historical numbers showed was possible. We over-estimated the energy use because initially the auditor misunderstood use of the plant-electric heaters. All the heaters combined to account for a large power use. Initially, the auditor assumed a use factor that was too high. Actually, the heaters were only used on the coldest nights of winter, and then they would cycle with only a portion being energized at any given time. The exercise of creating the energy balance helped the auditor understand how the plant used their heaters.

Faulty Understanding of Equipment Diversity

A 1-day visit to a plant is a small sample. The day of the visit may not have been a typical day. Observing that two identical pieces of equipment do not operate at the same time may be an aberration. Unless there is control equipment that prevents the operation at the same time, you cannot be sure. To approach this issue, you should interview plant personnel about the interactions between the equipment, so you can estimate the diversity of equipment operations. Again, you could also make periodic visits to observe how the equipment actually operates even if these visits are on the same day during your audit visit.

Faulty Understanding of Load Factors

You need a good understanding of the basic ideas of typical equipment design (or over-design). To approach this issue, you could take some sample measurements of equipment for large energy-consuming equipment to get an idea of the load factors.

Faulty Understanding of Utility Bills

Sometimes, some of the equipment will be separately metered, and you did not receive the bills for these meters. If you check the bills with the utility representative, you may understand the utility billing structures better than the plant personnel may. An alternative would be to interview the plant employee who pays the bills to make sure you have them all.

Faulty Measurement of Energy Use by the Utility Meter

Sometimes with the merger and divestiture of companies, a plant may be sold to two different parties. We found one such case where the plant meters were not properly divided. Therefore, one plant was unknowingly giving electricity away to another plant with a different owner. Sometimes meters are not working properly or meter readers have read them wrong. These problems need to be brought to the attention of company management and the utility company, so the problem can be solved.

FINE-TUNING THE ENERGY BALANCE

If the estimated demand and energy use do not match the historical demand and energy use within 2%, including miscellaneous, you must begin revising your assumptions to reconcile the collected data on energy-using equipment with the historical data. Often we were able to match historical energy use to within fractions of a percent. Once you have complete confidence in the data you have collected, then the only parameters that you can adjust or "tweak" are the load, utilization, and diversity factors. Again, the goal is to account for 90% of the historical demand and energy consumption for every type of energy. The other 10% you can consider caused by miscellaneous loads. By adjusting these three factors, you can develop a fairly accurate balance of the energy and demand use at a manufacturing plant.

How to Adjust the Energy Balance

There are eight possible mismatches between the total calculated facility demand (kWc) and energy use (kWhC) and the historical demand (kWh) and energy use (kWhH). You must adjust the load, utilization or diversity factors depending on which situation you have. As you adjust one of the parameters, you may find that you then have to adjust another to fine-tune your results. Table 1 shows the adjustment to make for each the situation.

Adjusting the Load Factor

As previously mentioned, we have found that most process motors have a load factor between 0.35 and 0.6. We generally start at 0.4. Some motors such as the air compressors and fans will have higher load factors typically from 0.8 to 0.9. If your total kW and kWh are a little too low

Table 1 Adjusting the load, utilization, and diversity factors

Situation	Demand	Energy	Adjustments
1	kWc < kWH	kWhc < kWhH	Increase the load factor on some of the motors
2	kWc > kWH	kWhc > kWhH	Decrease the load factor on some of the motors
3	kWc = kWH	kWhc < kWhH	Increase the utilization factor on some of the equipment
4	kWc = kWH	kWhc > kWhH	Decrease the utilization factor on some of the equipment
5	kWc < kWH	kWhc = kWhH	Increase the diversity factor on some of the equipment
6	kWc > kWH	kWhc = kWhH	Decrease the diversity factor on some of the equipment
7	kWc > kWH	kWhc < kWhH	Decrease the diversity factor and increase the utilization factor on some of the equipment
8	kWc < kWH	kWhc > kWhH	Increase the diversity factor and decrease the utilization factor on some of the equipment

(or too high), then increase (or decrease) the motor load factor slightly for the lightly loaded motors. However, if the total kW is significantly higher or lower than the historical demand, then you will have to look for some other reason (see Validating Energy Balance with Historical Use above). To change the energy and power use for a motor on the energy balance, you can change the load factor.

Adjusting the Utilization Factor

As discussed previously, we chose the annual hours of use for a piece of equipment as the operating hours for the plant or department. Then, we used the utilization factor to account for cycling of equipment, maintenance downtime etc. If your kWh is too low or too high, you can adjust the utilization factor to help reconcile the difference. You might want to adjust it for specific pieces of equipment rather than an across-the-board adjustment on all equipment. Changing the utilization factor changes only the estimated annual energy use for a piece of equipment.

Adjusting the Diversity Factor

We used the diversity factor to calculate the average demand when two (or more) similar pieces of equipment are highly unlikely to run at the same time. For example, if a plant had two pumps, but when one was running, the other was in standby mode, then the diversity factor for each pump would be 0.5. Another example would be a plant that has a large number of fans, but the probability of a fan running at the time of the peak was 75%. Thus, the diversity factor of each of the fans would be 0.75. Changing the diversity factor changes only the estimated annual demand for a line item on the energy balance for a piece of equipment.

DATA ANALYSIS

Once you are comfortable that your data represents the actual energy use (i.e., your calculated demand and energy use accounts for 90%, excluding miscellaneous, of the historical use), you can use the energy balance spreadsheet to produce several useful graphs that show the relative energy use of each set of equipment (lighting, motors, etc.), the relative energy use of groups of equipment by each separately metered area, and so forth. We used a pie chart to show the relative usage and cost of each type of electrical equipment. This pie chart gave us a good indication of the areas with the greatest opportunity for energy savings. It also allowed us to show the plant personnel where their energy was being used. In addition, viewing the pie charts helped UF IAC auditors with less experience gain a better feel for the areas to concentrate upon during subsequent audits for similar plants. See Fig. 2 for a sample pie chart based on our sample energy balance.

EXAMPLES OF BENEFITS RECEIVED USING AN ENERGY BALANCE

At the UF IAC, we have had many instances when the energy balance method described here has aided us with understanding the energy use of a facility and with recommendation ideas. Here are three examples of these instances.

Interactions between Recommendations

During the analysis of recommendations for a client, we made a series of interrelated recommendations including high-efficiency motors, demand shifting, and synchronous

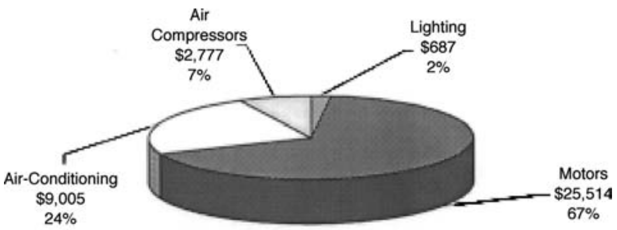

Fig. 2 Estimated cost of operation by type of electric device.

v-belts. Separately, these recommendations showed a total energy savings of about 50%, which seemed highly unlikely. After reviewing our energy balance, we realized that these recommendations were not mutually exclusive. A before-and-after energy balance showed that the actual savings from the combined measures was much less than 50%.

In another case, we prepared a series of lighting recommendations: T-8 lighting, occupancy sensors, photo-sensors, compact fluorescent lighting, and lower wattage halogen lamps. However, the combined savings would have saved more than the energy balance predicted that the lighting system used in total. Again, using the before-and-after energy balance pointed out the result of double-counting the savings.

Our most memorable example of the need for an energy balance was in our early audits when we used an initial motor load factor of 80% for a facility and calculated a savings in demand and energy that was higher than the total historical demand and energy use for the facility. At this point, we realized that we needed a tool for better analysis, and this gave rise to the development of our energy balance method of energy and demand analysis.

CONCLUSION

Before you can save money through the efficient use of energy, you must understand how that energy is used. One strategy would be to monitor equipment with an energy management system or some other monitoring method. Monitoring takes a period of observation and is costly. Even if the expense of this costly monitoring is undertaken, it is unclear if you will benefit from it without significant additional analysis. With the method we describe in this article, you can gain many of the benefits of the more costly methods with less cost. Maybe, after performing this method, you will find that installing an energy management system will yield appropriate benefits, or maybe you will find that the more costly methods will not yield an acceptable return on investment. Therefore, depending on the situation, the energy balance method may provide a relatively low-cost and reasonably accurate alternative to understanding the energy use at a facility.

Facility Energy Use: Benchmarking

John Van Gorp
Power Monitoring and Control, Schneider Electric, Saanichton, British Columbia, Canada

Abstract
Energy management practices have evolved significantly over the past decade, in many cases borrowing from advances in business management methods and information technology. One key aspect of this comprehensive approach to energy management is a focus on setting goals and measuring performance against these goals, a process that is often referred to as benchmarking.

An energy benchmark is a reference used to compare the performance of one energy system against another. This article describes several key concepts in the construction and use of energy benchmarks, including selection of data sources, data management concepts, constructing baseline benchmarks and analysis tips. Examples are used throughout the article to illustrate how benchmarks can be used to manage facility energy use.

INTRODUCTION

"What gets measured, gets managed"—Peter Drucker, business management theorist

Energy management practices have evolved significantly over the past decade, in many cases borrowing from advances in business management methods and information technology. The traditional approach to energy management focuses mainly on replacing existing equipment with new equipment that takes advantage of the latest energy efficiency technology. Modern practices extend beyond this focus on energy technology and take a comprehensive approach to the process of managing energy.

The ANSI/MSE 2000 standard[1] and the Energy Star Energy Management Guidelines[2] are examples of this more comprehensive approach to energy management. Both of these guidelines provide a framework for setting energy consumption goals, tracking performance against those goals, and communicating results. Both also emphasize the critical role that measurement and verification plays in the success of most energy management programs. One U.S. Department of Energy paper studied energy efficiency projects at more than 900 buildings and found that projects that implemented best practices in measurement and verification realized higher savings (both initially and over time) than comparable projects, yielding an additional return on investment of nearly 10%.[3]

One key aspect of this comprehensive approach to energy management is a focus on setting goals and measuring performance against these goals. The process of setting energy goals requires an understanding of current energy use and comparison of that use against one or more reference standards. This process is normally referred to as benchmarking.

Energy Benchmarks

An energy benchmark is a reference used to compare the performance of one energy system against another. Energy benchmarks are often used to compare the energy consumption of different types of equipment (such as motors and lights), buildings, and industrial processes. The benchmark used can either be internal or external, as described below:

- An internal energy benchmark is a reference built by an organization to compare similar energy systems within the organization. This comparison is normally used to highlight the most efficient energy systems and isolate the positive behaviors that drive this efficiency.
- An external energy benchmark is a reference built by industry associations and government organizations to compare similar energy systems. This reference is normally obtained through analysis of many similar energy systems operating in comparable environments. The best practice behaviors that drive the most efficient energy systems are often documented to help the organizations using the benchmark increase the performance of their own energy systems.

To create a true and accurate comparison, most energy benchmarks are normalized by some key driver of energy consumption, and important aspects of the environment that might affect the benchmark are stated. This results in a measurement reference that is common to both things being compared. Benchmarks for building energy use are commonly normalized by floor space, and benchmarks for industrial energy use are commonly normalized by some

Keywords: Energy benchmark; Energy analysis; Energy monitoring; Energy management; Measurement and verification.

unit of production. Environmental aspects that might affect the application of a benchmark include the major use of a building, occupancy, and climate.

To help illustrate this concept, some normalized energy benchmarks commonly used are:

- Building energy consumption: kWh per square foot (or per square meter).
- Manufacturing energy consumption: kWh per ton of production.

Government organizations, such as Energy Star, Natural Resources Canada, and Rebuild America, offer energy benchmarks for a variety of applications. Industry associations, such as the Canadian Pulp and Paper Association (CPPA), offer energy benchmarks relevant to members of their industries. Example energy benchmark guides include the following:

- *Benchmarking Your Facilities for Greater Success* from Rebuild America[4]
- *Benchmarking and Best Practices Guide for College Facility Managers* from Natural Resources Canada[5]

Some organizations may prefer to express an energy benchmark in terms of cost. A manufacturer, for example, might use both kWh-per-ton and energy-cost-per-ton benchmarks to track performance. Expressing a benchmark in terms of energy cost can be useful for cost accounting purposes, but the rate structure for many energy users can make such a calculation difficult. Such a benchmark should not be used for managing the efficiency of an energy system. Changes unrelated to energy consumption (such as changes in the energy rate charged by the local utility) can affect this metric.

Preparing for Benchmarking

Benchmarking preparations are described in the following steps:

- Benchmarking scope
- Selecting data sources
- Data management
- Constructing baseline benchmarks

Benchmarking Scope

The scope of a benchmarking exercise depends primarily on the energy management goals that will be supported. If the goal is simply to assess the current state of energy efficiency within an organization, or to implement a straightforward energy efficiency project, then benchmarking preparations will not be as extensive as they would be for a benchmarking effort designed to support a comprehensive energy management program. Data collection, monitoring, and reporting efforts for one-time benchmarking exercises normally require much less time (and expense) than efforts designed to create an active and ongoing benchmarking program.

Active benchmarking programs, however, can often help drive greater energy savings over a longer period.

Data Sources

Once the scope of the benchmarking effort has been determined, the next task is to find sources of the data required to build up the benchmarks. These data can be organized into two main categories:

- Static data such as equipment ratings and floor area. These are data that tend to change slowly (or not at all) over time.
- Dynamic data such as energy consumption and production volume. These data change frequently and need to be collected at regular intervals.

Most of the expense and effort involved in data management is due to dynamic data collection and processing. Collecting static data, such as floor area, can often be performed just once; dynamic data, such as energy consumption, on the other hand, requires a continuous effort. The number of dynamic data measurements should normally be kept to the minimum required to support energy management goals. Once these measurements have been determined, the time interval used for data collection should be short enough to provide the detail required to understand patterns of energy consumption. More than this level of detail will increase the cost of data management without resulting in a greater understanding of energy consumption.

Sources of dynamic energy consumption and normalizing data include the following:

- *Energy consumption from utility bills*. Energy consumption data can be manually entered from utility bills, but many utility companies will also offer billing data in an electronic format to their larger customers.
- *Energy consumption from "shadow" metering*. If detailed energy consumption data is required but not available from the utility company, a facility can install a separate meter at the utility service point to "shadow" the utility meter.
- *Energy consumption from sub-meters*. Benchmarking equipment or processes within an energy system may require the installation of separate meters to capture the data required.
- *Energy consumption from existing automation systems*. Some building and industrial automation systems can integrate with basic energy meters and collect energy consumption data.

- *Production data from existing automation systems.* Many manufacturing organizations record production volume using some form of information system, ranging from process historians in process control systems to shipment data in material resource planning (MRP) systems.
- *Temperature and humidity data.* Sources for this data range from a variety of publications and online weather services and to on-site weather stations.

Electricity and natural gas are the most common forms of energy monitored in benchmarking programs, but the information presented here can be applied to other forms of energy transfer as well (such as steam or chilled water). When aggregating or comparing different forms of energy, it is important to convert measurements to common units (such as BTUs) first. Energy management references, such as the *Energy Management Handbook*,[6] list conversion factors and instructions on their use.

Data Management

The next step after selecting which data needs to be collected and the source for this data is how this data will be managed, processed, and communicated. The choice of which data management approach to follow depends primarily on the energy management goal being supported. If the benchmarking exercise is intended to be a one-time comparison against internal or external benchmarks, then manual data entry into a spreadsheet may be sufficient. If benchmarking will be supporting an active energy management plan, and a large number of energy measurements are involved, then a more comprehensive energy information system will likely be required.

Here is a summary of both the spreadsheet and energy information system approaches:

- *Spreadsheet with manual data entry.* Energy consumption information obtained from utility bills or read directly from meters is manually entered into a spreadsheet. Simple calculations are used to divide energy values by the key normalizing value (such as floor area) to generate the benchmark measurement. This step is repeated for each energy system being monitored.
- *Enterprise energy management system.* Digital energy meters and manual data entry transmit measurements to a central server that archives and processes the data. Benchmarks are automatically calculated for all energy systems being monitored. Current and historical results are available as tables and graphs easily accessible by multiple users.

In addition to automating data collection and benchmark calculations, an energy information system can also collect and organize more detailed interval data for analysis of energy consumption patterns. If benchmarks indicate a sudden increase in energy consumption, this interval data can be crucial to understanding the drivers behind this sudden increase.

Fig. 1 shows the typical components that form a modern energy information system. Microprocessor-based devices measure energy use at key points within one or more facilities and communicate this data back to a server through a communications network. The software archives this data, processes it as required, and presents it to users in a variety of ways. Information can typically be accessed using a standard web browser or by receiving alert messages through wireless devices.

Constructing Baseline Benchmarks

When constructing an energy benchmark, an organization must select energy consumption data over some length of time. This baseline data set is selected to describe the current performance of an energy system. Data should be collected over a period of time that is long enough to capture nearly all of the operating modes of the energy system (through different seasons of the year or different levels of production, for example). The period selected for the baseline should not include major changes to the energy system (such as major equipment retrofits).

The example below illustrates the steps involved in building energy benchmarks.

Example 1. Energy benchmarks for a portfolio of office buildings.

A property management company with a portfolio of five office buildings suspects that some buildings are consuming much more energy than they should. A review of electric utility bills for all buildings over the past year indicates that consumption varies by a factor of five between the smallest and largest buildings!

An energy manager at the property management company has been given the task of benchmarking the energy efficiency of all five buildings against each other and against a recognized reference benchmark. The goal is to identify which buildings are the most and least energy efficient and to compare all buildings to the recognized reference benchmark. This benchmarking exercise will be the starting point towards understanding current energy use and launching a comprehensive energy management plan across the organization.

The energy manager takes the following steps to create energy benchmarks for the five office buildings:

- *Acquire electrical energy consumption data and normalizing data.* The energy manager obtains copies of the electric bills for each of the five buildings for the previous year. She creates a new spreadsheet and manually enters the consumption data for each building for each month of the year, starting with January. She

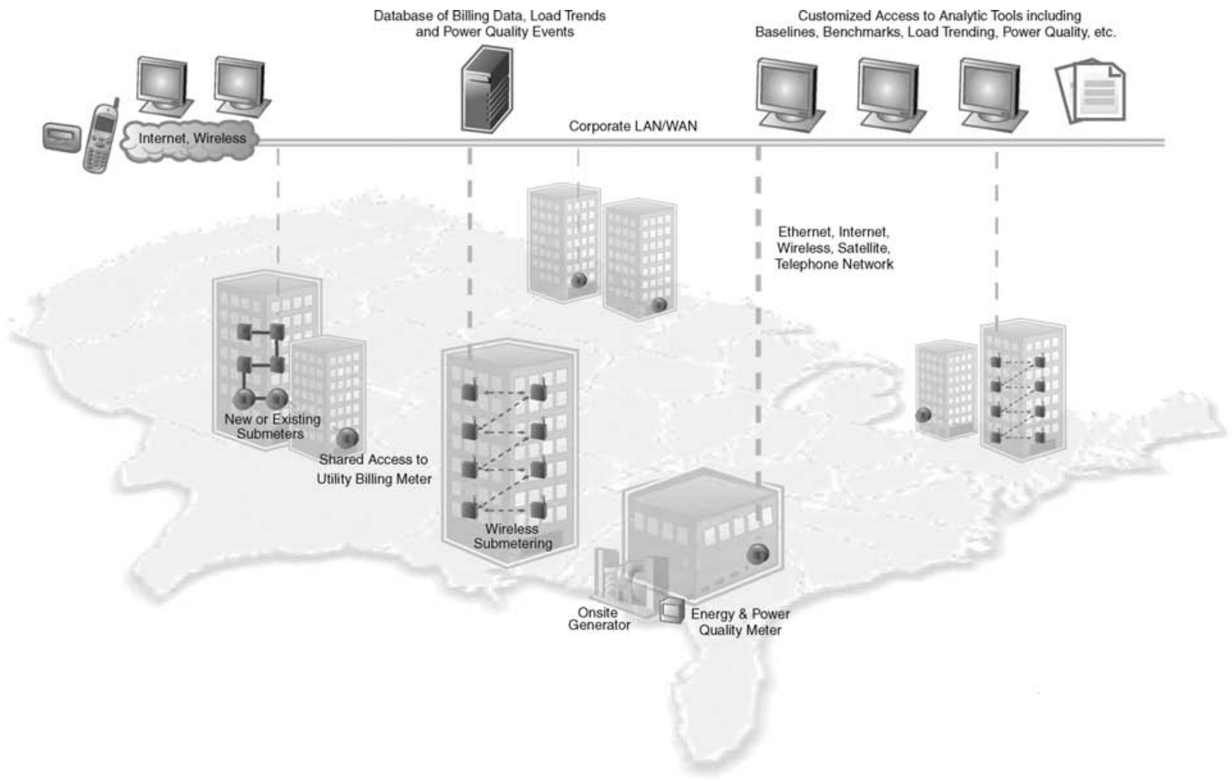

Fig. 1 Components of a typical enterprise energy management system.

also enters the total floor space for each of the five buildings.

- *Select an appropriate reference benchmark*. The energy manager decides to use reference benchmark values from the "Benchmarking Your Facilities for Greater Success" document from Rebuild America.[4] This document provides electrical energy consumption benchmarks for a variety of building types, based on data from a U.S. Department of Energy study in 1999. The energy manager decides to use the median annual benchmark value for office buildings, which is 11.7 kWh/ft^2.
- *Calculate annual total kWh/square foot benchmark values*. The monthly kWh consumption values for each building are totaled to get an annual consumption total. This total is then normalized by dividing by the floor area for the associated building to get annual kWh/ft^2 benchmarks for each of the five buildings.
- *Set baseline benchmark values for each building*. The benchmarks calculated in the step above are recorded as the baseline benchmarks for each building. These values will be used to track changes in energy efficiency over time.

Fig. 2 below compares the annual kWh/ft^2 benchmarks for each of the five buildings against each other, and against the Rebuild America reference benchmark. Buildings 1–3 consume more energy per square foot than the reference benchmark, and buildings 4 and 5 consume less. Initial interest in this energy benchmarking exercise arose when a review showed that the largest building consumed much more energy than the smallest building, but the energy manager is surprised to see that the benchmark comparison tells a different story. The largest building (building 4) is actually one of the most energy efficient buildings in the property management company's portfolio, and the smallest building (building 2) is one of the least efficient!

This example focused solely on monthly electrical energy consumption data from utility bills and a benchmarking exercise to examine where the buildings currently stand. This example also used a simplified approach to benchmarking by excluding factors that can influence energy consumption, such as outdoor temperature and manufacturing production volume. The next section describes how such benchmarks can be used on a continuous basis to support an energy management program.

Benchmarking in Action

Although benchmarking may first be approached as a one-time exercise to determine the energy efficiency of a facility, it delivers the most value when practiced on a

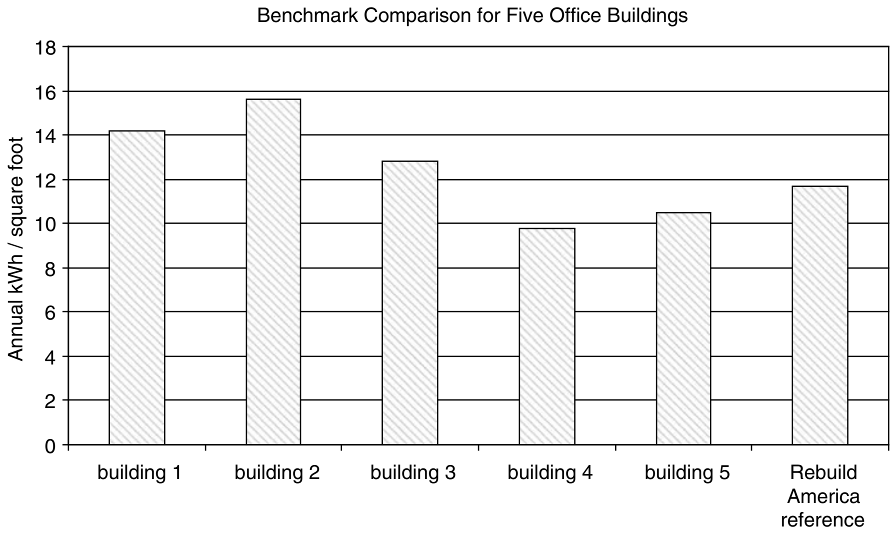

Fig. 2 Benchmark results for five office buildings.

continuous basis as part of a comprehensive energy management program. Energy benchmarks can provide a valuable summary of the performance of a variety of energy systems used throughout an organization. Different information users within an organization can be given the energy data they need in a manner that will help them support key energy management goals. Energy benchmarks can also be supported with additional drill-down details that help experts use the information to understand the drivers behind changes in energy consumption.

The sections below describe how energy benchmark information views can be configured for a variety of users to give them the information they need to support the success of an energy management program. The last section provides several tips designed to help energy managers uncover energy use patterns and get the most out of their benchmarking data.

Determine Benchmark Users

The first step in designing an energy benchmarking information system is to determine who will be using it, and how they will be using it. A variety of people within an organization can benefit from benchmarking information and use this information to support active energy management projects.

Some user roles and their typical energy benchmark information requirements include the following:

- *Executives*: Executives normally require only high-level benchmark summary data that shows energy efficiency performance against set goals. Executives may review benchmark summary reports once per quarter. If actual energy consumption is significantly higher than the target goals in an energy management plan, executives may request a more detailed report that explains the reason for a variance from planned consumption.
- *Facility engineering staff*: Facility personnel often require aggregated summary views backed by detailed time-series data that shows daily or hourly energy consumption and demand data. Engineering staff may review aggregated summary views once a week. If there are significant increases from energy consumption goals, engineers may review summary views and detailed time-series data once a day and take the actions necessary to put energy consumption back on track.
- *Tenants*: Tenants in retail or office space can receive monthly energy benchmark reports along with their utility bill. These reports typically compare the tenant's energy consumption against the least efficient, most efficient, and average energy consumption benchmarks for all of the tenants in the facility.
- *Department managers*: Managers that carry energy cost responsibilities in their budgets may receive benchmark information as part of a monthly report showing the performance of their department against budget. This benchmark report will typically show the energy consumption performance of the department against target goals, or compare performance to that of other departments.

Understanding who the users of a benchmarking information system will be provides the guidance needed to design the information views they will use to set energy management goals, track and correct for variances from plan, and proactively seek new opportunities for continuous energy efficiency improvement.

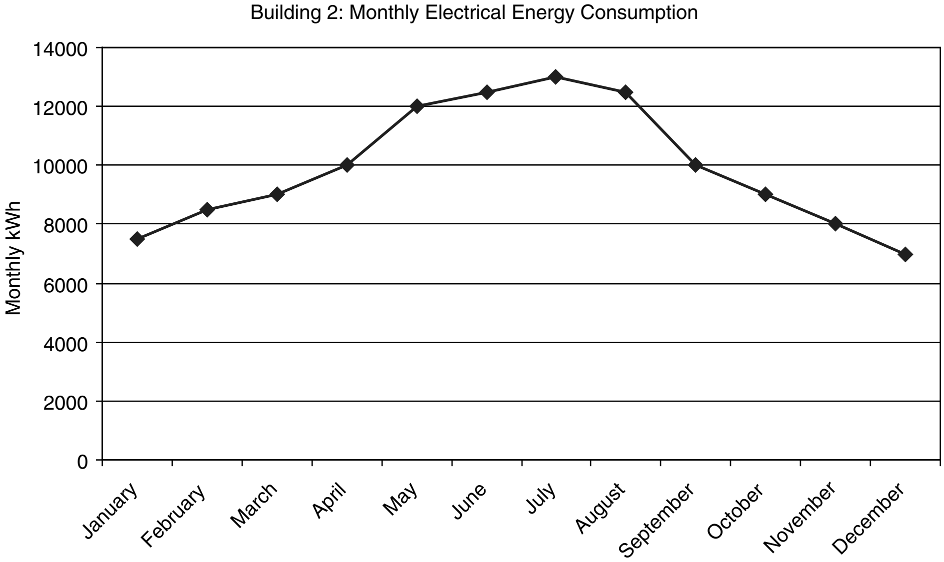

Fig. 3 Monthly kWh consumption values for the least efficient building.

Design Information Views

There are a variety of ways to display energy benchmark information and detailed data. Some example information views include:

- *Energy benchmarks in a table*. A table is often the best way to organize and display detailed energy benchmark values. A table might be used to show specific benchmark values for different buildings, tenants, or departments. If an energy management plan outlines targeted reductions in consumption over some time span, a table could be used to show the yearly energy consumption benchmark values over the time span.
- *Energy benchmarks in a bar chart*. Current and past energy benchmarks can be visually compared against target goals using a bar chart. Such a chart may show month-by-month actual values vs. target values for some energy system. A bar chart can also be used to compare benchmarks for different energy systems.
- *Drill-down data in a time-series chart*. To gain an understanding of what is driving significant increases or decreases in energy consumption, a time-series chart can provide a detailed view of the data behind an energy benchmark. Both actual and target values can be plotted over time to help an energy manager see where any deviations from an energy management plan exist.

Example 2. Drilling down into greater detail

An energy manager for a property management firm has created energy consumption benchmarks for five office buildings, as described in Example 1. Although energy consumption for the largest building is five times larger than the smallest, the bar chart created by the energy manager shows that the largest building (building 4) is actually one of the most efficient of the five buildings, and the smallest building (building 2) is one of the least efficient.

The energy manager decides to drill down into the data behind the energy consumption benchmark value for building 2 to gain a better understanding of its poor energy efficiency. She creates a new worksheet in the spreadsheet she used to calculate the energy benchmarks in Example 1 and enters the monthly kWh consumption values for building 2 from past utility bills. She then creates a time-series graph with kWh consumption on the *y*-axis and months of the year on the *x*-axis.

Fig. 3 shows the resulting time-series graph of the kWh consumption for building 2 over the year. It is easy to see that most energy consumption takes place during the summer months, which the energy manager does not find surprising; many buildings consume more electricity in the summer to run heating, ventilation, and air conditioning (HVAC) equipment to cool the building.

The energy consumed in the summer seems high to the energy manager, so she decides to use the data in her spreadsheet to build monthly kWh/ft^2 benchmarks to compare building 2 to one of the most efficient of the five buildings. She uses data for the months of May through August and normalizes the monthly electrical consumption data for building 2 and building 4 by the area of their floor space. Fig. 4 shows the resulting bar chart comparing energy benchmarks for both buildings for the months of May through August.

Benchmarking Analysis Tips

Once energy benchmarks have been established and standard information views created, most ongoing analysis

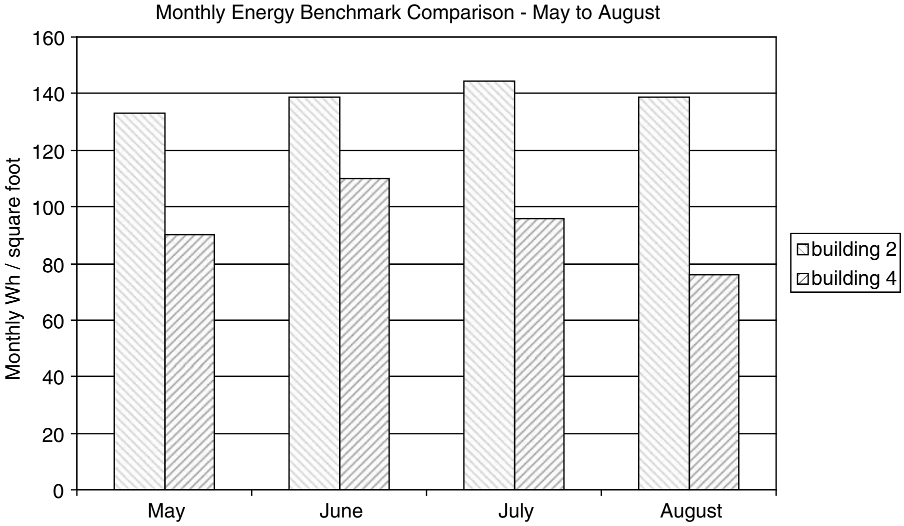

Fig. 4 Monthly energy consumption benchmarks for two buildings over summer.

effort will focus on detecting and understanding changes in energy consumption. The goal of most energy management programs is to first understand and then control energy consumption. The creation of energy benchmarks and baseline consumption profiles are key first steps towards understanding energy consumption. Control of energy consumption is driven by ongoing energy data analysis and taking the steps necessary to gain an understanding of how internal and external drivers are influencing consumption patterns.

One way to uncover hidden patterns of energy consumption is to organize and aggregate consumption data by some key driver of that consumption. Grouping energy consumption by time of use often proves useful in uncovering patterns of energy consumption, especially since time of use can be an excellent proxy for key drivers such as occupancy, outdoor temperature, and production. A few suggestions for time of use aggregations of energy consumption include the following:

- *Seasonal*: Aggregating energy consumption data by season is a simple way to estimate the impact of environmental conditions. Changes in outdoor temperature and daylight hours from season to season can influence the energy consumption of a variety of energy systems (such as HVAC and lighting systems). Example 3 below includes aggregation of energy consumption by season.
- *Weekday/weekend*: Aggregating energy consumption data by weekday and weekend is a simple way to estimate the impact of occupancy. Building occupancy will definitely impact energy consumption, and many buildings (such as offices and schools) have distinctly different hours of operation and levels of use on weekdays and weekends. Example 3 below includes aggregation of energy consumption by weekday/weekend.
- *Production shift*: Industrial energy consumption is primarily driven by production volume, which makes a schedule of production shifts a reasonable proxy for production activity. Manufacturing activity may not change much across seasons or differ by day of the week, but aggregating energy consumption by shifts may uncover interesting differences in efficiency from one shift to the next.

Detecting and determining the drivers behind anomalies in energy consumption patterns is also important to meeting the goals set in an energy management plan. Such anomalies need to be analyzed in order to determine their cause and steps need to be taken to minimize their impact in the future. Two types of anomalies to watch for include sudden spikes and sustained changes in energy consumption, as described below:

- *Spikes*: A sudden spike increase in energy consumption may simply indicate a temporary and infrequent change in equipment operation, such as a seasonal test of a building HVAC system. Such spikes should be investigated to ensure that they are not indicating something more serious, such as the pending failure of energy system equipment.
- *Sustained changes*: A sustained increase or decrease in energy consumption should be expected when there are major changes to an energy system, such as the expansion of a building or replacement of old equipment with more energy efficient equipment.

Unexpected changes should be investigated to determine the cause.

Finally, a greater understanding of energy system behavior can be achieved by creating information views that compare different measurements to one another. Some examples of comparison information views include the following:

- *Compare energy systems*: A common measurement (such as energy consumption) or benchmark for different energy systems is placed in a chart or table for comparison. Fig. 2 is an example of such a comparison. For accurate comparisons, ensure that the units of measure (such as kWh or kWh/ft^2) are the same and that the time range for the data sets is the same.
- *Energy consumption vs. potential driver*: This information view combines a measurement (such as energy consumption) against a potential driver of that measurement (such as external temperature). Such views can provide a quick (though informal) test of a link or correlation between one variable and another; a more thorough test would involve statistical techniques such as regression analysis.

The example below shows how an energy manager might further investigate the root cause of high energy use by organizing energy information and comparing it to a key driver, in this case time of week.

Example 3. Organizing benchmark data to uncover patterns.

To understand why the energy consumption for building 2 seems so high during the summer months, the energy manager contacts the local utility to see if daily energy consumption data for several buildings is available. Her utility account manager confirms that daily interval data is available, and at her request, sends a CD with daily energy consumption data for both buildings 2 and 4 for May–August.

The energy manager creates a new worksheet in the spreadsheet file she has been using so far and imports the daily energy consumption data from the CD. She then creates a new column and uses the "day of week" function to mark days as either weekday or weekend days. Finally, she aggregates weekday and weekend energy consumption for May–August for buildings 2 and 4 to see how they compare. Fig. 5 shows average daily energy consumption for May–August for both buildings, grouped by weekdays and weekends.

The chart in Fig. 5 makes it clear to the energy manager that much of the difference in energy consumption between buildings 2 and 4 is taking place on the weekends. To discover why, she contacts the building managers for both buildings to discuss building occupancy and operation during weekdays and weekends in the summer. Both managers confirm that the majority of their tenants operate between 9 a.m. and 5 p.m. during weekdays and are closed on weekends. The building managers also confirm that building automation systems are in place in their buildings, and that they are configured to operate in a "setback" mode during weekends to conserve energy. The manager for building 2 does admit, however, that the building automation system used in his building is quite old, and no one on his maintenance staff really knows how to operate it. The energy manager describes the results of her analysis so far, and suggests that the automation system may not be operating as expected. She recommends contacting the building automation

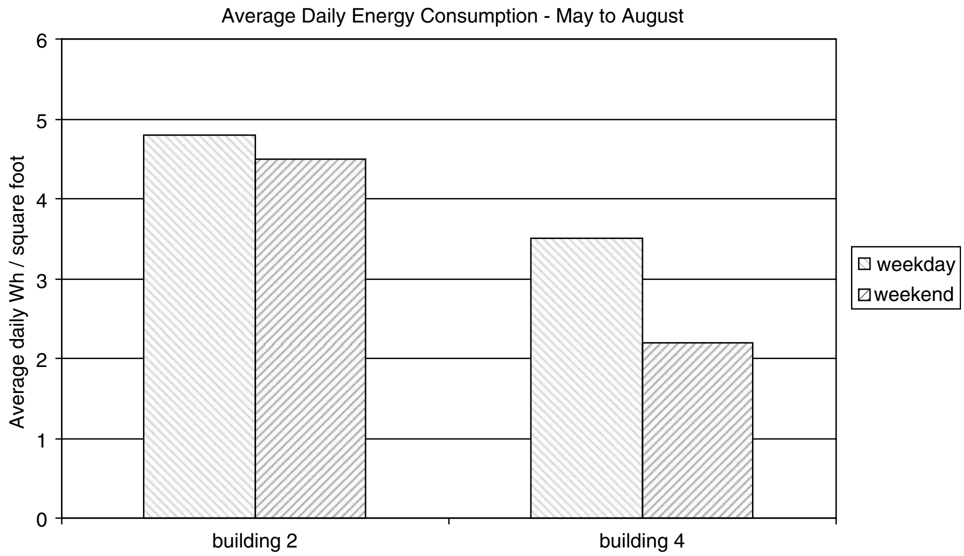

Fig. 5 Benchmark values (weekdays/weekends) for buildings 2 and 4 over summer months.

vendor's services group to confirm the setback configuration and schedule training for the maintenance staff.

CONCLUSION

Energy management practices have evolved significantly over the past decade, in many cases borrowing from advances in business management methods and information technology. In the past, there was a greater focus on equipment technology and less consideration of the management framework required to set and track performance against goals. Modern energy management practices increase and sustain energy savings by adopting the performance management approach integral to modern business and quality management programs.

Information systems that support activities like facility benchmarking are becoming a key part of modern energy management practice. In the past, such information systems were often prohibitively expensive, but advances in measurement and computer technologies are making such information systems cost effective for an increasing number of applications. A comprehensive energy management approach that sets and tracks efficiency goals and incorporates facility benchmarking will help drive increased (and more consistent) energy savings over time.

Facility Power Distribution Systems

Paul L. Villeneuve
University of Maine, Orono, Maine, U.S.

Abstract
Facility power distribution systems are very diverse. This diversity stems from a variety of items. Design code changes have resulted in evolving distribution system requirements. Furthermore, the owners and operators of the facilities have a varied set of concerns (financial, capacity, safety, etc.) that are to be incorporated into a power distribution system's design. Finally, a designer's experience often dictates the level of complexity that a design may entail. This entry attempts to address some of the basic concerns of the facility power distribution system designer. It provides a brief technical background as well as some straightforward recommendations.

INTRODUCTION

Electricity has been used in commercial and industrial facilities for over a century. Much of the manual labor that was routinely done has been replaced by relatively efficient motor-driven equipment. Furthermore, better monitoring and control has resulted in improved efficiency, higher yields, reduced emissions, and better working environments. It is fair to say that our ability to harness the power in electricity has been the most significant factor in improving our standard of living, enhancing our safety, and making our lives better.

The energy delivered by electricity has done many good things; however, that same energy can be destructive. Numerous fires, injuries, and fatalities have occurred due to the incorrect design of power systems or the failure of equipment. As a result, many design codes and standards governing power systems and equipment have been developed. These standards primarily focus on personnel and equipment safety. As a result, safety is often the most important consideration when designing or operating a facility power system. Further, the systems that are designed must be flexible enough to allow multiple operating conditions or plant configurations. Finally, power systems would not be viable unless they are economically feasible. As a result of all these considerations, it is the responsibility of the power system designer to ensure a safe system that provides for flexible equipment operation yet is economical to operate.

Because of increasing constraints and safety considerations, power systems continue to evolve. Until recently, on-site generation was not economically feasible for the majority of end users. Today, emerging technologies are allowing on-site generation which provide for additional sources of power, reducing energy costs, and enhancing efficiency. Electric utility providers have legitimate concerns regarding the effects that the on-site generation has on system reliability. As a result, these on-site generators create additional complexities in the design of facility power systems which the power system designer must factor in.

BASIC PRINCIPLES

Single- and Three-Phase Systems

Incoming utility power can be from a single-phase supply or a three-phase supply. A single-phase supply indicates that there is one independent phase capable of supplying electric power. However, most single-phase systems employ three separate conductors where current flow is permitted. These conductors originate at a single-phase utility step-down transformer. Two of the conductors are at the transformer's winding extremes. The third conductor is at the center of the transformer and is always tied to an earth ground. This type of configuration is called a center-tapped configuration. Single-phase systems were the original designs used in the early 1900s to provide power to all customers.

Three-phase systems were introduced to address the fact that large single-phase power requirements required large conductors. In a three-phase system, three independent phases are capable of supplying power. In most facility power distribution systems, there are four separate conductors where current flow is permitted; three-phase conductors and one neutral conductor. The neutral conductor is primarily used as a ground reference but can support current flow. In fact, three-phase systems with a neutral conductor can be used to provide phase-to-phase or phase-to-ground power. However, utilities require end users to balance their load so that each of the three-phases sees approximately the same load. This, in turn, limits the amount of neutral current flow.

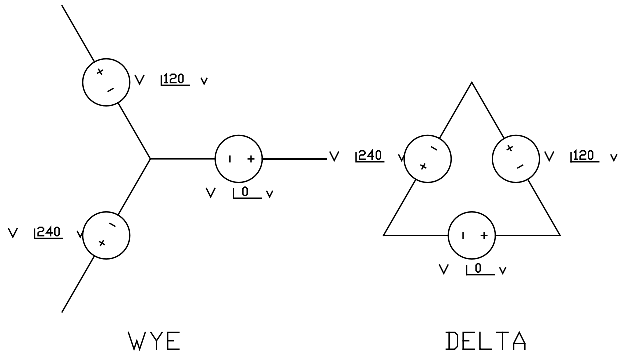

Fig. 1 Delta and wye configurations.

The neutral conductor is formed from the configuration of the utility's incoming three-phase transformer. The transformer can be configured in a delta or wye arrangement. The terms delta or wye come from the fact that the wye configuration looks like the letter Y and the delta configuration looks like the greek letter Δ. Fig. 1 shows how incoming power sources can be configured as a wye or a delta.

As shown in the figure, the center point of the wye connection can be physically accessed. This is the neutral point of the configuration. Note that there is no neutral point in the delta connection. The vast majority of three-phase distribution systems are tied together in a wye configuration.

With three-phase systems that are supplied by a wye configuration, there are two voltage magnitudes available. Looking at the figure, we see that there is a line to neutral voltage for each phase. This voltage is called the phase voltage or line-to-neutral voltage. To find the voltage magnitude across any two phases we apply Khirchoff's Voltage Law. Khirchoff's Voltage Law is based on the principle of conservation of energy and states that the sum of the voltages around a closed loop must equal zero. In a balanced system, the voltage magnitude across any two phases can be found from the magnitude of any phase voltage by multiplying the phase voltage by $\sqrt{3}$. Generally, loads are connected in a phase-to-phase configuration. This results in reduced cable sizes, due to the smaller levels of current demanded, and helps to ensure a balanced system.

Since single-phase power distribution systems have fairly straightforward design criteria, they are generally less complex. As a result, this article will emphasize the designs of three-phase power distribution systems.

Balanced and Unbalanced Systems

As we have already mentioned, the terms balanced and unbalanced describe the load that is on each phase relative to the other phases. In addition, these terms also describe the power supply. For a balanced system, all voltages must have identical magnitudes when measuring across any pair of phases. That is, the voltage vectors should have the same magnitude. Further, since the voltages are vectors, they must be evenly spaced by 120°. Refer to Fig. 1 to see how both delta- and wye-configured circuits are setup to be balanced.

Balanced loads are also preferred. Most three-phase loads are inherently balanced. For example, a three-phase motor has three independent sets of windings that are identical. Each of these windings is configured so that all three phases output the same mechanical power. As a result, the current delivered to each phase is approximately the same.

Unbalanced systems are those in which the supply is unbalanced and/or the loads are unbalanced. The vast majority of supplies are balanced. In addition, end users have no control over the supplies, so we will assume that if there is an unbalance, it is only because the loads are unbalanced. Loads can be connected to a wye-configured supply to access the phase-to-phase or phase-to-neutral voltage. In a delta configuration, only the phase-to-phase voltages are available. In either case, an unbalanced system occurs when all three phases do not have equal loading. To balance the load, simply reconnect the single-phase loads to the source so that they appear to carry the same load. Oftentimes, it is not possible to have a perfectly balanced system, but the power system designer should make all attempts to minimize the imbalance to within 10% of the loading on all phases.

In wye-configured systems, the unbalance results in the neutral voltage no longer being at 0 V. Since most wye-configured systems are grounded, a neutral current will flow through the ground. The higher the imbalance, the higher the neutral current flow will be. Transformers with primarily three-phase loads (most often medium voltage secondaries) have smaller neutral conductors than the phase conductors. Also, it is not unreasonable to use an uninsulated conductor to solidly tie the neutral of a three-phase system to a ground. Current through the neutral will cause a voltage to exist on the neutral, and improper operation may occur due to the uninsulated cable. Note that the grounding conductor is not the same as the neutral conductor for systems intending to supply single-phase loads. In the case of the system supplying single-phase loads, the neutral conductor must be insulated.

In delta-configured systems, the unbalance can be more troublesome. This is due to the fact that there is no neutral connection in which the unbalanced current can flow. The unbalanced current flow will actually travel within the delta causing the windings to heat up. This is an undesirable characteristic, as heating effects are occurring without any real work being accomplished. Furthermore, monitoring of unbalanced systems in a delta configuration is more difficult than in a wye configuration. The neutral connection of a wye configuration is generally readily accessible and monitored. Since the delta configuration has no neutral, a special configuration must be employed.

GENERAL SYSTEM DESIGN GUIDELINES

Grounding

Grounding is the most important factor when designing a facility's power distribution system. Good grounding results in high personnel safety, limits noise affects, and extends equipment life. Although grounding seems like a straightforward design consideration, there are a number of issues that make grounding somewhat of an art. In fact, there are numerous books and papers written on different grounding techniques and applications.

The key for grounding is to ensure safety of personnel. In ungrounded systems, an inadvertent ground will often go undetected. If personnel were to also inadvertently contact an ungrounded system with an inadvertent ground, they would provide a path to ground through their body and serious injury or death may result. By grounding the system, the first inadvertent ground is immediately detected and the system is usually taken offline automatically. This precludes personnel from any immediate danger. A very general rule of thumb to ensure proper grounding for personnel safety is to have numerous grounds. However, numerous grounds can result in multiple return paths and need to be evaluated, particularly when grounding the incoming service from the utility. Having numerous equipment grounds generally does not pose a problem, but they must be adequately sized so that faults can be cleared before the ground connections fail. National Fire Protection Agency (NFPA) Standard 70 (The National Electric Code) provides a table of required ground sizes based on the rating of the supply. Furthermore, the Institute of Electrical and Electronics Engineers (IEEE) provides Standard 142 (the Green Book), which contains many recommended grounding practices.

Numerous equipment grounds can introduce noise into the ground system. This is due to the fact that the ground system appears to be a closed loop permitting electromagnetic energy in the area to induce currents and voltages in the ground system. These induced currents and voltages create problems particularly for sensitive electronic equipment. To avoid induced currents and voltages in the ground system, use caution when closing the ground loop. Another option is to utilize an isolated ground for sensitive electronic equipment that is separate from the facility's power distribution system ground.

Grounding also provides protection against lightning phenomena. Much research has been done in the field to protect structures against lighting strikes. Detailed lightning protection is beyond the scope of this paper; however, interested readers may refer to NFPA 780 for recommendations.

Conductor Sizing

Cable and conductor sizing requires an understanding of the effects of current through a conductor. All materials will resist the flow of current through them. The term resistance describes the tendency to restrict to the current flow and is denoted in ohms (Ω). The higher the resistance, the harder the system must "work" to get current to flow. The work translates to power dissipation as heat. Clearly, a facility power distribution system's goal is low resistance to yield higher efficiencies.

The two most common conductors are copper and aluminum. These two are used due to their low resistivity (or high conductivity) and relatively low cost. Copper is more commonly used in insulated cables due to its lower resistance per unit area in addition to being more flexible. Aluminum conductors are more commonly used when the conductor is uninsulated as in the case of overhead cables on a utility pole line. In this case, the aluminum is reinforced with steel strands to increase its strength. Copper and aluminum are not always interchangeable. Due to a phenomenon called a galvanic reaction, copper to aluminum connections result in conductor corrosion. As a result, special terminators must be used when the two metals are to be interconnected.

Most heavier conductors utilize stranded conductors, i.e., they are made up of a number of smaller single strands. Stranding results in the improved flexibility of the conductor. Additionally, stranding also results in a lower overall AC resistance as opposed to a conductor made of a single strand with the same area. This is a result of a phenomenon called the skin effect. Extra flexible cable, sometimes called weld or locomotive cable, is used when specialty applications arise.

The amount of expected current to be delivered to a load helps to determine which cable size to use. The rule generally goes the higher the current, the larger the cable. In the United States, cables are sized using the American Wire Gauge (AWG). Typical power cable sizes in commercial or industrial facilities run from #12AWG to 750 thousands of circular mils (MCM). In addition to the current through the conductor, the ability to dissipate heat also dictates the conductor's size. For example, if many conductors are packed in close proximity to each other they will contribute to localized heating, increasing the ambient temperatures. In addition, conductors in air exhibit better cooling than those that are routed in raceway due to convection cooling. As a result, where the cable is routed must be taken into account when determining the required cable size.

For large loads, 750 MCM cable may not be sufficient. Options include utilizing a copper or aluminum bus as opposed to using cable or routing multiple conductors per phase. It is more common to use multiple conductors per phase due to the flexibility of the cable. There are a few concerns when using multiple conductors per phase. First, all the conductors must be the same guage and material (i.e., they must all be 500 MCM copper). Secondly, the corresponding number of conductors from the other phases must be routed in the same raceway. This is due to the fact the currents will be induced in the raceway unless the magnetic fields resulting from the current flow are cancelled out.

Additionally, the phase conductors have an insulation covering to prevent faults to ground. The heat generated in the conductor as a result of current flow must be dissipated through the insulation to the surrounding environment. This results in the conductor insulation being at a higher temperature than ambient. The heating effect results in reduced insulation life. As a result, manufacturers have developed various types of conductor insulation that can handle different temperatures. The conductors' insulation is typically rated for temperatures 60, 75, 90, or 105°C above an ambient temperature of 40°C. However, the power system designer must use caution when specifying insulation for a 90 or 105°C rise since many terminals of the end equipment are only rated for a 75°C increase.

Voltage Levels

A key design consideration in designing a facility power system is the voltage level employed at the facility. Newer industrial facility power distribution systems typically employ three-phase, 480 V incoming supplies while commercial facilities typically employ three-phase, 208 V or single-phase, 240/120 V. In either case, these systems are termed low voltage systems. In fact, voltage levels below 1000 V are considered low voltage systems. Some large industrial facilities may utilize medium voltage levels. A typical medium voltage used in industrial facilities is 4160 V, but may go as high as 13.8 kV. Higher medium voltage systems exist but are rarely found in industrial facilities. These higher voltages are typically found at generating facilities.

For industrial facilities, the items that dictate the necessary voltage levels are the output horsepower ratings of the motors in use at the facility. The greater the output ratings of the motors, the greater the current requirements are, which result in larger conductor sizes. Current industry practice is to specify motors up to about 3/4 HP as single-phase, 240 V motors, although single-phase, 240 V motors are available to about 10 HP. Motors that are greater than 3/4 HP, but less than either 250 or 350 HP are typically specified as three-phase, 480 V motors. Motors above 250 or 350 HP are usually specified as medium voltage motors.

SYSTEM PROTECTION

General Design Guidelines

Inevitably, all facility power distributions will experience faults. However, in a well designed system, equipment damage can be limited. Also, the location of the fault can be quickly located and repaired. Furthermore, isolation of some of the faults will allow the facility to continue to operate while the fault is being repaired.

In a poorly designed facility power distribution system, large portions of the facility will have to be taken off-line while a fault is repaired. Also, it may be very difficult to determine where the fault occurred. Furthermore, significant equipment damage is more likely in a poorly designed system, resulting in a long shutdown of the facility's power distribution system.

It is the responsibility of the power system's design engineer to determine the necessary system requirements. For example, a facility working with benign chemicals and relatively low temperatures may be willing to have a very simple power distribution system. On the other hand, a nuclear plant requires multiple layers of redundancy with complex switching schemes. This latter system would be very expensive, but the expense is required to ensure overall facility safety.

Power system protection has two separate concerns. The first is to detect a fault and the second is to isolate the fault. Fault detection depends upon the fault type. Isolation of the fault not only depends on the fault type but also on the severity of the fault.

Power System Faults

When we mention faults on a power system we are usually talking about short circuits. A short circuit occurs when a relatively low impedance path back to the source occurs. A low impedance path allows for current levels larger than the facility was designed for. The two most common types of short circuits are the single-line to ground fault and the three-phase fault. The single-line to ground fault is characterized by a single phase being subjected to a path to ground that is not anticipated. The three-phase fault is when all three phases are tied together with a low resistance.

The detection of faults is usually accomplished by seeing a larger than anticipated current in any phase or neutral of the conductor. The anticipated current can vary depending upon what is occurring in the system. For example, a motor starting and a transformer energizing result in very large but momentary currents, typically called inrush currents. This current is anticipated and the facility's power distribution system should be able to handle this current level without fault clearing. If these high levels of current are sustained, that is they are not momentary, then the protection system needs to react. Inrush levels of current exist for a few milliseconds for transformers or for a few milliseconds up to a minute depending upon the mechanical load connected to a motor. If the current is above these momentary levels, then a fault has likely occurred. Also, if the current is above the momentary levels for a longer than anticipated time, its likely that the motor has jammed. In either case, the primary difference between the jam and the fault condition is that the system reacts in a short time for sustained currents at the inrush level that exist longer than anticipated or trips instantaneously for currents above the inrush level. As a result, many facility distribution protection systems are equipped with devices that monitor and isolate systems under the instantaneous and short-time conditions.

In addition to the two conditions previously described, equipment failures may occur that are not immediately catastrophic but will be catastrophic to equipment if they are allowed to fester. However, if temporary overload operation of equipment that does not damage the equipment frequently occurs, the power distribution system must be able to identify when an overload has occurred versus when a fault has occurred. This operation allows for an above-normal current for a long time before tripping and is referred to as a long-time condition.

Another area of concern is that not all faults experience low-resistance faults. In the case of high-resistance faults, monitoring can be extremely challenging. However, most high-impedance faults will eventually switch to a low-impedance fault due to the destructive nature of the current. As a result, it is generally not a concern to have the additional detection devices for high-impedance faults.

Ground Fault Detection Methods

In most three-phase power distribution systems, neutral current is almost zero since the system is balanced. As a result, we can use the neutral current to detect minimal changes when an unanticipated unbalance occurs. This is typically denoted as ground fault protection. Ground fault protection can be accomplished directly by monitoring the current traveling through the neutral. Another option to monitor for a ground fault is to apply monitoring around all three of the phase conductors. If the current is balanced, no current is induced in the monitoring system. In an unbalanced situation, some residual current does not return through the three phases and is detected in the monitoring system. This is called a residual configuration. Ground fault protection is frequently used to detect when a single-line to ground fault occurs.

FAULT CURRENT

Fault Current Support

One key concept that is often misunderstood is that a sufficient fault current must exist to ensure mechanical device tripping. Whenever a fault occurs, voltage on the faulted phases tends to decrease. If the supply is weak, the voltage drop may be so significant that the fault current drops to a level below the protection of a system trip. In fact, a typical specification for on-site generation is to be able to provide 300% of the normal full load current for at least 10 s to allow a sufficient fault current to trip devices.

Fault Current Energy Sources and Levels

Due to the nature of faults, fault currents derive their energy not only from the power sources but also from rotating machines. Rotating machines operate on the principle of generating an internal voltage proportional to the mechanical load to limit the current flowing into the motor. This internal voltage is generated from the rotation of magnetic fields within the machine. When a fault occurs, the machine's terminal voltage typically goes to zero volts and the internal voltage source provides the fault current. In some machines, the fault current is only available for the first few electrical cycles (called a subtransient period). Other machines have several fields which allow for a fault current flow after the first few cycles. This is called the transient period and can last for up to 30 electrical cycles. Finally, machines that are operating as generators have external prime movers and voltage sources providing the necessary energy to provide fault current indefinitely. This period is called the steady-state.

All three currents can exist simultaneously. That is, the subtransient, transient, and steady-state fault currents exist immediately after the fault occurs. After two or three electrical cycles, the subtransient fault current decays away due to the rapid release of energy and only the transient and steady-state currents remain. After approximately 30 cycles, the transient fault current decays away leaving only the steady-state fault current. As a result, the magnitude of the current is greatest immediately after the fault has occurred and then decays to the constant steady-state level.

Fault Current Interrupting Devices

One of the properties associated with current flow is that a force is induced when current flows. The rule generally goes the greater the current, the greater the force. For proper protection, the system must be able to isolate faults by opening protective devices. Opening of these devices is accomplished with mechanical force. The mechanical force to open the device must be larger than the mechanical force that is induced from the fault current. As a result, protective devices are rated for a fault current rating as well as a continuous current rating. The continuous current rating is what the protective device can handle indefinitely without premature failure.

When a fault occurs, the protective device must be able to withstand the initial subtransient, plus transient, plus steady-state, currents. It is not required to interrupt this initial current surge as most protective devices cannot operate fast enough to detect the fault and then operate to interrupt the fault. In fact, many protective devices are rated for 3-cycle or 5-cycle operation which indicates the amount of time it takes for the device to operate.

For fuse-type protective devices, fault interruption is typically accomplished by a metallic element that melts due to the excessive heating caused by the large current flow. As a result, fuses can operate extremely fast. In fact, fuses are often used to provide a current limiting capability. The practice of current limiting introduces a resistance in line (in series) with the fault, thereby limiting its magnitude. Typically, current limiting fuses operate to limit the fault current within one-fourth of the electrical cycle. Current limiting fuses are often used in series with other protective devices that are not rated for as large a fault current interrupting capability as required. This frequently used technique is called series rating. However, NFPA 70 does not permit series rating unless the two protective devices in series have been properly tested and are UL listed for series rating. Current limiting fuses can have fault current interrupting capabilities to a fault current level of 200,000 Amps. Frequently, power system engineers utilize current limiting fuses to reduce fault current levels to more manageable levels. Another advantage of fuses is that they are relatively inexpensive.

There are several major disadvantages to utilizing fuses as protective devices. One disadvantage is that in the event that only one or two of the phases experiences a fault, only one or two of the fuses will operate. When this occurs, the supply source becomes unbalanced and the load is said to be "single-phasing." This situation can lead to equipment damage. As a result, fuse manufacturers have built devices that detect when one fuse has operated and then causes the remaining fuses to operate. Another disadvantage is that when a fuse operates, it can no longer be used. Although repeated faults are not expected under normal operation, repeated faults may occur particularly when a facility startup is occurring. This would require a large quantity of spare fuses which may not be desirable.

Another disadvantage is that fuse characteristics cannot be changed for a specific fuse. As a result, if different characteristics are desired, new fuses must be installed. In an industrial facility, it would not be uncommon to have many different protection requirements thereby requiring a large number of different fuses.

A fourth disadvantage, and the most significant, is that there is no way to remotely operate the fuses. That is, an operator must be physically at the switch that contains the fuses to either open or close the circuit supplying the load. Remote operation is frequently referred to as electrical operation as there is an electrical operator that interfaces with the device to open and close circuits. For loads that are always operating, remote operation isn't usually a requirement. However, many facility loads are cycled on and off and utilizing human operators to operate the protective devices is not practical.

Circuit Breakers and Contactors

Circuit breakers and contractors are two common devices that are utilized to allow remote operation. Not all circuit breakers are required to have remote operation capabilities. In fact, the design of circuit breakers is such that they will only operate sporadically. Usually, their operation is the result of a fault where special monitoring is required. Some of these breakers are only equipped with a shunt trip capability which only allows for breaker tripping. Contactors, on the other hand, are designed for repeated opening and closing but are not designed to be able to interrupt large fault currents. In fact, contactors usually only occur in series with fuses that will actually interrupt the large fault currents. The operation of the contactors during large fault currents is inhibited.

FAULT CURRENT COORDINATION

In many facility power distribution systems, it is very common to have a single main power distribution center. Smaller distribution systems that are fed from the main power distribution center are located throughout the facility for the purpose of concentrated power distribution. To limit the effect on the overall facility, a power system's designer should configure the system so that fault currents result in the minimum amount of service disruption. In order to accomplish this, upstream protective devices must coordinate their tripping characteristics with downstream devices. This is called protective device coordination and is accomplished by evaluating-time versus-current characteristic curves. A simple coordination curve is show in Fig. 2.

As shown on the curve, the *X*-axis is in amperes and the *Y*-axis is in seconds. For proper device coordination, the device closest to the fault should trip first. If the fault is upstream then the next closest device should trip. As a result, the trip curves for each protective device must be configured so that the device furthest downstream trips first and then progresses to the largest device. Relaying this to the curve requires that the trip curves progress from left to right for the farthest downstream device to the highest-level device.

In addition to protective device trip characteristics, coordination curves also contain motor starting characteristics and transformer inrush currents. These are shown so that devices are allowed to startup and run normally. In addition, cable melting times are shown. This is done to ensure that cables that supply current to the fault are not significantly damaged.

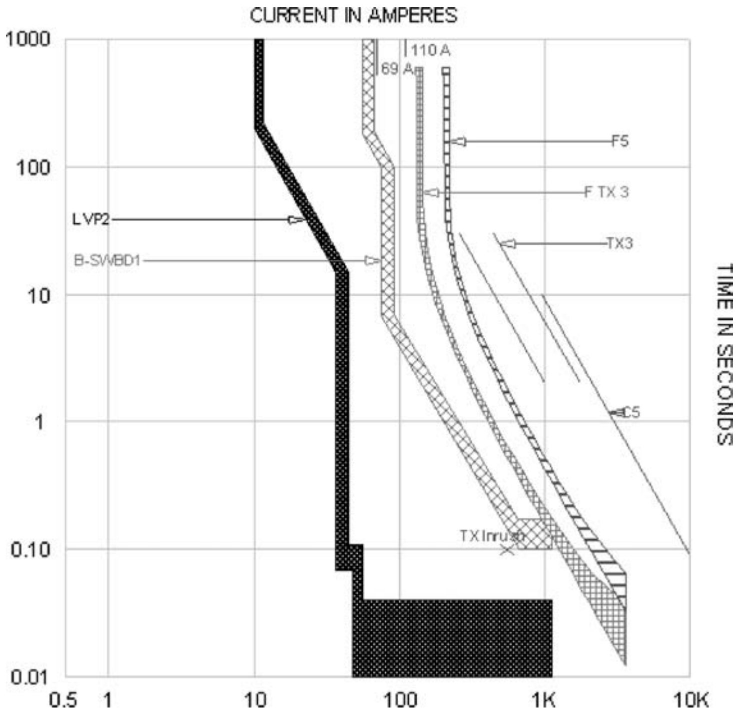

Fig. 2 Coordination curve.

OTHER FACILITY CONSIDERATIONS

Transformer Ratings

Specifying transformer parameters is another key concern for power system designers. The most important parameter is to specify the correct turns ratios so that proper levels are achieved. Typically, the designer will include transformer taps that can be adjusted when the transformer is de-energized. These taps allow periodic changes in supply voltages or loads and still provide approximate nominal voltages.

Another important parameter to specify is the continuous power rating of the transformer. The power system designer has to know the expected load of the facility as well as the anticipated growth of the facility load. If spurious conditions result in large load increases, transformers can be equipped with fan banks to increase their nominal ratings. In addition, the designer can specify a nominal power rating at a lower temperature rise than what the transformer insulation can handle. Then, when an overload is required, the transformer can continue to operate at a higher temperature rise without the insulation being damaged.

The other major concern for the power system designer is specifying the transformer characteristic impedance (normally called %Z). This value helps to determine the efficiency of the transformer. It also affects the fault current through a system. Typical transformer %Z values range from 2.25 to 5.75%. Transformer characteristic impedances are of large concern for facilities with generation capability. This is due to the fact that utilities require voltage support and may require the facility to reduce their generation to meet interconnection requirements. The transformer characteristic impedance consumes the magnetic energy that supports the voltage. Furthermore, large characteristic impedances cause large voltage drops in the system when high current demands exist. This may result in the misoperation of certain equipment due to the low voltage.

Direct Current Systems

Direct current systems are used in some facilities for critical or life-safety systems. Direct current power is readily available from batteries. As a result, when incoming utility power is lost, the batteries can support essential systems for a limited time. Direct current systems are so vital to the plant that they are permitted to be ungrounded to ensure their continued operation. However, even though these systems are ungrounded, ground detection systems are usually provided to indicate that a ground has occurred. This perpetuates the concept of maintaining personnel safety.

Variable Frequency or Variable Speed Drives

In older processes, many inefficient designs existed. This was acceptable since energy costs were relatively low and there was little equipment available to enhance system efficiency. However, the proliferation of variable frequency or variable speed drives has enhanced system efficiency. These drives operate by either adjusting the frequency or voltage of the power supply source. A major disadvantage of these drives is that they tend to create a non-sinusoidal output waveform. This results in harmonics that can cause equipment damage. Newer drive topologies utilize a higher number of pulses to create a more sinusoidal output waveform. Some drives still require isolation transformers to keep the harmonics from traveling back to the supply and negatively affecting the system.

Power Factor

Industrial facilities frequently have a poor power factor. The power factor determines the ratio of real power consumed to the total supplied power. A portion of the supplied power is considered "imaginary" in that it does no real work but is necessary for proper device operation. Generally, utilities require industrial facilities to have at least a 0.9 lagging power factor. The lagging term simply indicates that the industrial facility is receiving imaginary power, as opposed to supplying imaginary power (leading). If the facility's power factor is below 0.9 lagging, then the utility will charge a power factor penalty to the industrial facility. In the case where a poor power factor exists at a facility, power factor correction capacitors are specified for a facility. In fact, a common option when purchasing contactors for motor control is to include power factor correction capacitors since motors are the most frequent cause of poor power factors.

CONCLUSION

This paper has discussed the key items for consideration when designing and operating a facility's power system. It has attempted to give the reader a brief technical background of each of these items. while emphasizing the importance that safety plays in the design of a system. Although continued operation is desired, it is not more important than personnel safety. By taking into consideration the concepts discussed in this article, the reader should have a basic understanding of the items involved in designing a facility's power system.

Abstract

The Federal Energy Management Program's (FEMP'S) Operations and Maintenance Best Practices Guide (O&M BPG) highlights O&M programs targeting energy efficiency, which are estimated to save 5%–20% on energy bills without a significant capital investment. Depending on the federal site, these savings can represent thousands to hundreds of thousands of dollars each year, and many can be achieved with minimal cash outlays. In addition to energy/resource savings, a well-run O&M program will:

- Increase the safety of all staff because properly maintained equipment is safer equipment.
- Ensure the comfort, health, and safety of building occupants through properly functioning equipment, providing a healthy indoor environment.
- Confirm the design life expectancy of equipment.
- Facilitate compliance with federal legislation such as the *clean air act* and the *clean water act*.

The focus of this guide is to provide the federal O&M/energy manager and practitioner with information and actions aimed at achieving these savings and benefits. The O&M BPG was developed under the direction of the Department of Energy's Federal Energy Management Program.

GUIDE DESIGN AND LAYOUT

The guide currently consists of 11 chapters. Chapter 1 provides an introduction and an overview. Chapter 2 provides the rationale for "Why O&M?" Chapter 3 discusses O&M management issues and their importance. Chapter 4 examines computerized maintenance management systems (CMMS) and their role in an effective O&M program. Chapter 5 looks at the different types of maintenance programs and definitions. Chapter 6 focuses on maintenance technologies, particularly the most accepted predictive technologies. Chapter 7 discusses the process of building commissioning, particularly as it applies to existing buildings. Chapter 8 highlights the importance of metering and its role in O&M. Chapter 9 explores O&M procedures for the predominant equipment found at most federal facilities. Chapter 10 describes some of the promising O&M technologies and tools on the horizon to increase O&M efficiency, and Chapter 11 provides 10 steps to initiating an *operational efficiency* program.

The O&M environment is in a constant state of evolution, and the technologies and vocabularies are ever-expanding. Therefore, the guide contains a glossary of terms in Appendix A. Appendix B provides a list of federal contacts for training and assistance. Appendix C includes a list of organizations and trade groups that have interest or are related to O&M. And finally, Appendix D is a form that can be used to submit suggestions or revisions to the guide.

The goal of this article is to provide an overview of the O&M BPG—how and why it was developed—and to present in highlight form some of its sections. Each highlighted section will be referenced in parentheses in this article's section title.

INTRODUCTION (CHAPTER 1)

Effective O&M is one of the most cost-effective methods for ensuring reliability, safety, and energy efficiency. Inadequate maintenance of energy using systems is a major cause of energy waste in both the federal government and the private sector. Energy losses from steam, water and air leaks, uninsulated lines, maladjusted

Keywords: Operations; Maintenance; Efficiency; Metering; Commissioning; Preventive; Predictive; Reactive.

or inoperable controls, and other losses from poor maintenance are often considerable. Good maintenance practices can generate substantial energy savings and should be considered a resource. Moreover, improvements to facility maintenance programs can often be accomplished immediately and at a relatively low cost.

The purpose of the O&M BPG is to provide the operation and maintenance/energy manager and practitioner with useful information about O&M management, technologies, and cost-reduction approaches. To make this guide useful and to reflect the facility manager's needs and concerns, the authors met with O&M and energy managers via federal energy management program (FEMP) workshops. In addition, the authors conducted extensive literature searches and contacted numerous vendors and industry experts. The information and case studies that appear in the guide resulted from these activities.

It needs to be stated at the outset that the guide is designed to provide information on effective O&M as it applies to systems and equipment typically found at federal facilities. The guide "is not" designed to provide the reader with step-by-step procedures for performing O&M on any specific piece of equipment. Rather, the guide first directs the user to the manufacturer's specifications and recommendations. In no way should the recommendations in the guide be used in place of manufacturer's recommendations. The recommendations in the guide are designed to supplement those of the manufacturer, or, as is all too often the case, provide guidance for systems and equipment for which all technical documentation has been lost.

WHY O&M? (CHAPTER 2)

Definitions

Operations and maintenance. Decisions and actions regarding the control and upkeep of property and equipment is inclusive but not limited to the following: actions focused on scheduling, procedures, and work/systems control and optimization, and performance of routine, preventive, predictive, scheduled and unscheduled actions aimed at preventing equipment failure or decline with the goal of increasing efficiency, reliability, and safety.

Operational efficiency. It represents the life cycle cost-effective mix of preventive, predictive, and reliability centered maintenance technologies, coupled with equipment calibration, tracking, and computerized maintenance management capabilities, all targeting reliability, safety, occupant comfort, and system efficiency.

O&M Potential, Energy Savings, and Beyond

It has been estimated that O&M programs targeting energy efficiency can save between 5 and 20% on energy bills without a significant capital investment.[1] From small to large sites, these savings can represent thousands to hundreds of thousands of dollars each year, and many can be achieved with minimal cash outlays. Beyond the potential for significant cost and energy/resource savings, an O&M program operating at its peak "operational efficiency" has other important implications:

- A well-functioning O&M program is a safe O&M program. Equipment is maintained properly, mitigating any potential hazard arising from deferred maintenance.
- In most federal buildings, the O&M staff are responsible for not only the comfort, but also the health and safety of the occupants. Indoor air quality (IAQ) issues within these buildings are of increasing productivity (and legal) concern. Proper O&M reduces the risks associated with development of dangerous and costly IAQ situations.
- Properly performed O&M helps ensure that the design life expectancy of equipment can be achieved, and in some cases, exceeded. Conversely, the costs associated with early equipment failure are usually not budgeted for, and often come at the expense of other planned activities.
- An effective O&M program aids in a facility's compliance with federal legislation, such as the *clean air act* and the *clean water act*.
- A well functioning O&M program is not always reactive (answering complaints); rather, it is proactive in its response, and corrects situations before they become problems. This model minimizes callbacks and keeps occupants satisfied while allowing more time for scheduled maintenance.

O&M MANAGEMENT (CHAPTER 3)

O&M management is a critical component of the overall program. The management function should bind the distinct parts of the program into a cohesive entity. From our experience, the overall program should contain five very distinct functions making up the organization[2]: Operations, Maintenance, Engineering, Training, and Administration—OMETA.

Beyond establishing and facilitating the OMETA links, O&M managers have the responsibility of interfacing with other department managers and making their case against ever-shrinking budgets. Their roles also include project implementation functions, as well as the need to maintain the program and its goals.

Developing the Structure

Five well-defined elements of an effective O&M program include those presented above in the OMETA concept.[2]

While these elements (operations, maintenance, engineering, training, and administration) form the basis for a solid O&M organization, the key lies in the well-defined functions each brings and the linkages between organizations. A subset of the roles and responsibilities for each of the elements is presented in the guide; further information is found in Meador.[2]

Obtain Management Support

Federal O&M managers need to obtain full support from their management structure to carry out an effective maintenance program. A good way to start is by establishing a written maintenance plan and obtaining upper management approval. Such a management-supported program is very important because it allows necessary activities to be scheduled with the same priority as other management actions. Approaching O&M by equating it with increased productivity, energy efficiency, safety, and customer satisfaction are ways to gain management attention and support.

Measuring the Quality of your O&M Program

Traditional thinking in the O&M field focused on a single metric, reliability, for program evaluation. Every O&M manager wants a reliable facility; however, this metric alone is not enough to evaluate or build a successful O&M program.

Beyond reliability, O&M managers need to be responsible for controlling costs, evaluating and implementing new technologies, tracking and reporting on health and safety issues, and expanding their program. To support these activities, the O&M manager must be aware of various indicators that can be used to measure the quality or effectiveness of the O&M program. Not only are these metrics useful in assessing effectiveness, but they are also useful in the justification of costs for equipment purchases, program modifications, and staff hiring.

Below are a number of metrics that can be used to evaluate an O&M program. Not all of these metrics can be used in all situations; however, a program should use as many metrics as possible to better define deficiencies and, most importantly, publicize successes. The O&M BPG describes each of these metrics in detail.

- Capacity factor
- Work orders generated/closed
- Backlog of corrective maintenance
- Safety record
- Energy use
- Inventory
- Overtime worked
- Environmental record
- Absentee rate
- Staff turnover.

Selling O&M to Management

To successfully interest the management in O&M activities, O&M managers need to be fluent in the language spoken by management. Projects and proposals brought forth to management need to stand on their own merits and be competitive with other funding requests. While evaluation criteria may differ, generally some level of economic criteria will be used. O&M managers need to have a working knowledge of economic metrics such as:

- *Simple payback*—The ratio of total installed cost to first-year savings.
- *Return on investment*—The ratio of the income or savings generated to the overall investment.
- *Net present value*—The present worth of future cash flows minus the initial cost of the project.
- *Life-cycle cost*—The present worth of all costs associated with a project.

Program Implementation

Developing or enhancing an O&M program requires patience and persistence. Guidelines for initiating a new O&M program will vary by agency and management situation; however, some steps to consider are presented below:

- *Start small*—Choose a project that is manageable and can be completed in a short period of time, 6 months to 1 year.
- *Select troubled equipment*—Choose a project that has visibility because of a problematic history.
- *Minimize risk*—Choose a project that will provide immediate and positive results. This project needs to be successful, and therefore, the risk of failure should be minimal.
- *Keep accurate records*—This project needs to stand on its own merits. Accurate, if not conservative, records are critical to compare before and after results.
- *Tout the success*—When you are successful, this needs to be shared with those involved and with management. Consider developing a "wall of accomplishment" and locate it in a place where management will take notice.
- *Build off this success*—Generate the success, acknowledge those involved, publicize it, and then request more money/time/resources for the next project.

O&M Contracting

Approximately 40 percent of all non-residential buildings contract maintenance service for heating, ventilation, and air conditioning (HVAC) equipment.[3] Discussions with federal building managers and organizations indicate that this value is significantly higher in the federal sector, and the trend is toward increased reliance on contracted services. The O&M BPG explores this trend further and offers guidance on O&M contracting.

COMPUTERIZED MAINTENANCE MANAGEMENT SYSTEMS (CHAPTER 4)

A computerized maintenance management system (CMMS) is a type of management software that performs functions in support of management and tracking of O&M activities. CMMS systems automate most of the logistical functions performed by maintenance staff and management. CMMS systems come with many options and have many advantages over manual maintenance tracking systems. The O&M BPG presents the major capabilities, benefits, and potential pitfalls of CMMS.

TYPES OF MAINTENANCE PROGRAMS (CHAPTER 5)

What is maintenance and why is it performed? Past and current maintenance practices in both the private and government sectors would imply that maintenance is the actions associated with equipment repair after it is broken. The dictionary defines maintenance as follows: "The work of keeping something in proper condition; upkeep." This would imply that maintenance is actions taken to prevent a device or component from failing or to repair normal equipment degradation experienced with the operation of the device to keep it in proper working order. Unfortunately, data obtained in many studies over the past decade indicate that most private and government facilities do not expend the necessary resources to maintain equipment in proper working order. Rather, they wait for equipment failure to occur and then take whatever actions are necessary to repair or replace the equipment. Nothing lasts forever, and all equipment has some predefined life expectancy or operational life. For example, equipment may be designed to operate at full design load for 5000 h and may be designed to go through 15,000 start and stop cycles.

The design life of most equipment requires periodic maintenance. Belts need adjustment, alignment needs to be maintained, proper lubrication on rotating equipment is required, and so on. In some cases, certain components need replacement (e.g., a wheel bearing on a motor vehicle) to ensure the main piece of equipment (in this case a car) lasts for its design life. Anytime maintenance activities intended by the equipment's designer are not performed, we shorten the operating life of the equipment. But what options do we have? Over the last 30 years, different approaches to how maintenance can be performed to ensure, equipment reaches or exceeds its design life, have been developed in the United States. In addition to waiting for a piece of equipment to fail (reactive maintenance), we can utilize preventive maintenance, predictive maintenance, or reliability centered maintenance.

Chapter 5 of the O&M BPG provides a detailed description of each major maintenance program type (reactive, preventive, predictive, and reliability centered), including each program's advantages and disadvantages.

PREDICTIVE MAINTENANCE TECHNOLOGIES (CHAPTER 6)

Predictive maintenance attempts to detect the onset of a degradation mechanism with the goal of correcting that degradation prior to significant deterioration in the component or equipment.

The diagnostic capabilities of predictive maintenance technologies have increased in recent years with advances in sensor technologies. These advances, breakthroughs in component sensitivities, size reductions, and most importantly, costs have opened up an entirely new area of diagnostics to the O&M practitioner.

As with the introduction of any new technology, proper application and training is of critical importance. This is particularly true in the field of predictive maintenance technology, which has become increasingly sophisticated and technology driven. Most industry experts would agree (as well as most reputable equipment vendors) that this equipment should not be purchased for in-house use if there is not a serious commitment to proper implementation, operator training, and equipment upkeep. If such a commitment cannot be made, a site is well advised to seek other methods of program implementation,a preferable option may be to contract these services to an outside vendor and rely on their equipment and expertise.

Chapter 6 presents a detailed description and applications for predictive technologies including: thermography, oil analysis, ultrasonic analysis, vibration analysis, motor analysis, and performance trending.

COMMISSIONING EXISTING BUILDINGS (CHAPTER 7)

Commissioning of existing buildings is quickly becoming one of the most important topics in the building management arena. In general, commissioning is the process of ensuring that a building performs according to its design intent and its owner's and occupants' needs.[4] While additional research is needed to further pinpoint the costs and resulting benefits of commissioning new and existing buildings, numerous case studies have demonstrated resulting O&M-related energy efficiency improvements on the order of 5%–30% covering a wide range of building uses. Resulting simple payback periods are typically less than 2 years and often less than 0.5 years.

Definitions

There are a number of commissioning approaches that can be applied to building mechanical/electrical equipment and systems.

New building commissioning: New building commissioning (Cx) is a means to ensure through design reviews, functional testing, system documentation, and operator training that systems and equipment in new buildings are operating properly.

Re-commissioning: Re-commissioning (RCx), which is sometimes referred to as "retro-commissioning," is the practice of commissioning existing buildings—testing and adjusting the building systems to perform to satisfy the original design intent and/or optimize the systems to satisfy current operational needs. RCx relies on building and equipment documentation, along with functional testing to optimize performance.

Continual commissioning: Continual commissioning refers to a commissioning approach that is integrated into a facility's standard O&M program. As such, activities in support of the continual commissioning effort are completed on a regular basis, compared to recommissioning approaches that tend to be distinct events. By definition, continual commissioning works to ensure more stable building operations over time than the re-commissioning approaches.

Value re-commissioning: Value re-commissioning (VRCx) is the lowest cost option that focuses on the most common opportunities, ideally incorporating them into daily operating procedures. VRCx is the least comprehensive and requires the least specialized skillset. VRCx concentrates on the most common opportunities that typically carry the shortest payback periods. Therefore, VRCx is best applied in buildings where resources for structured re-commissioning or continual commissioning programs are not available. In addition to realizing highly cost-effective energy savings, tracking benefits (e.g., energy savings, cost savings, reduced occupant complaints) of VRCx activities can be helpful in developing justifications for funding requests of the more robust commissioning approaches.

Typical Findings from Existing Building Commissioning

Many case studies of existing building commissioning efforts have been published over the years. A review of case studies for multiple buildings published by Portland Energy Conservation, Inc. (PECI),[5] Texas A&M University,[6] Proceedings from National Building Commissioning Conferences, and FEMP Assessments of Load and Energy Reduction Techniques (ALERT) is useful in identifying measures most typically available in commercial building spaces. The most frequently cited measures/opportunities are:

- *Adjust reset temperatures and temperature settings*—settings are often adjusted over time based on personal preferences, to compensate for inadequate system operation, or to achieve energy savings. In addition, sensors require periodic recalibration.
- *Staging/sequencing of boilers, chillers, and air handling units*—equipment should be operated in the most efficient combination of chillers, boilers, and fans at varying load conditions.
- *Adjust and repair dampers and economizers*—malfunctioning or poorly tuned dampers (including seals, actuators, and linkages) and economizers result in (1) increased supply air fan energy in the closed position or require additional air heating and cooling when opened too much, (2) undesired building operating conditions due to lack of outside air, and (3) premature equipment degradation and replacement.
- *Modify control strategies for standard hours of operation*—motors, pumps, fans, and air handlers often operate on a 24/7 schedule even though not required by either the building tenants or the building operating plan.
- *Eliminate simultaneous heating and cooling*—heating and cooling systems for the same space can compete against each other due to improper set points.
- *Air and water distribution balancing and adjustments*—systems require rebalancing due to drift and changing building/workspace mission and/or tenant requirements.
- *Verify controls and control sequencing*—this includes enabling and re-enabling automatic controls for setpoints, weekends, and holidays. Verify that overrides are released.

The Commissioning Process

A four-step process for existing building commissioning is often recommended.[7]

Step 1: planning. The planning step includes developing and agreeing on the overall commissioning objectives and strategies, assembling the project team, and compiling and perusing building and equipment documentation. Examples of objectives could be a desire to optimize building operations to reduce operating costs, address complaints from occupants regarding air quality or comforts, create a model facility, and improve facility O&M including reducing emergency trouble calls. Regarding the commissioning team formation, considerations in forming the team could include contracted or in-house staff, level of effort required, desired and necessary qualifications, availability and use of resident knowledge, and available funding resources.

Step 2: Investigation. During this step the site assessment is completed, monitoring and functional test plans are developed and executed, test results are analyzed, a master list of deficiencies is compiled, and recommendations for improvements, including estimates of energy and cost savings, are generated and presented for consideration.

Step 3: Implementation. Accepted recommendations from the investigation step are put into place in the implementation step. Actions include making repairs and improvements, retesting and re-monitoring for results, fine-tuning improvements as needed, and revising estimated energy and cost savings.

Step 4: Hand-off and integration. Final documentation of the commissioning effort describing the process, individuals, systems information, and actions taken is developed in this step. Also developed is a plan for future commissioning efforts. Items addressed by the commissioning plan should include recommended procedures for specific building equipment, frequency of testing, analysis of results, periodic reporting, identification of key players, and budget requirements.

METERING FOR OPERATIONS AND MAINTENANCE (CHAPTER 8)

The Importance of Metering

Metering and sub-metering of energy and resource use is a critical component of a comprehensive O&M program. Metering for O&M and energy efficiency refers to the measurement of quantities of energy delivered (e.g., kilowatt-hours of electricity, cubic feet of natural gas, pounds of steam). Metering may also involve identifying times-of-use for the various energy sources, the instantaneous demand for energy, as well as identify energy use for a collection of buildings, individual buildings, rooms, or specific equipment (e.g., a boiler, chiller, or motor). With metering, you can:

- Monitor existing utility usage
- Verify utility bills
- Identify the best utility rate plans
- Measure, verify, and optimize equipment performance
- Isolate energy use and cost
- Measure, not estimate, tenant energy use
- Diagnose equipment and system operations
- Manage energy use.

Metering Applications

The uses for metered data vary from site-to-site and while not all sites have the same uses, some of the more common applications are presented below.[8]

- *Data recording*. Advanced meters can duplicate the conventional metering function of recording total consumption, plus offer enhanced functions such as time-of-use, peak demand, load survey, and power outage recording. For electric metering, advanced meters may also include recording of other electric characteristics, such as voltage, current, and power factor.
- *Total consumption*. This is the most basic data recording function, which duplicates the standard kilowatt-hour of electricity (kWh), hundred cubic feet volume (CCF) of gas, or gallons (gal) of water consumed between meter readings.
- *Time-of-use metering*. Different rates can be charged for on-peak and off-peak time periods by accumulating the total consumption during operator-defined time windows. The time windows may vary during both time of day and weekday/weekend/holiday.
- *Peak demand metering*. Billing of many larger commercial and industrial customers is based on total consumption and the highest 15-, 30-, or 60-minute demand during the billing period. The peak demand may be reported as a single highest value, highest four values, or highest value during each hour (all peak demand values must be accompanied by an associated time stamp).
- *Load survey (profile or time-series data)*. Energy consumption and conservation impact studies, as well as more complex analysis of system loading, require more detailed demand data. A load survey provides periodic consumption or demand data (in time increments of 1, 5, 15, 30, or 60 min).
- *Monitoring and control*. A two-way communication link between a central station and customer site provides the opportunity for integrating some other utility functions into the metering functions. Meters can be programmed to detect and report by exception (e.g., report only when a fault is detected) for power outage, leak detection, and tamper detection. The meter can also dispatch control functions, such as remote service disconnect/reconnect, demand-side management (DSM) load control, and load scheduling.
- *Load control*. Load control includes DSM control functions such as air conditioner and water heater load-shedding. The DSM load control could be triggered by a fixed algorithm operating independently or real-time central station control.
- *Load scheduling*. This includes scheduled start and stop of equipment to minimize or shift load to take maximum advantage of the demand and time-of-use billing rate structures.
- *Leak detection*. Continuous monitoring of gas or water usage can be used to detect leaks.

Steps in Meter Planning

The development of a federal metering program is highly dependant on a site's needs, existing metering equipment, and available infrastructure. When it comes to metering, *one size does not fit all*. Below are some very general guidelines identifying the steps and actions necessary for a quality metering program. These guidelines summarize information found in AEC;[9] EPRI;[10] and Sydlowski,[8] where more detailed information can be found.

- Formalize objectives and goals of metering program
  - —Identify and confirm goals of stakeholders/users
  - —Prioritize goals as near-term, mid-term, and long-term
  - —Formalize necessary/expected outcomes
- Develop program structure. Identify data needs, equipment needs, analysis methodologies, and responsible staff.
  - —Develop data and analysis needs based on necessary outcomes
  - —Develop equipment needs based on data needs
  - —Take advantage of existing infrastructure
  - —Identify responsible staff, preferably a metering "champion"
- Develop criteria for evaluating metering costs, benefits, and impacts to existing systems, infrastructure, and staff.
  - —Determine relative economics of proposal
  - —Justify with cost/benefit, return on investment, or payback metric
- Develop a prioritized implementation plan targeting manageable successes
  - —Screen opportunities based on success potential
  - —Start small/manageable—build off success
- Develop a sustainable plan targeting use, updates, calibration, maintenance, and program reinvestment.
  - —Maintain your investment
  - —Make this success visible
  - —Plan for future implementation/reinvestment.

O&M IDEAS FOR MAJOR EQUIPMENT TYPES (CHAPTER 9)

At the heart of all O&M lies the equipment. Across the federal sector, this equipment varies greatly in age, size, type, model, fuel used, condition, etc. While it is well beyond the scope of this guide to study all equipment types, we tried to focus our efforts on the more common types prevalent in the federal sector. The objectives of this chapter in the guide are:

- Present general equipment descriptions and operating principles for the major equipment types.
- Discuss the key maintenance components of that equipment.
- Highlight important safety issues.
- Point out cost and efficiency issues.
- Provide recommended general O&M activities in the form of checklists.
- Where possible, provide case studies.

The major equipment types covered in Chapter 9 include boilers, steam traps, chillers, cooling towers, energy management/building automation systems, pumps, fans, motors, air compressors, and lighting. At the end of each section in Chapter 9, a checklist of suggested O&M activities is provided. These checklists are not presented to replace activities specifically recommended by equipment vendors or manufacturers. In most cases, these checklists represent industry standard best practices for the given equipment. They are presented here to supplement existing O&M procedures, or to serve as reminders of activities that should be taking place.

O&M FRONTIERS (CHAPTER 10)

As old a topic as O&M is, there are a number of new technologies and tools targeting the increased efficiency of O&M. As with most new technology introduction, these tools are in various stages of commercialization; for up-to-date information on each tool contact information is provided. This chapter serves to highlight some of the more promising technologies targeting improved O&M and efficiency.

TEN STEPS TO *OPERATIONAL EFFICIENCY* (CHAPTER 11)

As defined, operational efficiency is the life-cycle, cost-effective mix of preventive, predictive, and reliability-centered maintenance technologies, coupled with equipment calibration, tracking, and computerized maintenance management capabilities, all targeting reliability, safety, occupant comfort, and system efficiency. Chapter 11 presents 10 simple steps to begin the path toward improved O&M and ultimately *operational efficiency*.

APPENDIXES

Four appendixes are provided in the O&M BPG. These are: Appendix A, a glossary of common terms; Appendix B, the FEMP staff contact list; Appendix C, a variety of O&M resources including relevant trade organizations and web sites; and Appendix D, a form to submit offering suggestions for the next version of the O&M BPG.

CONCLUSIONS

As FEMP's O&M program has matured, the O&M BPG has provided valuable guidance to federal building managers, O&M program managers, and building operations staffs. This guidance provides a starting point for establishing clear objectives and understanding benefits. It also can be used to (1) establish an effective long-range plan that involves all O&M-related staff functions, (2) measure existing program performance, (3) review and upgrade existing practices, and (4) plan for the future. This guide continues to assist federal building managers in realizing significant cost-effective energy savings and improved occupant satisfaction.

Fossil Fuel Combustion: Air Pollution and Global Warming☆

Dan Golomb
Department of Environmental, Earth and Atmospheric Sciences, University of Massachusetts—Lowell, Lowell, Massachusetts, U.S.A.

Abstract
Currently, fossil fuels supply about 86% of the global primary energy consumption for transportation, industrial, commercial and residential uses. Due to the combustion of fossil fuels, copious quantities of pollutants are emitted into the air, which impact the local, regional and global air quality. Regulatory agencies in most developed countries prescribe ambient standards (concentrations) for air pollutants at a level above which the pollutants could have an adverse impact on human health and the ecology. These agencies also prescribe emission standards for various industrial categories and for automobiles at a level that is considered safe for human health and the environment. The relationship between emissions and ambient concentrations is formulated by atmospheric models that take into account emission rates from various sources, transport by winds, dispersion by turbulence, and the removal processes of the pollutants by wet and dry deposition. It is technologically possible to significantly reduce the emissions of most pollutants by employing various pollution abatement technologies. The reduction of emissions of carbon dioxide, the major contributor to global warming, poses technological, economic, societal and political challenges of enormous magnitude.

INTRODUCTION

Currently, fossil fuels supply about 86% of global primary energy consumption (39% oil, 24% coal, and 23% natural gas), providing energy for transportation, electricity generation, and industrial, commercial and residential uses. The air emissions of fossil fuel combustion are transported by winds and dispersed by atmospheric turbulence, eventually falling or migrating to the surface of the earth or ocean at various rates. While in the atmosphere, pollutants cause considerable harmful effects on human health, animals, vegetation, structures, and aesthetics.

In recent decades, it has become evident that rising levels of atmospheric carbon dioxide (and other greenhouse gases) have already warmed the earth's surface slightly. It is predicted that, with continuous and increasing use of fossil fuels, the warming trend will increase. Most of the increase in carbon dioxide levels is a direct consequence of fossil fuel combustion.

The goal of this article is to describe the characteristics of fossil fuel-generated air pollutants, including carbon dioxide and other greenhouse gases, their transport and fate in the atmosphere, and their effects on human health, the environment, and global climate change.

AMBIENT AND EMISSION STANDARDS OF AIR POLLUTANTS

Air pollutants, when they exceed certain concentrations, can cause acute or chronic diseases in humans, animals, and plants. They can impair visibility, cause climatic changes, and damage materials and structures. Regulatory agencies in most developed countries prescribe ambient standards (concentrations) for air pollutants. The standards are set at a level below which it is estimated that no harmful effect will ensue to human health and the environment. On the other hand, if the standards are exceeded, increased human mortality and morbidity, as well as environmental degradation, is expected. For example, in the United States, the Environmental Protection Agency (EPA) sets National Ambient Air Quality Standards (NAAQS) for six pollutants, the so-called criteria pollutants: carbon monoxide (CO), nitrogen dioxide (NO_2), ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), and lead (Pb). The standards are listed in Table 1. In the past, particulate matter was regulated regardless of size (the so-called Total Suspended Particles, TSP). Starting in 1978, particles were regulated with an aerodynamic diameter less than 10 μm. This is called PM_{10}. In 1997, a new standard was introduced for particles with an aerodynamic diameter less than 2.5 μm. This is called $PM_{2.5}$. The reason for regulating only small particles is that these particles can be

Stille, Eds.; Geological Society, Special Publications: London, 236, 2004. with permission from the Geological Society.

Keywords: Air pollution; Dry deposition; Fossil fuels; Global warming; Pollutant transport and dispersion; Pollution abatement; Wet deposition.

Table 1 U.S. 2000 National ambient air quality standards (NAAQS)

Pollutant	Standard	Averaging time
Carbon monoxide	9 ppm (10 mg/m^3)	8-h[a]
	35 ppm (40 mg/m^3)	1-h[a]
Lead	1.5 $\mu g/m^3$	Quarterly Average
Nitrogen dioxide	0.053 ppm (100 $\mu g/m^3$)	Annual (arithmetic mean)
Particulate matter (PM_{10})	50 $\mu g/m^3$	Annual[b] (arithmetic mean)
	150 $\mu g/m^3$	24-h[a]
Particulate matter ($PM_{2.5}$)	15.0 $\mu g/m^3$	Annual[c] (arithmetic mean)
	65 $\mu g/m^3$	24-h[d]
Ozone	0.08 ppm	8-h[e]
Sulfur oxides	0.03 ppm	Annual (arithmetic mean)
	0.14 ppm	24-h[a]
	—	3-h[a]

[a] Not to be exceeded more than once per year.
[b] To attain this standard, the 3-year average of the weighted annual mean PM_{10} concentration at each monitor within an area must not exceed 50 $\mu g/m^3$.
[c] To attain this standard, the 3-year average of the weighted annual mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors must not exceed 15.0 $\mu g/m^3$.
[d] To attain this standard, the 3-year average of the 98th percentile of 24-h concentrations at each population-oriented monitor within an area must not exceed 65 $\mu g/m^3$.
[e] To attain this standard, the 3-year average of the fourth-highest daily maximum 8-h average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.

lodged deep in the alveoli of the lungs, and hence are detrimental to our health, whereas the larger particles are filtered out in the upper respiratory tract. While there is a standard for lead concentrations in the air, this pollutant is no longer routinely monitored. With the phasing out of leaded gasoline in the 1970s, lead concentrations in the air steadily declined, and allegedly, in the United States, airborne lead no longer poses a health hazard. (Of course, lead in its other forms, such as in paint, pipes, groundwater, solder, and ores, is still a hazard.)

In addition, the EPA sets emission standards for stationary and mobile sources. Stationary sources include power plants, incinerators, steel, cement, paper and pulp factories, chemical manufacturers, refineries, and others. Mobile sources include automobiles, trucks, locomotives, ships, and aircraft. As an example, Table 2 lists the U.S. emission standards (New Source Performance Standards) for fossil-fueled steam generators, which include large fossil-fueled power plants and industrial boilers that were constructed after 1970. The emission standards are set in terms of mass emitted per fuel heat input (g/GJ). However, in 1978, new regulations were implemented. Instead of numerical emission standards, EPA prescribed *emission control technologies*, the so-called best available control technologies (BACT), purporting to reduce emissions to a minimum with practical and economic pollution abatement devices. For example, current BACT for sulfur oxides is a "scrubber," usually employing a slurry of pulverized limestone ($CaCO_3$) counter-flowing to the flue gas that contains the sulfur oxides. For control of nitric oxides (NO_x), the current BACT is the low-NO_x-burner (LNB). Because the LNB reduces NO_x emissions only up to 50%, new sources may be required to employ more efficient NO_x-reducing technologies, such as selective catalytic reduction (SCR) or selective non-catalytic reduction (SNCR), based on ammonia or urea injection into the flue gas. For control of particulate matter, the current prescribed technology is the electrostatic precipitator (ESP). Because the ESP is not efficient in removing sub-micron and 1–2 μm particles, and in view

Table 2 U.S. new source performance standards (NSPS) for fossil fuel steam generators with heat input > 73 MW

Pollutant	Fuel	Heat input (g/GJ)
SO_2	Coal	516
	Oil	86
	Gas	86
NO_2	Coal (bituminous)	260
	Coal (subbituminous)	210
	Oil	130
	Gas	86
PM[a]	All	13

[a] PM, particulate matter. For PM emissions an opacity standard also applies, which allows a maximum obscuration of the background sky by 20% for a 6-min period.

1994	0.25	2.11	0.25	0.05	0.50	3.42	0.60	0.06

[a] Test method changed in 1971.

of the new $PM_{2.5}$ standard, new sources may be required to install instead of an ESP a Fabric Filter (FF), also called a bag house. The FF consists of a porous fabric or fiberglass membrane that filters out efficiently the smallest particles, albeit at an increased cost and energy penalty compared to the ESP. The detailed description of the workings of these emission control technologies is beyond the scope of this article; the reader is referred to the excellent handbooks on the subject.[1,2]

Table 3 lists the U.S. emission standards in units of mass emitted per length traveled (g/km) for passenger cars and light trucks for the different model years from 1968 to 1994. At present, the 1994 standards are still in effect. Notice that light truck standards are not as strict as those for light duty vehicles. This dichotomy is very controversial, because the light truck category includes sport utility vehicles (SUV), minivans, and pick-up trucks, which are mostly used for personal and not for cargo transport. Therefore, their emission standards ought to be equal to those for passenger cars. Until now, these vehicles captured the majority of sales in the United States. (With rising gasoline prices, this trend may be reversed.) The achievement of the emission standards relies on emission control technologies. For unleaded gasoline-fueled vehicles, the prevailing control technology is the three-way catalytic converter, which simultaneously reduces carbon monoxide (CO), nitric oxides (NO_x), and fragmentary hydrocarbon (HC) emissions. Unfortunately, the catalytic converter would not work on diesel-fueled vehicles, because the relatively high sulfur and particle emissions from diesel engines would poison the catalyst. Automobile and truck manufacturers are intensively investigating possible technologies that would reduce emissions from diesel-fueled autos and trucks.

In addition to the aforementioned criteria pollutants, one finds in the air a host of other gaseous and particulate pollutants, generally designated as hazardous air pollutants (HAP), or simply *air toxics*. The EPA has identified 189 HAPs. Of course, not all HAPs are related to fossil fuel usage. Examples of fossil fuel HAPs are products of incomplete combustion (PIC), volatile organic compounds (VOC), polycyclic aromatic hydrocarbons (PAH), toxic metals (e.g., mercury, cadmium, selenium, arsenic, vanadium, etc.) Many of the fossil fuel related HAPs are found as condensed matter on particles emitted by stationary sources (e.g., fly ash from power plants) or mobile sources (e.g., exhaust smoke from trucks). While HAPs may be more harmful to our health than the criteria pollutants (some of them are carcinogens), it is difficult to establish a dose–response relationship. Therefore, instead of setting HAP emission standards, the EPA mandates that specific control technologies be installed on major emitting sources. These are called maximum achievable control technologies (MACT). For example, for toxic volatile gases, the most often used control technologies are physical adsorption on porous adsorbents (usually activated carbon), or chemical absorption in solvents, including water, that have a large absorption capacity for these gases. When the concentration of toxic gases in the effluent is high, secondary incineration of the effluent may be warranted. For detailed descriptions of MACTs, the reader is also referred to the appropriate handbooks.[1,2]

POLLUTANT TRANSPORT AND DISPERSION

When air pollutants exit a smoke stack or exhaust pipe (called the *sources*), they are transported by winds and dispersed by turbulent diffusion. Winds blow from high pressure toward low-pressure cells at speeds that depend on the pressure gradient. Because of the Coriolis force, wind trajectories are curvilinear in reference to fixed earth coordinates, although within a relatively short (few to tens of km) distance, wind trajectories can be approximated as linear. Winds have a horizontal and vertical component. Over flat terrain, the horizontal component predominates; in mountainous and urban areas with tall buildings, the vertical component can be significant, as well at the land/sea interface.

In the bottom layer of the atmosphere, called the troposphere, the temperature usually declines with altitude. For a dry atmosphere, the temperature gradient is $-9.6°C/km$. This is called the *dry adiabatic lapse rate*. In a moist atmosphere, the temperature gradient is less. Under certain conditions (e.g., nocturnal radiative cooling of the earth surface), the temperature gradient may even become positive. This is called *inversion*. The global and temporal average temperature gradient in the troposphere is $-6.5°C/km$. When a negative temperature gradient exists, upper parcels of the air are denser than lower ones, so they tend to descend, while lower parcels buoy upward, giving rise to eddy or turbulent mixing. The more negative the temperature gradient, the stronger the turbulence, and the faster the dispersion of a pollutant introduced into the troposphere. Wind shears also cause turbulence. A wind shear exists when, in adjacent layers of the atmosphere, winds blow in different directions and speeds.

During an inversion, there is little turbulence, and a pollutant will disperse very slowly. Inversions may also occur aloft, that is, a negative temperature gradient exists at the bottom, followed by a positive gradient above. The layer up to the altitude at which the inversion occurs is called the *mixing layer* and the altitude at the inversion is called the *mixing height*. The shallower the mixing layer, the greater chances for air pollution episodes to develop, because pollutants emitted near the ground are confined to the shallow mixing layer. This often occurs in cities such as Los Angeles, Houston, Atlanta, Salt Lake City, Denver, Mexico City, Sao Paulo, Athens, Madrid, Rome, and Istanbul. Some of these cities are surrounded by mountain chains. In the basin of the mountain chain, or in the valley, the mixing layer is shallow, and the winds in the layer are usually weak, leading to poor ventilation. During the morning rush hour, pollutants are emitted into the shallow mixing layer, where they are concentrated because of the "lid" imposed by the inversion aloft. Later in the day, when solar radiation breaks up the inversion, the pollutants disperse to higher altitude, and the pollutant concentration becomes more diluted. The photo in Fig. 1 shows a pollution episode in Los Angeles. The mixing height extends only to the middle of the tall building. The lower part is obscured by the smog, the upper part, which is above the mixing layer, is in relatively clear air.

Fig. 1 Los Angeles smog. Note the low inversion beneath which the smog accumulates. Above the inversion, the air is relatively clear. Photo by the South Coast Air Quality Management District.

Air Quality Modeling

The estimation of ambient pollutant concentrations in space and time due to emissions of single or multiple sources is called air quality modeling (AQM), or source–receptor modeling (SRM). The basic ingredients of AQM are the emission strengths of the sources, meteorological conditions, and solar irradiation. Air quality models are of the trajectory-type, where the coordinate system moves together with the plume of pollutants, or grid-type, where the coordinate system is fixed over an area, and the emission strengths and meteorological variables are inserted in each grid of the model domain. Some models consider only conservative pollutants, where the emitted pollutant does not change en route to the receptor. Other models consider chemical transformation processes and "sinks," e.g., dry and wet deposition to the ground. Air quality models where transformation and deposition processes need to be considered are acid deposition, regional haze, and photo-oxidants.

Acid Deposition

While commonly called acid rain, acid deposition is a better term, because deposition can occur both in the wet and dry form. The ingredients of acid deposition are sulfuric and nitric acids. The primary pollutants are SO_2 and NO_x, which is the sum of NO and NO_2 molecules. Both SO_2 and NO_x result from fossil fuel combustion. Sulfur is a ubiquitous ingredient of coal and petroleum. When these fuels are burned in air, SO_2 is emitted from a smoke stack or the exhaust pipe of a vehicle. Coal and petroleum also contain nitrogen in their molecular make-up, resulting in NO_x emissions when these fuels are combusted in air. In addition, some NO_x is formed from the recombination of air oxygen and nitrogen at the high flame temperatures. So, even the combustion of natural gas, which has no nitrogen in its molecular make-up, produces some NO_x.

Primary emitted SO_2 and NO_x are transformed in the atmosphere to sulfuric and nitric acids. The resulting acids can be either deposited in the dry phase on land or water, a process called dry deposition, or scavenged by falling rain drops or snow flakes, resulting in wet deposition.[3] Acid deposition modeling is successful in predicting the amount of acid deposition given the emission strength of the precursors SO_2 and NO_x.[4] From these models, it was concluded that acid deposition within a geographic domain is approximately linearly dependent on SO_2 and NO_x emission strength in that domain, so a certain percentage of precursor emission reduction results in a proportional deposition reduction of sulfuric or nitric acid. Indeed, in countries and continents where serious curtailments of precursor emissions have been made, a proportional reduction of acid deposition occurred. In the United States, as a result of reducing emissions of SO_2 by approximately one-half since the enactment of the Clean Air Act of 1990, sulfuric acid deposition has declined by approximately one-half.[5] Nitric acid deposition has not fallen appreciably, because the control of NO_x is much more difficult to accomplish than the control of SO_2, especially from dispersed sources such as commercial and residential boilers and furnaces, automobiles, and diesel trucks.

Regional Haze

Small particles (also called fine particles or aerosols), less than 1–2 μm in diameter, settle very slowly on the ground. Small particles can be either in the solid or liquid phase. For example, fly ash or smoke particles are solid; mist is liquid. Small particles can be of natural origin (e.g., volcanic dust, wind blown soil dust, forest and brush fires) or of anthropogenic origin (e.g., fly ash, diesel truck smoke). They can be emitted as primary particles or formed by transformation and condensation from primary emitted gases. They can travel hundreds to thousands of kilometers from their emitting sources. The particles can envelope vast areas, such as the northeastern or southwestern United States, southeastern Canada, western and central Europe, and southeastern Asia. Satellite photos often show continental areas covered with a blanket of haze. The haze may extend far out over the ocean. This phenomenon is called regional haze. Small particles are efficient scatterers of sunlight. Light scattering prevents distant objects from being seen. This is called visibility impairment. Fig. 2 shows an encroaching haze episode on a mountain chain in Vermont. As the haze thickens, distant mountain peaks are no longer visible, and eventually neighboring peaks disappear. Increasing concentration of particles in urbanized parts of continents causes the loss of visibility of the starlit nocturnal sky. These days, small stars, less than the fifth order of magnitude, rarely can be seen from populated areas of the world.

The composition of fine particles varies from region to region, depending on the precursor emissions. In the northeastern United States, central Europe, and southeastern Asia, more than half of the composition is made up of sulfate particles, due to the combustion of high sulfur coal and oil. The rest is made up of nitrate particles, carbonaceous material (elemental and organic carbon), and crustal matter (fugitive particles from soil, clay, and rock erosion).

Photo-Oxidants

The family of photo-oxidants includes tropospheric ozone, O_3 (the bad ozone), ketones, aldehydes, and nitrated oxidants, such as peroxyacetylnitrate (PAN) and peroxybenzoylnitrate (PBN). The modeling of photo-oxidants is more complicated than that of acid deposition.[6] Here, the primary precursor is NO_x, which as mentioned previously,

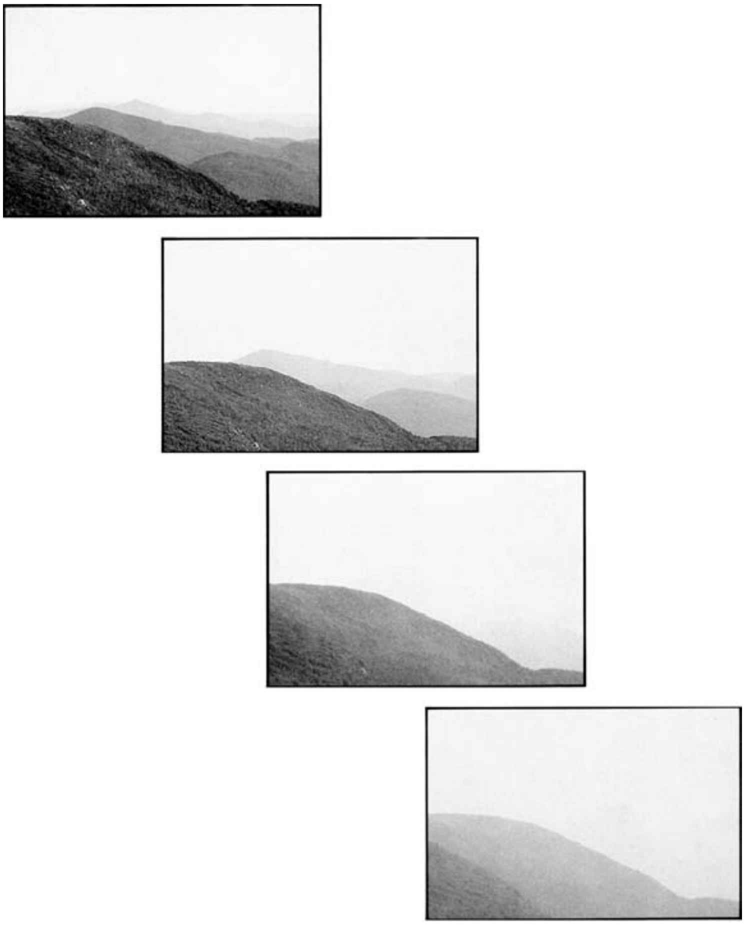

Fig. 2 Regional haze in the Vermont green mountains. Note that as the pollution episode progresses, adjacent peaks are no longer visible. Photo by the Vermont agency of environmental conservation.

is emitted because of fossil fuel combustion. A part of NO_x is the NO_2 molecule, which splits (photo-dissociates) by solar ultraviolet and blue photons into NO and atomic oxygen. The photo-dissociation rate is dependent on solar irradiation, which, in turn, is dependent on latitude, season, time of day, and cloudiness. Atomic oxygen combines with molecular oxygen to form O_3. The NO that is formed in the photo-dissociation is quickly re-oxidized into NO_2 by peroxy radicals, RO_2, present in the polluted atmosphere. The peroxy radicals are formed from VOCs that are emitted as a consequence of incomplete combustion of fossil fuels, or from evaporation and leakage of liquid fossil fuels and solvents. The VOCs are oxidized in a complicated sequence of photo-chemical reactions to the peroxy radicals. The oxidation rates of VOCs are also dependent on solar irradiation and on the specific VOC molecule. Long- and branch-chained hydrocarbons (e.g., *n*-octane and *iso*-octane) are more reactive then short- and straight-chained ones (e.g., methane and ethane); unsaturated hydrocarbons (e.g., ethene) are more reactive than saturated ones (e.g., ethane). Aromatic hydrocarbons (e.g., benzene) are more reactive than aliphatic ones (e.g., hexane), and so on.

Thus, photo-oxidants have two kinds of precursors, NO_x and VOCs, which make abatement of these secondary pollutants, as well as their modeling, so complicated. First of all, as mentioned previously, complete NO_x emission control is difficult to accomplish, because in addition to coming from large stationary sources, NO_x is emitted from a myriad of dispersed sources, such as home and commercial furnaces and boilers, automobiles, trucks, off-road vehicles, aircraft, locomotives, and ships. In principle, anthropogenic VOCs could be substantially controlled, for example, by ensuring complete combustion of the fossil fuel, or with the catalytic converter on automobiles. But, not all VOCs are of anthropogenic origin. Trees and vegetation emit copious quantities of VOCs, such as terpenes and pinenes, which are pleasant smelling, but they do participate in photo-chemical reactions that produce photo-oxidants. Even though great effort and expenses are being made in many developed countries to control precursors, photo-oxidant

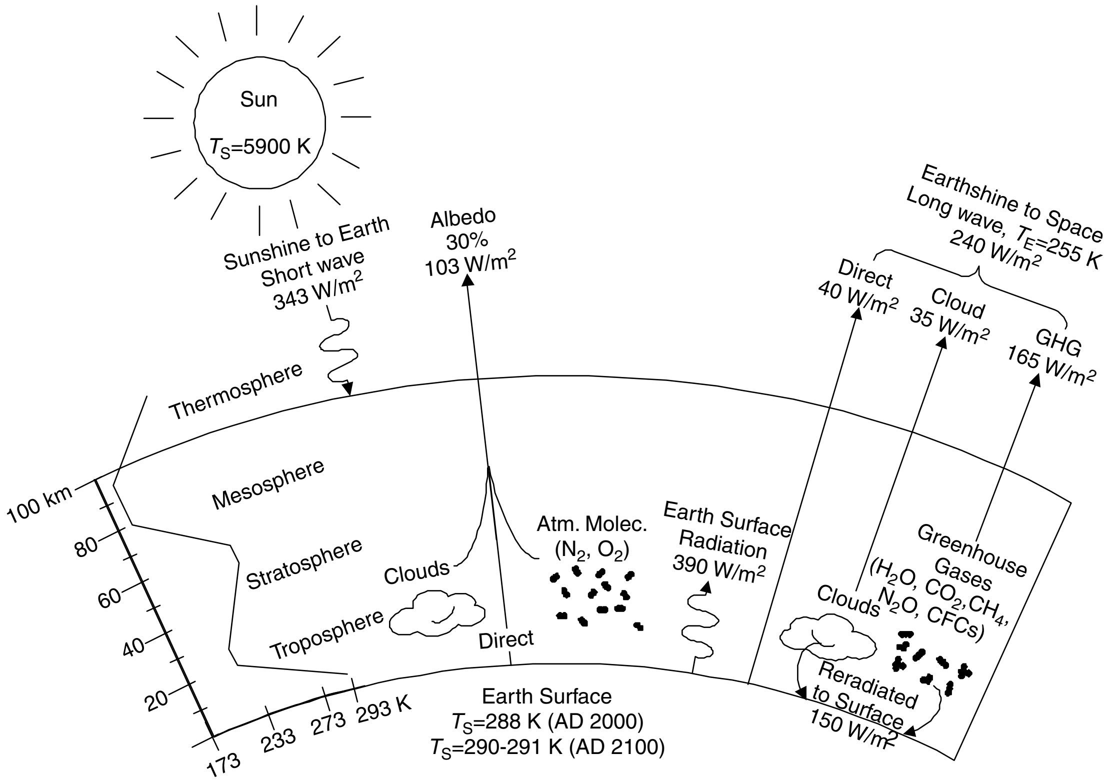

Fig. 3 Schematic of the greenhouse effect.

concentrations over urban-industrial continents have improved only slightly, if at all. In less developed countries that do not have the means of controlling photo-oxidant precursors, their concentrations are on a steady increase.

GLOBAL WARMING

Of all environmental effects of fossil fuel usage, global warming, including its concomitant climate change, is the most perplexing, potentially most threatening, and arguably most intractable problem. It is caused by the ever-increasing accumulation in the atmosphere of carbon dioxide (CO_2) and other gases, such as methane (CH_4), nitrous oxide (N_2O), and chloro-fluoro-carbons (CFC), collectively called greenhouse gases (GHG). Atmospheric aerosols, natural as well as anthropogenic, also may contribute to global warming.

The term greenhouse effect is derived by analogy to a garden greenhouse. There, a glass-covered structure lets in the sun's radiation, warming the soil and plants that grow in it, while the glass cover restricts the escape of heat into the ambient surroundings by convection and radiation. Similarly, the earth atmosphere lets through most of the sun's radiation, which warms the earth surface, but the GHGs and some aerosols trap outgoing terrestrial infrared (IR) radiation, keeping the earth's surface warmer than if the GHGs and aerosols were absent from the atmosphere.

A schematic of the greenhouse effect is represented in Fig. 3. To the left of the schematic is the atmospheric temperature structure, which defines the various spheres. In the troposphere, the temperature decreases on average by 6.5°C/km. This sphere is thoroughly mixed by thermal and mechanical turbulence, and this sphere contains most of the air pollutants mentioned in the previous sections. In the stratosphere, the temperature increases steadily. Because of the positive temperature gradient, this sphere is very stable with very little turbulence and mixing. At about 50–60 km height, the temperature declines again with altitude, giving rise to the mesosphere. Finally, above 90–100 km, the temperature gradient reverses itself, and becomes positive. The highest sphere is called the thermosphere. Its temperature can reach hundreds to one thousand degrees, depending on solar radiation intensity that directly heats this sphere.

The average solar radiation that impinges on the top of the atmosphere is about 343 W/m^2. This is the annual, diurnal, and spatial average irradiation. Of this irradiation, currently about 30% (103 W/m^2) is immediately reflected into space by land, ocean, icecaps, and clouds, and scattered into space by atmospheric molecules. The reflected and scattered sunlight is called albedo. The albedo may not remain constant over time. With increased melting of the ice caps, and increased cloud cover, in part due to anthropogenic influences, the albedo may change over time. The remaining 70% of solar irradiation heats the earth's surface, land, and oceans. Currently, the global average surface temperature is 288 K (about 15°C). A body (the so-called black body) that is heated to 288 K radiates 390 W/m^2. The earth's surface radiation occurs in the far IR. This is called earth shine. A part of the earth shine is reflected back to the earth's surface by clouds and aerosols; another part is first absorbed by certain gaseous molecules, and then re-radiated back to the surface. The absorption/re-radiation occurs by poly-atomic molecules, including water vapor and the GHGs: CO_2, CH_4, N_2O, O_3, CFCs, and others. The reflection and re-radiation to the earth's surface of the outgoing terrestrial IR radiation is causing the earth's surface to become warmer than it would be merely by solar irradiation. This is the greenhouse effect. With increasing concentrations of anthropogenic GHGs and aerosols, the earth's surface temperature will increase. It should be emphasized that the greenhouse effect is not due to trapping of the incoming solar radiation, but outgoing terrestrial IR radiation. In fact, because of the trapping of earth shine by GHGs, the upper layers of the atmosphere (primarily the stratosphere) will become colder, not warmer.[7]

The extent of global warming can be predicted by radiative transfer models. These models include the radiative properties of GHGs and their distribution in the earth's atmosphere, as well as the temperature and pressure gradients in the atmosphere. There is general agreement among the models as to the extent of surface warming due to GHG absorption/re-radiation, called radiative forcing. Based on the models, it is predicted that the average earth surface temperature will increase as shown in Fig. 4. The middle, "best," estimate predicts a rise of the earth's surface temperature by the end of the 21st century of about 2°C; the "optimistic" estimate predicts about 1°C, and the "pessimistic" estimate predicts about a 3°C rise. The optimistic estimate relies on the slowing of CO_2 and other GHG emissions; the pessimistic estimate relies on "business-as-usual," i.e., on the continuing rate of growth of CO_2 and other GHG emissions, and the "best" estimate is somewhere in between.[8] If the GHG concentrations increase in the atmosphere at their current rate, by the year 2100, CO_2 will contribute about 65% to global warming, CH_4 15%, N_2O 10%, and CFC about 5%–10%. (By international conventions, CFCs are being phased out entirely. But because of their very long lifetime in the atmosphere, they still will contribute to global warming by the year 2100.)

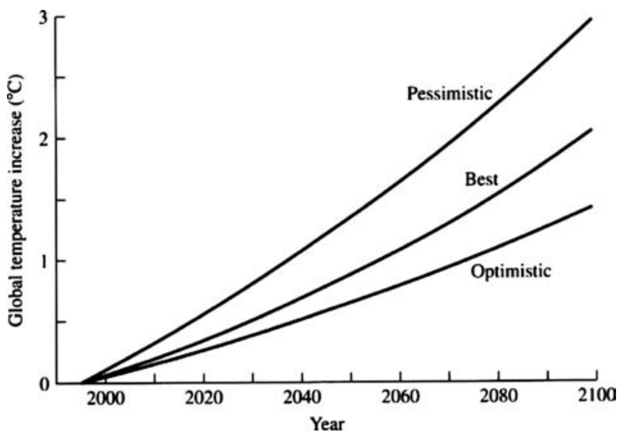

Fig. 4 Projected trend of the earth surface temperature increase. Upper curve: pessimistic scenario with no emission curtailment; lower curve: optimistic scenario with significant emission curtailment; middle curve: in-between scenario.
Source: From Cambridge University Press (see Ref. 8).

In addition to radiative forcing, global warming may be enhanced by the so-called feedback effects. For example, water vapor is a natural GHG. When the temperature of the ocean surface increases, the evaporation rate will increase. As a consequence, the average water vapor content of the atmosphere will increase. This causes more absorption of the outgoing infrared radiation and more global warming. Furthermore, increased evaporation may cause more cloud formation. Clouds and aerosols also can trap outgoing terrestrial radiation, further increasing global warming. Melting icecaps and glaciers decrease the reflection of incoming solar radiation (reduced albedo), which also increases global warming. The prediction of the feedback effects is more uncertain than the prediction of radiative forcing, but generally, it is assumed that the feedback effects may double the surface temperature increases because of radiative forcing alone.

Has the surface temperature already increased due to anthropogenic activities? Fig. 5 plots the global average surface temperature over the last century and a half. Even though there are large annual fluctuations, the smoothed curve through the data points indicates an upward trend of the temperature. From 1850, the start of the Industrial Revolution, to date, the global average surface temperature increased by about 0.5°C–1°C. This is in accordance with radiative models that predict such a trend, considering the increase of GHG concentrations over that period.

Other Effects of Global Warming

Because of increased GHG concentrations in the atmosphere, the earth's surface temperature may rise, as discussed in the previous section. The surface temperature rise may cause several ancillary effects on global climate and hydrogeology, which in turn will affect human habitat, welfare, and ecology.

Sea Level Rise

With increasing surface temperatures, the average sea level will rise because of three factors: melting of polar ice caps, receding of glaciers, and thermal expansion of the

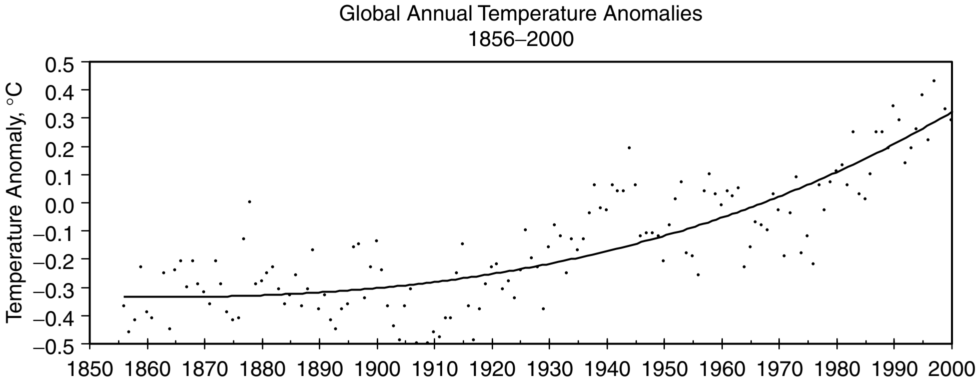

Fig. 5 Global average surface temperature trend 1850–2000. Source: From Oak Ridge National Laboratory (see Ref. 9).

ocean surface waters. Combining all three factors, it is estimated that by the end of the next century, the average sea level may be 30–50 cm higher than it is today. This can seriously affect low-lying coastal areas, such as The Netherlands in Europe, Bangladesh in Asia, and low-lying islands in the Pacific and other oceans.[8]

Climate Changes

Predicting global and regional climatic changes because of average surface temperature rise is extremely difficult and fraught with uncertainties. It is expected that regional temperatures, prevailing winds, and storm and precipitation patterns will change, but where and when, and to what extent changes will occur, is a subject of intensive investigation and modeling on the largest available computers, the so-called supercomputers. Climate is not only influenced by surface temperature changes, but also by biological and hydrological processes, and by the response of ocean circulation, which are all coupled to temperature changes. It is expected that temperate climates will extend to higher latitudes, probably enabling the cultivation of grain crops further toward the north than at present. But crops need water. On the average, the global evaporation and precipitation balance will not change much, although at any instant, more water vapor (humidity) may be locked up in the atmosphere. However, precipitation patterns may alter, and the amount of rainfall in any episode may be larger than it is now. Consequently, the runoff (and soil erosion) may be enhanced, and areas of flooded watersheds may increase. Hurricanes and typhoons spawn in waters that are warmer than 27°C, in a band from 5 to 20° north and south latitude. As the surface waters become warmer, and the latitude band expands, it is very likely that the frequency and intensity of tropical storms will increase.

The sea level and climatic changes may cause a redistribution of agricultural and forestry resources, a considerable shift in population centers, and incalculable investments in habitat and property protection.

Greenhouse Gas Concentrations Trends

Currently, about 6.8 Gt/y of carbon (25 Gt/y CO_2) are emitted into the atmosphere by fossil fuel combustion. Another 1.5 ± 1 Gt/y are emitted due to deforestation and land use changes, mainly artificial burning of rain forests in the tropics, and logging of mature trees, which disrupts photosynthesis. Fig. 6 plots the trend of atmospheric concentrations of CO_2, measured consistently at Mauna Loa, Hawaii since 1958 to date. At present, the average CO_2 concentration is about 375 parts per million by volume (ppmv). The plot shows seasonal variations due mainly to assimilation/respiration of CO_2 by plants, but there is a steady increase of the average concentration at a rate of approximately 0.4%/y. If that rate were to continue into the future, a doubling of the current CO_2 concentration would occur in about 175 years. However, if no measures are taken to reduce CO_2 emissions, then due to the population increase, and the concomitant enhancement of fossil fuel use, the rate of growth of CO_2 concentration will increase more than 0.4%/y, and the doubling time will be achieved sooner.

Methane emissions are in part due to fossil energy usage, because CH_4 leaks from gas pipes, storage tanks, tankers, and coal mine shafts. Anthropogenic emissions of CH_4 from fossil fuel usage amount to about 100 Mt/y. However, CH_4 is also emitted from municipal waste landfills, sewage treatment, biomass burning, cultivated rice paddies, enteric fermentation of cattle, and other anthropogenic activities, so that the total amount of CH_4 emissions is about 400 Mt/y. Currently, the average atmospheric concentration of CH_4 is about 1.7 ppmv, growing at about 0.6%/y. Nitrous oxide (N_2O) is a minor product of combustion of fossil fuels. Currently, the concentration of N_2O is about 0.3 ppmv, growing by about 0.25%/y. CFCs are not directly associated with fossil fuel

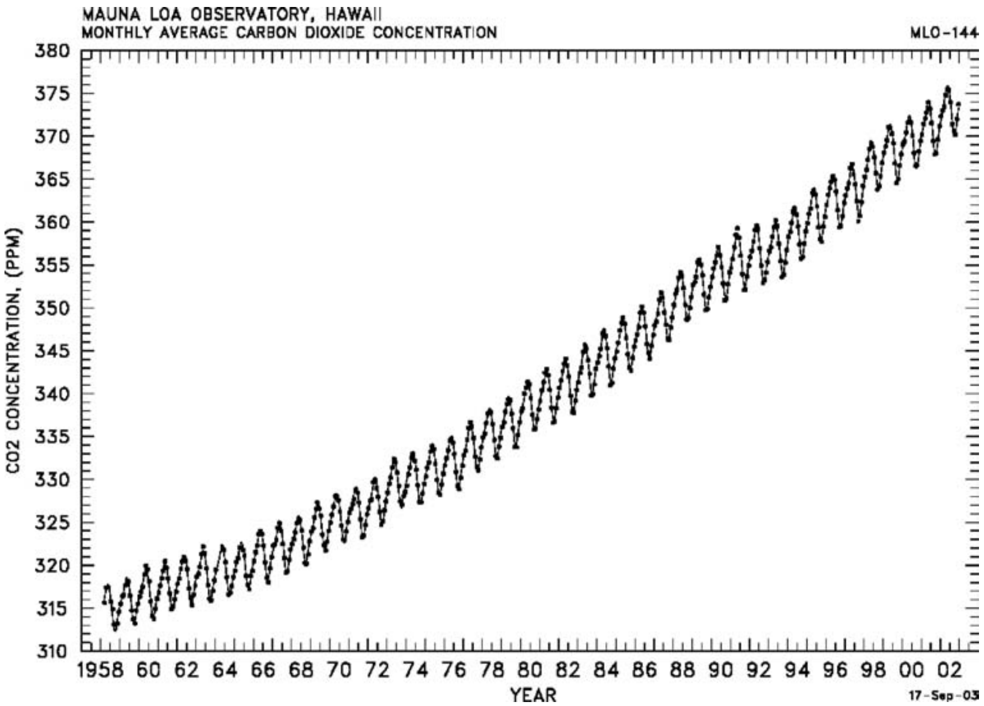

Fig. 6 Carbon dioxide concentration trend 1958–2002.
Source: From Oak Ridge National Laboratory (see Ref. 9).

usage; however, they are emitted inadvertently from energy using devices, such as refrigerators, air conditioners, chillers, and heat pumps. Current concentrations of the various CFCs are about 0.5 parts per billion by volume (ppbv), and their concentrations are slowly declining due to the phase-out of production of CFCs.

What Can be Done about Global Warming

Global warming could be lessened by reducing significantly the emissions of GHGs into the atmosphere. Most GHG emissions are a consequence of fossil fuel use. While it is important to reduce the emissions of all GHGs, the greatest preventative measure would come from reducing CO_2 emissions. CO_2 emission reductions can be accomplished by a combination of several of the following approaches.

Demand-side Conservation and Efficiency Improvements

This includes less space heating and better insulation, less air conditioning, use of more fluorescent instead of incandescent lighting, more energy efficient appliances, process modification in industry, and very importantly, more fuel efficient automobiles. Some measures may even incur a negative cost, i.e., consumer savings by using less energy, or at least a rapid payback period for the investment in energy saving devices.

Supply-side Efficiency Measures

Here we mean primarily increasing the efficiency of electricity production. Natural gas combined cycle power plants (NGCC) emit less CO_2 than single cycle coal fired power plants. First, because NG emits about one-half the amount of CO_2 per fuel heating value than coal, and second, because the thermal efficiency of combined cycle power plants is in the 45%–50% range vs the 35%–38% range of single cycle plants. In the future, integrated coal gasification combined cycle power plants (IGCC) may come on-line with a thermal efficiency in the 40%–45% range reckoned on the basis of the coal heating value. Furthermore, IGCC may enable the capture of CO_2 at the gasification stage, with subsequent sequestration of the captured CO_2 in geologic and deep ocean repositories.

Shift to Non-Fossil Energy Sources

The choices here are agonizing, because the largest impact could be made by shifting to nuclear and hydro electricity, both presently very unpopular and fraught with environmental and health hazards. The shift to solar, wind, geothermal, and ocean energy is popular, but because of their limited availability and intermittency, and because of their larger cost compared to fossil energy, a substantial shift to these energy sources cannot be expected in the near future.

None of these options can prevent global warming by itself. They have to be taken in combination and on an incremental basis, starting with the least expensive ones and progressing to the more expensive ones. Even if the predictions of global climate change were to turn out exaggerated, the fact that fossil fuel usage entails many other environmental and health effects, and the certainty that fossil fuel resources are finite, makes it imperative that we curtail fossil energy usage as much as possible.

SUMMARY AND CONCLUSIONS

The use of fossil fuels to supply energy for the use of the world's population has resulted in the release to the atmosphere of troublesome chemical byproducts that present harm to humans and other natural species. These effects can be localized (near the emission source), can extend to large regional areas (involving sub-continents), and can even cover the globe, from pole to pole. A large portion of the human population is exposed to one or more of these environmental effects. The scientific understanding of how fossil fuel use causes these effects is well advanced, providing quantitative means for explaining what is currently observed and predicting what changes will occur in the future from projected future fuel consumption. These projections provide a basis for modifying the amount and character of future energy supply so as to lessen harmful environmental consequences. The technological systems that employ fossil fuel energy have been developed to lessen the amounts of harmful emissions, albeit at significant energy and economic cost. Further improvements can be expected, but at increasing marginal cost. The most severe emission control problem, in terms of economic and energy cost, is CO_2, a major contributor to global warming. The implementation of policies by national governments and international bodies to curtail the use of fossil energy and the concomitant emissions of CO_2 will become a growing task for humankind in this century.

Fuel Cells: Intermediate and High Temperature

Xianguo Li

Gholamreza Karimi

Department of Mechanical Engineering, University of Waterloo, Waterloo, Ontario, Canada

Abstract

This entry provides an overview of intermediate- and high-temperature fuel cells, including phosphoric acid fuel cells, molten carbonate fuel cells, and solid oxide fuel cells. For each of them, a brief description is given of their operational characteristics, acceptable contamination levels, major technical barriers to commercialization, technological status, economics, and major intended applications.

INTRODUCTION

The three major types of low-temperature fuel cells were described in the previous entry, titled "Low Temperature Fuel Cells." This entry will elaborate on intermediate- and high-temperature fuel cells, including phosphoric acid fuel cells (PAFCs), molten carbonate fuel cells (MCFCs), and solid oxide fuel cells (SOFCs). The PAFC is the most commercially developed fuel cell. It is being used for distributed or on-site cogeneration in such locations as hospitals, hotels, offices, and schools. It can also be used in large vehicles (buses, etc.). The operating temperature range of PAFC is between 160 and 220°C, and its efficiency is approximately 40% lower heating value (LHV). The high-temperature MCFCs and SOFCs boast advantages over conventional power-generating systems in terms of fuel flexibility, modularity, low emission of NO_x and SO_x pollutants, and environmental friendliness. They also demonstrate relatively high tolerance to trace levels of impurities in the gas stream. In addition, due to their high operating temperatures (typically in the range of 600°C–1000°C), hydrocarbon fuels such as methane and natural gas can be reformed within the stack, eliminating the need for expensive external reforming systems. The high operating temperatures require that most applications for these fuel cells be limited to large, stationary power plants, although SOFCs are also being considered as auxiliary powers for large transport vehicles (trucks). The high-quality heat produced in cogeneration power systems can be applied to space heating, industrial processing, and even steam turbines to generate more electricity, improving the system efficiencies to high levels (up to 70% [LHV]).

Keywords: Fuel cells; Phosphoric acid; Molten carbonate; Solid oxide.

PHOSPHORIC ACID FUEL CELLS

The phosphoric acid fuel cell (PAFC) is the most advanced type of fuel cell and is considered to be "technically mature" and ready for commercialization after nearly 40 years of research, development, and demonstration (RD&D) and an expenditure of over half a billion dollars. Therefore, the PAFC has been referred to as the first-generation fuel cell technology. Unlike the alkaline fuel cell systems, which were primarily developed for space applications, the PAFC was targeted initially for terrestrial applications with the carbon dioxide-containing air as the oxidant gas and hydrocarbon-reformed gas as the fuel for electrochemical reactions and electric power generation.

The basic components of a phosphoric acid fuel cell are the electrodes, consisting of finely dispersed platinum catalyst or carbon paper; an SiC matrix holding the phosphoric acid; and a bipolar graphite plate with flow channels for fuel and oxidant. The operating temperature ranges between 160 and 220°C, and it can use hydrogen, hydrogen-enriched gas produced from hydrocarbons (typically natural gas), or alcohols as the anodic reactant. In the case of hydrogen produced from a reformer with air as the anodic reactant, a temperature of 200°C and a pressure as high as 8 atm are required for better performance. Phosphoric acid fuel cells are advantageous from a thermal management point of view. The rejection of waste heat and product water is very efficient in this system, and the waste heat, at about 200°C, can be used efficiently for the endothermic steam-reforming reaction. The waste heat can also be used in cogeneration for space heating and hot water supply.

However, the PAFC cannot tolerate the presence of carbon monoxide and H_2S, which are commonly present in the reformed fuels. These contaminants poison the catalyst and decrease its electrochemical catalytic activity. A major challenge for using natural gas reformed fuel, therefore, lies in the removal of carbon monoxide to a level of less than 200–300 ppm. Carbon monoxide tolerance is higher at an operating temperature above 180°C. However, removal of sulfur is still essential. Further, the PAFC demonstrates an inferior performance, primarily due to the slow oxygen reduction reaction at the cathode. Therefore, the PAFC is typically operated at a higher temperature (near 200°C) for better electrochemical reactivity and smaller internal resistance, due mainly to the phosphoric acid electrolyte. As a result, PAFC exhibits the problems of both high- and low-temperature fuel cells, and perhaps none of the advantages of either option.

The PAFC system is the most advanced fuel cell system for terrestrial applications. Its major use is in on-site integrated energy systems to provide electrical power in apartments, shopping centers, office buildings, hotels, and hospitals. These fuel cells are commercially available in the range from 24 V/250 W portable units to 200 kW on-site generators. Phosphoric acid fuel cell systems of 0.5–1.0 MW are being developed for use in stationary power plants of 1–11 MW in capacity. The power density of a PAFC system is about 200 mW/cm^2, and the power density for a 36 kW brassboard PAFC fuel cell stack has been reported to be 0.12 kW/kg and 0.16 kW/L. The most advanced PAFC system is the PC-25 from International Fuel Cells in Connecticut (now it is named PureCell™ 200 under UTC Power). It costs about $3000 U.S./kW (the best technology possible for the PAFCs), while the conventional thermal power generation system costs only about $1000 U.S./kW. Thus, it is believed that the PAFC is not commercially viable, even though the U.S. Department of Energy (DOE) and the U.S. Department of Defense (DOD) have been subsidizing half of the cost to gain operational and maintenance experience for practical fuel cell systems. Although Japan seems determined to push ahead for this fuel cell technology, interest in the PAFC systems is waning in the United States and Europe.

MOLTEN CARBONATE FUEL CELLS

Introduction

The molten carbonate fuel cell (MCFC) is often referred to as the second-generation fuel cell because its commercialization is expected to come to fruition after that of the PAFC. It is believed that the development and technical maturity of the MCFC are approximately 5–7 years behind the PAFC. At present, the MCFC has reached the early demonstration stage of precommercial stacks, marking the transition from fundamental and applied research and development (R&D) to product development. Molten carbonate fuel cells are being targeted to operate on coal-derived fuel gases or natural gas. This contrasts with the previously discussed PAFCs, which prefer natural gas as primary fuel.

The MCFC operates at higher temperatures than all other fuel cells described so far. The operating temperature of the MCFC generally ranges from 600 to 700°C (typically 650°C). Such high temperatures produce high-grade waste heat, suitable for fuel processing, cogeneration, or combined cycle operation, and leading to higher electric efficiency. It also yields the possibility of utilizing carbonaceous fuels (especially natural gas) directly, through internal reforming to produce the fuel (hydrogen) ultimately used by the fuel cell electrochemical reactions. This results in simpler MCFC systems (i.e., without external reforming or fuel processing subsystems), less parasitic load, and less cooling power requirements, leading to higher overall system efficiency as well. The high operating temperature reduces voltage losses due to reduced activation, ohmic, and mass transfer polarization. The activation polarization is reduced to such an extent that it does not require such expensive catalysts, as do low-temperature fuel cells and even PAFCs. It also offers great flexibility in the use of available fuels (i.e., through in situ reforming of fuels). It has been estimated that the MCFC can achieve an energy conversion efficiency of 52%–60% (LHV) from chemical energy to electrical energy with internal reforming and natural gas as the primary fuel. Some studies have indicated that the MCFC efficiency of methane-to-electricity conversion is the highest attainable by any fuel cell or other single pass/simple cycle generation scheme.

Basic Operating Principle

Fig. 1 illustrates a schematic of a MCFC. A MCFC consists of two porous gas-diffusion electrodes (anode and cathode) and a carbonate electrolyte in liquid form. The electrochemical reaction occurring at the anode and the

cathode is

$$\text{Anode}: \quad H_2 + CO_3^{2-} = H_2O + CO_2 + 2e^-$$

$$\text{Cathode}: \quad \frac{1}{2}O_2 + CO_2 + 2e^- = CO_3^{2-}$$

and the net cell reaction is

$$H_2 + \frac{1}{2}O_2 = H_2O.$$

Besides the hydrogen oxidation reaction at the anode, other fuel gases (such as carbon monoxide, methane, and higher hydrocarbons) are also oxidized by conversion to hydrogen. Although direct electrochemical oxidation of carbon monoxide is possible, it occurs very slowly compared to that of hydrogen. Therefore, the oxidation of carbon monoxide is mainly via the water–gas shift reaction

$$CO + H_2O = CO_2 + H_2$$

which, at the operation temperature of the MCFC, equilibrates very rapidly at catalysts such as nickel. Therefore, carbon monoxide becomes a fuel instead of a contaminant, as in the previously described low-temperature fuel cells. Direct electrochemical reaction of methane appears to be negligible. Hence, methane and other hydrocarbons must be steam-reformed, which can be done either in a separate reformer (external reforming) or in the MCFC itself (the so-called internal reforming).

As a result, water and carbon dioxide are important components of the feed gases to the MCFCs. Water, produced by the main anode reaction, helps shift the equilibrium reactions to produce more hydrogen for the anodic electrochemical reaction. Water must also be present in the feed gas, especially in low-Btu (i.e., high carbon monoxide content) fuel mixtures, to prevent carbon deposition in the fuel gas flow channels supplying the cell or even inside the cell itself. Carbon dioxide, from the fuel exhaust gas, is usually recycled to the cathode as it is required for the reduction of oxygen.

The MCFCs use a molten alkali carbonate mixture as the electrolyte, which is immobilized in a porous lithium aluminate matrix. The conducting species is carbonate ions. Lithiated nickel oxide is the current material of choice for the cathode, and nickel, cobalt, and copper are currently used as anode materials, often in the form of powdered alloys and composites with oxides. As a porous metal structure, it is subject to sintering and creeping under the compressive force necessary for stack operation. Additives such as chromium or aluminum form dispersed oxides and thereby increase the long-term stability of the anode with respect to sintering and creeping. Molten carbonate fuel cells normally have 75%–80% fuel (hydrogen) utilization.

Acceptable Contamination Levels

Molten carbonate fuel cells do not suffer from carbon monoxide poisoning—in fact, they can utilize carbon monoxide in the anode gas as the fuel. However, they are extremely sensitive to the presence of sulfur (<1 ppm) in the reformed fuel (as hydrogen sulfide, H_2S) and oxidant gas stream (SO_2 in the recycled anode exhaust). The presence of HCl, HF, HBr, etc. causes corrosion, while trace metals can spoil the electrodes. The presence of particulates of coal/fine ash in the reformed fuel can clog the gas passages.

Major Technological Problems

The main research efforts involving the MCFCs are focused on increasing lifetime and endurance, and reducing long-term performance decay. The main determining factors for the MCFCs are electrolyte loss, cathode dissolution, electrode creepage and sintering, separator plate corrosion, and catalyst poisoning for internal reforming.

Electrolyte loss results in increased ohmic resistance and activation polarization, and it is the most important and continuously active factor in causing long-term performance degradation. It is primarily a result of electrolyte consumption by the corrosion/dissolution processes of cell components, electric potential-driven electrolyte migration, and electrolyte vaporization. Electrolyte evaporation (usually Li_2CO_3 and/or K_2CO_3) occurs either directly as carbonate or indirectly as hydroxide.

The cathode consists of NiO, which slowly dissolves in the electrolyte during operation. It is then transported toward the anode and precipitates in the electrolyte matrix as Ni. These processes lead to a gradual degradation of cathode performance and shorting of the electrolyte matrix. The time at which shorting occurs depends not only on the CO_2 partial pressure and the cell temperature, but also the matrix structure (i.e., porosity; pore size; and, in particular, thickness of the matrix). Experience indicates that this cell shorting mechanism tends to limit stack life to about 25,000 h under the atmospheric reference gas conditions and much shorter for real operating conditions.

Electrode, especially anode, creepage and sintering (i.e., a coarsening and compression of electrode particles) result in increased ohmic resistance and electrode polarization. NiO cathodes have quite satisfactory sinter and creepage resistance. Creep resistance of electrodes has an important effect on maintaining low-contact resistance of the cells and stacks. The corrosion of the separator plate depends on many factors, such as the substrate; possible protective layers; composition of the electrolyte; local potential and gas composition; and oxidizing and reducing atmospheres at the cathode and anode, respectively.

Poisoning of the reforming catalyst occurs within direct internal reforming MCFCs. It is caused by the evaporation of the electrolyte from the cell components, condensation on the catalyst (which is the coldest spot in the cell), and liquid creep within the cell.

Technological Status

Molten carbonate fuel cell technology is in the first demonstration phase, under product development with full-scale systems at the 250 kW–2 MW range. The short-term goal is to reach a lifetime of 25,000 h, and the ultimate target is 40,000 h. It is estimated that the capital cost is between $1000 and $1600 U.S./kW for the MCFC power systems. The cost breakdown is, at full-scale production levels, about one-third for the stack and two-thirds for the balance of the plant. It is also generally accepted that the cost of raw materials will constitute about 80% of total stack costs. Although substantial development efforts supported by fundamental research are still needed, the available knowledge and number of alternatives will probably make it possible to produce precommercial units in the earlier part of the coming decade at a capital cost of $2000–$4000 U.S./kW. Precompetitive commercial units may be expected some years later, by which time further cost reduction to full competitiveness will be guided by extensive operating experience and increased volume production.

Applications

The MCFCs are being developed for their potential as baseload utility generators. However, they are best applied to distributed power generation and cogeneration for capacities less than 20 MW in size, and in this size range, MCFCs are 50%–100% more efficient than turbines—the conventional power generator. Other applications are foreseen, including pipeline compressor stations, commercial buildings, industrial sites in the near future, and repowering applications in the longer term. Due to its high operation temperature, it has very limited potential for transportation applications. This is because of its relatively low power density and long startup times. However, it may be suitable as a powertrain for large surface ships and trains.

SOLID OXIDE FUEL CELLS

Introduction

Solid oxide fuel cells have emerged as serious alternative high-temperature fuel cells, and they have often been referred to as third-generation fuel cell technology because their commercialization is expected after PAFCs (the first generation) and MCFCs (the second generation).

The SOFC is an all-solid-state power system, including the electrolyte, and it is operated at a high temperature of around 1000°C for adequate ionic and electronic conductivity of various cell components. The all-solid-state cell composition makes the SOFC system simple in concept, design, and construction; two-phase (gas–solid) contact for the reaction zone reduces corrosion and eliminates all the problems associated with the liquid electrolyte management of MCFCs. The high-temperature operation results in fast electrochemical kinetics (i.e., low activation polarization) and no need for noble metal catalysts. The fuel may be gaseous hydrogen, an H_2/CO mixture, or hydrocarbons because the high-temperature operation makes the internal in situ reforming of hydrocarbons with water vapor possible. It is important to note that in SOFCs, carbon monoxide is no longer a contaminant; rather, it becomes a fuel. Even with external reforming, the SOFC fuel feedstock stream does not require extensive steam reforming with shift conversion, as it does for the low-temperature fuel cell systems. More important, the SOFC provides high-quality waste heat, which can be utilized for cogeneration applications or CC operation for additional electric power generation. The SOFC operating condition is also compatible with the coal gasification process, which makes SOFC systems highly efficient when using coal as the primary fuel. It has been estimated that the chemical-to-electrical energy conversion efficiency is at least 50%–60% (LHV), and some estimates go as high as 70%–80% (LHV). Additionally, nitrogen oxides are not produced, and the amount of carbon dioxide released per kilowatt hour is around 50% less than for power sources based on combustion because of the high efficiency of the SOFC.

Basic Operating Principle

As mentioned earlier, both hydrogen and carbon monoxide can be oxidized in the SOFCs directly. Hence, if hydrogen or a hydrogen-rich gas mixture is used as fuel, and oxygen (or air) is used as oxidant, the half-cell reaction becomes (Fig. 2)

$$\text{Anode}: \quad H_2(g) + O^{2-} = H_2O(g) + 2e^-$$

$$\text{Cathode}: \quad 2e^- + \frac{1}{2}O_2(g) = O^{2-}$$

and the overall cell reaction becomes

$$H_2(g) + \frac{1}{2}O_2(g) = H_2O(g).$$

However, if carbon monoxide is provided to the anode instead of hydrogen, the anode reaction becomes

$$\text{Anode}: \quad CO(g) + O^{2-} = CO_2(g) + 2e^-$$

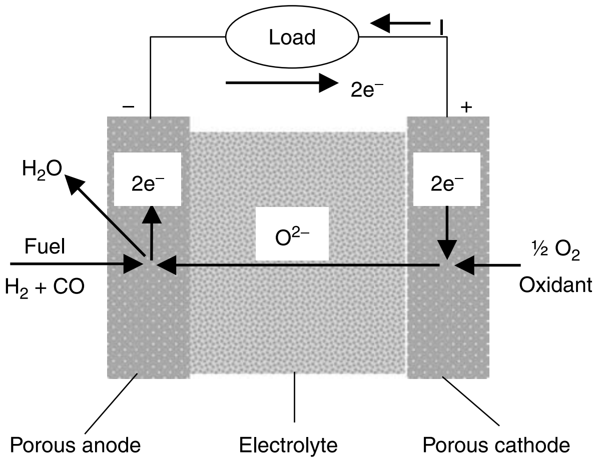

Fig. 2 Schematic of a solid oxide fuel cell (SOFC).

With the cathode reaction remaining the same, the cell reaction becomes

$$CO(g) + \frac{1}{2}O_2(g) = CO_2(g).$$

If the fuel stream contains both hydrogen and carbon monoxide, as is the case for hydrocarbon reformed gas mixtures—especially from the gasification of coal—the oxidation of hydrogen and carbon monoxide occurs simultaneously at the anode, and the combined anode reaction becomes

$$\text{Anode}: \quad aH_2(g) + bCO + (a + b)O^{2-} = aH_2O(g) + bCO_2 + 2(a + b)e^-$$

Consequently, the corresponding cathode and overall cell reaction become

$$\text{Cathode}: \frac{1}{2}(a + b)O_2 + 2(a + b)e^- = (a + b)O^{2-}$$

$$\text{Cell}: \quad \frac{1}{2}(a + b)O_2 + aH_2 + bCO = aH_2O + bCO_2$$

The solid electrolyte in SOFCs is usually yttria-stabilized zirconia (YSZ); thus, a high operating temperature of around 1000°C is required to ensure adequate ionic conductivity and low ohmic resistance. This is especially important because the cell open-circuit voltage is low as compared with low-temperature fuel cells—typically between 0.9 and 1 V under the typical working conditions of the SOFCs. The high-temperature operation of the SOFCs makes the activation polarization very small, resulting in the design operation in the range dominated by the ohmic polarization. The conventional material for the anode is nickel–YSZ-cermet, and the cathode is usually made of lanthanum–strontium-manganite. Metallic current collector plates of a high-temperature, corrosion-resistant, chromium-based alloy are typically used. Recently, low-temperature SOFCs are under intensive R&D, with operating temperatures ranging from 600 to 800°C. At such lower temperatures, cheaper materials are expected to be used for the cell components, including interconnectors. However, low-temperature SOFCs are still in their early stage of development, and significant technical issues need to be resolved before precommercial demonstration of the technology.

Acceptable Contamination Levels

Because of their high temperatures, the SOFCs can better tolerate impurities in the incoming fuel stream. They can operate equally well on dry or humidified hydrogen or carbon monoxide fuel, or on mixtures of them. But hydrogen sulfide (H_2S), hydrogen chloride (HCl), and ammonia (NH_3) are impurities typically found in coal-gasified products, and each of these substances is potentially harmful to the performance of SOFCs. The main poisoning factor for SOFCs is H_2S. Though the sulfur tolerance level is approximately two orders of magnitude greater than other fuel cells, the level is below 80 ppm. However, studies have shown that the effect of hydrogen sulfide (H_2S) is reversible, meaning that the cell performance will recover if hydrogen sulfide is removed from the fuel stream or clean fuel is provided after the contaminant poison has occurred.

Major Technological Problems

The high-temperature operation of the SOFCs places stringent requirements on materials used for cell construction, and appropriate materials for cell components are very scarce. Therefore, the key technical challenges are the development of suitable materials and the fabrication techniques. Of the material requirements, the most important consideration is the matching of the thermal expansion coefficients of electrode materials with those of the electrolyte to prevent cracking or delamination of SOFC components either during high-temperature operation or heating/cooling cycles. One of the remedies for the thermal expansion mismatch is to increase the mechanical toughness of the cell materials by developing new materials or by doping the existing materials with SrO and CaO.

The electrode voltage losses are reduced when the electrode material possesses both ionic and electronic conductivities (the so-called mixed conduction), for which the electrochemical reactions occur throughout the entire surface of the electrode rather than only at the three-phase interface of, for example, the cathode, the air (gas phase), and the electrolyte. Therefore, it is important for performance enhancement to develop mixed-conduction

Table 1 Operational characteristics and technological status of intermediate and high temperature fuel cells

Type of fuel cells	Operating temperature (°C)	Power density (mW/cm^2) (present) projected	Projected rated power level (kW)	Fuel efficiency	Lifetime projected (h)	Capital cost projected (U.S.$/kW)	Application areas
PAFC	160–220	(200) 250	100–5,000	55	>40,000	3,000	Dispersed & distributed power
MCFC	600–700	(100) >200	1,000–100,000	60–65	>40,000	1,000	Distributed power generation
SOFC	800–1,000	(240) 300	100–100,000	55–65	>40,000	1,500	Baseload power generation; auxiliary power for large transport vehicles

materials for both the cathode and anode, which have a good thermal expansion match with the electrolyte used and good electrical conductivity to reduce the ohmic polarization that dominates the SOFC voltage losses.

Another focus of current development is the intermediate-temperature SOFCs, operating at around 800°C for better matching with the bottoming turbine cycles and lessening requirements for the cell component materials. Again, appropriate materials with adequate electrical conductivity are the key areas of the development effort, and thermal expansion matching among the cell components is still necessary.

Technological Status

There are three major configurations for SOFCs: tubular, flat plate, and monolithic. Even though SOFC technology is in the developmental stage, the tubular design has gone through development at Westinghouse Electric Corporation since the late 1950s, and it is now being demonstrated at user sites in a complete operating fuel cell power unit of nominal 25 kW (40 kW maximum) capacity. The flat plate and the monolithic designs are at a much earlier development status, typified by subscale, single-cell, and short stack development (up to 40 cells). The present estimated capital cost is $1500 U.S./kW but is expected to be reduced with improvements in technology. Therefore, the SOFCs may become very competitive with the existing technology for electric power generation. However, it is believed that the SOFC technology is at least 5–10 years away from commercialization.

Applications

Solid oxide fuel cells are very attractive in electrical utility and industrial applications. The high operating temperature allows them to use hydrogen and carbon monoxide from natural gas steam reformers and coal gasification plants—a major advantage as far as fuel selection is concerned. Solid oxide fuel cells are being developed for large (>10 MW, especially 100–300 MW) baseload stationary power plants with coal as the primary fuel. This is one of the most lucrative markets for this type of fuel cell.

A promising field for SOFCs is the decentralized power supply in the MW range, where the SOFC gains interest due to its capability to convert natural gas without external reforming. In the capacity range of one MW to some tens of MWs, the predicted benefits in electrical efficiency of SOFC-based power plants over conventional methods of electricity generation from natural gas can only be achieved by an internal-reforming SOFC. So internal reforming is a major target of present worldwide SOFC development.

Another application that is gaining momentum is as auxiliary power for large transport vehicles (e.g., heavy-duty transport trucks), although this application is still in its early stage.

CONCLUDING REMARKS

A summary of the preceding description of the three major types of intermediate- and high-temperature fuel cells—namely, the phosphoric acid, molten carbonate, and SOFCs—is provided in Table 1, including operational characteristics and technological status.

Phosphoric acid fuel cells are the most commercially developed fuel cells operating at intermediate temperatures. Phosphoric acid fuel cells are being applied for distributed or on-site cogeneration in such locations as hospitals, hotels, offices, schools, etc. with relative high conversion efficiency. The high-temperature fuel cells, like MCFCs and SOFCs, may be most appropriate for cogeneration and combined cycle systems (with gas or steam turbines as the bottoming cycle). Molten carbonate fuel cells have the highest energy efficiency attainable from methane-to-electricity conversion (in the size range of 250 kW–20 MW), whereas SOFCs are best suited for baseload utility applications operating on coal-derived gases. A recent interest in SOFCs is as auxiliary power for large transport vehicles. It is estimated that MCFC technology is 5–10 years away from commercialization, and SOFC development will likely follow even later.

Fuel Cells: Low Temperature

Xianguo Li
Department of Mechanical Engineering, University of Waterloo, Waterloo, Ontario, Canada

Abstract
This entry provides an overview of low-temperature fuel cells, including alkaline fuel cells, proton exchange membrane fuel cells, and direct methanol fuel cells. For each of them, a brief description is given of their operational characteristics, acceptable contamination levels, major technical barriers to commercialization, technological status, economics, and major intended applications.

INTRODUCTION

Fuel cell technology has improved dramatically over the past few years, once again capturing public and industry attention concerning the prospect of fuel cells as practical power sources for terrestrial applications. The fuel cell is a highly energy-efficient and environmentally friendly technology for power generation that is also compatible with alternative fuels, renewable energy sources, and carriers for sustainable development.

Fuel cells offer additional advantages for both mobile and stationary power generation applications. The fuel cell, as an electrochemical device, has no moving components except for peripheral equipment. As a result, its operation is very quiet, virtually without vibration and noise. It is capable of on-site cogeneration with no need for long-distance power transmission lines that consume approximately 10% of electric energy delivered to consumers in North America. Its inherent modularity allows for simple construction and operation. It has possible applications in baseload electricity generation as well as in dispersed, distributed, and portable power generation because it may be made in any size raging from a few watts up to a megawatt-scale plant with equal efficiency. Its fast response to changing load conditions while maintaining high efficiency makes it ideally suited to load-following applications. Its high efficiency results in lower chemical, thermal, and carbon dioxide emissions for a given amount of power generation.

At present, fuel cell technology is being used routinely in many specific areas, notably in space explorations, where fuel cells operate on pure hydrogen and oxygen with over 70% [lower heating value (LHV)] efficiency and produce potable water as the only byproduct. There are now approximately 200 fuel cell units (for terrestrial applications) operating in 15 countries. Technical progress has been impressive in terms of higher power density, better performance, reduced capital, and reduced maintenance and operation cost. Competitively priced fuel cell-based power generation systems with advanced features are being developed, including utility power plants and zero-emission vehicles. In light of decreasing fossil fuel reserves and increasing energy demands worldwide, fuel cells will probably become one of the major energy technologies with strong international competition in the 21st century.

Outside of the space industry, the major commercial applications of fuel cells include electric power generation in the utility industry and a zero-emission powertrain in the transportation sector. For these practical applications, the efficiencies of fuel cells range somewhere from 40 to 65%, based on the LHV of hydrogen. Typically, a single cell's electric potential is only about 1 V, and this decreases due to various loss mechanisms under operational conditions. Thus, multiple cells must be connected in series to achieve a useful voltage. These connected cells are often referred to as a fuel cell stack. A fuel cell system consists of one or more fuel cell stacks connected in series or parallel, and the auxiliaries whose composition depends on the type of fuel cells and the kind of primary fuels used. The major accessories include a thermal management (or cooling) subsystem, a fuel supply, a storage and processing subsystem, and an oxidant (typically air) supply, and conditioning subsystem.

There are six major types of fuel cells that have been under research, development, and demonstration (RD&D) for practical applications. They are:

- Alkaline fuel cells (AFCs)
- Proton exchange membrane fuel cells (PEMFCs)
- Direct methanol fuel cells (DMFCs)
- Phosphoric acid fuel cells (PAFCs)
- Molten carbonate fuel cells (MCFCs)
- Solid oxide fuel cells (SOFCs)

A critical parameter that determines the potential applications of each type of fuel cell is the operating temperature. For instance, AFCs, DMFCs, and PEMFCs

Keywords: Fuel cells; Alkaline; Proton exchange membrane; Direct methanol.

have potential applications in transportation because of their low operating temperatures. Consequently, they have a very short startup period, consisting of only a few minutes. These types of fuel cells are discussed in the first entry, under the title "Low Temperature Fuel Cells." Meanwhile, phosphoric acid, molten carbonate, and SOFCs producing high-temperature heat are more complex to run and are better suited for stationary applications like combined heat and power generation (CHP). The fuel cells in this category will be discussed in the second entry, titled "Intermediate and High Temperature Fuel Cells."

The following sections describe each of the three low-temperature fuel cells. Their technological status is presented with respect to their basic operating principles, acceptable contamination levels, state-of-the-art technology, major technical barriers to commercialization, economics, and suitability for utility and transportation applications.

ALKALINE FUEL CELLS

Alkaline fuel cells are among the first fuel cells to have been studied and developed for practical applications, and they are the first fuel cells to have been applied successfully to routine applications, including space-shuttle missions in the United States and similar space exploration endeavors in China and Europe, where pure hydrogen and oxygen are used as reactants. Because of their success in the space programs, AFCs are also the type of fuel cells studied in the largest number of fuel cell development programs for terrestrial applications, particularly in Europe. However, almost all of the AFC development programs have now ended, with only a few remaining activities related to the AFC RD&D still taking place in Europe.

Alkaline fuel cells have the highest energy conversion efficiency among all types of fuel cells under the same operating conditions if pure hydrogen and pure oxygen are used as reactants. This is one reason why AFCs were selected for the U.S. space-shuttle missions. The AFCs used in the shuttle missions are operated at about 200°C for maximum performance (i.e., high energy conversion efficiency of over 70% and high power density, both of which are critical for space applications), and the alkaline electrolyte is potassium hydroxide (KOH) solution immobilized in an asbestos matrix. The AFCs must operate at high pressure to prevent boiling and depletion of the liquid electrolyte. These severe operating conditions of high temperature and high pressure dictate an extremely stringent requirement for cell component materials because they must withstand the extreme corrosive oxidizing and reducing environment of the cathode and anode. To meet these space-program requirements, precious metals such as platinum, gold, and silver are used for the electrodes, but these precious metals need not be present for the electrochemical reactions leading to electric power generation. Each shuttle flight contains a 36 kW AFC power system. Its purchase price is about $28.5 million U.S., and it costs NASA an additional $12 million to $19 million U.S. annually for operation and maintenance. Although the manufacturer claims about 2400 h of lifetime, NASA's experience indicates that the real lifetime is only about 1200 h. With sufficient technology development, 10,000 h are expected to be the life potential (or upper limit) for the AFC system in the coming years—a prediction based on the nature of the AFC systems and the data accumulated on both stacks and single cells.

The typical working temperature of AFC power systems for commercial and terrestrial applications ranges from 20 to 90°C, and the electrolyte is a KOH solution (30%–35%). There are four different AFC cell types investigated:

- Cell with a free liquid electrolyte between two porous electrodes
- ELOFLUX cell with liquid KOH in the pore systems
- Matrix cell with the electrolyte is fixed in the electrode matrix
- Falling film cell

Research groups worked on the development of technical AFC systems, although most of these groups have now terminated their research. The group names and the current status of their work are listed below:

- Siemens, Erlangen, Germany: stopped working on the AFCs
- VARTA AG, Kelkheim, Germany: terminated working on preparation of technical electrodes and technical fuel stacks in 1993
- GH, Kassel, Germany: stopped working on preparation of technical electrodes and technical fuel cell stacks in 1994
- ISET, Kassel, Germany: stopped working on technical AFC systems in 1994
- DLR-ITT (German Aerospace Research Establishment), Stuttgart, Germany: stopped working on the investigation of the degradation of technical electrodes, the development of new catalysts for AFCs, and the theoretical simulation of stacks and systems in 1994
- ELENCO, Antwerpen, Belgium: stopped working on electrodes, stacks, and systems, as well as the bus demonstration program (went bankrupt in 1995)
- Royal Institute of Technology, Stockholm, Sweden: working on the field of stationary fuel cells powered by biofuels
- Hoechst AG, Frankfurt, Germany: terminated working on AFC electrodes and stopped development of the falling film cell

- Technical University, Graz, Austria: planning an investigation of degradation effects
- Zevco, London, England: demonstration of AFCs for mobile applications, particularly for bus with ELENCO's technology

The following is a list of some selected technical applications and demonstration projects for AFCs in Europe in recent years:

- Space applications
  - AFC system for the European space shuttle HERMES (Siemens, ELENCO, VARTA/GHK)
  - Bipolar matrix AFC system Photon (Ural Electrochemical Integrated Plant)
- Vehicles
  - Forklift truck, VARTA AFC
  - Volkswagon (VW) van, 14 kW ELENCO AFC and battery
  - VW van, 17.5 kW Siemens AFC
  - Submarine, 100 kW Siemens AFC
  - EUREKA-Bus, 80 kW ELENCO AFC and battery
- Decentralized energy supply
  - Meteorological station, 5 kW, VARTA AFC for long-term operation
  - TV-transmitting installation Ruppertshain, 100 kW VARTA AFC
  - Mobile current supply unit for the Belgian Geological Service, 40 kW ELENCO AFC
- Energy storage
  - Solar hydrogen-demonstration plant in Neunburg vorm Wald, 6.5 kW Siemens AFC
  - Solar hydrogen system at Fachhochschule Wiesbaden, 1.2 kW ELENCO AFC

Many problems concerning AFCs are described in the literature. The most important include:

- *Method of preparing the electrode*. The electrodes consist of porous material covered with a layer of catalyst. In general, it is very difficult to distribute the catalyst at the surface and produce a defined pore system for transporting the reactants.
- *Costs of the electrode, stacks, and fuel cell systems*. The preparation of electrodes with noble metal catalysts is very expensive. In general, the electrodes are manufactured in a small-scale production with high overhead costs.
- *Lifetime of the electrode/degradation*. The electrolyte is very corrosive, and the catalyst materials are sensitive to high polarization. Using nickel and silver as catalysts to reduce the costs of the fuel cell leads to a high degradation of these catalysts.
- *Diaphragm made of asbestos*. The diaphragm of low-temperature AFCs is made of asbestos, but this material is a health hazard, and in some countries its use is even banned. Therefore, new diaphragms should be developed, but it is difficult to find a material with similar behavior in an alkaline electrolyte.
- *Carbon dioxide-contaminated fuel and oxidant streams resulting in carbonating of electrolyte and electrodes*. The electrolyte's intolerance of carbon dioxide is the most important disadvantage of air-breathing AFCs with reformulated gases from primary fossil fuels.

Other problems associated with AFC power systems relate to the safety and reliability of AFC power systems. For example, the liquid KOH electrolyte contained in an asbestos matrix can withstand only a 5 psi limit of pressure differential between the anode and cathode reactant gases. This dictates the need for sophisticated pinpoint pressure control during operation, including the transient, startup, and shutdown processes. There is also a safety issue due to the great likelihood of mixing the reactants in the AFC system, with the potential result of a serious fire. In terms of general safety considerations, the use of the corrosive potassium hydroxide electrolyte in the AFCs requires hazardous materials, and the handling of the asbestos matrix poses potential hazards to one's health. With flowing reactant gases, the potential for the gradual loss of the liquid electrolyte, drying of the electrolyte matrix, reactant crossover of the matrix, and ensuing life-limiting reactant mixing (or actual AFC stack failure due to fire) is very real in the AFC system.

The major technical challenge is that alkaline electrolytes, like potassium or sodium hydroxide, are adversely affected by 300–350 ppm of carbon dioxide. Atmospheric air has carbon dioxide concentration in both cathode and anode gases greater than 10–100 ppm by volume. Most applications require the use of atmospheric air as the oxidant due to technical and economic considerations. For municipal electric applications, hydrocarbon fuels, especially natural gas, are expected to be the primary fuel. When they are reformed into hydrogen-rich gases, they invariably contain a significant amount of carbon dioxide. For example, steam-reforming of natural gas results in a reformate gas consisting of approximately 80% hydrogen; 20% carbon dioxide; and a trace amount of other components, such as carbon monoxide. In addition, the carbonaceous products of aging and corrosion shorten AFC life because they degrade the alkaline electrolyte. Whether they originate as impurities in the gaseous reactants or from some fuel cell materials, oxides of carbon will chemically react with the alkaline electrolyte and produce irreversible decay, subsequently decreasing performance and shortening life span. As a result, AFCs are currently restricted to specialized applications where pure hydrogen and oxygen are utilized. The revival of AFC technology will depend almost completely on successfully solving the "CO_2 syndrome"—i.e., efficiently and economically scrubbing carbon dioxide.

Foss–Gre

Claims have been made of successful resolution of carbon dioxide poisoning in the AFCs, especially in utility applications. Some optimistic estimates indicate that AFC stack costs are similar to all other low-temperature fuel cell systems. Production costs for the AFC systems seem to be the lowest. A price of approximately $400–$500/kW U.S. has been quoted by using present-day technologies and knowledge in large-scale production. However, small-scale commercial production cost is estimated to be five to ten times higher.

PROTON EXCHANGE MEMBRANE FUEL CELLS

Introduction

The PEMFC is also called the solid polymer (electrolyte) fuel cell. It is perhaps the most elegant of all fuel cell systems in terms of design and mode of operation. It was the first type of fuel cell put into practical application in the Gemini space missions between 1962 and 1966. It consists of a solid polymeric membrane acting as the electrolyte. The solid membrane is an excellent proton conductor, sandwiched between two platinum-catalyzed porous carbon electrodes. It has fast start capability and yields the highest output power density among all types of fuel cells. Because of the solid membrane as electrolyte, there is no corrosive fluid spillage hazard, and there is a lower sensitivity to orientation. The electrolyte is not volatile, and there are minimal corrosion concerns. It has zero pollutant emissions, with only potable water as a byproduct when hydrogen is used as fuel. As a result, the PEMFC is particularly suited for vehicular power application, although it is also being considered for stationary and portable power application (albeit to a lesser degree).

The proton-conducting polymer membrane belongs to a class of materials known as ionomers or polyelectrolytes, which contain functional groups that will dissociate in the presence of water. The dissociation produces ions fixed to the polymer and simple counter-ions, which can exchange freely with ions of the same sign from the solution. The polyelectrolytes currently available feature cations as the counterions. For hydrogen, the cation is a proton.

The membrane must be fully hydrated to have adequate ion conductivity. As a result, the fuel cell must be operated under conditions where the byproduct water does not evaporate faster than it is produced, and the reactant gases, both hydrogen and oxygen, need to be humidified. Managing water and temperature in the membrane is critical for efficient cell performance; dynamic controls are needed to match the varying operating conditions of the fuel cell. Because of the limitations imposed by the membrane and problems with the water balance, the operating temperature of PEMFCs is usually less than 120°C—typically 80°C. This rather low operating temperature requires the use of noble metals as catalysts in both the anode and cathode side, with generally higher catalyst loadings than those used in PAFCs.

Currently, the polymer electrolyte is made of a perfluorinated sulfonic acid membrane; it is essentially acid, though in solid polymeric form. Hence, a PEMFC is essentially an acid electrolyte fuel cell, with its operational principle nearly the same as a PAFC. As a result, most PEMFC design, material selection, component fabrication, etc. are similar to those of PAFCs. The only difference is the humidification of reactant gases dictated by the membrane performance. Reactant humidification is often achieved by a number of techniques—e.g., by passing the gas stream through a water column, by using in-stack humidification sections of the cell and membrane arrangement, and by spraying water into the reactant streams. In the early stages of PEMFC development, the membranes were based on polystyrene, but since 1968, a Teflon-based product known as Nafion by DuPont has been used. This offers high stability, high oxygen solubility, and high mechanical strength.

Basic Operating Principle

The schematic of a single PEM fuel cell is illustrated in Fig. 1. The PEMFC requires hydrogen gas as the fuel and oxygen (typically air) as the oxidant. The half-cell reactions are

$$\text{Anode}: \quad H_2 = 2H^+ + 2e^-$$

$$\text{Cathode}: \quad \tfrac{1}{2}O_2 + 2H^+ + 2e^- = H_2O$$

and the overall cell reaction is

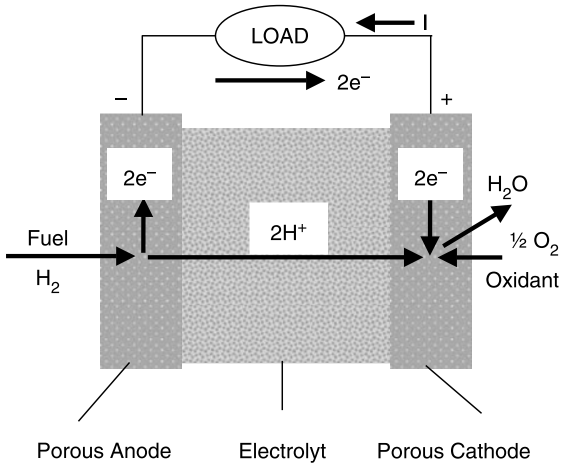

Fig. 1 Schematic of a PEMFC.

$$H_2 + \tfrac{1}{2}O_2 = H_2O + \text{Heat Generated} + \text{Electric Energy}.$$

The current PEMFCs use perfluorinated sulfonic acid membrane (almost exclusively Nafion) as the proton-conducting electrolyte; carbon paper or cloth as the anode and cathode backing layers; and platinum or its alloys, either pure or supported on carbon black, as the catalyst. The bipolar plate with the reactant gas flow fields is often made of graphite plate. The stoichiometry is between 1.1 and 1.2 for the fuel, and 2 for the oxidant (oxygen). The PEMFCs usually operate at about 80°C and 1–8 atm pressure. The pressures, in general, are maintained equally on either side of the membrane. Operation at high pressure is necessary to attain high power densities, particularly when air is chosen as the cathodic reactant.

To prevent the membrane dryout from leading to local hot spots, crack formation, performance degradation, and lifetime reduction, both fuel and oxidant streams are fully humidified, and the operating temperature is limited by the saturation temperature of water corresponding to the operating pressure. The liquid water formed at the cathode does not dissolve in the electrolyte membrane and is usually removed from the cell by the excess oxidant gas stream. The accumulation of liquid water in the cathode backing layer blocks the oxygen transfer to the catalytic sites, resulting in the phenomenon called water flooding, which causes performance reduction. Local hot and cold spots will cause the evaporation and condensation of water. Thus, an integrated approach to thermal and water management is critical to PEMFCs' operation and performance, and a proper design must be implemented.

Acceptable Contamination Levels

As an acid electrolyte fuel cell operating at low temperature, the PEMFC is primarily vulnerable to carbon monoxide poisoning. Even a trace amount of carbon monoxide (CO) drastically reduces the performance levels, although the CO poisoning effect is reversible and does not cause permanent damage to the PEMFC system. Further, performance reduction due to CO poisoning can take up to two hours to reach steady state. This transient effect may have profound implications for transportation applications. Therefore, the PEMFC requires the use of a fuel virtually free of CO (it must be less than a few parts per million). Additionally, high-quality water free of metal ions should be used for the cell cooling and reactant humidification to prevent the contamination of the membrane electrolyte. This requirement has a severe implication on the materials that can be used for cell components. On the other hand, carbon dioxide does not affect PEMFC operation and performance except through the effect of reactant dilution (the Nernst loss). However, carbon dioxide can produce carbon monoxide in the presence of water vapor available in the PEMFCs via reverse water–gas shift reaction. PEMFCs are also susceptible to the poisoning of sulfur and its compounds—hydrogen sulfide in particular—although this is less quantified than the CO poisoning at this stage of development.

Major Technological Problems

For practical applications, PEMFC performance in terms of energy efficiency, power density (both size and weight), and capital cost must be improved further. This can be accomplished by systematic research in:

- New oxygen reduction electrocatalysts. This includes the reduction of precious-metal platinum and its alloys loading from 4 to 0.4 mg/cm^2 or lower without affecting the long-term performance and the lifetime, and the development of CO-tolerant catalysts.
- New types of polymer electrolyte with higher oxygen solubility, thermal stability, long life, and low cost. A self-humidified membrane or a polymer without the need of humidification will be ideal for PEMFC operation and performance enhancement with significant simplification of system complexities and reduction of cost.
- Profound changes in oxygen (air) diffusion electrode structure to minimize all transport-related losses. The minimization of all transport losses is the most promising direction for PEMFC performance improvement.
- Optimal thermal and water management throughout the individual cells and the whole stack to prevent local hot and dry spot formation and to prevent water flooding of the electrode.

Fig. 2 illustrates the schematic of a PEMFC stack and its major components. In addition to the above issues, the development of low-cost lightweight materials for construction of reactant gas flow fields and bipolar plates is one of the major barriers to the large-scale commercialization of PEMFCs. A successful solution to this problem will further increase the output power density, and such a solution includes an optimal design of flow fields with the operating conditions and an appropriate selection of materials and fabrication techniques. As much as a 20% improvement in the performance of PEMFC stacks can be obtained just through the appropriate design of flow channels. The current leading technologies for bipolar plate design include injection-molded carbon–polymer composites, injection-molded and carbonized amorphous carbon, assembled three-piece metallic, and stamped unitized metallic.

Technological Status

Proton exchange membrane fuel cells have achieved a high power density of over 1 kW/kg and 1.0 kW/L for the stack—perhaps the highest among all types of fuel cells currently under development. It is also projected that the power density may be further improved, to between 2 and 3 kW/L, with unitized metallic (stainless steel) bipolar plates. The capital cost varies from the most optimistic estimate of $1500/kW U.S. to the most pessimistic estimate of $50,000/kW U.S. at the current technology, and is projected to reach approximately $30/kW U.S. for net system power, assuming a 10-fold to 20-fold reduction in the membrane and catalyst cost, and also considering large-scale productions. It is expected that PEMFC technology is between five and ten years away from commercialization. Precommercial demonstrations for buses and passenger vehicles are under way with increasing intensity; the first demonstration for residential combined heat and power application began in late 1999. The use of PEMFCs in powering portable and mobile electronics (such as laptops) has also already begun. Tables 1 and 2 show the technical targets set by the U.S. Department of Energy for the year 2010 and 2015, as well as the technical achievements made so far (up to 2005). Table 3 shows the technical progresses up to 2005 and the technical targets for 2007 and 2010 set by Ballard Power Systems, a world leader in PEMFC technology development for transportation applications.

Applications

Proton exchange membrane fuel cells have a high power density, a variable power output, and a short startup time due to low operating temperatures; the solid polymer electrolyte is virtually corrosion free and can withstand a large pressure differential (as high as 750 psi, reported by NASA) between the anode and cathode reactant gas streams. Accordingly, PEMFCs are suitable for use in the transportation sector, and they are currently considered the best choice for zero-emission vehicles. Their high power density and small size make them primary candidates for light-duty vehicles, though they are also used for heavy-duty vehicles. However, conventional gasoline and diesel engines are extremely cheap (estimated to cost between $30 and $50/kW U.S.). Therefore, the cost of PEMFC systems must be lowered by at least two to three orders of magnitude to become competitive with that of conventional heat engines in the transportation arena.

A reformer with carbon monoxide and sulfur cleaning is necessary for electricity generation from hydrocarbon fuels. The cost of the reforming system is estimated to be about the same as the cost of the fuel cell stack itself, as well as that of other ancillary systems. Additionally, the optimal chemical to electric conversion efficiency is approximately 40%–45% (LHV), and the low operating temperature makes the utilization of waste heat difficult or impossible for the reforming of hydrocarbon fuels, cogeneration of heat, and combined cycles. On the other hand, conventional thermal power plants with combined

gas and steam turbines boast energy efficiency approaching 60% (LHV), with a very low capital cost of $1000/kW U.S. Therefore, the best possible application of PEMFC systems is to use them in remote regions, as well as for combined heat and power application in residential sectors.

In addition, NASA is testing the feasibility of using PEMFC power systems for its space programs (mainly space-shuttle missions) in place of its three current 12 kW AFC power modules. As discussed in the AFCs section, NASA is motivated by the extremely high cost, low lifetime, and maintenance difficulty associated with its present-day AFC systems. Currently, NASA's feasibility study is in its second phase, using parabolic flight tests in airplanes to simulate low-gravity environments. If everything proceeds accordingly, NASA will conduct real-time tests in shuttles within a couple of years.

DIRECT METHANOL FUEL CELLS

Introduction

The fuel cells described above require the use of gaseous hydrogen or liquid/solid hydrocarbon fuels (e.g., methanol reformed to hydrogen). Pure oxygen or oxygen in air is used as the oxidant. Hence, these fuel cells are often referred to as hydrogen–oxygen or hydrogen–air fuel cells. The use of gaseous hydrogen as a fuel presents a number of practical problems, including storage system weight and volume, as well as handling and safety issues, especially for consumer and transportation applications. Although liquid hydrogen has a higher energy density, the liquefaction of hydrogen requires roughly one-third of the specific energy, and the thermal insulation required increases the volume of the reservoir significantly. The use of metal hydrides decreases the specific energy density, and the weight of the reservoir becomes excessive. The size and weight of a power system are both extremely important for transportation applications, as they directly affect fuel economy and vehicle capacity—such factors are less critical for stationary applications. The low volumetric energy density of hydrogen also limits the distance between vehicle refuelings.

Methanol as a fuel offers ease of handling and storage as well as potential infrastructure capability for distribution. Methanol also has a higher theoretical energy density than hydrogen (5 kWh/L compared with 2.6 kWh/L for liquid hydrogen). Easy refueling is another advantage for methanol. However, a reformer is needed in conventional hydrogen–air or hydrogen–oxygen fuel cells, which adds complexity and cost, as well as leading to the

Table 2 Technical targets for PEM fuel cell stacks operating directly on hydrogen for transportation application (80 kWe net power)[a]

production of undesirable pollutants such as carbon monoxide. The addition of a reformer also increases response time.

Therefore, direct oxidation of methanol is an attractive alternative in light of its simplicity. The DMFCs utilizing a proton exchange membrane (PEM) have the capability of efficient heat removal and thermal control through the circulating liquid, as well as elimination of the humidification required to prevent membrane dryout. These two characteristics have to be accounted for in both direct and indirect hydrogen systems, as they impact the systems' volume and weight, and consequently the output power density.

Basic Operating Principle

Fig. 3 illustrates the basic operating principle of a DMFC. The DMFC allows for the direct use of an aqueous, low-concentration (3%) liquid methanol solution as the fuel. Air is the oxidant. The methanol and water react directly in the anode chamber of the fuel cell to produce carbon dioxide and protons that permeate the PEM and react with the oxygen at the cathode. The half-cell reactions are

$$\text{Anode}: CH_3OH(l) + H_2O(l) = CO_2(g) + 6H^+ + 6e^-$$

$$\text{Cathode}: 6H^+ + 6e^- + \tfrac{3}{2}O_2(g) = 3H_2O(l)$$

and the net cell reaction is

$$CH_3OH(l) + \tfrac{3}{2}O_2(g) = CO_2(g) + 2H_2O(l).$$

Because the PEM (typically Nafion 117) is used as the electrolyte, the cell operating temperature is usually less than the water boiling temperature to prevent the dryout of the membrane. Typically the operating temperature is

Table 3 Technical progresses made and targets set by Ballard Power Systems for PEM fuel cell stacks operating directly on hydrogen for transportation application

Characteristic	2002	2003	2004	2005	2007	2010
Stack power density (kWe/L)	0.777	0.905	1.205	1.470	1.80	2.50
Cost (US$/kWe)	150	134	103	73	60	30

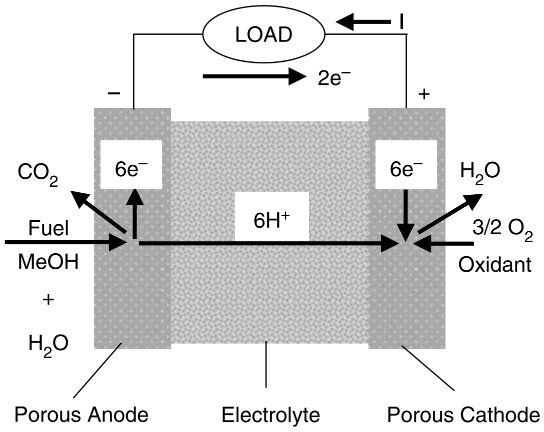

Fig. 3 Schematic of a DFMC.

around 90°C; the operating pressure ranges from one to several atmospheres; and methanol is fed to the cell in liquid form (the so-called liquid-feed DMFCs). Vapor-feed DMFCs have also been considered that operate above 100°C—then heat must be needed to vaporize methanol before feeding into the cell because methanol under the room condition is in liquid form.

Acceptable Contamination Levels

The system is extremely sensitive to CO and hydrogen sulfide (H_2S). Carbon monoxide may exist as one of the reaction intermediaries, and it can poison the catalyst used. There are arguments as to whether CO is present in the anode during the reaction. Sulfur may be present if methanol is made of petroleum oils; if so, the sulfur must be removed. Further, several other reaction intermediaries can poison the catalyst as well.

Major Technological Problems

The PEM used in the DMFCs is Nafion 117, which is the same as employed in the PEMFCs. Although it works well in both types of cells, it is expensive and has only one supplier. Because the electrolyte in DMFCs is essentially acid, expensive precious metals (typically platinum or its alloys) are used as the catalyst. However, the most serious problem is the so-called methanol crossover. This phenomenon is caused by the electro-osmotic effect. When the protons migrate through the electrolyte membrane, a number of water molecules are dragged along with each proton; because methanol is dissolved in liquid water on the anode side, the methanol is dragged through the membrane electrolyte (along with the protons and water) to reach the cathode side. Fortunately, the methanol at the cathode is oxidized into carbon dioxide and water at the cathode catalyst sites, producing no safety hazards. But the methanol oxidation at the cathode does not produce useful electric energy. The development of a new membrane with low methanol crossover is a key to the success of DMFCs.

Such a low methanol crossover membrane has a number of advantages. First, it reduces the methanol crossover, enhancing fuel utilization and increasing energy efficiency. Second, it reduces the amount of water produced at the cathode, leading to a lower activation and concentration polarization, and allowing for a higher cell voltage at the same operating current. Third, it allows for higher methanol concentration in the fuel stream, resulting in better performance.

Technological Status

Direct methanol fuel cells are the least developed of the fuel cell technologies. Though methanol itself has simpler storage requirements than hydrogen and is easier to make and transport, its electrochemical activity is much slower than that of hydrogen; its oxidation rate is about four orders of magnitude smaller than that of hydrogen. Also, the conversion takes place at low temperatures (about 80°C–90°C), and contamination is a serious problem.

The state-of-the-art performance boasts an energy conversion efficiency of 34% (LHV) from methanol to electricity at 90°C using 20 psig air—that is, a cell voltage of 0.5 V (corresponding to a voltage efficiency of 42%) together with the methanol crossover. This accounts for 20% of the current produced (equivalent to a fuel efficiency of 80%). This 20% methanol crossover occurs when the fuel stream used is an aqueous solution containing only 3% methanol. It has been projected that with better membranes being developed by the University of Southern California (USC), as well as improvements in membrane electrode assembly, a cell voltage of 0.6 V can be achieved with only 5% methanol crossover. This is equivalent to 50% voltage efficiency and 95% fuel efficiency, resulting in an overall stack efficiency of 47% (LHV) from methanol to electricity. The DMFC system efficiency will be lower due to the running of auxiliary systems.

The DMFC power system is underdeveloped, and until now, no one could demonstrate any feasibility for commercialization. It remains in the laboratory scale of small demonstrators in the sub-kW range. As such, no system cost estimate is available or has ever been attempted. However, the current DMFCs use essentially the same cell components, materials, construction, and fabrication techniques as the PEMFCs; therefore, it is expected that the system and component costs will be similar to those of the PEMFCs. One company was recently formed to explore the potential of DMFC systems and to develop DMFC for transportation applications. However, judging by the progress of other fuel cells, such systems are at least ten years away from demonstrating any realistic practical applications.

Table 4 Operational characteristics and technological status of various fuel cells

Type of fuel cells	Operating temperature (°C)	Power density (mW/cm^2) (present) projected	Projected rated power level (kW)	Fuel efficiency	Lifetime projected (h)	Capital cost projected (U.S.$/kW)	Application areas
AFC	60–90	(100–200) > 300	10–100	40–60	> 10,000	> 200	Space, transportation
PEMFC	50–80	(350) > 600	1–1000	45–60	5,000	30	Transportation
					> 40,000	> 500	Stationary
					> 2,500	> 1000	Space
DMFC	90	(230) ?	1–100	34	> 10,000	> 200	Transportation

Applications

Direct methanol fuel cells offer a potential for high power density and cold-start capabilities, a convenience for onboard fuel storage, and compatibility with existing refueling infrastructure. Therefore, DMFCs are the most attractive for applications in which storage or generation of hydrogen requires significant effort and has a negative impact on the volume and weight of the system. As a result, DMFCs have great potential for portable and transportation applications, including small appliances, laptop computers, cell phones, automobiles, trains, and ships. In terms of utility applications, small DMFC units will have potential for use in residential and office buildings, hotels, hospitals, etc. Because methanol can be made from agricultural products, its use is also compatible with renewable energy sources to allow for sustainable development.

CONCLUDING REMARKS

A summary of the preceding descriptions of the three major types of low-temperature fuel cells—the AFCs, PEMFCs, and DFMCs—is provided in Table 4, including the operational characteristics and technological status.

For stationary cogeneration, the most economic fuels currently are fossil fuels. Although AFCs demonstrate the best performance when operating on pure hydrogen and oxygen, their intolerance of carbon dioxide eliminates their potential role for utility applications. Proton exchange membrane fuel cells will require complex fuel processing and conditioning subsystems for the reforming of hydrocarbon fuels (notably natural gas), the removal of impurities (including carbon monoxide and sulfur compounds), and external humidification devices. PEMFCs operating directly on hydrogen are believed to be the most promising candidates for transportation applications due to their high power density, fast startup, high efficiency, and easy and safe handling. The main challenges to their commercialization are the cost and durability (or lifetime). PEMFCs will be best for light-duty vehicle applications. Due to the difficulty of onboard fuel (hydrogen) storage and the lack of infrastructure for fuel (hydrogen) distribution, DFMCs are believed by some to be the most appropriate technology for vehicular application, and they are also suited for portable applications due to the high energy density of methanol. PEMFCs are believed to be between five and ten years away from commercialization, while DFMCs are still early in their technological development. Finally, AFCs may stand the best chance for transportation use as far as weight and startup are concerned. Their use is limited only because of their inability to tolerate carbon dioxide contamination in both the fuel and oxidant streams.

INTRODUCTION

The word "geothermal" comes from the Greek words geo (earth) and therme (heat). So, geothermal means earth heat. Geothermal energy is the thermal energy within the earth's crust—the thermal energy in rock and fluid (water, steam, or water containing large amounts of dissolved solids) that fills the pores and fractures within the rock, sand, and gravel. Calculations show that the earth, originating from a completely molten state, would have cooled and become completely solid many thousands of years ago without an energy input in addition to that of the sun.[1] It is believed that the ultimate source of geothermal energy is radioactive decay within the earth.

Geothermal energy utilization is basically divided into two categories, i.e., electric energy production and direct uses. The distribution of the various categories of direct use worldwide is approximately 32% for geothermal heat pumps, 30% for bathing and swimming (including balneology), 20% for space heating (of which 83% is for district heating), 7.5% for greenhouse and open-ground heating, 4% for industrial process heat, 4% for aquaculture pond and raceway heating, <1% for agricultural drying, <1% for snow melting and cooling, and <0.5% for other uses. The equivalent annual savings in fuel oil amounts to 170 million barrels (25.4 million tonnes) and 24 million tonnes in carbon emissions to the atmosphere.[2]

Most of the world's geothermal power plants were essentially built in the 1970s and 1980s as a solution to the 1973 oil crisis. There was an immediate need to generate electricity from alternative energy resources and geothermal energy was essentially given particular attention in this regard.

Lund et al.[2] have recently reported that the world total installed capacity by the end of 2004 for direct use of geothermal energy was 27,825 MW, almost a twofold increase over the 2000 data, growing at a compound rate of

12.9% annually. The total annual geothermal energy utilization became 261,418 TJ (72,622 GWh), almost a 40% increase over the 2000 data, growing at a compound rate of 6.5% annually. During the past ten years, the installed capacity has increased by 12.4%/year and the use has increased by 8.8%/year. The countries with the largest installed capacity and annual energy use are the United States, Sweden, China, Iceland, and Turkey, accounting for about 66% of the installed capacity and 60% of the annual energy use.

In this article, some historical background on geothermal and geothermal energy applications are presented, some technical, economical, environmental and sustainability aspects of geothermal energy are discussed, and performance evaluations tools in terms of energy and exergy analyses for such geothermal energy systems are outlined. A case study is also presented to highlight the importance of exergy use as a potential tool for system analysis, design, and improvement.

HISTORICAL BACKGROUND

Archaeological evidence shows that the first human use of geothermal resources in North America occurred more than 10,000 years ago with the settlement of Paleo-Indians at hot springs.[3] The springs served as a source of warmth and cleansing, with their minerals as a source of healing. While people still soak in shallow pools heated by the earth, engineers are developing technologies that will allow people to probe more than 15 km below the earth's surface in search of geothermal energy.

Here, Table 1 presents a summary table of historical events that have shaped the growth of geothermal energy from its origins to the present.

TECHNICAL ASPECTS OF GEOTHERMAL ENERGY

The details on the technical and fundamental aspects of geothermal energy are well outlined in,[4] and a brief summary of them is presented here.

The discovery that the temperature in deep mines exceeded the surface temperature implied the existence of a source of deep geothermal energy. The average geothermal gradient (or the increase in temperature with depth) near the surface, say within a few km, is about 0.03°C/m, i.e., 30°C/km, but values as low as about 10°C/km are found in ancient continental crust and very high values (>100°C/km) are found in areas of active volcanism.[7]

In some areas, geothermal energy is a viable economic alternative to conventional energy generation. Commercially viable geothermal fields have the same basic structure. The source of heat is generally a magmatic intrusion into Earth's crust. The magma intrusion generally measures 600°C–900°C at a depth of 7–15 km. The bedrock containing the intrusion conducts heat to overlying aquifers (i.e., layers of porous rock such as sandstone that contain significant amounts of water) covered by a dome-shaped layer of impermeable rock such as shale or by an over-lying fault thrust that contains the heated water or steam. A productive geothermal source generally produces about 20 tons (18.1 metric tons) of steam or several hundred tons of hot water per hour. Historically, some heavily exploited geothermal fields have had decreasing yields due to a lack of replenishing water in the aquifer rather than to cooling of the bedrock.

There are three general types of geothermal fields: hot water, wet steam, and dry steam. Hot water fields contain reservoirs of water with temperatures between 60 and 100°C and are most suitable for space heating and agricultural applications. For hot water fields to be commercially viable, they must contain a large amount of water with a temperature of at least 60°C and lie within 2000 m of the surface. Wet steam fields contain water under pressure and usually measure 100°C. These are the most common commercially exploitable fields. When the water is brought to the surface, some of the water flashes into steam and the steam may drive turbines that can produce electrical power. Dry steam fields are geologically similar to wet steam fields, except that superheated steam is extracted from the aquifer. Dry steam fields are relatively uncommon. Because superheated water explosively transforms into steam when exposed to the atmosphere, it is much safer and generally more economical to use geothermal energy to generate electricity, which is much more easily transported.

The thermal efficiency of steam plants is defined as the ratio of the net power generated to the energy of the geothermal fluid at the plant site, and it ranges from 10 to 17%, respectively. These low percentages are due to geothermal resources being at relatively low temperatures. The thermal efficiency of binary cycle plants, defined as the ratio of the net power generated to the energy of the brine at the plant site, ranges from 2.8 to 5.5%, respectively. These percentages are even lower because binary design plants use lower-temperature geothermal resources available for power generation.[8]

To be commercially viable, geothermal electrical generation plants must be located near a large source of easily accessible geothermal energy. A further complication in the practical utilization of geothermal energy is derived from the corrosive properties of most groundwater and steam. In fact, prior to 1950, metallurgy was not advanced enough to enable the manufacture of steam turbine blades resistant to corrosion. Geothermal energy sources for space heating and agriculture have been used extensively in Iceland, and to some degree, Japan, New Zealand, and the former Soviet Union countries. Other applications include paper manufacturing and water desalination.

Table 1 Some worldwide historical events of geothermal energy, including some recent activities in Canada

Date	Event
Prehistory	Use of caves' geothermal energy for winter warmth and summer cooling; people gathering at hot springs to enjoy warmth from deeper geothermal resources
Early history	The Romans used geothermally heated water in their bathhouses for centuries. The Romans also used the water to treat illnesses and heat homes. In Iceland and New Zealand, many people cooked their food using geothermal heat. Some North American native tribes also used geothermal vents for both comfort heat and cooking temperatures. Most of these early uses of the earth's heat were through the exploitation of geothermal vents. Early peoples also utilize near-constant subsurface temperatures (geothermal energy) to keep vegetables in root cellars from freezing or spoiling
1860s	Energy from hot springs begins to be used in the United States to heat homes and bathhouses
1886	Hot water from the Banff, Alberta hot springs piped to hotels and spas
1904	Italian scientist Piero Ginori Conti invents the first geothermal electric power plant
1946	First ground-source geothermal heat pump installed at the Commonwealth Building in Portland, Oregon
1958	The first turbine-generator sets in Wairakei "A" Station were synchronized to the national grid in New Zealand—the first geothermal electrical development in the world using "wet steam"
1960	Pacific Gas and Electric begins operation of first large-scale geothermal power plant at the Geysers north of San Francisco, producing 11 megawatts. 69 geothermal generating facilities are in operation at 18 resource sites around the United States
1970s	During the oil crisis of 1973, many countries begin exploring alternative sources of energy, including geothermal energy. This sparks government-sponsored renewable energy research programs in Germany, Sweden, Canada, the United Kingdom, and the United States. Geothermal heat pumps and underground thermal energy storage systems gain popularity as a means to reduce heating and cooling costs, especially in commercial and institutional buildings
1975	Drilling begins to assess high-temperature geothermal resources for electricity generation in British Columbia
1976–1986	Ten-year federal research program assesses geothermal energy resources, technologies, and opportunities for Canada. In the early 1980s, some plants in Indonesia, Kenya, Turkey, the Philippines, and Portugal (Azores) were built
1990s	As public concerns about environmental issues such as air pollution and climate change grow, governments in Canada and elsewhere take a greater interest in using renewable energy as a way to decrease greenhouse gases and other emissions
1990	Ontario Hydro funds a program to install geothermal heat pumps in 6749 residences not served by natural gas
2004	Western GeoPower Corp. applies for government approvals to build a $340 million, 100-megawatt geothermal power plant at Meager Creek, northwest of Whistler, B.C., which could begin producing power as early as 2007. Manitoba government announces program to provide loans of to $15,000 towards installation of geothermal heat pump systems
2005	There are 25 countries producing over 54,000 GWh/year of electricity from geothermal energy from over 8700 MW_e of installed capacity

Source: From Refs. 5 and 6.

In summary, while geothermal energy is generally considered a nonpolluting energy source, water from geothermal fields may often contain some amounts of hydrogen sulfide and dissolved metals, making its disposal difficult. That is why depending on the location and area, a careful treatment is required.

Here, Table 2 presents a summary of the types of geothermal resources, reservoirs temperatures, reservoirs fluids, applications, and systems.

GEOTHERMAL ENERGY AND ENVIRONMENTAL IMPACT

Problems with energy supply and use are related not only to global warming but also to such environmental concerns as air pollution, acid precipitation, ozone depletion, forest destruction, the emission of radioactive substances, etc. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impacts. Much evidence exists that suggests the future will be negatively impacted if humans keep degrading the environment.[9]

One solution to both energy and environmental problems is to make better use of renewable energy resources, particularly geothermal resources. This cause is sometimes espoused with a fervor which leads to extravagant and impossible claims being made. Engineering practicality, reliability, applicability, economy, scarcity of supply, and public acceptability should all be considered accordingly.[10]

In order to achieve the energetic, economic, and environmental benefits that geothermal resources offer, the following integrated set of activities should be acted accordingly:

1. *Research and Development*: Research and development priorities should be set in close consultation with industry to reflect their needs. Most research is

Table 2 Geothermal resource types, applications and system types

Reservoir temperature	Reservoir fluid	Applications	Systems
High temperature (>220°C)	Water or steam	Power generation	Flash steam
			Combined (flash and binary) cycle
		Direct use	Direct fluid use

Medium temperature (100°C–220°C)	Water	Power generation	Binary cycle
		Direct use	Direct fluid use
			Heat exchangers
			Heat pumps
Low temperature (50°C–150°C)	Water	Direct use	Direct fluid use
			Heat exchangers
			Heat pumps

Source: Adapted from World Bank (see Ref. 11).

conducted through cost-shared agreements and falls within the short-to-medium term. Partners in these activities should include a variety of stakeholders in the energy industry, such as private sector firms, utilities across the country, provincial governments, and other federal departments.

2. *Technology Assessment*: Appropriate technical data should be gathered in the lab and through field trials on factors such as cost benefit, reliability, environmental impact, safety, and opportunities for improvement. These data should also assist the preparation of technology status overviews and strategic plans for further research and development.
3. *Standards Development*: The development of technical and safety standards is needed to encourage the acceptance of proven technologies in the marketplace. Standards development should be conducted in cooperation with national and international standards-writing organizations as well as other national and provincial regulatory bodies.
4. *Technology Transfer*: Research and development results should be transferred through the sponsorship of technical workshops, seminars and conferences, as well as through the development of training manuals and design tools, web tools, and the publication of technical reports.

Such activities will also encourage potential users to consider the benefits of adopting geothermal energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of geothermal energy technologies, particularly for district heating applications and power generation.

GEOTHERMAL ENERGY AND SUSTAINABILITY

Sustainable development requires a sustainable supply of clean and affordable energy resources that do not cause negative societal impacts.[12] Supplies of such energy resources as fossil fuels and uranium are finite. Energy resources such as geothermal resources are generally considered renewable and therefore sustainable over the relatively long term.

Sustainability often leads local and national authorities to incorporate environmental considerations into energy planning. The need to satisfy basic human needs and aspirations combined with increasing world population will make the need for successful implementation of sustainable development increasingly apparent. Various criteria that are essential to achieving sustainable development in a society include:

- Information about and public awareness of the benefits of sustainability investments,
- Environmental education and training,
- Appropriate energy and exergy strategies,
- The availability of renewable energy sources and cleaner technologies,
- A reasonable supply of financing, and
- Monitoring and evaluation tools.

Geothermal as a renewable energy has an important role to play in meeting future energy needs in both rural and urban areas. The development and utilization of geothermal energy applications should be given a high priority, especially in light of increased awareness of the adverse environmental impacts of fossil-based generation. The need for sustainable energy development is increasing rapidly in the world. Widespread use of geothermal energy is important for achieving sustainability in the energy sectors in both developing and industrialized countries.

Geothermal energy can be a key component for sustainable development for three main reasons, as follows:

- They may generally cause environmental impact much less than other energy resources. The variety of geothermal energy applications provides a flexible array of options for their use.
- They are considered renewable, and such energy resources can provide a reliable and sustainable supply of energy almost indefinitely. In contrast, fossil fuel and uranium resources are diminished by extraction and consumption.
- They favor both system centralization and decentralization and local solutions that are somewhat independent of the national network, thus enhancing the flexibility of the system and providing economic benefits to small isolated populations. Also, the small scale of the equipment, depending on the application, often reduces the time required from initial design to operation, providing greater adaptability in responding to unpredictable growth and changes in energy demand.

Not all renewable energy resources are inherently clean, meaning they cause no burden on the environment in terms of waste emissions, resource extraction, or other environmental disruptions. Nevertheless, use of geothermal resources almost certainly can provide a cleaner and more sustainable energy system than increased controls on conventional energy systems.

To seize the opportunities, it is essential to establish a geothermal energy market and gradually build up the experience with the cutting-edge technologies. The barriers and constraints to the diffusion of geothermal energy use should be removed. The legal, administrative, and financing infrastructure should be established to facilitate planning and the application of geothermal energy projects. Government can and should play a useful role in promoting geothermal energy technologies through funding and incentives to encourage research and development as well as commercialization and implementation in both urban and rural areas.

PERFORMANCE EVALUATION

From the thermodynamics point of view, exergy is defined as the maximum amount of work that can be produced by a system or a flow of matter or energy as it comes to equilibrium with a reference environment. Exergy is a measure of the potential of the system or flow to cause change as a consequence of not being completely in stable equilibrium relative to the reference environment. Unlike energy, exergy is not subject to a conservation law (except for ideal, or reversible, processes). Rather, exergy is consumed or destroyed due to irreversibilities in any real process. The exergy consumption during a process is proportional to the entropy created due to irreversibilities associated with the process.

Exergy analysis is a technique that uses the conservation of mass and conservation of energy principles together with the second law of thermodynamics for the analysis, design, and improvement of geothermal energy systems as well as other systems. It is also useful for improving the efficiency of energy-resource use, for it quantifies the locations, types, and magnitudes of wastes and losses. In general, more meaningful efficiencies are evaluated with exergy analysis rather than energy analysis because exergy efficiencies are always a measure of how nearly the efficiency of a process approaches the ideal. Therefore, exergy analysis identifies accurately the margin available to design more efficient energy systems by reducing inefficiencies. We can suggest that thermodynamic performance is best evaluated using exergy analysis because it provides more insights and is more useful in efficiency-improvement efforts than energy analysis. For exergy analysis, the characteristics of a reference environment must be specified. This is commonly done by specifying the temperature, pressure, and chemical composition of the reference environment. The results of exergy analyses, consequently, are relative to the specified reference environment, which in most applications is modeled after the actual local environment. The exergy of a system is zero when it is in equilibrium with the reference environment.

Energy and exergy balances for an unsteady-flow process in a system during a finite time interval can be written as:

$$\text{Energy input} - \text{Energy output} = \text{Energy accumulation} \quad (1)$$

$$\text{Exergy input} - \text{Exergy output} - \text{Exergy consumption} = \text{Exergy accumulation} \quad (2)$$

For a general steady-state, steady-flow process, it is assumed that the accumulation terms in the above equations become zero. Therefore, input terms become equal to output terms.

For a steady-state, steady-flow process, the mass balance equation can be expressed as

$$\Sigma \dot{m}_{in} = \Sigma \dot{m}_{out} \quad (3)$$

For a general steady-state, steady-flow process, the general energy and exergy balance equations can also be written more explicitly as

$$\dot{Q} + \Sigma \dot{m}_{in} h_{in} = \dot{W} + \Sigma \dot{m}_{out} h_{out} \quad (4)$$

and

$$\Sigma \left(1 - \frac{T_0}{T_s}\right) \dot{Q}_s + \Sigma \dot{m}_{in}(h_{in} - T_0 s_{in}) + \dot{E}x_d = \dot{W} + \Sigma \dot{m}_{out}(h_{out} - T_0 s_{out}) \quad (5)$$

We can generally define the energy and exergy efficiencies as follows

$$\eta = \frac{\dot{E}_{net}}{\dot{E}_{tot}} \quad (6)$$

and:

$$\psi = \frac{\dot{E}x_{net}}{\dot{E}x_{tot}} \quad (7)$$

For further details of the energy and exergy analysis, see Dincer and Rosen.[12]

In addition to the above analysis, several researchers[13–17] have introduced some resource classification criteria and performance and quality parameters as explained below:

Geothermal resources are classified as low, intermediate, and high enthalpy resources according to their reservoir temperatures, as mentioned earlier. The ranges may vary from one researcher to another. For example, Dickson and Fanelli[13] classified them as low (<90°C), medium (between 90 and 150°C) and high (>150°C), respectively. However, Lee et al. (2001) have come up with another approach based on their quality rather than their temperature through specific exergy index (SExI), as follows:

$$\text{SExI} = \frac{h_{brine} - 273.16 s_{brine}}{1192} \quad (8)$$

with the following criteria:

- Specific exergy index < 0.05 for low quality geothermal resources
- 0.05 ≤ SExI < 0.5 for medium quality geothermal resources
- Specific exergy index ≥ 0.5 for high quality geothermal resources

(Note that here, the demarcation limits for these indices are exergies of saturated water and dry saturated steam at 1 bar absolute.)

van Gool[18] has also noted that maximum improvement in the exergy efficiency for a process or system is obviously achieved when the exergy loss or irreversibility ($\dot{E}x_{in} - \dot{E}x_{out}$) is minimized. Consequently, he suggested the concept of an exergetic "improvement potential" when analyzing different processes. This improvement potential on the rate basis, denoted $\dot{\text{I}}\text{P}$, is given by[16]:

$$\dot{\text{I}}\text{P} = (1 - \psi)(\dot{E}x_{in} - \dot{E}x_{out}) \quad (9)$$

Xiang et al.[17] have also introduced some additional thermodynamic parameters to use for geothermal energy applications, as follows:

- Fuel depletion rate : $\delta_i = \frac{\dot{E}x_i}{\dot{F}_{tot}}$ (10)
- Relative irreversibility : $\chi_i = \frac{\dot{E}x_i}{\dot{E}x_{tot}}$ (11)
- Productivity factor : $\xi_i = \frac{\dot{E}x_i}{\dot{P}_{tot}}$ (12)
- Exergetic factor : $\beta_i = \frac{\dot{F}_i}{\dot{F}_{tot}}$ (13)

Note that in the calculations, the temperature T_0 and pressure P_0 of the environment are often taken as

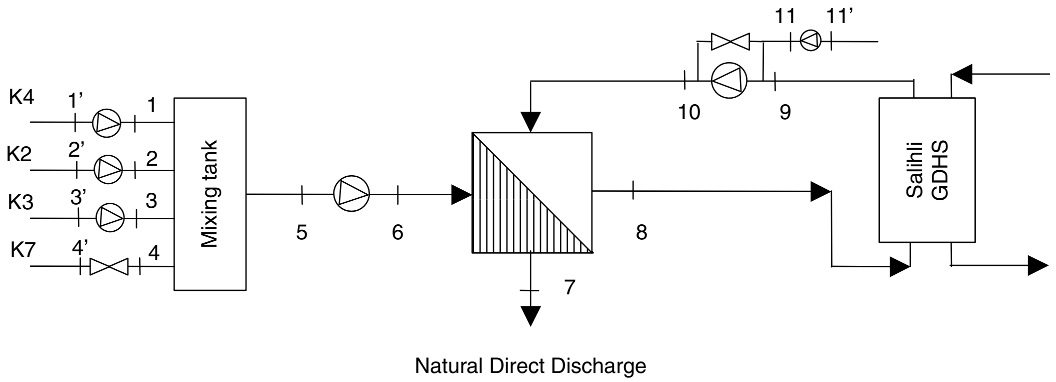

Fig. 1 A schematic of the Salihli geothermal district heating system (SGDHS).

standard-state values, such as 1 atm and 25°C. However, these properties may be specified differently depending on the application. T_0 and P_0 might be taken as the average ambient temperature and pressure, respectively, for the location at which the system under consideration operates. Or, if the system uses atmospheric air, T_0 might be specified as the average air temperature. If both air and water from the natural surroundings are used, T_0 would be specified as the lower of the average temperatures for air and water.

Detailed energy and exergy as well as exergoeconomic analysis methodologies for geothermal energy systems are given elsewhere.[19–22]

CASE STUDY

Here, a case study analysis of Salihli geothermal district heating system (SGDHS), which has a maximal yield of 87 L/s at an average reservoir temperature of 95°C with a minimal capacity of 838 MW[19] is presented. The SGDHS was originally designed for 20,000 residences equivalence. Of these, 2400 residences equivalence are heated by geothermal energy as of February 2004. The outdoor and indoor design temperatures for the system are 4 and 22°C, respectively.

Fig. 1 illustrates a schematic of the SGDHS where two hospitals and official buildings heated by geothermal energy were also included. The SGDHS consists mainly of three cycles, such as: (a) the energy production cycle (geothermal well loop and geothermal heating center loop), (b) the energy distribution cycle (district heating distribution network), and (c) the energy consumption cycle (building substations). At the beginning of 2004, there were seven wells ranging in depth from 70 to 262 m in the SGDHS. Of these, five wells were in operation at the date studied and two wells (K5 and K6) were out of operation. Four wells (designated as K2–K4, and K7) and one well (K1) are production and balneology wells, respectively.

The well head temperatures of the production wells vary from 56 to 115°C while the volumetric flow rates of the wells range from 2 to 20 L/s. The geothermal fluid is basically sent to two primary plate type heat exchangers and is cooled to about 45°C as its heat is transferred to secondary fluid.

The geothermal fluid (7) is discharged via natural direct discharge with no recharge to the Salihli geothermal field production, but reinjection studies are expected to be completed in the near future. The temperatures obtained during the operation of the SGDHS are, on average, 98/45°C for the district heating distribution network and 62/42°C for the building circuit. By using the control valves for flow rate and temperature at the building main station, the needed amount of water is sent to each housing unit and the heat balance of the system is achieved.

Table 3 Salihli geothermal district heating system (SGDHS) data and energetic, exergetic, and thermodynamics parameter calculated

[a]Based on the exergy (or energy) input to thermal water and water.

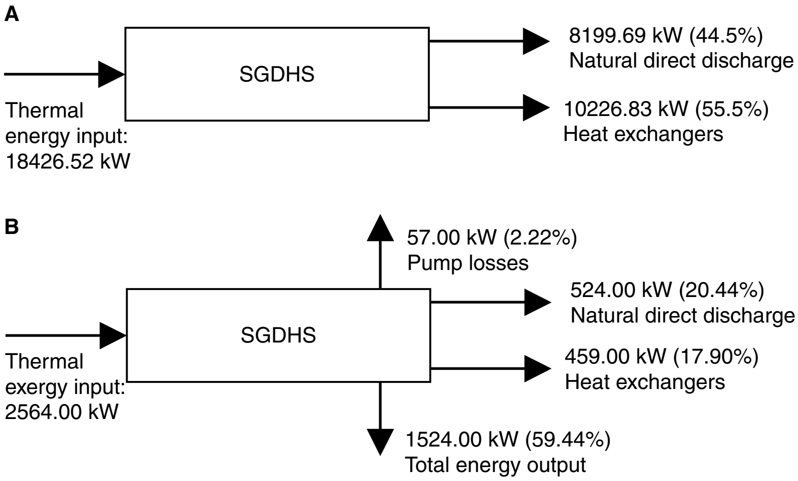

Fig. 2 System flow diagrams for (A) energy and (B) exergy.

Geothermal fluid collected from the four production wells at an average well heat temperature of 95.5°C is pumped to the inlet of the heat exchanger mixing tank later a main collector (from four production wells) with a total mass flow rate of about 47.62 kg/s. Geothermal fluid of intermingling molecules of different species through molecular diffusion was neglected in this study. As a result, not only irreversibility of the mixing tank was assumed equal to zero, but also heat losses from the tank and main collector pipe line (5–6) through the mixing process were neglected.

In the SGDHS investigated, the thermal data on pressures, temperatures, and flow rates of the fluids were measured using a number of devices and employed in the models. The detailed information is presented in Ozgener et al.[19]

RESULTS AND DISCUSSION

The thermodynamic data used in the case study are based on the actual data taken from the SGDHS on 1 February 2004. The number of the wells in operation in the Salihli geothermal field may normally vary depending on the heating days as well as the operating strategy. Taking into account the four productive wells when this study was conducted and using Eq. 8, the SExI is found to be 0.049, which is very close to the limit of the medium quality geothermal resources. This represents that the Salihli geothermal field falls into the low quality geothermal resources according to the classification of Lee.[15]

The total mass flow rates of the geothermal fluid at the inlet of the heat exchanger (the total mass flow rate of the production wells) were measured to be 47.62 kg/s at an average temperature of 44.2°C on 1 February 2004. If hot water losses measured in the district heating distribution network are above 5 m^3/h, the water is generally added via a pump (using pressurized water tanks) to the network in order to cover the leaks taking place. However, the hot water losses were neglected in this study as these losses were below 5 m^3/h on the day of the study.

The calculation results, based on the actual data taken, are presented in Table 3. These include all energetic and exergetic parameters as well as other thermodynamic parameters along with the efficiencies. The energy and exergy efficiencies of the SGDHS are determined to be 55.5 and 59.4%, respectively. Here, the exergy efficiency is higher due to the recirculation and heat recovery processes.

The energy and exergy flow diagrams are presented in Fig. 2. As illustrated in Fig. 2a, the natural direct discharge of the system accounts for 44.5% of the total energy input. An investigation of the exergy flow diagram given in Fig. 2b shows that 40.56% (accounting for about 1040 kW) of the exergy entering the system is lost, while the remaining 59.44% is utilized.

The highest exergy loss of 20.44% occurs from the natural direct discharge in this study. The second largest exergy destruction occurs from the heat exchanger with 17.90% (about 459 kW) of the total exergy input. This is followed by the total exergy destruction associated with the pumps amounting to some 57 kW, which accounts for 2.22% of the exergy input to the system.

In addition, the exergetic improvement potential (IP) rate of Van Gool's[18] is found to be 106.04 kW for the plate-type heat exchanger installed in the SGDHS. Furthermore, in order to improve the system efficiency, natural direct discharge should be decreased.

CONCLUSIONS

In this article, some historical background on geothermal energy resources and applications have been presented, some technical, economical, environmental, and sustainability aspects of geothermal energy have been discussed, and performance evaluations tools in terms of energy and exergy analyses for such geothermal energy systems have been outlined. A case study has also been presented to highlight the importance of exergy use as a potential tool for system analysis, design, and improvement.

Geothermal Heat Pump Systems

Greg Tinkler
RLB Consulting Engineers, Houston, Texas, U.S.A.

Foss–Gre

Abstract
Geothermal heat exchanger technology is the most efficient method of heating, cooling, or refrigerating any enclosure that can be conditioned. The earth's thermal mass has an almost-endless capacity to absorb and store heat. Geothermal heat pumps (GHPs) first became well known in the energy crises of the 1970s in the United States; they had been used in Europe for many years before that. Since then, this technology had been researched and implemented successfully in projects of all sizes—from small mobile homes to large schools and universities and to complete developments with multiple systems. These systems can refrigerate down to below 0°F and heat water for domestic use up to 120°F. Geothermal systems have been applied successfully to projects around the world, from inside the Arctic Circle to the desert regions. Geothermal systems have been applied to projects from large buildings in the country to medium-size structures in Manhattan.

The larger the demand placed on an heating, ventilation, air conditioning and refrigeration (HVAC/R) system, the faster the payback period for the upfront capital cost. Vertical geothermal heat pump systems can usually be built for about the same cost as a 4-pipe chiller/boiler system.

Geothermal technologies are considered to be renewable energy as well as energy-efficient technologies. These systems should never be overlooked when thinking about designing any system for the purpose of conditioning space or the temperature of a material or process. These systems are not complicated and can be among the simplest systems for the purposes to which they are applied. This entry explains some of the basic concepts and terms used in this industry.

INTRODUCTION

Use of the earth's resources as a medium for transferring heat is a technology that can be utilized for heating, cooling, and refrigeration. The technology can be referred to as geoexchange systems, ground source heat pumps, ground coupled heat pumps, or earth coupled systems. These interchangeable names all refer to the use of geothermal heat pump (GHP) systems.

The U.S. Department of Energy (Environmental Protection Agency (EPA)) has proclaimed that GHP systems are the most efficient technology available for space conditioning. Typical savings on the total energy use of the building can be from 10 to 50%, depending upon the demand placed on the space conditioning systems. Energy savings realized against the most efficient water-cooled chiller systems can be 10%, whereas savings against typical air-to-air technologies can be as high as 50%. Geothermal heat pump systems in most states have been declared not only energy efficient, but also renewable energy. These distinctions qualify the GHP system for most state energy requirements and/or tax incentives. Geothermal heat pump systems contribute to points necessary for Leadership in Energy and Environmental Design (LEED) certification.

Geothermal heat pump systems are becoming more widely used because they are both renewable energy and energy efficient. This is one technology that fits into both categories. This article is intended to describe the technology as well as the benefits of using these systems.

For a discussion of this topic, some terms and conversion rates should be defined.

Keywords: Geothermal; Geoexchange; Ground source heat pump; Earth heat exchanger; Ground coupled heat pump; Closed loop system; Pond heat exchanger.

TERMS

British thermal unit (Btu) is the amount of heat that it takes to raise 1 lb of water 1°F. This is the typical unit of measure for heating systems in the United States.

Ton (ton) is 12,000 Btu/h and is defined as the amount of heat that it takes per hour to melt 1 ton of ice in a 24-hour period. In the United States, most "air-cooled" cooling systems are sized or measured based on how many tons of heat they can transfer. A ton is a unit of flow and not a unit of volume. Ton-hour is the expression of volumetric heat.

Kilowatt (kW) is a unit of measure for both heat and electricity. With electricity, a kilowatt is 1000 W. A watt is calculated by multiplying volts times amps for air conditioning systems with only resistive loads. With heat, 1 kW = 3412.83 Btu. Kilowatts are a unit of flow and not a unit of volume. Volume is usually expressed in kilowatt per hour. In European and other countries, the term kilowatt is used to express the amount of heat that the cooling system or heating system can move.

Coefficient of performance (COP) is a relationship of watts-out to watts-in or kilowatts-out divided by kilowatts-in. Receiving 4 kW of heat from a machine by buying 1 kW of energy from the electric plant to operate the machine, for example, represents a COP equal to 4. You may see this term used in both the United States and Europe as a unit of measure of the performance of a heating and/or cooling system.

Energy efficiency ratio (EER) is a term used to describe the efficiency of a cooling system in the United States. The EER is computed by dividing the british thermal unit per hour that the unit produces by the amount of watts bought from the utility company to run that machine. When attempting to discover the EER listed on a piece of equipment, a seasonal energy efficient ratio (SEER) may be listed instead. The SEER is not the same as the EER. The SEER is not an easily calculated value because it requires a run-test at some temperature condition, of the air streams, to determine the value. The SEER may not represent the actual performance when installed on a project.

Greenhouse gas (GHG) is the byproduct/pollution generated either from a furnace/boiler or from a power plant burning a fossil fuel to generate the electricity used by the machine. Typical GHG produced are carbon dioxide (CO_2), sulfur dioxide (SO_2), and nitrous oxide (NOx). Cars produce CO_2, for example, which is a source of pollution in most metropolitan areas. Trees consume CO_2 and emit O_2. Greenhouse gas pollution is sometimes expressed in the equivalent number of trees it would take to neutralize the pollutant or in the equivalent number of cars it would take to release the same amount of CO_2.

THE GHP SYSTEM

The principle of a GHP system is to transfer heat to and from the earth. In cool weather, the earth's natural heat is collected through a series of pipes called the loop. A fluid circulating in the loop (usually water) carries this heat from the earth to the GHP. Then, an indoor GHP unit uses electrically driven compressors and heat exchangers to concentrate the earth's heat and release it inside the facility at a higher temperature. In typical systems, ducted fans distribute the heat to various rooms.

In warm weather, the process is reversed to cool the facility. This is done by drawing excess heat from the facility; transferring the heat to the fluid using the GHP; and then expelling the heat to the loop, where it is absorbed by the earth. Geothermal heat pump units provide cooling in the same way that a refrigerator operates—by drawing heat from the interior, not by injecting cold air.

Example System 1

Tinkler and Nilsson[1,2] provide the following example, which describes the operation of a residential GHP system and the related measures of COP, energy usage, and efficiency.

The average COP of a typical GHP system during the first ten years is:

- Heating mode—COP: 4.5
- Cooling mode—COP: 4.

Heating Mode

To produce 4.5 kW (15.3 thousand Btu/h) of heating in a building, the GHP system uses 1 kW of electricity and 3.5 kW (11.9 thousand Btu/h) of the earth's natural energy (Fig. 1).

[4.5 = 1 + 3.5]

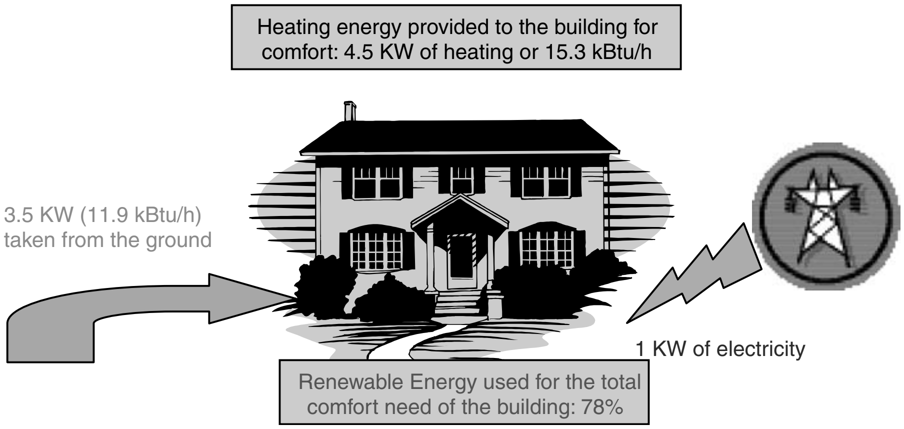

Fig. 1 Operation of a residential Geothermal heat pump (GHP) system: Heating mode.

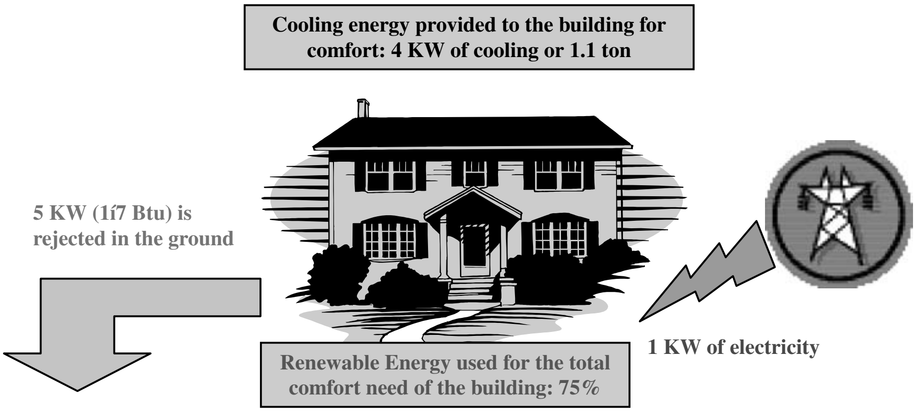

Fig. 2 Operation of a residential Geothermal heat pump (GHP) system: Cooling mode.

The GHP system's COP=4.5 when a conventional gas furnace has a COP of 0.8.

Cooling Mode

To produce 4 kW (1.1 ton) of cooling in a building, the GHP system uses 1 kW of electricity to reject 5 kW (1.7 kBtu/h) in the earth (Fig. 2).

$$[4 = 1 + (-5)]$$

The GHP system has an EER of 14 when a conventional air conditioner (air-cooled) system would have an EER of 9.[1]

Example System 2

An environmental benefit of a GHP system is GHG emission reduction. To illustrate this benefit, consider a 350-ton HVAC retrofit project in Texas, at Lubbock Christian University. The annual emission reduction would be

Carbon dioxide (CO_2) in pounds	Sulfur dioxide (SO_2) in grams	Nitrogen oxide (NO_X) in grams
9,71,998	6,17,039	8,61,661

This is equivalent to preserving 3.61 acres of land from deforestation or taking 95 passenger cars off the road for a year.[2]

These emissions reductions are calculated using System Analyzer software from Trane (a division of American Standard Companies, Inc.). They are based on the electricity and gas savings and on the energy mix of the state. The conversion for cars and trees can be determined by using the EPA Web site.[3]

GHP Compared with Conventional HVAC

The American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE) reported typical findings for GHP systems compared with conventional HVAC systems:

- *Energy*. Geothermal can reduce energy demand (kW) and energy consumption (kW/h) by 40% compared with air source heat pumps and by more than 70% compared with electric resistance heating with standard air conditioning equipment, according to the EPA. Usually, HVAC accounts for approximately 60%-plus of the annual energy bills of a building.
- *Operation and maintenance*. Geothermal (GHP) can reduce up to six times the costs of the HVAC operation and maintenance costs (Table 1).

Table 1 Findings for GHP systems compared with conventional HVAC system.

	Ground source heat pump (closed loop)	Split system heat pump	Reciprocating chiller + gas-fired boiler	Water source heat pumps + gas-fired boiler
Total maintenance costs per year per cooling ft^2 (cents/year/cooled ft^2)	8.9	34.5	56	63.3
Comparison with ground source heat pump system	—	+288%	+529%	+611%

Source: Study American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE) 2000 based on a sample of 170 buildings-update on maintenance and services costs of commercial buildings ground source heat pump system (see Ref. 4).

- *System life*. According to ASHRAE, geothermal cooling and heating indoor equipment has a rated equipment life of more than 25 years. The exterior portion of the system—the underground loop field—has a rated materials life of more than 100 years.[4]

TYPES OF EARTH HEAT EXCHANGERS

The term geothermal usually applies to the technology of using water source heat pumps (extended range) connected to a thermal mass. The most widely used form is composed of several vertical boreholes, tied in parallel, that are drilled deep into the earth. The thermal mass of the earth is used as the heat sink/heat source, depending on the climate and the application. Other thermal mass technologies are ponds or lakes with a heat exchanger in the bottom of the body of water. A third form is horizontal trenches up to 6 ft deep with several looped pipes buried in those trenches. A final form is the use of groundwater volumes pumped from below the earth's surface up to a heat exchanger in the building.

There may also be a combination of these forms on any site. On the Lubbock Christian University campus, for example, are three of the four examples shown in Fig. 3: a vertical closed loop, a water supply and reinjection well, and a pond loop (currently under construction).

Over the past few decades, the commercial/industrial/institutional markets have grown significantly. In the commercial market, large metropolitan areas offer the greatest challenge for developing geothermal systems because of the access to land to tap the earth's thermal mass. To combat this challenge, commercial projects have installed groundwater systems using a local surface water source. When this is not feasible, they have turned to more advanced geothermal systems, such as standing column well technology or hybrid systems tied to a cooling tower or boiler to supplement the geothermal heat exchanger.

Another resourceful solution uses the high-rise building's dewatering system. In several areas of the country, high-rise buildings have a dewatering system to keep their underground structure from flooding. This is an excellent water stream that can be a significant volume of water in which to transfer heat.

One of the reasons why geothermal is so efficient is that the operating temperature difference between the evaporator and the condenser is low compared with other systems. This is more evident in commercial refrigeration systems, in which the temperature difference can go from a 0°F box to a 65°F earth rather than from a 0°F box to a 100°F rooftop. This reduced temperature differential is what makes geothermal more efficient than any other system. Even with future technological advances in equipment, the GHP system will still be more efficient, because these same enhanced components can be integrated into the geothermal system, which will improve their performance even more.

ORGANIZATIONS

States usually regulate drilling into the earth, and those regulations need to be known before beginning to design a

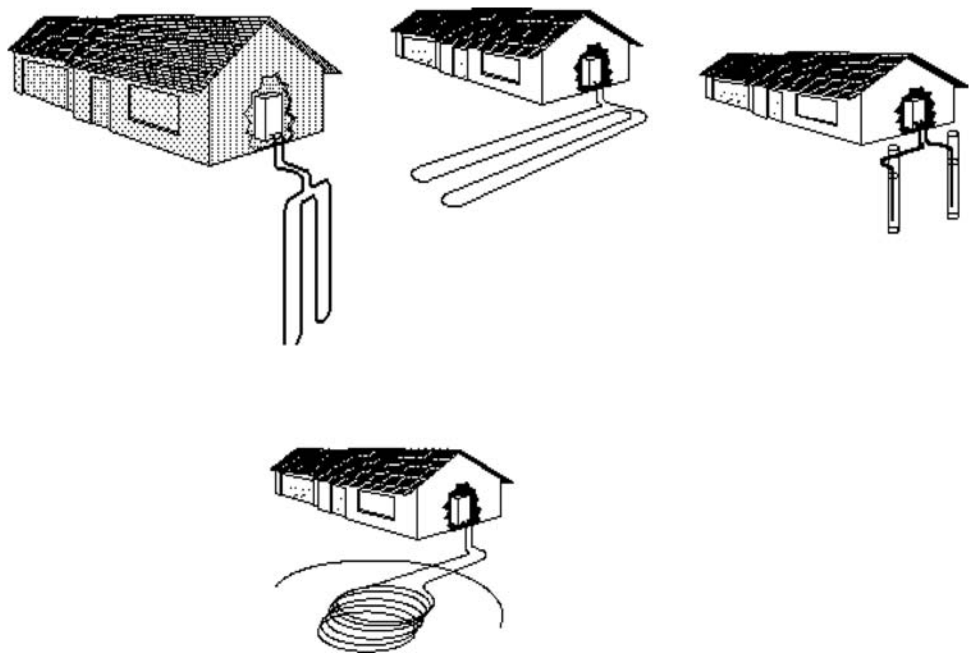

Fig. 3 Types of Earth heat exchangers.

geothermal system. Investigation should also be performed for local regulations that will impact the project. Sources of information about these systems can be found through the local utility companies, the International Ground Source Heat Pump Association (IGSHPA), the Geothermal Heat Pump Consortium (GHPC), and ASHRAE, to name just a few.

These systems have existed in Europe for many years, with significant research being done by Lund University in Sweden. In the United States, research has been performed by ASHRAE, IGSHPA (located at Oklahoma State University), the University of Alabama, and the Geo-Heat Center at the Oregon Institute of Technology. There are also several certified geothermal designers (CGD) in the United States who have been certified by the Association of Energy Engineers (AEE) to design these systems.

DEVELOPING A SYSTEM

The Building

In developing a GHP system, the standard terms used in the HVAC/R market still apply. The first phase in the design is the same with any HVAC system: begin by doing a load calculation for the system. A load calculation is a means of calculating how much heat is entering or leaving the space that is to be conditioned. It can be a space that people will occupy, such as a home or an office building, a refrigeration box for storing frozen foods, or heating the domestic water in a sports complex for people to shower. Anything that can be done with typical HVAC/R systems can be done with a geothermal system. There are all types of (GHP) systems for conditioning air or water for any type of service that is needed. Where geothermal systems differ in sizing from the typical systems is in the thermal mass, as discussed above.

At the beginning of the load calculation, a useage schedule needs to be assigned to every load that makes up the total load. Remember that a ton (kW) is a rate of flow and not a volume of heat, like ton-hour or kilowatt per hour. Here is an analogy for understanding this concept:

Think of designing a swimming pool. The first decision is how big to make the pool. An initial question would be how many people are going to be swimming at one time. The next things to determine are what the people will be doing in the pool and how much water will be forced out of the pool during the activity, because the water removed will have to be replaced. For the purpose of this analogy, the swimming pool will be filled using a garden hose.

As with typical load calculations, a coincident peak load (usually around July 21 or December 21) that represents the maximum heat transfer rate is needed to size the equipment. This is a rate of flow and does not represent the volume of heat being moved in either direction over time. Thus, a question emerges: how long will it take the garden hose to fill the pool?

The questions above are the same types of information needed to size a geothermal system. Apply this to another example calculation. The total equipment needed on the coincidental peak load days is 100 ton (351.6 kW). This load may exist for only a few hours of the 8760 h in each year, but the system may use 40 ton (140.6 kW) of the 100 ton for 1500 h of the year. The remaining hours of the 8760 h in the year will be at other partial-load conditions or even completely off. This is the information needed to figure out how much total heat is being put into a thermal mass that is going to absorb and store it for many days.

This principle of storing and reuse is what makes this technology a renewable energy. The heat that the system pulls out of the building in the summer will be held in the thermal mass until the next winter, when the system wants to pull the heat back out of the thermal mass and reuse it to heat the building. The object of the design is to make sure that the thermal mass is of sufficient size to store the heat annually or if it is imbalanced over the life of the system. The perfect system design is one in which the heat being put into the thermal mass in the summer is equal to the heat that needs to be pulled out in the winter. This is very rarely the case, however. In completing the calculation, one thing that is often missed is the internal heat of the machines performing the heat transfer. A 5-ton (17.5 kW), 10 EER machine, for example, can put 7 ton (24.6 kW) into the thermal mass but needs to extract only 3 ton (10.5 kW) from the thermal mass to produce its rated capacity. The 4 ton difference (7 − 3 ton) needs to be added into the equation. Therefore, the perfectly balanced system is not a balanced load calculation—there needs to be a higher heating requirement in the building than what needs to be rejected to the thermal mass.

The most important factor in a successful geothermal project is a thorough understanding of the heat to be transferred to and from the thermal mass. Typical software for doing these types of load calculations is readily available; programs include DOE2, TRACE 700, Energy Plus, and HAP.

The Thermal Mass

Once the heat volume is determined the next thing to examine is the thermal mass that will be used to transfer the heat to/from. If the system is to use the earth as the thermal mass, consultation with a professional geologist is recommended. A professional geologist can assist in understanding the thermal conductivity and deep-earth temperature for any site. There are also companies that will travel to the site, drill a borehole, and test the geological formation for these characteristics. The deep-earth average temperature is important because it is the starting point for transferring heat to and from the earth at this site. If a deep-earth average temperature is 50°F, for example, the cooling performance is going to be very good. On the other hand, if a deep-earth average temperature is 70°F, heating will produce better results. The thermal conductivity of the soils on each particular site will determine how fast heat moves through those particular soils in that particular borehole. Remember that the soil can vary widely from one site to the next and from one borehole to another, even at the same job site. There is no rule of thumb here, and it would be ill advised to try to apply one.

When the load profile is established and the thermal mass that is going to be used for heat storage is identified, the design can begin. Several programs available for sizing geothermal heat exchangers are GCHPcalc, GLHEPRO, GLCS, GL Design, GeoDeveloper, and GeoEase. Keep in mind that all the factors basically form a circular reference; no one factor is the driving force for the optimal design. All the variables interact and are dependent on one another for how they will react within the total system design of both the building and the thermal mass.

A Single Borehole

Another variable to recognize is borehole resistance. The thermal properties of the fluid that is carrying the heat to the thermal mass from the building equipment, and vice versa, should be known. The thermal properties of the thermal mass also should be known. Borehole resistance occurs between the fluid and the thermal mass as the heat passes from one to the other. The turbulence of the fluid, the type of pipe material, and the type of grout used in the borehole are examples of what creates the borehole resistance. The fluid must be turbulent, with a recommended Reynolds number between 2500 and 5000. Making the fluid more turbulent does not increase the heat transfer, but instead results in increased pumping energy to overcome friction losses in the pipe. Using too much pumping energy can negate the savings created by the GHP system.

The heat must be transferred from the fluid into the high-density polyethylene (HDPE) pipe that the loop is made of, then through the grout, and into the earth. Understanding the borehole resistance, how the borehole will be constructed by the contactor, and the equipment used to build the heat exchanger are important factors. Being familiar with the equipment that is readily available in the area or that may be used on the job site will need to be factored into the design. Requiring thermal conductivity tests during the construction process and verifying that the methods used in the construction process are within an acceptable range of the assumptions used in the design are parts of a good quality-assurance/quality-control protocol. There are software packages available for back-calculating the borehole resistance of a known construction method.

Grout is another very important factor in how the heat exchanger and borehole will perform. This is also one of the materials usually covered by state regulations on how a borehole is to be constructed. The grout is used to fill the annular space between the loop and the wall of the borehole created by the drill bit. Grout is one of the leading factors in borehole resistance, as discussed above. Although there is much debate about how to grout a borehole and what type of material should be used, it is an industry recommendation that this annular space be filled, and that the mixture used to fill it be determined during the design phase and be continuous throughout the construction process.

Some of the grouts typically used in geothermal heat exchangers are a 40% solids bentonite, a thermally enhanced bentonite, and a thermally enhanced cementitious-based grout. Some states may also allow the use of other materials, which cannot be covered within the limits of this entry. Investigation of all grouts available within the confines of the regulations for an area can be delivered by the contractors who may perform the work.

Fig. 4 is a cutaway diagram of a typical borehole. The loop is a long U-bend made out of HDPE.

OTHER CONSIDERATIONS

Another variable mentioned only slightly above is pumping. American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. has conducted several studies on the performance of pumping within geothermal systems. Investigation into pumping alternatives should be conducted so that enhanced energy savings can be achieved within the constraints of the design. Alternatives might include variable-speed pumping with the use of a variable-frequency drive on the pump motor or the use of distributive pumping techniques if the load

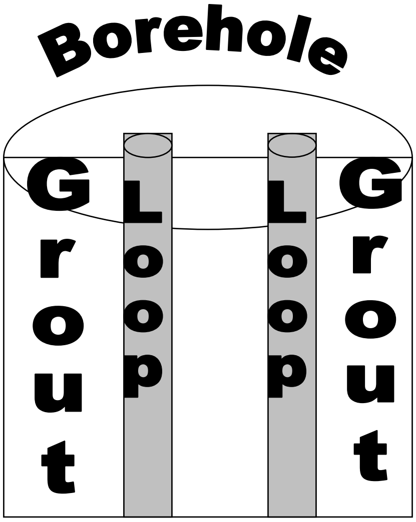

Fig. 4 Cutaway representation of a typical borehole.

profile indicates a high degree of diversity within the use of the facility.

One final factor in the design of the piping system is to remember that—as in any hydronic system—air is its worst enemy. These systems must be designed with purge and flush ports. These ports are a set of valves teed into the system to allow an external pump to be attached to the pipe. The minimum flow rate of the external pump must achieve a 2 ft/min flush rate to remove all air from the system. It is recommended that a fill line and an air-removal device be placed in the piping system. The properties of HDPE dictate that it have a large expansion coefficient, in that for every 10°F that the fluid temperature changes and for every 100 ft of pipe, the pipe will expand 1 ft. This expansion is a large volume that needs to be replaced by additional fluid if the system is very large. In residential systems that are very small, the designer may not want to consider a fill line, because it may create a water issue should a pump seal fail or another failure occur. Because HDPE is not 25/50-(flame spread/smoke developed) rated and should not be run in plenum spaces, the use of this pipe inside a building is restricted. The use of HDPE offers a considerable capital savings, however, if the building design can avoid running the pipe in plenum spaces.

CONCLUSION

Geothermal heat pump systems are the most efficient systems available today for many projects. This technology has been proved over time, and the tools necessary for a successful project exist in the market today. Design guides are available from ASHRAE (www.ashrae.org) and IGSHPA (www.igshpa.okstate.edu), as are other standards and specifications for these types of systems.

Nathan E. Hultman
Science, Technology, and International Affairs, Georgetown University, Washington, D.C., U.S.A.

Abstract

The global-mean temperature at Earth's surface has increased by about 0.6°C (1.1°F) over the past century. Most of this warming is due to the excess greenhouse gases emitted to the atmosphere by human activities such as fossil fuel use, agriculture practices, and land-use change. Many changes in natural systems have already resulted from this warming, including melting of glaciers and ice caps, increasing sea level, extended growing seasons, changes in precipitation regimes, and changes in the geographical distributions of plant and animal species. Current projections, based on reasonable assumptions of future energy-use practices, indicate that Earth will continue to warm during the 21st Century and beyond, in part because parts of the Earth system respond slowly to changes in greenhouse gas levels.

INTRODUCTION

For the past century, Earth's climate has been changing due to human activities. Observations show that Earth's surface warmed by approximately 0.6°C (1.1°F) on average in the 20th Century. Much of this warming has been attributed to increasing abundances of greenhouse gases emitted to the atmosphere by human activities, although it is difficult to quantify this contribution against the backdrop of natural variability and climate-forcing uncertainties. Atmospheric abundances of the major anthropogenic greenhouse gases (carbon dioxide; methane; nitrous oxide; halocarbons manufactured by humans, such as chlorofluorocarbons; and tropospheric ozone) reached their highest recorded levels at the end of the 20th Century, and all but methane have continued to rise. Major causes of this rise have been fossil fuel use, agriculture, and land-use change.

The emerging impacts of climate change on natural systems include melting glaciers and ice caps, the rising sea level, extended growing seasons, changes in precipitation regimes, and changes in the geographical distributions of plant and animal species. Additional impacts, to which it may be difficult for human and natural systems to adapt, could arise from events whose triggers are poorly understood. Human-induced global warming will continue during the 21st Century and beyond, because many parts of the Earth system respond slowly to changes in greenhouse gas levels and because altering established energy-use practices is difficult. Uncertainties remain about the magnitude and the impacts of future climate change, largely due to gaps in understanding of climate science and the socioeconomic drivers of climate change.

THE CLIMATE SYSTEM AND THE NATURAL GREENHOUSE EFFECT

While climate conventionally has been defined as the long-term statistics of the weather (e.g., temperature, cloudiness, precipitation), improved understanding of the atmosphere's interactions with the oceans, the cryosphere (ice-covered regions of the world), and the terrestrial and marine biospheres has led scientists to expand the definition of climate to encompass the oceanic and terrestrial spheres as well as chemical components of the atmosphere (Fig. 1). Physical processes within the atmosphere are influenced by ocean circulation, the reflectivity of Earth's surface, the chemical composition of the atmosphere, and vegetation patterns, among other factors.

The Sun provides almost all of Earth's energy. Solar radiation intercepted by Earth first encounters the atmosphere, which allows most of it to pass to Earth's surface. The intensity of radiation at the surface depends on the amount of incident radiation and on the orientation of the surface with respect to that radiation. The surface either reflects or absorbs this incoming radiation. Different surfaces reflect different amounts of sunlight. The fraction of solar energy reflected is defined as a surface's albedo. Albedos range from about 10% for open water, dark soil, and asphalt to about 80% for fresh snow.[1] Earth's average albedo is about 31%.

Although we do not normally think of it as a radiative body, Earth—like all bodies with a nonzero temperature—emits electromagnetic radiation. For Earth's temperature, most of this radiation is in the form of infrared light. In the absence of an atmosphere, all the radiation emitted by Earth would escape to space. The balance of incoming solar radiation and outgoing infrared radiation would result in a global-mean temperature for Earth of 255 K (−18°C/0°F). However, some molecules in Earth's atmosphere absorb some of this outgoing infrared light, thereby increasing their temperature. These greenhouse gases in the atmosphere emit some energy back toward Earth, warming Earth's surface. This natural greenhouse effect, which is present in the absence of human activities, raises the global-mean surface temperature from 255 K to a comfortable 288 K (or about 15°C/59°F).[2]

Greenhouse gases that are present naturally in the atmosphere include water vapor (H_2O), carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and ozone (O_3). The most common greenhouse gas by quantity and the one exerting the greatest influence on the climate is water vapor; however, because water has a very short lifetime in the atmosphere (~1 week), any human perturbation will dissipate quickly. In most cases, the "greenhouse effect" or "climate change" refers not to this natural phenomenon but to additional, anthropogenic enhancements to the atmosphere's capacity to trap heat. Much higher concentrations of CO_2, CH_4, and N_2O have been observed in the past century than were naturally present for the past 1000 years (Fig. 2) and likely much

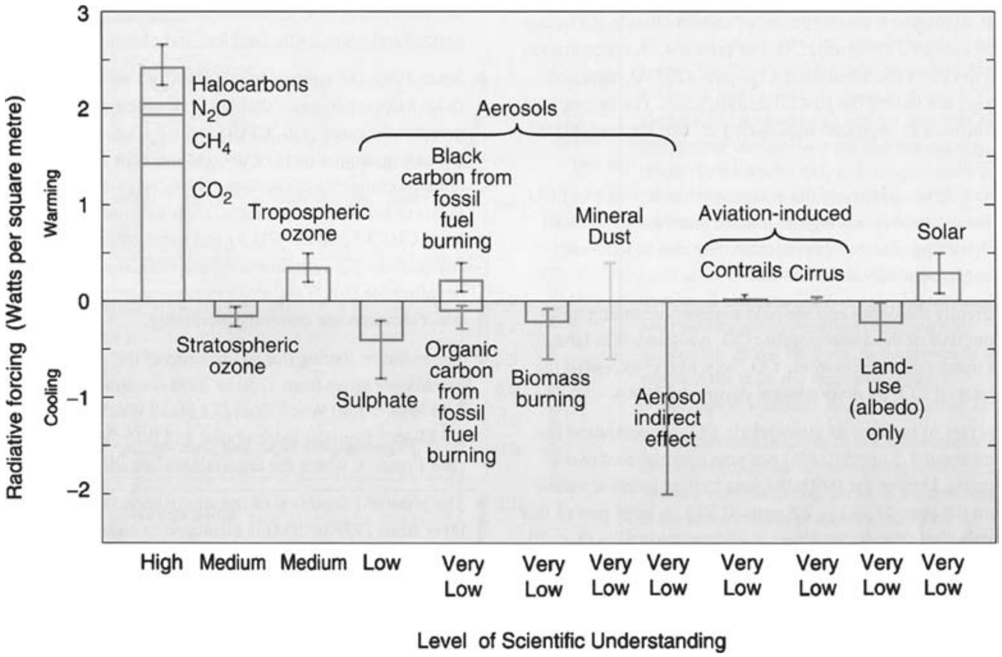

Fig. 3 Estimated radiative forcings since preindustrial times for Earth and the troposphere system. The height of the rectangular bar denotes a central or best estimate of the forcing, while each vertical line is an estimate of the uncertainty range associated with the forcing, guided by the spread in the published record and physical understanding, and with no statistical connotation. Each forcing agent is associated with a level of scientific understanding, which is based on an assessment of the nature of assumptions involved, the uncertainties prevailing about the processes that govern the forcing, and the resulting confidence in the numerical values of the estimate. On the vertical axis, the direction of expected surface temperature change due to each radiative forcing is indicated by the labels "warming" and "cooling."
Source: From Intergovernmental Panel on Climate Change (see Ref. 10).

longer.[3] Earth's surface is warmer now on average than it was at any time during the past 400 years, and it is likely warmer now than it was at any time in the past 2000 years.[4]

CLIMATE FORCINGS AND FEEDBACKS

Factors that affect climate change are usefully separated into forcings and feedbacks. Climate forcings are energy imbalances imposed on the climate system either externally or by human activities.[5] Examples include human-caused emissions of greenhouse gases, as discussed in the preceding section, as well as changes in solar energy input; volcanic emissions; deliberate land modification; or anthropogenic emissions of aerosols, which can absorb and scatter radiation. Climate forcings can be either direct or indirect. Direct radiative forcings are simple changes to the drivers of Earth's radiative balance. For example, added CO_2 absorbs and emits infrared radiation. Indirect radiative forcings create a radiative imbalance by first altering climate system components that lead to consequent changes in radiative fluxes; an example is the effect of aerosols on the precipitation efficiency of clouds. Fig. 3 provides a summary of the estimated contribution from major climate forcings. Additional information about specific climate forcings is provided in the discussion below.

Climate feedbacks are internal climate processes that amplify or dampen the climate response to an initial forcing.[6] An example is the increase in atmospheric water vapor that is triggered by an initial warming due to rising CO_2 concentrations, which then acts to amplify the warming through the greenhouse properties of water vapor (Fig. 4). Other climate feedbacks involve snow and ice cover, biogeochemistry, clouds, and ocean circulation. Some of the uncertainty about how the climate will change in the future stems from unresolved research questions on climate change feedbacks.

Natural Climate Forcings: Solar and Volcanic Variability

Variations in the Sun's activity and in Earth's orbital parameters cause natural forcing of climate. Radiometers on various spacecraft have been measuring the total solar irradiance since the late 1970s. There is an 11-year cycle in total solar irradiance of peak-to-peak amplitude ~1 W m^{-2} (0.1%) in the past three cycles. Allowing for reflection of 30% of this incident energy (Earth's albedo) and averaging over the globe, the corresponding climate forcing

Foss–Gre

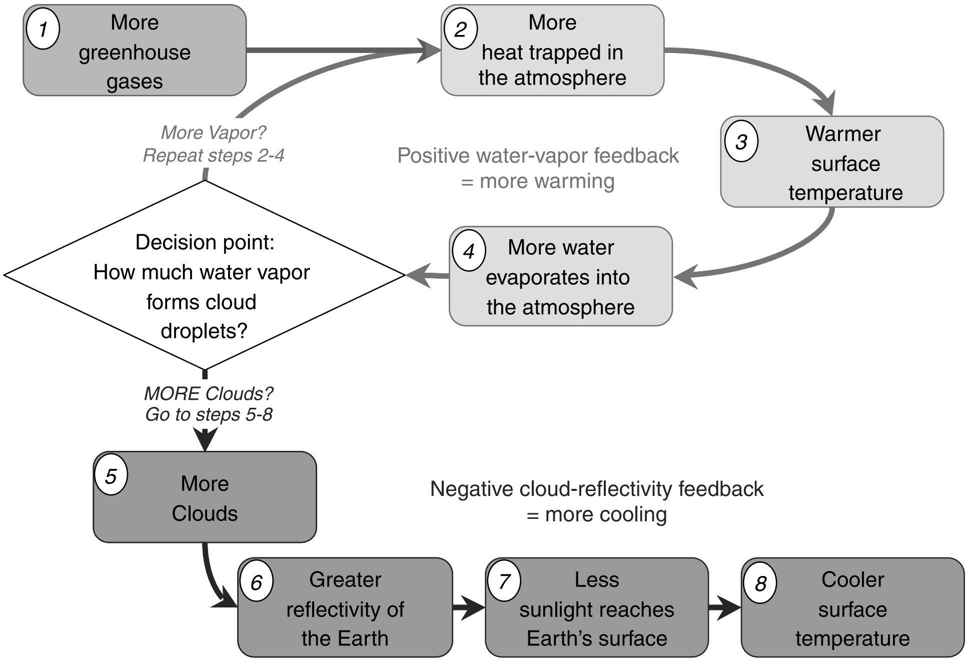

Fig. 4 This schematic illustrates just two out of the dozens of climate feedbacks identified by scientists. The warming created by emitting more greenhouse gases leads to evaporation of water into the atmosphere. But water itself is a greenhouse gas and can cause even more warming via positive water-vapor feedback. On the other hand, if the water vapor leads to more clouds, the result could be to counteract some of the warming because clouds can reflect incoming sunlight back to space. This chain of events is negative cloud-reflectivity feedback. Trying to understand whether water vapor will create more clouds and what kinds of clouds water vapor will create is a major research objective right now. The answer depends on weather patterns, where the evaporation takes place, and the amount of small soot particles suspended in the air.

is of order 0.2 W m^{-2}, although recent analyses have found little secular trend in solar irradiance over the past 30 years.[7] Knowledge of solar irradiance variations prior to 1979 is less certain, as it relies upon models of how sunspot and facular influences relate to solar irradiance observed since then. These models are used to extrapolate variations back to about 1610, when telescopes were first used to monitor sunspots. The amount of energy Earth receives from the Sun also depends on Earth's distance from the Sun, which does not remain constant. The eccentricity of Earth's orbit (currently 0.0167) and the tilt of its axis relative to the orbital plane result in continual changes to the amount and distribution of energy Earth receives. In modern times, this variation is $\pm 3.5\%$ during the year, with maximum energy and minimum distance in January.

Volcanic forcing has been the dominant source of natural global radiative forcing over the past millennium. Emissions from volcanic eruptions have multiple effects on climate, as listed in Table 1.[8] The greater prevalence of explosive volcanic activity during both the early and the late 20th Century and the dearth of eruptions from 1915 to 1960 represent a significant natural radiative forcing of 20th-Century climate.[9] Similarly, longer-term volcanic radiative forcing has been associated with a significant long-term forced cooling from 1000 to 1900, resulting from a general increase in explosive volcanic activity in later centuries.

Greenhouse Gas Forcing

The role of greenhouse gases in the climate system is well understood by scientists because instruments can accurately measure the abundances of these gases in the atmosphere and their radiative properties. The concentrations of CO_2, CH_4, N_2O, various halocarbons, and O_3 have increased substantially since preindustrial times, and they are the greatest contributors to total anthropogenic radiative forcing.[10] Many of these greenhouse gases are emitted primarily as a byproduct of fossil fuel combustion.

For a given gas, the total amount of heat-trapping ability depends on the efficiency of heat trapping for a given unit of gas (i.e., radiative forcing), the number of units present in the atmosphere, and the average length of time a given unit spends in the atmosphere. While these three components are enough to characterize a single gas, the large number of gases has prompted the development of an index called the global warming potential (GWP), which represents the relative impact of a particular greenhouse gas on the atmosphere's radiative balance.[10] See Table 2 for some GWP calculations. As the standard

Table 1 Effects of large explosive volcanoes on weather and climate

Effect and mechanism	Begins	Duration
Reduction of diurnal cycle	Immediately	1–4 days
Blockage of shortwave and emission of longwave radiation		
Reduced tropical precipitation	1–3 months	3–6 months
Blockage of shortwave radiation, reduced evaporation		
Summer cooling of Northern Hemisphere tropics and subtropics	1–3 months	1–2 years
Blockage of shortwave radiation		
Reduced Sahel precipitation	1–3 months	1–2 years
Blockage of shortwave radiation, reduced land temperature, reduced evaporation		
Stratospheric warming	1–3 months	1–2 years
Stratospheric absorption of shortwave and longwave radiation		
Winter warming of Northern Hemisphere continents	6–18 months	1 or 2 winters
Stratospheric absorption of shortwave and longwave radiation, dynamics		
Global cooling	Immediately	1–3 years
Blockage of shortwave radiation		
Global cooling from multiple eruptions	Immediately	Up to decades
Blockage of shortwave radiation		
Ozone depletion, enhanced UV radiation	1 day	1–2 years
Dilution, heterogeneous chemistry on aerosols

Foss–Gre

reference gas, CO_2 has a GWP of 1, by definition. Over a time horizon of 100 years, CH_4 and N_2O have GWPs of 23 and 296, respectively. In other words, 1 additional kg of CH_4 in the atmosphere absorbs as much radiation as 23 additional kg of CO_2. However, these numbers change if the time horizon shifts.[10] By allowing greenhouse gases to be compared directly, GWPs enable policies that can reduce total climate impact by addressing the least-cost abatement options first.[11,12]

Atmospheric Aerosol Forcing

Aerosols are small particles or liquid droplets suspended in the atmosphere. Aerosols both scatter and absorb radiation, representing a direct radiative forcing. Scattering generally dominates (except for black carbon particles) so that the net effect is of cooling. The average global mean of aerosol-direct forcing from fossil fuel combustion and biomass burning is in the range of -0.2 to -2.0 W m^{-2}.[10] This large range results from uncertainties in aerosol sources, composition, and properties used in different models. Recent advances in modeling and measurements have provided important constraints on the direct effect of aerosols on radiation.[13–15] Aerosols have several indirect effects on climate, all arising from their interaction with clouds—particularly from their roles as cloud condensation nuclei (CCN) and ice nuclei (Table 3).

Land-Use Change Forcing

Land-use changes include irrigation, urbanization, deforestation, desertification, reforestation, the grazing of domestic animals, and dryland farming. Each of these alterations in landscape produces changes in radiative forcing, both directly and indirectly.[16,17] Direct effects include the change of albedo and emissivity resulting from the different types of land covers. For example, the development of agriculture in tropical regions typically results in an increase of albedo from a low value of forest canopies (0.05–0.15) to a higher value of agricultural fields, such as pasture (0.15–0.20). The Intergovernmental Panel on Climate Change (IPCC)[10] reports the globally averaged forcing due to albedo change alone as -0.25 ± 0.25 W m^{-2}. Significant uncertainties remain in estimating the effect of land-use change on albedo because of the complexity of land surfaces (e.g., the type of vegetation, phenology, density of coverage, soil color).

Indirect effects of land-cover change on the net radiation include a variety of processes related to (1) the ability of the land cover to use the radiation absorbed at the ground surface for evaporation, transpiration, and sensible heat fluxes (the impact on these heat fluxes caused by changes in land cover is sometimes referred to as thermodynamic forcing); (2) the exchange of greenhouse and other trace gases between the surface and the atmosphere; (3) the emission of aerosols (e.g., from dust); and (4) the distribution and melting of snow and

Table 2 Radiative forcing characteristics of some major greenhouse gases

	Contribution to direct radiative forcing		Concentration in 1998	Lifetime (yrs)	Global warming potential (GWP) for different time horizons		
	W m^{-2}	%			20 yrs	100 yrs	500 yrs
Carbon dioxide (CO_2)	1.46	60	365 ppm	5–200[a]	1	1	1
Methane (CH_4)	0.48	20	1745 ppb	12.0	62	23	7
Nitrous oxide (N_2O)	0.15	6	314 ppb	114	275	296	156
Halocarbons and related compounds	0.34	14	—	0.3–3200	40–15100	12–22200	4–16300

Total direct radiative forcing uncertainty is approximately 10%. The abbreviations parts per million (ppm) and parts per billion (ppb) refer to the ratio of greenhouse gas molecules to molecules of dry air.
[a] No single lifetime can be defined for CO_2 because it is affected by multiple removal processes with different uptake rates.
Source: From Intergovernmental Panel on Climate Change (see Ref. 10).

ice.[5] These effects are not yet well characterized or quantified.

EVIDENCE OF HUMAN-INDUCED CLIMATE CHANGE

Because we do not have a "control Earth" against which to compare the effects of our current changing atmosphere, incontrovertibly linking human activities and observed climate change is difficult. Scientists therefore rely on multiple, overlapping evidence of changes and then compare observed patterns of change with what our scientific understanding indicates should happen under anthropogenic climate change. This two-stage concept of discovering changes in climate and linking them to human activity is called detection and attribution. Evidence used to detect climate change is summarized in this section, and the use of climate models for attribution is discussed in the following section.

One piece of evidence of global warming is an increase in surface temperature since the 1900s, with particularly rapid increases since the late 1970s (Fig. 5). This dataset caused some controversy when researchers discovered that readings taken near the surface of Earth with thermometers appeared to be higher than readings of the lower atmosphere taken by satellites from above. Subsequent studies concluded that the warming trend in global-mean surface temperature observations during the past 30 years is undoubtedly real and is substantially greater than the average rate of warming during the 20th Century.[18] Satellite-and balloon-based observations of middle-troposphere temperatures, after several revisions of the data, now compare reasonably with one another and with observations from surface stations, although some uncertainties remain.[19,20]

The ocean, which represents the largest reservoir of heat in the climate system, has warmed by about 0.118°C (0.212°F), averaged over the layer extending from the surface down to 700 m, from 1955 to 2003 (Fig. 6).[21] Approximately 84% of the total heating of Earth's system (oceans, atmosphere, continents, and cryosphere) over the past 40 years has gone into warming the oceans. Recent studies have shown that the observed heat storage in the oceans is what would be expected by a human-enhanced greenhouse effect. Indeed, increased ocean heat content accounts for most of the planetary energy imbalance (i.e., when Earth absorbs more energy from the Sun than it emits back to space) simulated by climate models.[22]

Changes in several other climate indicators have been observed over the past decades, providing a growing body of evidence consistent with a human impact on the climate. For example, reductions in snow and ice cover are one important indicator.[10] Satellite observations indicate that snow cover has decreased by about 10% since the 1960s, while spring and summer sea-ice extent in the

Table 3 Overview of the different aerosol indirect effects associated with clouds

Effect	Cloud type	Description	Sign of top of the atmosphere radiative forcing
First indirect aerosol effect (cloud albedo or Twomey effect)	All clouds	For the same cloud water or ice content more but smaller cloud particles reflect more solar radiation	Negative
Second indirect aerosol effect (cloud lifetime or Albrecht effect)	All clouds	Smaller cloud particles decrease the precipitation efficiency, thereby prolonging cloud lifetime	Negative
Semidirect effect	All clouds	Absorption of solar radiation by soot leads to evaporation of cloud particles	Positive
Glaciation indirect effect	Mixed-phase clouds	An increase in ice nuclei increases the precipitation efficiency	Positive
Thermodynamic effect	Mixed-phase clouds	Smaller cloud droplets inhibit freezing, causing super cooled droplets to extend to colder temperatures	Unknown
Surface energy budget effect	All clouds	The aerosol-induced increase in cloud optical thickness decreases the amount of solar radiation reaching the surface, changing the surface energy budget	Negative

Northern Hemisphere has decreased by about 10%–15% since the 1950s. The shrinking of mountain glaciers in many nonpolar regions has also been observed during the 20th Century.

ATTRIBUTION OF OBSERVED CLIMATE CHANGE TO HUMAN INFLUENCE

An important question in global climate change is to what extent the observed changes are caused by the emissions of greenhouse gases and other human activities. Climate models are used to study how the climate operates today, how it may have functioned differently in the past, and how it may evolve in response to forcings. Built using our best scientific knowledge of atmospheric, oceanic, terrestrial, and cryospheric processes, climate models and their components are extensively tested against the full suite of observations of current and past climate to verify that they simulate a realistic version of the climate. Discrepancies between models and observations provide indications that we need to improve understanding of

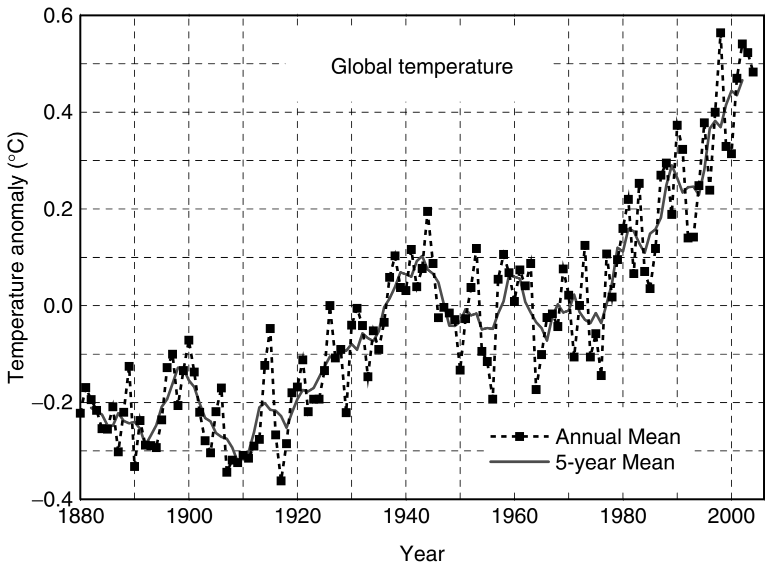

Fig. 5 Global annual-mean surface air temperature change derived from the meteorological station network. Data and plots are available from the Goddard Institute for Space Sciences (GISS) at http://data.giss.nasa.gov/gistemp/graphs.

physical processes, model representations of the processes, or in some cases the observations themselves. Hence, climate models contain our accumulated wisdom about the underlying scientific processes and can be no better than our observations of the system and our understanding of the climate.

Fig. 7 shows how scientists have used climate models to make the case that human activities have perturbed the climate since preindustrial times. In this experiment, the model is run with three different sets of climate forcings: (a) natural only, (b) anthropogenic only, and (c) natural and anthropogenic. When the natural or anthropogenic forcings are employed separately, the model is unable to reproduce the global-mean variation of temperature anomalies over the simulated time period. Only when both sets of forcings are used does the model capture the

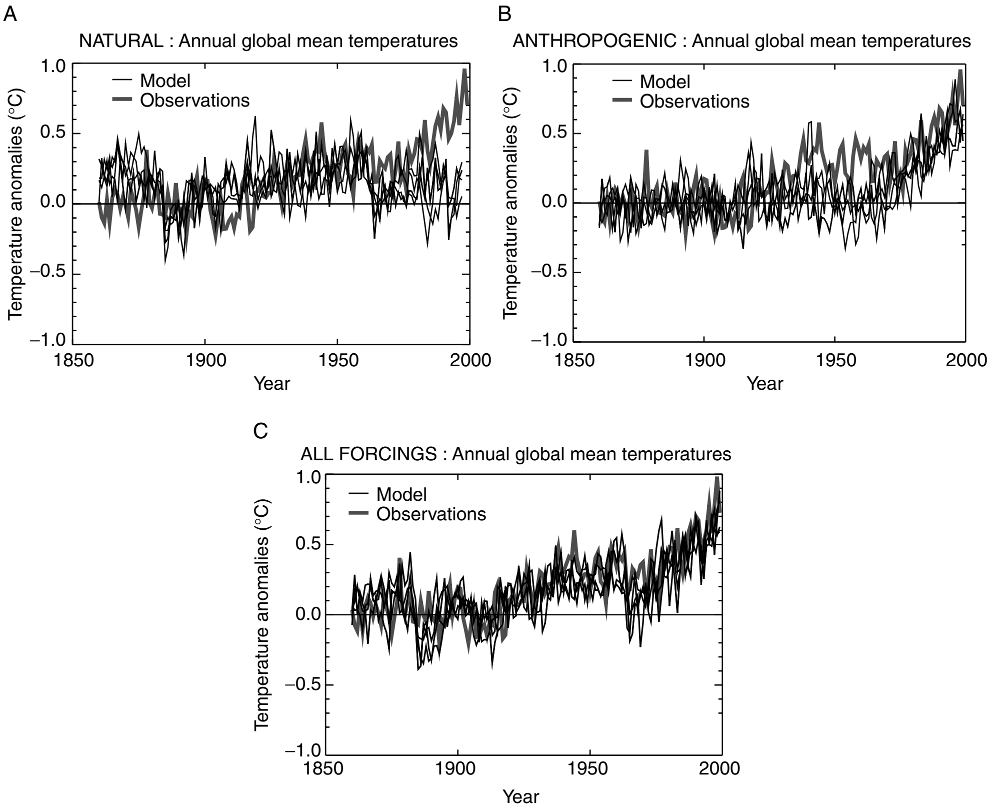

Fig. 7 Climate model results with (A) solar and volcanic forcings only; (B) anthropogenic forcings only; and (C) all forcings, both natural and anthropogenic.
Source: From Intergovernmental Panel on Climate Change (see Ref. 10).

nature of the variations, providing evidence that human activities have caused a significant fraction of warming in the past 150 years.[10]

PROJECTIONS FOR FUTURE CLIMATE CHANGE

The IPCC has concluded that by 2100, global surface temperatures will likely be from 1.4 to 5.8°C (2.5°F–10.4°F) above 1990 levels (Fig. 8) and that the combined effects of ice melting and seawater expansion from ocean warming will cause the global-mean sea level to rise by between 0.1 and 0.9 m.[10] Uncertainties remain about the magnitude and impacts of future climate change, largely due to gaps in understanding of climate science and the difficulty of predicting societal choices.

Climate changes in the coming century will not be uniformly distributed; some regions will experience more warming than others. There will be winners and losers from the impacts of climate change, even within a single region, but globally, the losses are expected to far outweigh the benefits. A changed climate will increase the likelihood of extreme heat and drought events.[23] High latitudes and polar regions are expected to see comparatively greater increases in average temperatures than lower latitudes, resulting in melting of permafrost and sea ice, which will result in additional costs for residents and in disruption to wildlife and ecosystems.[24] Precipitation changes, which are of great importance to agriculture, may have even more regional variability that is hard to predict.

Finally, several elements of Earth's system seem to be vulnerable to rapid destabilization. For example, the West Antarctic ice sheet and the Greenland ice sheet may be more prone to rapid melting than previously thought, and the loss of either of these would result in a large sea-level rise greater than 5 m. Moreover, the stability of the oceanic circulation that brings heat to Northern Europe has also been questioned. Because of feedback processes and the large uncertainty in system sensitivity, these outcomes are not easy to model and are usually not included in the gradual climate change projections quoted above.

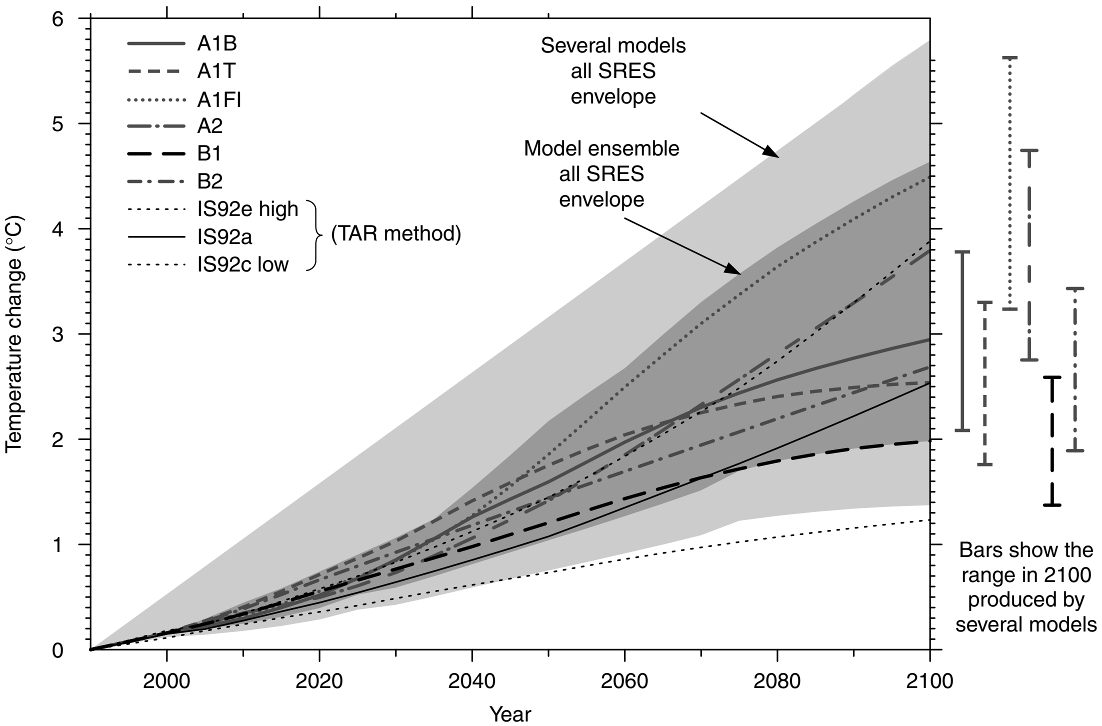

Fig. 8 Climate models are often used to simulate possible future climates to help inform decisions about policy responses to potential climate changes. This figure shows the range of plausible global-mean temperature change over the next 100 years, simulated by a collection of models. The spread in 2100 temperatures from 1.4 to 5.8°C reflects two factors: (1) Each model was run multiple times using different scenarios (indicated by different line textures) for future climate forcings, and (2) each model makes different assumptions about how the climate responds to those forcings. The scenarios range from those that assume continued acceleration of greenhouse gas emissions to those that assume more moderate growth or leveling off of emissions rates. SRES refers to the collection of scenarios presented in the Special Report on Emissions Scenarios. TAR refers to the IPCC Third Assessment Report.
Source: From Intergovernmental Panel on Climate Change (see Ref. 10).

Nevertheless, they are nontrivial threats and represent active areas of current research.

Unfortunately, the regions that will be most severely affected are often the regions that are the least able to adapt. Bangladesh, one of the poorest nations in the world, is projected to lose 17.5% of its land if sea level rises about 1 m (40 in.), displacing tens of thousands of people.[10] Several islands throughout the South Pacific and Indian Oceans will be at similar risk for increased flooding and vulnerability to storm surges. Although wetland and coastal areas of many developed nations—including the United States—are also threatened, wealthy countries may be more able to adapt to sea-level rise and threats to agriculture. Solutions could include limiting or changing construction codes in coastal zones and developing new agricultural technologies.

CONCLUSION

Research conducted to understand how the climate system may be changing—and in turn affecting other natural systems and human society—has led to significant advancement in scientific understanding, but many questions remain. Society faces increasing pressure to decide how best to respond to a changing climate and associated global and regional changes.

One way to address global climate change is to take steps to reduce the amount of greenhouse gases in the atmosphere. Because CO_2 and other greenhouse gases can remain in the atmosphere for many decades, the climate-change impacts from concentrations today will likely continue throughout the 21st Century and beyond. Failure to implement significant reductions in net greenhouse gas emissions now will make the job much harder in the future—both in terms of stabilizing CO_2 concentrations and in terms of experiencing more significant impacts. While no single solution can eliminate all future warming, many potentially cost-effective technological options could contribute to stabilizing greenhouse gas concentrations. These options range from personal choices such as driving less to national choices such as regulating emissions or seeking technologies to remove greenhouse gases from the atmosphere to international choices such as sharing energy technologies.

At the same time, it will be necessary to seek ways to adapt to the potential impacts of climate change. Climate is becoming increasingly important to public and private decision-making in various fields such as emergency management, water-quality assurance, insurance, irrigation and power production, and construction. For example, developing practical, "no regrets" strategies that could be used to reduce economic and ecological systems' vulnerabilities to change could provide benefits whether a significant climate change ultimately occurs or not. No-regrets measures could include low-cost steps to improve climate forecasting; to slow biodiversity loss; to improve water, land, and air quality; and to make institutions—such as the health care enterprise, financial markets, and transportation systems—more resilient to major disruptions.

Abstract
This book contribution discusses green energy for sustainable development and presents some key parameters and strategies to increase green-energy-based sustainability and the global peace level. The effects of technological, sectoral, and practical application impact ratios on green energy impact ratios and the green-energy-based sustainability ratio are also examined thoroughly. In addition, the key role of hydrogen, one of the most green energy carriers for the future, is discussed in terms of global unrest and global peace.

INTRODUCTION

Green energy can be considered a catalyst for energy security, sustainable development, and social, technological, industrial, and governmental innovations in a country. An increase in the green energy consumption of a country provides a positive impact on the economic as well as the social development of the country. Moreover, the supply and utilization of low-priced green fuel is particularly significant for global stability and peace because energy plays a vital role in industrial and technological developments around the world.

Critical energy issues in the 21st century will likely include energy security for almost 7 billion people, the expected global population by the middle of the 21st century, and global warming, mainly caused by CO_2 emissions generated from the combustion of fossil fuels.[1,2] Fossil fuels have caused some major problems for human health and human welfare due to their extensive use in various industrial and nonindustrial sectors. In reality, the main source of these problems is the extensive use of fossil-based technologies and strategies used by humans to govern throughout the centuries. In recent decades, the world has struggled with shortages of fossil fuels, pollution, and increased global energy requirements due to fast population growth, fast technological developments, and higher living standards. These factors have led to world population transition, migration, hunger, environmental (especially air and water pollution) problems, deteriorating health and disease, terrorism, energy and natural resources concerns, and wars. Also, problems with energy supply and use are related not only to global unrest, but also to such environmental concerns as air pollution, acid precipitation, ozone depletion, forest destruction, and the emission of radioactive substances. These issues must be taken into consideration simultaneously if humanity is to achieve a bright energy future with minimal environmental impact. Other environmental considerations have been given increasing attention by energy industries and the public. The concept that consumers share responsibility for pollution and its cost has been increasingly accepted. In some jurisdictions, the prices of many energy resources have increased over the last one to two decades, in part to account for environmental costs. Global demand for energy services is expected to increase by as much as an order of magnitude by 2050, while primary-energy demands are expected to increase by 1.5 ± 0.3 times.[2] Accordingly, humans have reached energy shortage and pollution levels that are not tolerable anymore. The urgent need in this regard is to develop green-energy-based permanent solutions for a sustainable future without any negative environmental and societal impacts. As a consequence, investigations for green energy should be encouraged particularly for green-energy-based sustainability and future world stability.

In this book contribution, the authors present key information on green-energy-based sustainability and global stability in accordance with major considerations that are presented in the following subtitles. In addition, this presents some key parameters like the green energy impact ratio and the green-energy-based sustainability ratio. Moreover, anticipated patterns of future energy use and consequent environmental impacts (focusing on acid precipitation, stratospheric ozone depletion, and the greenhouse effect) are comprehensively discussed. Also, potential solutions to current environmental problems are identified along with green energy technologies. The relationships between green energy and sustainable development are described. Throughout the article, several

Keywords: Green energy; Energy; Exergy; Environment; Sustainability; Parameters.

issues relating to green energy, the environment, and sustainable development are examined from both current and future perspectives. The specific objectives of this book contribution can be enumerated as follows:

- To help understand the main concepts and issues about green energy use and sustainability aspects
- To develop relationships between green energy use and sustainability development
- To encourage the strategic use and conservation of green energy sources
- To provide methods for energy security, implementation, and development
- To increase motivation on the implementation of green energy strategies for better energy supply
- To provide solutions to reduce negative environmental impacts by considering the possible green energy strategies
- To discuss possible green energy strategies for sectoral use

GREEN ENERGY

The most important property of green energy sources is environmental compatibility. In line with this characteristic, green energy sources will likely become the most attractive energy sources in the near future and will be the most promising energy sources for the technological and environmental perspectives of the 21st century, particularly in the context of sustainable development for the future. Green energy is one of the main factors that must be considered in discussions of sustainable development and future world stability. Several definitions of sustainable development have been put forth, including the following common one: "development that meets the needs of the present without compromising the ability of future generations to meet their own needs."[3,4] There are many factors that can contribute to achieving sustainable development. One of them is the requirement for a supply of energy resources that is fully sustainable. A secure supply of green energy resources is generally agreed to be a necessary but not sufficient requirement for development within a society.

Furthermore, sustainable development within a society demands a sustainable supply of green energy sources and an effective and efficient utilization of green energy technologies. Green energy can be defined as an energy source that has zero or minimum environmental impact, is more environmentally benign and more sustainable, and is produced from solar, hydro, biomass, wind, and geothermal, etc. energies. These types of green energy reduce the negative effects of fossil energy resources and the overall emissions from electricity generation and decrease greenhouse gases. They give an opportunity to take an active role in improving the environment and meet clean energy demand for both industrial and nonindustrial applications. Considering the benefits of green energy, it can be said that the sustainability of green energy supply and progress is assumed to be a key element in the interactions between nature and society. In addition, sustainable development requires a supply of energy resources that is sustainably available at reasonable cost and causes no or minimal negative societal impacts. Clearly, energy resources such as fossil fuels are finite and thus lack the characteristics needed for sustainability while others such as green energy sources are sustainable over the relatively long term.[5] Particularly, low-priced green energy is the most essential means for increasing the sustainable technological development and industrial productivity as well as people's living standards in a society. Therefore, achieving solutions to the energy shortages and environmental problems presented today requires long-term potential actions for sustainable development. In this regard, green energy sources and technologies appear to be the one of the most efficient and effective solutions. It can be said that one solution to the impending energy shortage and environmental problems is to make much more use of green energy sources and technologies. Another important solution is to develop permanent and effective sustainable green energy strategies for the increase of sustainable global stability.[1,6] For these purposes, engineering practicality, reliability, applicability, economy, scarcity of supply, and public acceptability should also be considered.

GREEN ENERGY AND ENVIRONMENTAL CONSEQUENCES

Some of the global problems affecting world stability are presented in Fig. 1. Fossil fuel utilization effects such as global climate change, world energy conflicts, and energy source shortages have increasingly threatened world stability. These negative effects may be observed locally, regionally, and globally.

This concern arises due to world population growth, fast technological development, and increasing energy demand. In the past, fossil energy sources could be used to solve world energy problems. However, in this century, fossil fuels cannot continue indefinitely as the principal energy sources due to the rapid increase of world energy demand and energy consumption. Due to world population growth and the advance of technologies that depend on fossil fuels, the reserves of fossil fuels eventually will not be able to meet world energy demand. Energy experts point out the fact that reserves account for less than 40 years for petroleum, 60 years for natural gas, and 250 years for coal.[1] The increase of the energy consumption and energy demand indicates our dependence on the fossil fuels. If the increase of fossil fuel utilization continues in this manner, it is likely that the world will be affected by many negative problems due to fossil fuels. As one

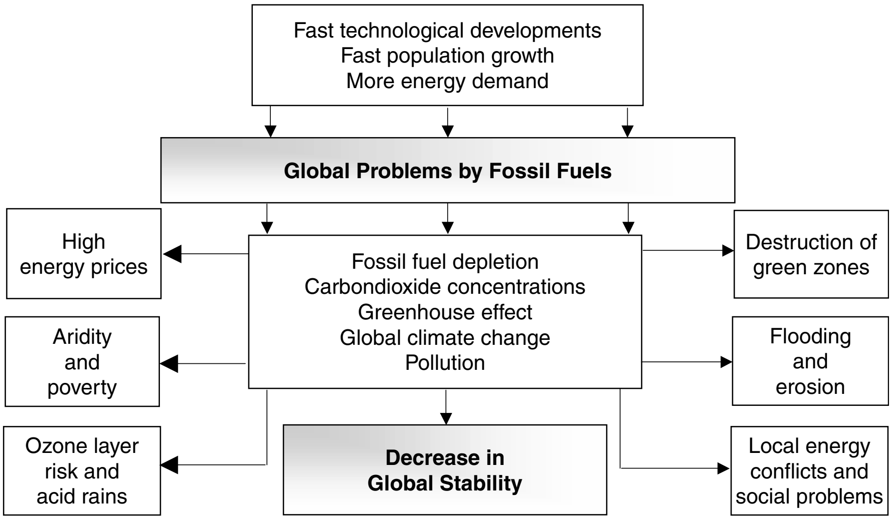

Fig. 1 Problems affecting global stability.

Foss—Gre

outcome, global stability will probably decrease. This effect is presented as flow chart in Fig. 2. For instance, shortages of fossil fuel reserves and global environmental problems will likely lead to global unrest throughout the world. As a result, local, regional, and world conflicts may appear across the world.

To further support these arguments, the observed and predicted consumptions of world primary energy, fossil fuels, and green energy from 1965 to 2050 are displayed in Fig. 3 based on the data taken from literature.[7,8]

According to Fig. 3, the quantities of world primary energy consumption are expected to reach 16502 Mtoe (Million tons of oil equivalent) by the year 2050. World population is now over 6 billion, double the population of 40 years ago, and it is likely to double again by the middle of the 21st century. The world's population is expected to rise to about 7.0 billion by 2010. Even if birth rates fall so that the world population becomes stable by 2050, the population will still be about 10 billion. Because the population is expected to increase drastically, conventional energy resource shortages are likely due to insufficient fossil fuel resource supplies. In the near future, therefore, green energy will become increasingly important to compensate for shortages of conventional resources. The correlations that have been applied here are as follows:

For world primary energy consumption :

$$\text{WPEC} = 143.57 \times Y - 277808 \quad (R^2 = 0.9902) \tag{1}$$

For world fossil fuel consumption :

$$\text{WFFC} = 113.61 \times Y - 219092 \quad (R^2 = 0.9968) \tag{2}$$

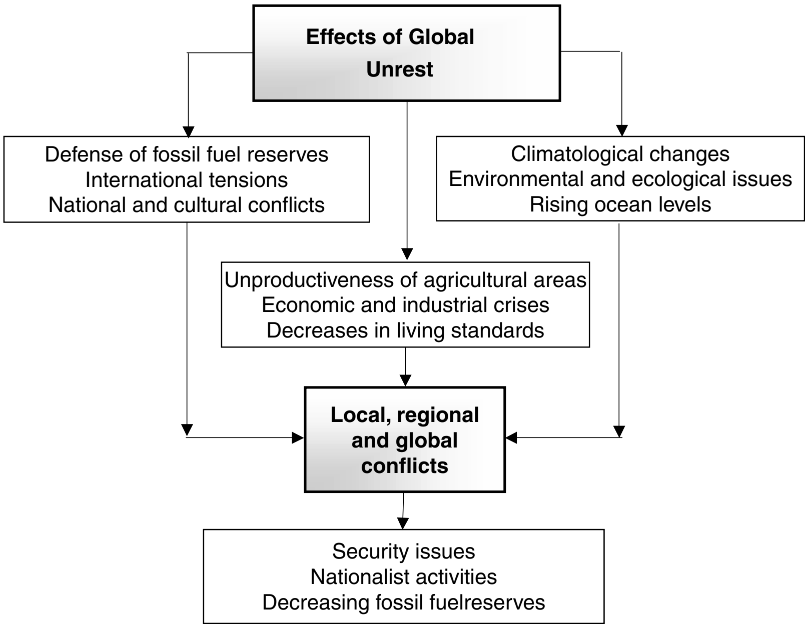

Fig. 2 Some possible effects and results of the global unrest.

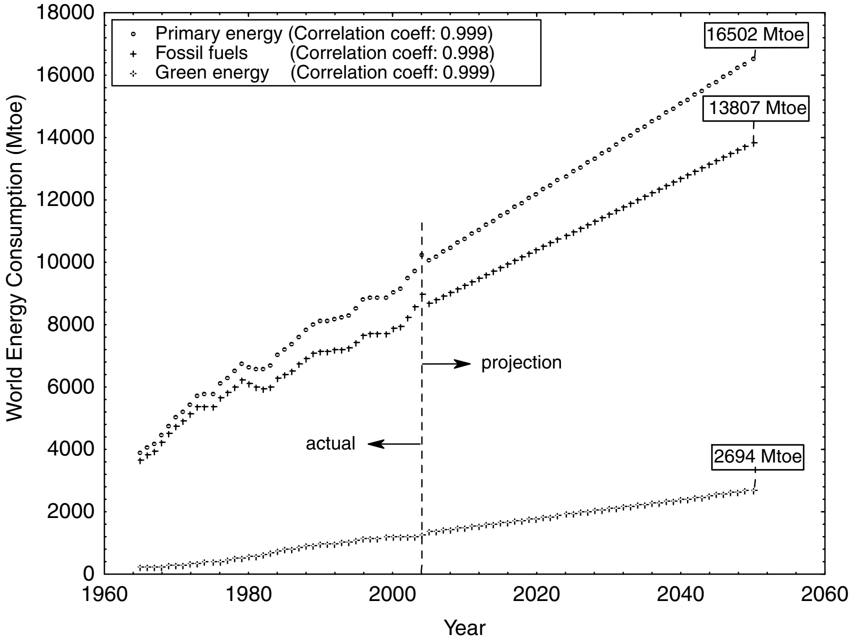

Fig. 3 Observed and projected quantities of world primary energy, fossil fuels, and green energy consumptions (Mtoe: million tons of oil equivalent).

For world green energy consumption :

$$\text{WGEC} = 29.956 \times Y - 58715 \quad (R^2 = 0.9985) \tag{3}$$

Here, WPEC is world primary energy consumption (Mtoe); WFFC, world fossil fuel consumption (Mtoe); WGEC, world green energy consumption; Y is time (years); and R is the correlation coefficient.

Energy shortages will accelerate the fluctuations of energy prices and economic recessions and decrease living standards and increase the unrest among countries. Decreased available fossil fuel reserves and increased fuel costs since the middle to late 1900s have led to variations in lifestyles and standards of life. These effects have, in some regions, decreased living standards of entire societies. Countries that need more energy resources have been purchasing cheaper energy sources. Countries that look after the future welfare of their societies have received the attention of countries that possess fossil fuel supplies, posing the potential for world conflict. Problems are often attributed to decreases in fossil fuel energy reserves. Those who seek a clean world must find appropriate alternatives to fossil fuels. Why not green energy? Green energy that is abundantly available all over the world can help:

- Reduce or stop conflicts among countries regarding energy reserves
- Facilitate or necessitate the development of new technologies
- Reduce air, water, and land pollution and the loss of forests
- Reduce illnesses and deaths caused by direct or indirect use of energy

Therefore, green energy and related technologies are needed to improve global stability by reducing the harmful effects of fossil-based energy consumption. Thus, the importance of green energy in reducing world problems and achieving a sustainable energy system should be emphasized and a transition to the green economy should be encouraged.

ENERGY, ENVIRONMENT, AND SUSTAINABILITY

Environmental concerns are an important factor in sustainable development. For a variety of reasons, activities that continually degrade the environment are not sustainable over time, e.g., the cumulative impact on the environment of such activities often leads over time to a variety of health, ecological, and other problems. A large portion of the environmental impact in a society is associated with its utilization of energy resources. Ideally, a society seeking sustainable development utilizes only energy resources that release no or minimal emissions to the environment and thus cause no or little environmental impact. However, because all energy resources lead to some environmental impact, it is reasonable to suggest that some (not all) of the concerns regarding the limitations imposed on sustainable development by environmental emissions and their negative impacts can be in part overcome through increased energy efficiency. Clearly, a strong relation exists between energy efficiency and environmental impact because for the same services or products less resource utilization and pollution is normally associated with increased energy efficiency. While not all green energy resources are inherently clean, there is such a diversity of choices that a shift to renewables carried out in the context of sustainable development could provide a far cleaner system than would be feasible by tightening controls on conventional energy.[9] Furthermore, being by nature site-specific, they favor power system decentralization and locally applicable solutions more or less independent of the national network. It enables citizens to perceive positive and negative externalities of energy consumption. Consequently, the small scale of the equipment often makes the time required from initial design to operation short, providing greater adaptability in responding to unpredictable growth and changes in energy demand. In this regard, sustainability often leads local and national authorities to incorporate environmental considerations into energy planning. The need to satisfy basic human needs and aspirations combined with the increasing world population will make the need for successful implementation of sustainable development increasingly apparent. Various criteria that are essential to achieving sustainable development in a society are as follows[3,4,10]:

- Information about and public awareness of the benefits of sustainability investments, environmental education, and training
- Appropriate energy strategies
- The availability of green energy resources and technologies
- A reasonable supply of financing
- Monitoring and evaluation tools

Environmental concerns are significantly linked to sustainable development. Activities which continually degrade the environment are not sustainable. For example, the cumulative impact on the environment of such activities often leads over time to a variety of health, ecological, and other problems. Clearly, a strong relation exists between efficiency and environmental impact because for the same services or products, less resource utilization and pollution is normally associated with increased efficiency.[3] Improved energy efficiency leads to reduced energy losses. Most efficiency improvements produce direct environmental benefits in two ways. First, operating energy input requirements are reduced per unit of output and pollutants generated are correspondingly reduced. Second, consideration of the entire life cycle for energy resources and technologies suggests that improved efficiency reduces environmental impact during most stages of the life cycle. In recent years, the increased acknowledgment of humankind's interdependence with the environment has been embraced in the concept of sustainable development. With energy constituting a basic necessity for maintaining and improving standards of living throughout the world, the widespread use of fossil fuels may have impacted the planet in ways far more significant than first thought. In addition to the manageable impacts of mining and drilling for fossil fuels and discharging wastes from processing and refining operations, the greenhouse gases created by burning these fuels is regarded as a major contributor to a global warming threat. Global warming and large-scale climate change have implications for food chain disruption, flooding, and severe weather events.

Therefore, use of green energy sources can help reduce environmental damage and achieve sustainability. The attributes of green energy technologies (e.g., modularity, flexibility, low operating costs) differ considerably from those for traditional, fossil-fuel-based energy technologies (e.g., large capital investments, long implementation lead times, operating cost uncertainties regarding future fuel costs). Green energy technologies can provide cost-effective and environmentally beneficial alternatives to conventional energy systems. Some of the benefits of the green energy-based systems are as follow[3,10]:

- They are relatively independent of the cost of oil and other fossil fuels, which are projected to rise significantly over time. Thus, cost estimates can be made reliably for green energy systems and they can help reduce the depletion of the world's nongreen energy resources.
- Implementation is relatively straightforward.
- They normally cause minimum environmental degradation and so they can help resolve major environmental problems. Widespread use of green energy systems would certainly reduce pollution levels.
- They are often advantageous in developing countries. In fact, the market demand for renewable energy technologies in developing nations will likely grow as they seek a better standard of living.

Under these considerations, green energy resources have some characteristics that lead to problematic but often solvable technical and economic challenges:

- Generally diffuse
- Not fully accessible
- Sometimes intermittent
- Regionally variable

The overall benefits of green energy technologies are often not well understood, leading to such technologies often being assessed as less cost-effective than traditional technologies. For green energy technologies to be assessed comprehensively, all of their benefits must be considered. For example, many green energy technologies can provide, with short lead times, small incremental capacity additions to existing energy systems. Such power generation units usually provide more flexibility in incremental supply than large devices like nuclear power stations.

Foss–Gre

GREEN ENERGY AND SUSTAINABLE DEVELOPMENT

Sustainability has been called a key to the solution of current ecological, economic, and developmental problems by Dincer and Rosen[10] A secure supply of energy resources is generally agreed to be a necessary but not sufficient requirement for development within a society. Furthermore, sustainable development demands a sustainable supply of energy resources that, in the long term, is readily and sustainably available at reasonable cost and can be utilized for all required tasks without causing negative societal impacts. Supplies of such energy resources as fossil fuels (coal, oil, and natural gas) and uranium are generally acknowledged to be finite; other energy sources such as sunlight, wind and falling water are generally considered renewable and therefore sustainable over the relatively long term. Wastes (convertible to useful energy forms through, for example, waste-to-energy incineration facilities) and biomass fuels are also usually viewed as sustainable energy sources.

In general, the implications of these statements are numerous and depend on how sustainable is defined.[3] For sustainable development, green energy can play an important role for meeting energy requirements in both industrial and local applications. Therefore, development and utilization of green energy sources and technologies should be given a high priority for sustainable development in a country. The need for sustainable energy development is increasing rapidly in the world. Widespread use of green energy sources and technologies is important for achieving sustainability in the energy sectors in both developing and industrialized countries. Thus, green energy resources and technologies are a key component of sustainable development for three main reasons:

- They generally cause less environmental impact than other energy sources. The variety of green energy resources provides a flexible array of options for their use.
- They cannot be depleted. If used carefully in appropriate applications, green energy resources can provide a reliable and sustainable supply of energy almost indefinitely.
- They favor system decentralization and local solutions that are somewhat independent of the national network, thus enhancing the flexibility of the system and providing economic benefits to small isolated populations. Also, the small scale of the equipment often reduces the time required from initial design to operation, providing greater adaptability in responding to unpredictable growth and changes in energy demand.

Major considerations involved in the development of green energy technologies for sustainable development as modified from[10] are presented in Fig. 4.

As a consequence, it can be said that green energy and technologies are definitely needed for sustainable development that ensures a minimization of global unrest.

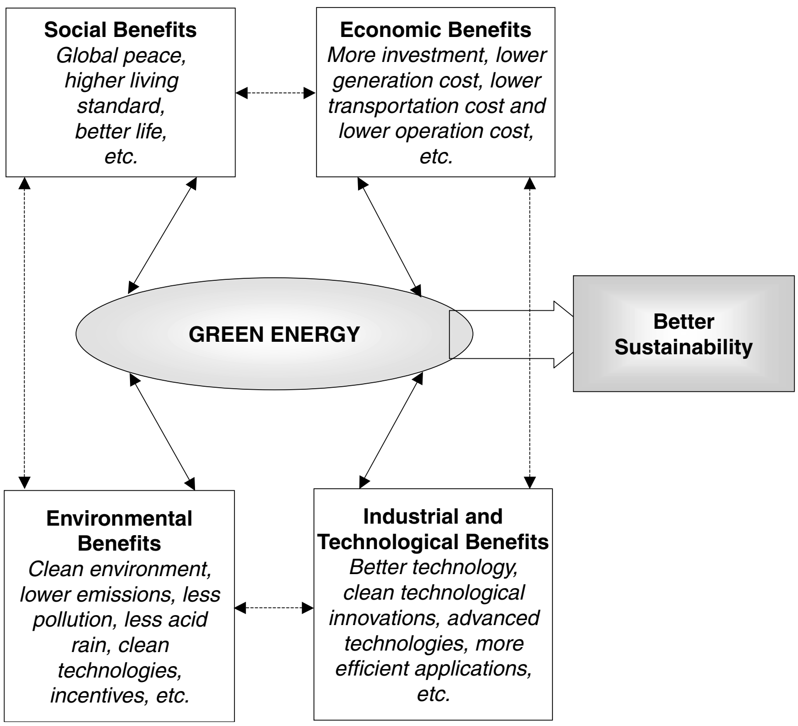

Fig. 4 Major considerations involved in the development of green energy technologies for sustainable development.

The relation between green energy and sustainability is of great significance to the developed countries as well as developing or less developed countries. Moreover, examining the relations between green energy sources and sustainability makes it clear that green technology is directly related to sustainable development. Therefore, attaining sustainable development requires that green energy resources be also used, and is assisted if resources are used efficiently.[4,10] Thus, if sustainable green energy technologies are effectively put into practice, the countries may maximize the benefits from the green energy sources and technologies while minimizing the global unrest[1] associated with the use of fossil fuel energy sources. It expected that this initiative can contribute to development over a longer period of time, i.e., to make development more sustainable.

GREEN ENERGY RESOURCES AND TECHNOLOGIES

Since the oil crises in the early 1970s, there has been active worldwide research and development in the field of green energy resources and technologies. During this time, energy conversion systems that were based on green energy technologies appeared to be most attractive because of facts such as the projected high cost of oil and the cost effectiveness estimates and easy implementation of green energy technologies. Furthermore, in more recent times, it has been realized that green energy sources and technologies can have a beneficial impact on essential technical, environmental, economic, and political issues of the world. As pointed out by Hartley,[3,9] green energy technologies produce marketable energy by converting natural phenomena into useful energy forms. These technologies use the energy inherent in sunlight and its direct and indirect impacts on the earth (photons, wind, falling water, heating effects, and plant growth), gravitational forces (the tides), and the heat of the earth's core (geothermal) as the resources from which they produce energy. These resources represent a massive energy potential which dwarfs that of equivalent fossil resources. Therefore, the magnitude of these is not a key constraint on energy production.

However, they are generally diffused and not fully accessible, some are intermittent, and all have distinct regional variabilities. Such aspects of their nature give rise to difficult, but solvable, technical, institutional, and economical challenges inherent in development and the use of green energy resources. Despite having such difficulties and challenges, the research and development on green energy resources and technologies has been expanded during the past two decades because of the facts listed above. Recently, significant progress has been made by (1) improving the collection and conversion efficiencies, (2) lowering the initial and maintenance costs, (3) increasing the reliability and applicability, and (4) understanding the phenomena of green energy technologies.

Green energy technologies become important as environmental concerns increase, utility (hydro) costs climb, and labor costs escalate.[3,9] The uncertain global economy is an additional factor. The situation may be turned around with an increase in research and development in the advanced technologies fields, some of which are closely associated with green energy technologies. This may lead to innovative products and job creation supported by the governments. The progress in other technologies, especially in advanced technologies, has induced some innovative ideas in green energy system designs. The ubiquitous computer has provided means for optimizing system performance, costs/benefits, and environmental impacts even before the engineering design was off the drawing board. The operating and financial attributes of green energy technologies, which include modularity and flexibility and low operating costs (suggesting relative cost certainty) are considerably different than those for traditional, fossil-based technologies, whose attributes include large capital investments, long implementation lead times, and operating cost uncertainties regarding future fuel costs. The overall benefits of green energy technologies are often not well understood and consequently they are often evaluated to be not as cost effective as traditional technologies. In order to comprehensively assess green energy technologies, however, some of their benefits that are often not considered must be accounted for. Green energy technologies, in general, are sometimes seen as direct substitutes for existing technologies so that their benefits and costs are conceived in terms of assessment methods developed for the existing technologies. Many government organizations and universities recognize the opportunity and support the efforts to exploit some commercial potential by:

- Analyzing opportunities for green energy and working in consultation with industry to identify research, development, and market strategies to meet technological goals.
- Conducting research and development in cooperation with industry to develop and commercialize technologies.
- Encouraging the application of green energy technologies to potential users, including utilities.
- Providing technical support and advice to industry associations and government programs that are encouraging the increased use of green energy. In order to realize the energy and the economic and environmental benefits that green energy sources offer, the following integrated set of activities should be acted on accordingly.[3,9,10]
- Conducting research and development. The priorities should be set in close consultation with industry to

reflect their needs. Most research is conducted through cost-shared agreements and falls within the short-to-medium term. Partners in research and development should include a variety of stakeholders in the energy industry such as private sector firms, utilities across the country, provincial governments, and other federal departments.

- Assessing technology. Data should be gathered in the lab and through field trials on factors such as cost benefit, reliability, environmental impact, safety, and opportunities for improvement. This data should also assist the preparation of technology status overviews and strategic plans for research and development.
- Developing standards. The development of technical and safety standards is needed to encourage the acceptance of proven technologies in the marketplace. Standards development should be conducted in co-operation with national and international standards writing organizations as well as other national and provincial regulatory bodies.
- Transferring technology. Research and development results should be transferred through the sponsorship of technical workshops, seminars, and conferences, as well as through the development of training manuals and design tools and the publication of technical reports. Such activities will also encourage potential users to consider the benefits of adopting green energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of green energy technologies in a country's remote communities.

Such activities will also encourage potential users to consider the benefits of adopting renewable energy technologies. In support of developing near-term markets, a key technology transfer area is to accelerate the use of green energy technologies in a country's remote communities.

ESSENTIAL FACTORS FOR SUSTAINABLE GREEN ENERGY TECHNOLOGIES

There are various essential parameters, as outlined and detailed in Fig. 5. These factors can help in identifying and achieving required green energy strategies and technologies for sustainable development. As shown Fig. 5, green energy technologies are largely shaped by broad and powerful trends that are rooted in basic human needs. In conjunction with this, the increasing world population requires the definition and successful implementation of green energy technologies. Briefly, the important parameters and their interrelations, as outlined in Fig. 5, are definitely required to carry out the best green energy

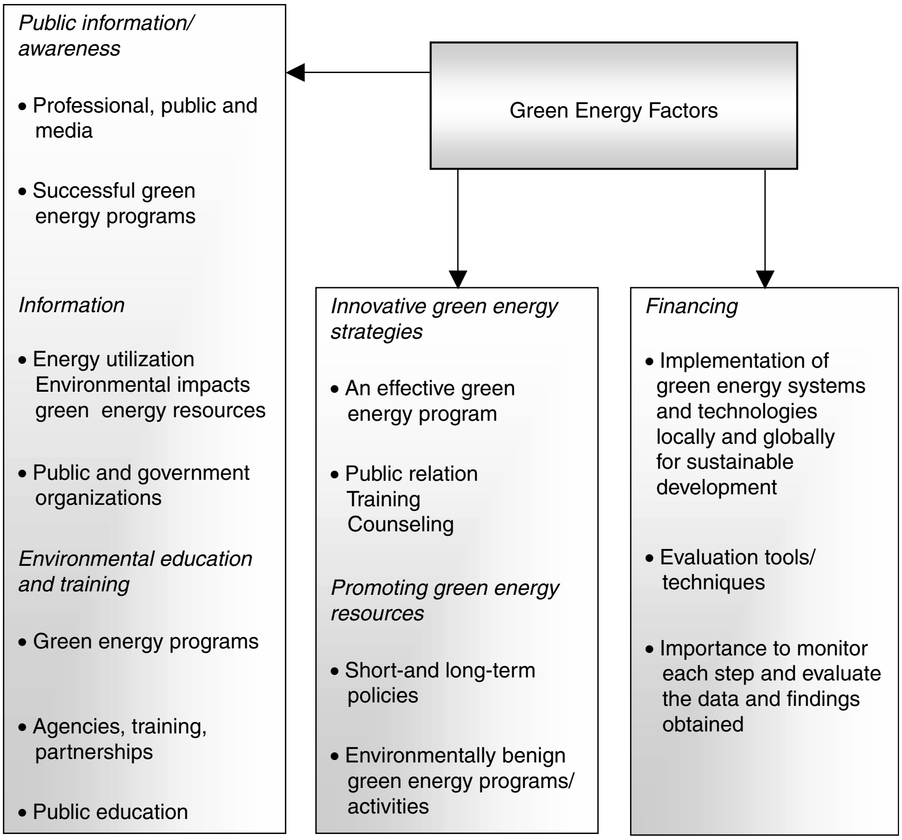

Fig. 5 Essential factors for green energy technologies.

program and to select the most appropriate green energy technologies for sustainable development.

EXERGETIC ASPECTS OF GREEN ENERGY TECHNOLOGIES

The impact of energy resource utilization on the environment and the achievement of increased resource-utilization efficiency are best addressed by considering exergy. The exergy of an energy form or a substance is a measure of its usefulness, quality, or potential to cause change and provide the basis for an effective measure of the potential of a substance or energy form to impact the environment. In practice, a thorough understanding of exergy and the insights it can provide into the efficiency, environmental impact, and sustainability of green energy technologies are helpful if not required for the engineer or scientist working in the area of green-energy-based environmental systems.[4,11] For green energy technologies, applications of exergy methods can have numerous broad and comprehensive benefits:

- A better knowledge of the efficiencies and losses for the technologies and systems and how they behave and perform
- A clearer appreciation of the environmental impacts of green energy technologies as well as the mitigation of environmental that they can facilitate
- Better identification of the ways green energy technologies can contribute to sustainable development

GREEN ENERGY APPLICATIONS

Green energy technologies are expected to play a key role in sustainable energy scenarios for the future. The foremost factor that will determine the specific role of green energy and technologies will likely be energy demand. Therefore, in order to compensate the energy requirement, it will be possible to produce green energy from renewable energy sources such as hydraulic, solar, wind, geothermal, wave and biomass, etc. If so, the green energy and technologies can be utilized for many application fields as shown in Fig. 6.

Thus, it can be said that green energy and technologies, which are abundantly available, can help:

- Provide more environmentally benign and more sustainable future
- Increase energy security
- Facilitate or necessitate the development of new, clean technologies
- Reduce air, water, and soil pollution and the loss of forests
- Reduce energy-related illnesses and deaths
- Reduce or stop conflicts among countries regarding energy reserves

Therefore, green energy and related technologies are needed to ensure global stability by reducing the harmful effects of fossil-based energy consumption. Thus, the importance of green energy in reducing the world problems and achieving a sustainable energy system should be emphasized considering the sustainable green energy strategies; and a transition to green energy economy should be encouraged and developed countries in particular should increase investments in green energy and technologies.

GREEN ENERGY ANALYSIS

In light of the above major considerations, in order to accelerate the use of green energy sources and technologies and the implementation of green energy strategies, and in this regard, to describe the relationship between the global stability and sustainable development, some key steps are presented as follows:

- Key strategies
- Green energy based sustainability ratio
- Global unrest and peace

Green-Energy-Based Sustainable Development Ratio

In order to discuss the key role of green energy for sustainable development and global stability, the general algebraic form of the equation that is the green-energy-based sustainable development ratio should be presented based on the above strategies. For this purpose, the works that were early presented by Midilli et al.[1,2,6,12] and Dincer[3,10] were taken as the reference basis. The following important parameters, which are sectoral, technological, and practical application impact ratios, are taken into consideration to estimate the green-energy-based sustainable development ratio. The detailed derivations of these parameters are presented in the literature.[2] Briefly, the green-energy-based sustainable development ratio is mainly based on the following parameters:

- *Sectoral impact ratio*, (R_{si}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,si}$) of public, private, and media sectors for transition to green-energy-based technologies, and depending on the total green energy financial budget (C_{geb}), as a reference parameter.[2]
- *Technological impact ratio*, (R_{ti}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,ti}$)

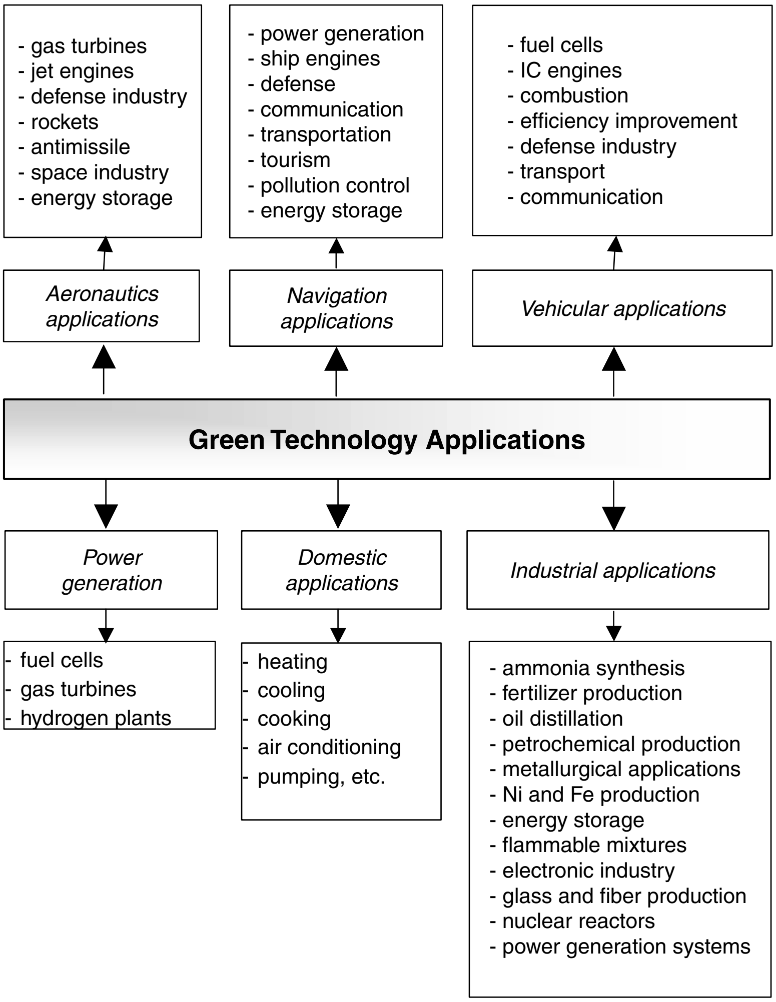

Fig. 6 Possible application fields of green energy and technologies for sustainable development.

for research and development, security, and analysis of green-energy-based technologies, and also depending on the total green energy financial budget (C_{geb}) as a reference parameter.[2]

- *Practical application impact ratio*, (R_{pai}) (ranging from 1 to 1/3), is based on the provided financial support ($C_{p,pai}$) for projection, production, conversion, marketing, distribution, management, and consumption of green fuel from green energy sources, and also depending on the total green energy financial budget (C_{geb}), as a reference parameter.[2] Here, it should be emphasized that these parameters can be defined as the ratio of the provided financial support to the total green energy financial budget in a country. In addition, it should be always remembered that it is assumed that the financial share of each parameter is equal to one-third of the total green energy financial budget in a country. Utilization ratio of green energy depends on the green energy utilization and the world primary energy quantity. Green-energy-based global stability is a function of utilization ratios of coal, petroleum, and natural gas, and utilization ratios of green energy at certain utilization ratios of these fuels, and utilization ratio of green energy. Therefore, the green-energy-based sustainable development ratio is written in algebraic form as follows[2]:

$$R_{ges} = R_{gei} \times R_{geu} \tag{4}$$

where
$R_{gei} = (R_{si} + R_{ti} + R_{pai})$, green energy impact ratio;
$R_{si} = C_{p,\ si}/C_{geb}$, sectoral impact ratio, which is estimated based on the provided financial support of the public, private, and media sectors for transition to green energy ($C_{p,si}$) and also the green energy budget allocation of a country (C_{geb});
$R_{ti} = C_{p,\ ti}/C_{geb}$, technological impact ratio, which is estimated based on the provided financial supports for research and development, security, and analysis of green-energy-based technologies ($C_{p,ti}$) and also the green energy budget allocation of a country (C_{geb});
$R_{pai} = C_{p,\ pai}/C_{geb}$, practical application impact ratio, which is estimated based on the provided financial supports for projection, production, conversion,

marketing, distribution, management, and consumption of green fuel from green energy sources, and also the green energy budget allocation of a country (C_{geb});

$R_{geu} = 1 - Q_{wffc}/Q_{wpec}$, green energy utilization ratio, which is also defined as a function of fossil fuel utilization ratio (R_{ffu}).

Here Q_{wffc} explains world fossil fuel consumption (M) and Q_{wpec} world primary energy consumption (M).

Global Unrest and Peace

Fossil fuels such as petroleum, coal, and natural gas, which have been extensively utilized in industrial and domestic applications for a long time, have often been the cause of global destabilization and unrest. This problem is likely to increase in significance in the future and suggests the need for investigations of, among other factors, the role of hydrogen energy relative to future global unrest and global peace. In general, the global unrest arising from the use of fossil fuels is considered as a function of the usage ratios of these fossil fuels.[12] In order to estimate the level of global unrest, it is important to select a proper reference value. Therefore, it is assumed that the lowest value of global unrest and the highest value of global peace are equal to 1, which is a reference point to evaluate the interactions between global unrest and global peace.[12] Consequently, the general algebraic case form of global unrest expression is as follows[12]:

$$GU = \left\{ 1 - \left[\left(\frac{q_p}{q_{wpec}} + \frac{q_c}{q_{wpec}} + \frac{q_{ng}}{q_{wpec}} \right) - (r_{H_2-p} + r_{H_2-c} + r_{H_2-ng}) \right] \right\}^{-1} \quad (5)$$

where q_p, q_c and q_{ng} define the consumption quantities of petroleum, coal, and natural gas, respectively; q_{wpec} defines the quantity of world primary energy consumption; r_{H_2-p} is the utilization ratio of hydrogen from nonfossil fuels at a certain utilization ratio of petroleum; r_{H_2-c} is the utilization of hydrogen from nonfossil fuels at a certain utilization ratio of coal; r_{H_2-ng} is the utilization of hydrogen from nonfossil fuels at a certain utilization ratio of natural gas. The values of q_p, q_c, q_{ng}, and q_{wpec} can be taken from the literature.[8] The values for r_{H_2-p}, r_{H_2-c} and r_{H_2-ng} can be taken depending on the utilization ratios of the petroleum, coal, and natural gas presented in the literature.

In order to estimate the level of global peace quantitatively, it is assumed that the highest value of global peace is equal to 1, which is a reference point to evaluate the interactions between global unrest and global peace.[12] Thus, the relationship between global unrest and global peace can be written as a function of the utilization ratio of hydrogen from nonfossil fuels. The general algebraic case form of global peace expression proposed is as follows:

$$GP = \frac{U_{H_2}}{Q_{wpec}} \times \frac{1}{(GU)} \quad (6)$$

where U_{H_2} defines the utilization of hydrogen from nonfossil fuels, which can be taken from the literature.

CASE STUDY

The first case study is given to determine the green-energy-based sustainability ratio depending on the three subcases that are carried out based on the sectoral impact ratio, the technological impact ratio, and the practical application impact ratio by using actual data from the literature.[8] All cases are presented in Table 1. The results of the first case study are presented in Figs. 7 and 8a–c.

The second case study is performed to determine the global unrest and global peace level based on the predicted utilization ratios of hydrogen from nonfossil fuels. In this regard, two important empirical relations that describe the effects of fossil fuels on world peace and global unrest are taken into consideration for this case study. The results of this case study are presented in Fig. 9.

Results and Discussion

In accordance with the objective of this article, the projection data is obtained using actual data of primary energy, fossil fuel, and green energy consumptions. Considering the technological impact ratio (max. value = 1/3 of the green energy financial budget), the sectoral impact ratio (max. value = 1/3 of the green energy financial budget allocation), and the practical application impact ratio (max. value = 1/3 of the green energy financial budget allocation), three cases are analyzed and discussed in detail in this part.

Fig. 7 shows the variations of the fossil fuel utilization ratio (world fossil fuel consumption/world primary energy consumption) as a function of the green energy utilization ratio (world green energy consumption/world primary energy consumption). It is found out from this figure that the fossil fuel utilization ratio decreases depending on the rise of the year while green energy utilization ratio increases. For example, the green energy utilization ratio was 5.71% in 1970, 8.25% in 1980, 11.67% in 1990, and 13.27% in 2000 while the fossil fuel utilization ratio was 94.29% in 1970, 91.75% in 1980, 88.32% in 1990, and 86.77% in 2000, based upon the actual data. However, it is observed that the green energy utilization ratio increased and reached 12.31% while fossil fuel utilization ratio decreased to 87.69% in 2004. Based on the projected data, it expected that green energy utilization ratio will reach

Table 1 The cases depending on green energy impact ratio for the green-energy-based sustainability ratio

Effect of variable parameters (ε)			10%	30%	50%	70%	90%
Cases		Percent of total financial budget for green energy	Green energy impact ratio (R_{gei})				
I	2 constant parameters	$n/3$	0.699	0.766	0.833	0.899	0.966
	1 variable parameter	$k\times(1/3)\times\varepsilon$					
II	1 constant parameter	$n/3$	0.400	0.533	0.666	0.800	0.933
	2 variable parameters	$k\times(1/3)\times\varepsilon$					
III	3 variable parameters	$k\times(1/3)\times\varepsilon$	0.100	0.300	0.500	0.700	0.900

Here, n defines the number of constant parameters; k, the number of variable parameters.

almost 13.52% in 2006, 14.09% in 2012, 14.58% in 2018, 15.01% in 2024, and 15.38% in 2030. However, it is expected that the fossil fuel utilization ratio will decrease to almost 86.48% in 2006, 85.91% in 2012, 85.42% in 2018, 85.99% in 2024, and 84.62% in 2030. Thus, in order to increase the green energy utilization ratio and to reduce the harmful effects resulting from the fossil fuel consumption, the investments on green energy should be encouraged and the green energy strategies should be put into practice for sustainable development.

First, it should be stated that one or two of the parameters that are sectoral, technological, and practical application impact ratios can be selected as constant parameters. As shown in Table 1, a variable and two constant parameters are considered in Case 1, two variables and one constant parameter are considered in Case 2, and three variable parameters are considered in Case 3. When Case 1 is applied for green energy supply and progress, it is found that the green energy impact ratio changes between 0.699 and 0.966 depending on the percentages of the variable parameter. In the application of Case 2 it is obtained that the green energy impact ratio varies between 0.40 and 0.933 depending on the percentages of two variable parameters. In the application of Case 3, it is calculated that the green energy impact ratio changes from 0.1 to 0.9 depending on the percentages of three variable parameters. When the three Cases are compared to each other, it can be said that the highest values of green energy impact ratio are found by applying Case 1, and also that Case 3 gives the lowest green energy impact ratios. Thus, Case 1 should be selected to

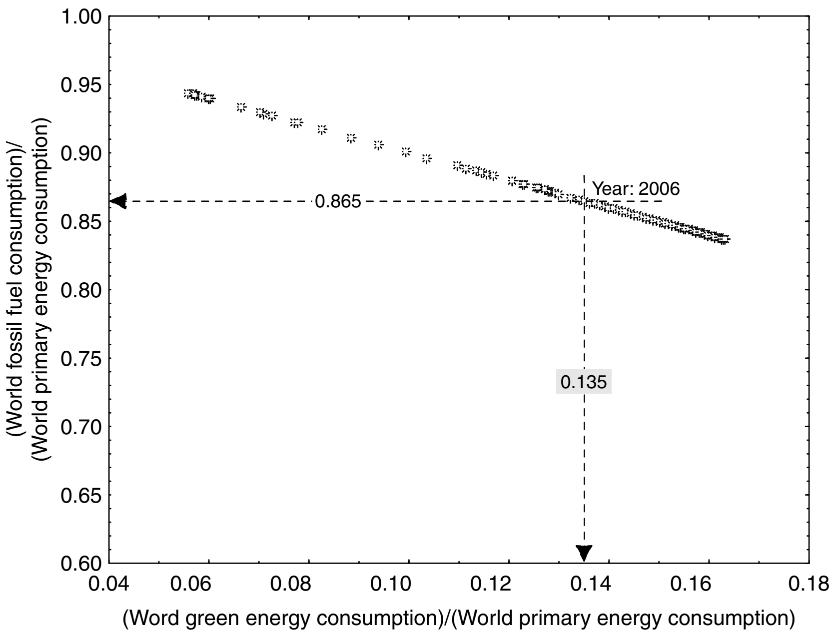

Fig. 7 World fossil fuel consumption ratio as a function of green energy consumption ratio.

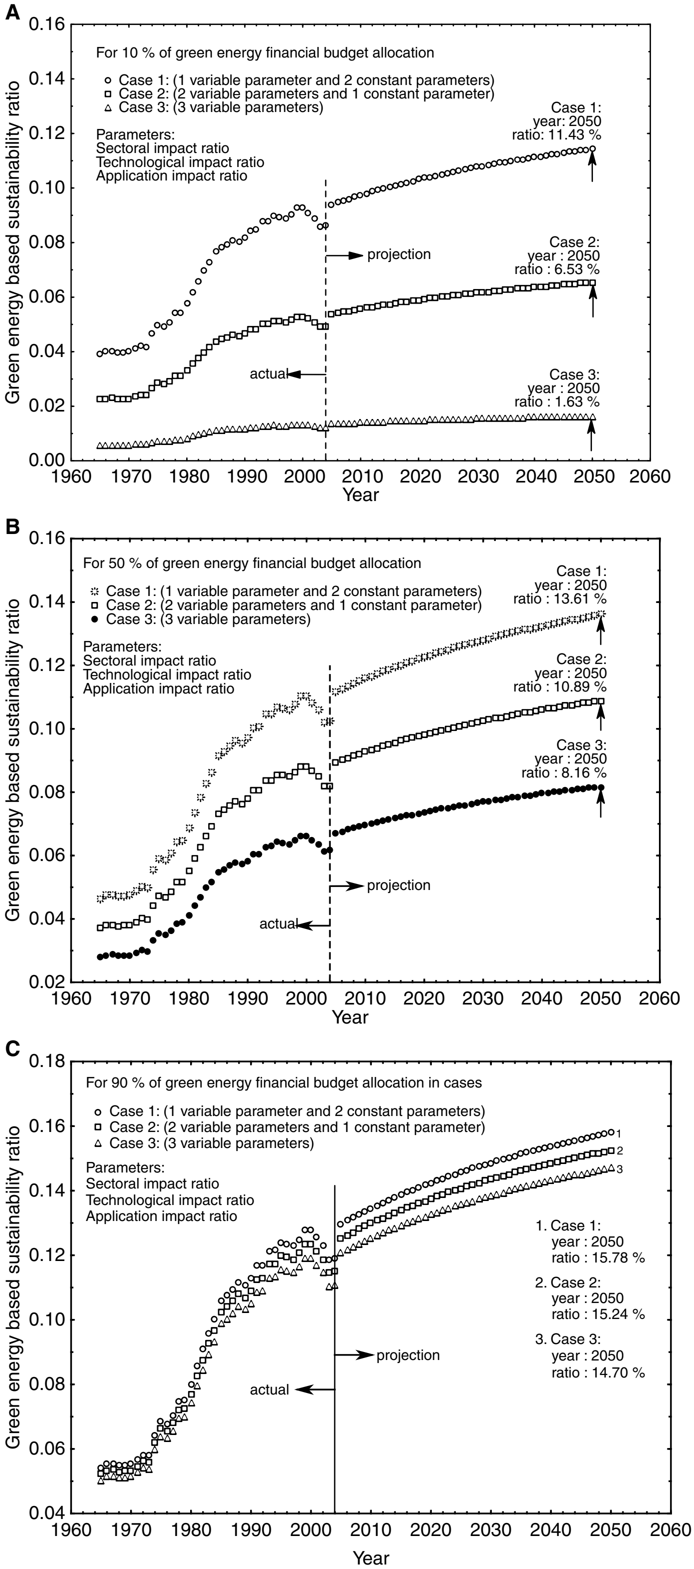

Fig. 8 (a) Green-energy-based sustainability ratio versus time depending on the actual and projected green energy consumption data for 10% of green energy financial budget allocation. (b) Green-energy-based sustainability ratio versus time depending on the actual and projected green energy consumption data for 50% of green energy financial budget allocation. (c) Green-energy-based sustainability ratio versus time depending on the actual and projected green energy consumption data for 90% of green energy financial budget allocation.

increase the green energy impact ratio and the green-energy-based sustainability ratio.

Fig. 8a–c show a variation of the green-energy-based sustainability ratio (R_{ges}) as a function of year by depending on the percentages of the green energy financial budget as 10%, 50%, and 90%, or the effect of the parameters in the Cases, respectively. The values of green-energy-based sustainability ratios were calculated using Fig. 4.

As shown in these figures, the values of R_{ges} increase with time based on the cases. The highest values of R_{ges} are

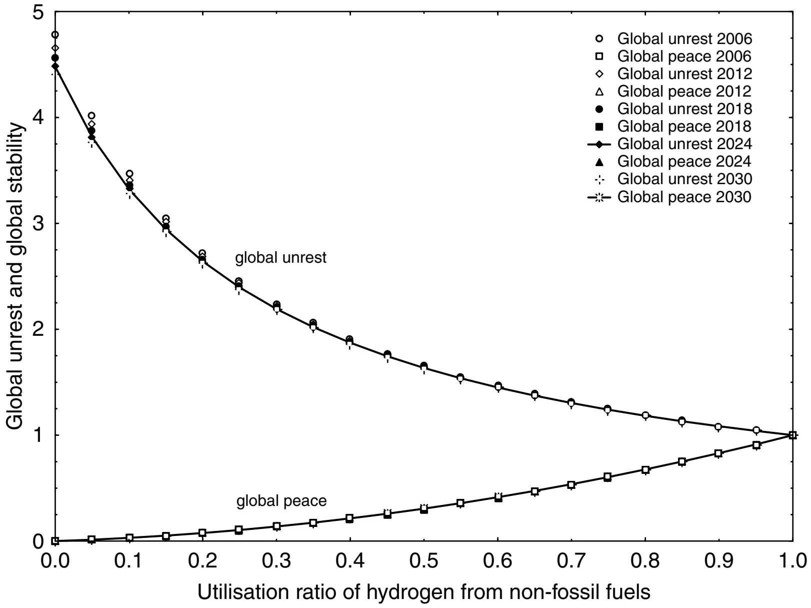

Fig. 9 Comparison of levels of global unrest and global stability as a function of hydrogen utilization ratios from nonfossil fuels.

obtained when Case 1 is applied, as shown in Fig. 8a–c. For example, the green-energy-based sustainability ratios are estimated to be 9.46% in 2006, 9.86% in 2012, 10.21% in 2018, 10.50% in 2024, and 10.76% in 2030 in case of 10% of green energy financial budget; 13.06% in 2006, 13.62% in 2012, 14.09% in 2018, 14.51% in 2024, and 14.86% in 2030 in case of 90% of green energy financial budget.

It is important to implement green energy strategies through green energy systems and applications for sustainable future. If so, the green-energy-based sustainability ratio increases and green energy is more easily supplied, thus its technologies are more preferred and applied. Hence, as long as sustainable green energy strategies are increasingly applied and the green technologies are more utilized and encouraged, the negative effects stemming from the fossil fuel utilization will decrease and the green-energy-based sustainability ratio will increase.

Fig. 9 compares the levels of global unrest and global peace as a function of the predicted utilization ratio of hydrogen from nonfossil fuels. Fig. 6 indicates that there is an inversely proportional relationship between global peace and global unrest, depending on the utilization ratio of hydrogen from nonfossil fuels.

To better appreciate this figure, some of the key energy-related reasons for global unrest need to be understood. They include:

- Increases in fossil fuel prices
- Environmental effects of energy use, including pollution due to emissions, stratospheric ozone layer depletion, and global warming
- Decreases in the amount of fossil fuel available per capita and the associated decrease in living standards
- Increases in energy demand due to technological developments attributable to and based on fossil fuels
- Depletion of fossil fuel reserves
- Increases in conflicts for fossil fuel reserves throughout the world
- The lack of affordable and practical alternative energy sources to fossil fuels

It is found out from Fig. 9 that an increase in hydrogen utilization accordingly decreases the reasons for global unrest, allowing the benefits of global peace to be realized over time; and the lowest levels of global unrest occur when hydrogen from nonfossil fuels is substituted completely for fossil fuels. In general, the level of global unrest is higher than 1 and the problems causing global unrest can be reduced by using hydrogen energy from nonfossil sources instead of fossil fuels. Fig. 5 suggests that the utilization of hydrogen from nonfossil fuels at certain ratios of petroleum, coal, and natural gas decreases the amount of fossil fuel consumption and thus reduces the level of global unrest closer to 1. As shown in Fig. 9, it is expected that, depending on the actual and projected fossil fuel consumption data, the levels of global unrest will be approximately 4.78 in 2006, 4.66 in 2012, 4.56 in 2018, 4.48 in 2024, and 4.41 in 2030 when the utilization ratio of hydrogen is zero. If the utilization ratio of hydrogen from nonfossil fuels is lower than 100%, the level of global peace is less than 1 and the reasons for global unrest increase. Therefore, it is beneficial to encourage the utilization of hydrogen from nonfossil fuels in place of fossil fuels. The highest level of global peace is attained when 100% of hydrogen from nonfossil fuels is used in place of fossil fuels. Some advantages of having the highest level of global peace are:

- Lifetimes of fossil fuel reserves are extended and real fossil fuel prices, consequently, can be held constant or reduced relative to present prices.
- Environmental effects from using fossil fuels are reduced or prevented because of the utilization of hydrogen from renewable energy sources and technologies.
- Technological developments based on hydrogen from nonfossil fuels increase and the requirement of technologies based on fossil fuels decrease.
- Living standards are probably higher than at present due in part to the increased consumption of the technologies related to hydrogen from sustainable green energy sources.
- Pressures to discover energy sources reduce because hydrogen can be abundantly produced and conflicts for energy supplies subside.

To increase global peace, the relationship of hydrogen to renewable energy sources needs to be understood, as does the importance of producing hydrogen from renewable energy sources.

Fig. 10 describes routes using sustainable green energy sources for green power production. It is expected that the utilization of sustainable green energy sources will reduce the negative energy-related environmental effects such as global climate change and emissions of CO, CO_2, NOx, SOx, nonmethane hydrocarbons, and particulate matter. In this regard, some potential solutions to decreasing the global unrest associated with the harmful pollutant emissions have evolved, including[3]:

- Education and training for a sustainable future
- Renewable energy technologies
- Energy conservation (efficient energy utilization)
- Cogeneration and district heating
- Energy storage technologies
- Alternative energy dimensions for transport
- Energy source switching from fossil fuels to environmentally benign energy forms
- Coal cleaning technologies
- Optimum monitoring and evaluation of energy indicators
- Policy integration
- Recycling
- Process change and sectoral shiftment
- Acceleration of forestation
- Carbon or fuel taxes
- Greener materials substitution
- Promoting public transport
- Changing life styles
- Increasing public awareness

Considering the above explanations, the following important remarks can be extracted. Fossil fuel consumption and green energy consumption are expected to reach 13807.2 and 2694.9 M, respectively, by the year 2050. This increase indicates that humans will still be dependent on fossil fuels. Based on the projected data, the green energy consumption ratio expects that the green energy utilization ratio will reach almost 16.33% and the fossil fuel utilization ratio will decrease to almost 83.67% in 2050. If the increase of fossil fuel consumption continues in this manner, it is likely that the world will be affected by many negative problems due to fossil fuels. More utilization of fossil fuels will harm world stability and increase local and global environmental problems, resulting in increasing global unrest. It is thus suggested

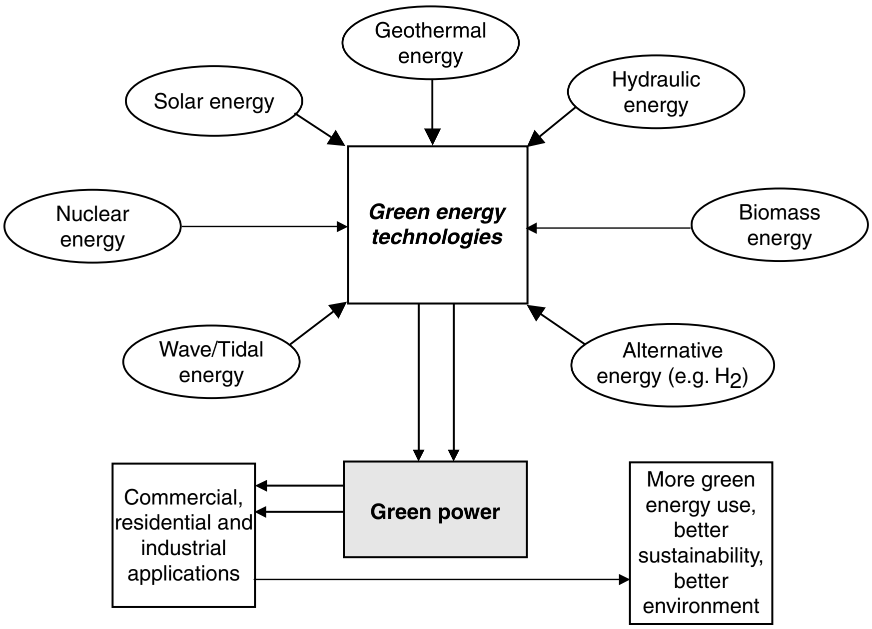

Fig. 10 Routes for green power production from sustainable green energy sources.

that the utilization of fossil fuels should be reduced, and fossil-based technologies should be gradually converted to green-energy-based technologies.

Case 1 gives better results than Case 2 and Case 3. Therefore, for a higher green energy impact ratio in practice, Case 1 should be applied to increase the green energy sustainability ratio depending on the green energy strategies. Moreover, Case 1 gives the best results of the green-energy-based sustainability ratio depending on the green energy impact ratio and the green energy utilization ratio.

The approximate quantified measures developed for level of global peace (ranging between 0 and 1) and level of global unrest (ranging between 1 and ∞) expressions can help understand and measure levels of global unrest and global peace. The highest level of global peace occurs when GP $=1$ and correspondingly, the lowest level of global unrest when GU $=1$, and efforts to increase global peace and stability should cause the values of GP and GU to shift towards these limiting cases. Hydrogen from nonfossil fuels can replace oil, coal, and natural gas to reduce the level of global unrest.

Sustainable green energy strategies are definitely required to ensure the global stability by reducing the harmful effects of fossil-based energy consumption. So, it is suggested that the importance of green energy and technologies that probably reduce world problems and achieve a sustainable energy system should be emphasized with consideration of the sustainable energy strategies. Moreover, a transition to the green-energy-based economy should be encouraged and developed countries in particular should increase investments in green energy and technologies. Progress of green energy and technologies is based on sustainable green energy strategies for future green energy scenarios. The foremost factor that will determine the specific role of green energy and technologies will likely be energy demand. In order to balance the energy demand now and in the future, it is suggested thatsustainable green energy sources and technologies be taken into consideration to increase the sustainable development in a country.

CONCLUSION

Green energy for sustainable development has been discussed and some key parameters to increase green-energy-based sustainability and the global peace level have been presented. The effects of technological, sectoral, and practical application impact ratios on the green energy impact ratio and the green-energy-based sustainability ratio are examined thoroughly. In addition, the key role of hydrogen—one of the most green energy carriers for the future—is discussed in terms of global unrest and peace. Accordingly, sustainable green energy and technologies are definitely required to ensure global stability by reducing the harmful effects of fossil-based energy consumption. The most important scenario that encourages the transition to green energy and technologies and promotes green-energy-based technologies is to supply the required incentives and interactions among the countries, scientists, researchers, societies, and all. Therefore, the investments in green energy supply should be, for the future of world nations, encouraged by governments and other authoritative bodies who, for strategic reasons, wish to have a green alternative to fossil fuels.

Greenhouse Gas Emissions: Gasoline, Hybrid-Electric, and Hydrogen-Fueled Vehicles☆

Robert E. Uhrig
University of Tennessee, Knoxville, Tennessee, U.S.A.

Abstract
In another chapter of this encyclopedia (Hybrid-Electric Vehicles: Plug-In Configuration), the author showed that it was theoretically possible for plug-in hybrid-electric light transportation vehicles to utilize electricity provided by electric utilities to displace almost 75% of the energy of gasoline used by light transportation vehicles. (Uhrig, R.E. Using plug-in hybrid vehicles to drastically reduce petroleum-based fuel consumption and emissions. The BENT of Tau Beta Pi, 2005; XCLI (2), 13–19.). The chapter indicated that there also is a significant reduction in the greenhouse gases emitted into the atmosphere by the plug-in hybrid vehicles, but no quantitative assessment is provided. The purpose of this chapter is to provide quantitative comparisons between all of the various hybrid-electric options. Comparisons are also made with greenhouse gas emissions from hydrogen-fueled vehicles. The results shown in tables indicate that greenhouse gas emissions are small or negligible when the electricity or hydrogen is produced using nuclear or solar (wind, photovoltaic, hydro, or renewable) energy. However, when fossil fuels (coal, oil, or natural gas) are used, the greenhouse gas emissions are greater than for gasoline-fueled vehicles in most cases.

INTRODUCTION

In another chapter of this encyclopedia (Hybrid-Electric Vehicles: Plug-In Configuration), the author showed that it was theoretically possible for plug-in hybrid-electric light transportation vehicles to utilize electricity provided by electric utilities to displace almost 75% of the energy of gasoline used for light transportation vehicles (automobiles, SUVs, pickup trucks, minivans, etc.). It was also shown that replacing this gasoline energy with electricity would require 200–250 GW of new electrical generating capacity. Calculations based on the results in another chapter in this encyclopedia (Transportation Systems: Hydrogen Fueled) show that about 930 GW of new electrical generating capacity would be required to produce hydrogen by electrolysis to replace all hydrocarbon fuels used in all U.S. transportation systems (including heavy trucks, aircraft, military vehicles, etc.). Hence, the choice of fuels for of these new electrical generating plants could have a large environmental impact if a significant fraction of gasoline used for light and heavy vehicle transportation was replaced by electricity or hydrogen.

☆ The material in this article was originally published as "Greenhouse gas emissions from gasoline, hybrid-electric, and hydrogen-fueled vehicles" by Uhrig, R.E. in the "Proceedings of the Climate Change Technology Conference," Ottawa, Ontario, Canada, May 9–12, 2006. It is presented here with permission of the Engineering Institute of Canada (EIC), the sponsoring organization.

Keywords: Greenhouse gases; Carbon dioxide; Alternate automotive fuels; Emissions.

GREENHOUSE GASES

Sunlight enters the atmosphere striking the earth, and it is reflected back towards space as infrared radiation (heat energy). Greenhouse gases absorb this infrared radiation, trapping the heat in the atmosphere. Until about 150 years ago, the amount of energy absorbed was about the same as the amount of energy radiated back into space. At that time, this equilibrium was upset, and the concentration of greenhouse gases—especially CO_2 (carbon dioxide)—began to increase. The concentration is continuing to increase at a rate that seems to parallel the increase in production of CO_2. During the same period, the average temperature of the atmosphere increased with subsequent climate changes in a manner that is thought by many to be a cause-effect relationship.[3]

The principal greenhouse gases are water vapor (60%–65%) and CO_2 (20%–25%). Water vapor stays in the atmosphere for a relatively short time—a matter of hours or days—whereas CO_2 has an average residence period of about a century. As a result, the amount of water vapor remains relatively constant related to the rate at which it is produced by weather phenomena, while CO_2 tends to accumulate as the amount emitted increases. All other greenhouse gases (10%–20%) such as methane, ozone, nitrous oxide, and carbon monoxide tend to have less effects on the atmosphere over time because of their small quantities or short residence times. Hence, the only greenhouse gas considered in this analysis is CO_2.

In contrast with the "well to wheels" approach that includes the emissions produced by processing the original fuel, this analysis starts with the fuel used to generate electricity or to produce hydrogen. This simplification does not materially change the relationship between the emissions of greenhouse gases by the various processes analyzed.

MODELS USED FOR ANALYSES

The models to quantitatively evaluate the greenhouse gas emissions, specifically carbon dioxide, when electrical energy or hydrogen is used to replace gasoline as an automotive fuel are those used in the author's previous publications.[7,8] These models were based on information provided by or extrapolated from data provided by the Department of Energy (DOE) Energy Information Administration (EIA).[2]

These models utilize the following data:

1. There were 225 million light transportation vehicles in the United States in 2004, including 133 million automobiles and 92 million light truck-based vehicles (sport utility vehicles, vans, pickup trucks, passenger minivans, and delivery vans).
2. On any given day, 50% of these vehicles traveled less than 32.2 km (20 mi).
3. The average distance traveled by each vehicle in the United States was 19,749 km/year (12,264 mi/year). This distance traveled by each average vehicle is derived from the 9 million barrels of oil per day used to make gasoline for the 225 million light vehicles having an average fuel consumption of 8.51 km/l (20 mi/gal), the approximate average gasoline mileage reported by EIA.[2]
4. The quantitative index used for comparing electricity and hydrogen produced by different methods using different source fuels is kilograms of CO_2 per vehicle-year (pounds per vehicle-year) for the average distance traveled by each vehicle in the United States—19,749 km/year (12,264 mi/year). Actual emissions of specific vehicles may be greater or less than the values presented here depending upon whether the fuel consumption of the particular vehicle is greater or less than the average value of 8.51 km/l (20 mi/gal).

CO_2 EMISSIONS FOR GASOLINE-FUELED LIGHT VEHICLES

TerraPass, a vendor dealing in carbon dioxide emission credits, has developed a "carbon dioxide calculator" that gives the emission of carbon dioxide for virtually all American automobiles for the past 20 years.[6] Experimenting with this calculator shows that the quantity of carbon dioxide, the most important greenhouse gas from combustion of gasoline in internal combustion engines, emitted per unit of time is a direct function of the amount of gasoline used in that time. This calculator utilized the fact that the combustion of 1 gal of gasoline emits 2.35 kg of CO_2 per liter (19.56 lbs of CO_2 per gallon) of gasoline. Because the average gas mileage in our model is 8.51 km/l (20 mi/gal), the annual emission of carbon dioxide is

$$\frac{19,749\ \text{km/year} \times 2.35\ \text{kg}\ CO_2\ \text{per liter}}{8.51\ \text{km/liter}}$$
$$= 5,458\ \text{kg/vehicle-year}$$
$$(11,997\ \text{lb}\ CO_2\ \text{per vehicle-year})$$

Clearly, the amount of CO_2 for smaller vehicles is less than for larger vehicles because the gasoline mileage is greater. However, the model for this analysis deals with average vehicles that achieve 8.51 km/l (20 mi/gal)—the reference performance used for all comparisons.

CO_2 EMISSIONS FOR MICRO, MILD, AND FULL HYBRID VEHICLES

Because of the energy to propel all traditional types of hybrid vehicles is provided by gasoline, we will utilize the increased fuel mileages assigned in the author's earlier publication[8] and reduce the total CO_2 emissions for traditional hybrid-electric vehicles accordingly, as shown in Table 1.

These values are for hybrid vehicles of a size corresponding to a traditional vehicle that attains 8.51 km/l (20 mi/gal). A larger or smaller vehicle would have higher or lower emissions, respectively.

CO_2 EMISSIONS FOR PLUG-IN HYBRID-ELECTRIC VEHICLES

The model utilized in the author's hybrid article[8] has half the vehicles traveling 24.2 km (15 mi) per day on electricity, or 8816 km (5475 mi) per year. The other half of the vehicles travel 56.4 km (35 mi) per day, or 20,572 km (12,775 mi) per year on electricity. These assumptions result in an average of 14,694 km (9125 mi) per year on electricity for all vehicles.

Table 1 Emissions for hybrid-electric vehicles

	Gasoline mileage		CO_2 per vehicle-year	
Type hybrid	**km/l**	**mi/gal**	**Kg**	**lb**
Micro hybrid	9.35	22	4,955	10,906
Mild hybrid	10.62	25	4,362	9,598
Full hybrid	12.32	29	3,761	8,274

The second half of these vehicles must also travel an additional 5055 km (3139 mi) per year as a full hybrid using gasoline at 12.32 km/l (29 mi/gal). Because the average total distance traveled by each car per year is 19,749 km (12,264 mi), the distance traveled using gasoline is 25.6% of the average distance each vehicle travels. The other 74.4% of this distance is traveled using electricity generated by a utility using nuclear fuels, fossil fuel, solar energy (wind, hydro, or photovoltaic systems), or renewable energy systems. Such a substitution of electricity for gasoline would save 6.7 million of the 9.0 million barrels of oil per day used in the United States for light vehicle transportation.

Electricity Generated Using Nuclear, Solar, and Renewable Fuels

Plug-in hybrid vehicles have two sources of CO_2—the CO_2 emitted due to operation in the full-hybrid mode and the CO_2 emitted in generating the electrical energy used for the rest of the time. Because nuclear, solar, and renewable fuels generate a net of zero CO_2, the only CO_2 generated is by operation in the full-hybrid mode for 25.6% of the distance traveled. Hence, the emission is 25.6% of the value in Table 1 for a full-hybrid, 964 kg (2122 lb) per vehicle-year.

Electricity Generated Using Fossil Fuels (Natural Gas, Oil, and Coal)

When the electricity is supplied by utilities using fuels that emit carbon dioxide during combustion, this CO_2 from generating electricity must be added to the CO_2 of the full-hybrid operation discussed above. Data on actual emissions from fossil power plants in the United States for 1999 (the last year for which complete data is available), provided by EPA and (DOE) (DOE–EIA 1999), show the emission rates in Table 2 below.

In a previous Chapter (Hybrid-Electric Vehicles: Plug-In Configuration), it was established that 0.374 kWh/km (0.603 kWh/mi) was a reasonable average expenditure of electrical energy for hybrid vehicles that would be comparable to a vehicle getting 8.51 km/l (20 mi/gal) of gasoline using an internal combustion engine. Previously in this chapter, it was shown that the average distance traveled by all plug-in hybrid vehicles while operating on electricity alone was 14,694 km/year (9125 mi/year). Hence, the electricity used is

$$(14,694\ \text{km/year}) \times (0.374\ \text{kWh/km}) = 5,496\ \text{kWh/year}.$$

If we multiply this value by the amount of CO_2 emission per kilowatt-hour for the three fossil fuels given in Table 2 and add the 964 kg/vehicle-year (2122 lb/vehicle-year) of CO_2 for operation in the hybrid mode, we get the results for fossil fuels given in Table 3.

Table 2 Emission rates for fossil fuels

Fuel to generate electricity	% of total generation	CO_2 emission rate	
		kg/kwh	lb/kwh
Coal	51.0	0.952	2.095
Oil	3.2	0.895	1.969
Natural gas	15.2	0.600	1.321
Renewables	0.6	0 (net)	0 (net)
Non-fossil[a]	30.0	0	0

[a]Nuclear, Solar, Wind, and Hydro.

HYDROGEN FUELED VEHICLES

The emission of carbon dioxide from vehicles utilizing electricity generated with fuel cells operating on hydrogen is negligible except for the emissions from the various processes used to produce the hydrogen. These emissions of carbon dioxide from the production processes must be taken into account to give a valid comparison with emissions of greenhouse gases from the other vehicle configurations and their potential impact upon climate and weather modification.

STEAM METHANE REFORMING

Some 95% of hydrogen used today is produced by steam methane reforming (SMR) from natural gas (∼98% methane—CH_4). The two steps of SMR are

$$CO_4 + H_2O + \text{Heat (206 kJ/mol)} \xrightarrow{\text{Catalyst}} CO + 3H_2$$

(Steam Reforming Reaction)

$$CO + H_2O \xrightarrow{\text{Catalyst}} CO_2 + H_2 + \text{Heat (41 kJ/mol)}.$$

(Water–Gas Shift Reaction)

Table 3 Emissions for fossil fuels

Fuel to generate electricity	Emissions of CO_2	
	kg/vehicle-year	lb/vehicle-year
Coal	6,205	13,650
Oil	5,889	12,956
Natural gas	4,271	9,396

Source: From Energy Information Administration (see Ref. 1).

The hydrogen comes from the methane and the steam. The steam reforming reaction is endothermic with the required 206 kJ/mol heat energy normally produced by combustion of some of the methane. The water–gas shift reaction is exothermic, providing 41 kJ/mol heat energy that, if recovered, can reduce the amount of methane burned. Then the methane burned has to provide only the net 165 kJ/mol that represents ~17% of the total methane energy. About 3.3 mol of hydrogen (~83% of the theoretical maximum of 4 mol of hydrogen from CH_4) are produced for each mol of methane. A well-designed SMR plant will yield hydrogen having about 80% of the energy of the methane supplied. Unfortunately, SMR produces CO_2 in both the methane combustion and in the water–gas shift reaction.

Emissions of Vehicles Using Hydrogen Produced by SMR

In an earlier publication,[8] it was established that 0.228 kWh/km (0.367 kWh/mi) of mechanical energy at the tire-pavement interface corresponded to 8.51 km/l (20 mi/gal). If we use the following efficiencies:

70% efficiency for the electric motor drive (electricity to mechanical energy at the tire-pavement interface), the same used in the above reference,
60% efficiency (hydrogen to electricity) for the fuel cell, and
85% efficiency is distributing and dispensing the hydrogen to the fuel cell, the needed energy of the hydrogen input to the fuel cell is

$$\frac{0.228 \text{ kWh/km}}{0.70 \times 0.60 \times 0.85} = 0.638 \text{ kWh/km } (1.028 \text{ kWh/mi})$$

of hydrogen energy. Because the average total distance traveled per vehicle is 19,749 km/year (12,264 mi/year), the total kilowatt-hour per vehicle-year is

$$(19,749 \text{ km/year}) \times (0.638 \text{ kWh of } H_2 \text{ energy/km}) = 12,607 \text{ kWh of } H_2 \text{ energy/vehicleyear.}$$

The energy of hydrogen (lower heating value) is 119.9 MJ/kg (51,600 Btu/lb), so the amount of H_2 used per year is

$$\frac{12,607 \text{ kWh per vehicle-year}}{119.9 \text{ MJ/kg} \times 0.278 \text{ kWh/MJ}} = 379 \text{ kg } H_2 \text{ per vehicle-year } (834 \text{ lb } H_2 \text{ per vehicle-year}).$$

Goswami indicates that SMR produces a net of 0.43 mol of CO_2 for each mol of H_2 produced using SMR.[4] Because the molecular weights of CO_2 and H_2 are 44 and 2, respectively, the specific CO_2 emission can be calculated by

$$(0.43 \text{ mol } CO_2/\text{mol } H_2) \times \frac{(44 \text{ gm/mol } CO_2)}{(2 \text{ gm/mol } H_2)} = 9.46 \text{ gm } CO_2/\text{gm } H_2 = 9.46 \text{ kg } CO_2/\text{kg } H_2$$

and the total emission of CO_2 per vehicle-year is

$$(379 \text{ kg } H_2 \text{ per vehicle-year}) \times (9.46 \text{ kg } CO_2 \text{ per kg } H_2) = 3,585 \text{ kg } CO_2 \text{ per vehicle-year } (7,888 \text{ lb } CO_2 \text{ per vehicle-year}).$$

Emission for Vehicles Using Hydrogen Produced by SMR with Heat Provided by a High-Temperature Nuclear Reactor

Recent work in Japan has demonstrated the feasibility of substituting high-temperature heat from a gas cooled nuclear reactor to replace the heat supplied by the combustion of methane. This increases the amount of hydrogen produced to 4 moles per mole of methane and eliminates the CO_2 produced by combustion of methane, but not the CO_2 produced by the water–gas shift reaction. The overall reaction of the steam reforming and water shift reactions is the production of 1 mole of CO_2 and 4 mol of hydrogen for each mole of CH_4. Hence, multiplying this ratio by the molecular weights and the amount of hydrogen used per year gives

$$\frac{1 \text{ mol } CO_2}{4 \text{ mol } H_2} \times \frac{44}{2} \times 379 \text{ kg } H_2 \text{ per vehicle-year} = 2,084 \text{ kg } CO_2 \text{ per vehicle-year } (4,586 \text{ lb } CO_2 \text{ per vehicle-year}).$$

EMISSIONS FOR VEHICLES USING H_2 PRODUCED BY ELECTROLYSIS

Conventional electrolysis of water to produce hydrogen is a well-developed technology and production units as large as 10 MWe are commercially available today. However, the typical overall efficiency of hydrogen production using electrolysis based on the thermal content of the generating plant fuel is about 25% today, consisting of two components—about 33% efficiency in converting fossil or nuclear fuel to electricity and about 75% in using electricity to separate water into hydrogen and oxygen. If a high-temperature gas-cooled reactor or a modern high-efficiency gas-fired combined cycle plant is used, the overall efficiency in producing hydrogen could approach 45%.

A leading manufacturer of electrolysis equipment indicated that 1 MW of electricity can generate 0.52 ton (1040 lb) of hydrogen per day or 0.473 kg H_2/kW day (1.04 lb H_2/kW day).[5] In the case of SMR, it was calculated that the hydrogen required per year for a vehicle using hydrogen to travel 12,260 mi/year was 379 kg of H_2/vehicle-year (832 lb/vehicle-year). Hence, the amount of electricity required per year is

$$\frac{(379 \text{ kg } H_2/\text{year}) \times (24 \text{ h/day})}{0.473 \text{ kg } H_2/\text{kW day}} = 19,230 \text{ kWh/year}.$$

The carbon dioxide emitted for hydrogen-fueled vehicles is the carbon dioxide emitted in producing the electricity required to produce the hydrogen. The choices of fuel for generating electricity are coal, oil, natural gas, nuclear energy, and solar energy (wind, photovoltaics, and hydro). Hence, the emissions of carbon dioxide are the product of the kilowatt-hour per year and the appropriate emission per kilowatt-hour from Table 2 for the fuel used.

Emissions for Vehicles Using H_2 Produced by Electrolysis Using Solar, Nuclear, and Renewable Energy

Because none of these energy sources emit carbon dioxide when generating electricity, there are no emissions of greenhouse gases associated with these arrangements.

Emissions for Vehicles Using H_2 Produced by Electrolysis Using Fossil Energy (Coal, Oil, and Natural Gas)

The emissions of carbon dioxide for these fossil fuels are the products of the 19,230 kWh/year and the appropriate emission per kilowatt-hour for the fuel as given in Table 2. The results are shown in Table 4.

Table 4 Emissions for fossil electrolysis

Fuel	kg CO_2/year	lb CO_2/year
Natural gas	11,538	25,384
Oil	17,211	37,963
Coal	18,307	40,276

EMISSIONS FOR VEHICLES USING H_2 PRODUCED BY THERMOCHEMICAL PROCESSES

The overall efficiency of the thermochemical process of producing hydrogen, such as the sulfur–iodine process, approaches 50% at 900°C, while the overall efficiency of the electrolysis process is about 25%. Hence, for the same fuel, the carbon dioxide emissions will be half as much for thermochemical processes as for electrolysis.

Emissions for Vehicles Using Hydrogen Produced by Thermochemical Processes Using Solar, Nuclear, and Renewable Energy

Because none of these energy sources emit carbon dioxide when generating electricity, there are no emissions of carbon dioxide associated with these arrangements.

Emissions for Vehicles Using Hydrogen Produced by Thermochemical Processes Using Fossil Energy (Natural Gas, Oil, and Coal)

The emissions of carbon dioxide for these fossil fuels are half of those for electrolysis, as shown in Table 4. The results are shown in Table 5.

RESULTS AND CONCLUSIONS

The results of this analysis are presented in Tables 6 and 7, which provide emissions of carbon dioxide for the various hybrid and hydrogen-fueled vehicle arrangements for the reference case of 8.50 km/l (20 mi/gal) for the average vehicle being driven 19,749 km/year (12,264 mi/year).

Plug-in Hybrid-Electric Vehicles

In Table 6, the vehicle emissions of CO_2 for all traditional hybrid-electric vehicles are inversely related to the gas mileage. The gasoline mileage for micro, mild, and full hybrids are assumed to be 9.35, 10.62, and 12.32 km/l (22, 25, and 29 mi/gal), respectively. These are reasonable overall values for the newer, larger hybrid vehicles that have larger gasoline engines and electric motors such as the Toyota Highlander and Honda Accord hybrids.

Table 5 Emissions for hydrogen produced by thermochemical processes by fossil fuels

Fuel	kg CO_2/year	lb CO_2/year
Natural gas	5,769	12,692
Oil	8,605	18,932
Coal	9,153	20,138

Table 6 Comparison of emissions of carbon dioxide for hybrid vehicles

Vehicle emissions of carbon dioxide	kg CO_2/vehicle-year	lb CO_2/vehicle-year
Reference gasoline vehicle average 8.51 km/l (20 mi/gal)	5,500	12,000
Micro-hybrid vehicle 9.35 km/l (22 mi/gal)	4,950	10,900
Mild-hybrid vehicle 10.62 km/l (25 mi/gal)	4,350	9,600
Full-hybrid vehicle 12.32 km/l (29 mi/gal)	3,750	8,300
Plug-in hybrid vehicle		
Electricity generated with nuclear	950	2,100
Electricity generated with solar energy	950	2,100
Electricity generated with renewable	950	2,100
Electricity generated with natural gas	4,250	9,400
Electricity generated with oil	5,900	13,000
Electricity generated with coal	6,200	13,700

Vehicle travels 19,749 km (12,264 mi) per year.

The rounded emissions in Table 6 for electricity generated using oil and coal are greater than for the reference case of gasoline. However, the emission of a plug-in hybrid vehicle where the electricity is generated by nuclear or solar energy is less than 20% of the reference gasoline case. Hence, the only way to significantly improve the greenhouse gas situation if plug-in hybrids are implemented on a large scale is to use only nuclear energy, solar (wind, hydro, or photovoltaic) energy, or renewables to generate the needed electricity. Because hydro power is virtually out of the question due to limited sites and environmental concerns, renewables have large land requirements, and both photovoltaic and wind are intermittent in nature with availabilities of less than about 30%, nuclear power would appear to be the primary choice.

Hydrogen-Fueled Fuel Cell Vehicles

The vehicle emissions of CO_2 for hydrogen-fueled fuel-cell-driven vehicles are presented in Table 7, where the emissions have been rounded off. Because fuel cells do not

Table 7 Comparison of emissions of carbon dioxide for hydrogen fueled fuel cell vehicles

Vehicle emissions of carbon dioxide	kg CO_2/vehicle-year	lb CO_2/vehicle-year

Generated using renewables	0	0

Vehicle travels 19,749 km (12,264 mi) per year.

emit CO_2, the only emissions are from the processes used to produce the hydrogen. The carbon dioxide emissions for hydrogen produced by steam methane reforming, electrolysis, and thermochemical methodologies are given.

Perhaps the most important observation is that, contrary to the widespread belief that hydrogen-fueled vehicles produce no greenhouse gases, the emissions for hydrogen-fueled vehicles vary widely depending upon the method used to generate the electricity or heat to produce the hydrogen. In the case of electrolysis, in which the electricity is generated using nuclear, solar, and renewable energy, the average annual emissions per vehicle-year are negligible. However, the emissions for fossil fuels (natural gas, oil, and coal) are about 11,500, 17,200, and 18,300 kg/year (25,300, 37,800, and 40,200 lb/year), respectively—almost three times those for plug-in hybrid vehicles. These are extremely large emissions compared to almost any other method investigated here.

The emissions for producing hydrogen for a hydrogen-fueled vehicles using SMR produces CO_2 by two methods: combustion of some of the methane to drive the reaction and the water–gas shift reaction. These reactions produce about 3600 kg (7900 lb) CO_2 per vehicle-year, about the same as a full-hybrid vehicle.

If the heat required to drive the reaction in steam methane reforming can be supplied by an outside source such as a high temperature gas cooled reactor, then the emission of CO_2 is reduced to about 2100 kg (4600 lb) per vehicle-year.

The conclusion is that using hydrogen in fuel cells to propel vehicles is a complex process with many steps (converting thermal energy to electricity to hydrogen to electricity to propelling the vehicle), each consuming considerable energy. Hence, the resulting CO_2 emissions when fossil fuels are used to generate the electricity for electrolysis or thermochemical processes are correspondingly high. Given the concerns about the influence of CO_2 on weather and climate, it seems compelling that fossil fuels not be used in producing electricity for electrolysis or thermochemical processes to produce hydrogen for transportation.

Heat and Energy Wheels

Carey J. Simonson
Department of Mechanical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Abstract
This article discusses the construction and operation of heat and energy wheels, as well as their effectiveness in transferring heat and moisture between air streams. Heat wheels transfer sensible heat between two air streams with different temperatures, while energy wheels transfer heat and moisture between two air streams with temperature and water vapor concentration differences. Heat and energy wheels have high effectiveness values and low pressure drops, making them both economical and environmentally friendly.

INTRODUCTION

Heat wheels, as the name implies, are rotating heat exchangers that transfer heat between two different air streams (Fig. 1). Energy wheels are very similar to heat wheels except that they are designed to transfer moisture, as well as heat, between the two air streams. They are called energy wheels (and sometimes enthalpy wheels or desiccant-coated heat wheels) because they transfer sensible energy that results from temperature differences between the two air streams and latent energy that results from water vapor concentration differences between the two air streams. Heat and energy wheels are gaining popularity in building heating, ventilating, and air conditioning (HVAC) systems mainly because of their very high energy transfer effectivenesses. Heat/energy wheels are made of many different materials for heat transfer, with desiccants utilized for moisture transfer. This article presents the construction and operation of heat/energy wheels, as well as their effectiveness in transferring heat and moisture between air streams. Economic and environmental issues are also presented.

Heat Wheels

Heat wheels are rotating exchangers that transfer sensible heat between two air streams with different temperatures. These wheels have been used for half a century in gas turbine plants and electrical power generating stations to recover thermal energy from the exhaust gases and preheat inlet combustion air, thus increasing the overall plant thermal efficiency.[1–3] Typical rotating speeds are in the order of 20–30 revolutions per minute (rpm).

Keywords: Heat transfer; Moisture transfer; Rotating exchanger; Payback; Life cycle costs; Environmental impacts; Life cycle analysis; Effectiveness.

Energy Wheels

Energy wheels transfer both heat and moisture between two air streams. They have more recently been developed for transferring heat and moisture between buildings' supply and exhaust air streams. Their market share has increased significantly in the last decade, and energy wheels make up over half of all new air-to-air heat/energy exchangers installed in buildings. Their popularity can be attributed to increases in required outdoor ventilation rates in the late 1980s and a recent emphasis on improving worker productivity and health by improving the thermal comfort and indoor air quality conditions in buildings where humidity is a key variable.[4–6]

After standard ventilation rates were sharply decreased to reduce energy use in buildings in 1975,[7] the number of buildings with air quality problems resulting from high indoor air concentrations of contaminants increased significantly. Inadequate mechanical ventilation for new air-tight buildings, constructed in the 1970s and 1980s, led to many new and unforeseen indoor air quality problems.[8] As a result, most industrial countries revised their ventilation standards to include higher outdoor ventilation air flow rates. For example, the 1989 and 2004 ASHRAE ventilation standards[9,10] specify required ventilation air flow rates, which are about three times larger than they were in 1975,[7] to maintain acceptable indoor air quality for a wide range of building types and spaces. In terms of improved productivity, it has been estimated that the annual benefit would be $55 billion if all U.S. buildings were upgraded to meet current ventilation standards.[11] The average economic payback time is expected to be 1.6 years.

Naturally, the costs and environmental impacts of energy consumption have dictated that improvements in productivity, health, comfort, and indoor air quality should be achieved with minimal energy consumption, and energy wheels have been favored because the energy associated with moisture transfer (humidification or

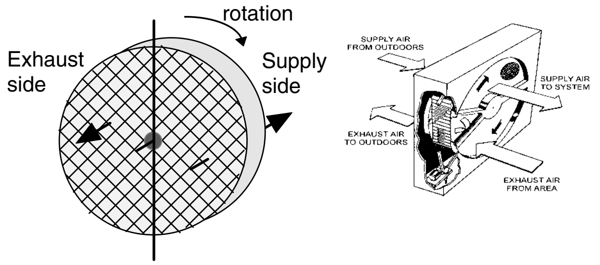

Fig. 1 Schematic of a heat/energy wheel transferring energy between the supply and exhaust air streams of a building.
Source: From 2004 ASHRAE Handbook-HVAC systems and equipment handbook. [17] American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc., www.ashrae.org (see Ref. 17).

dehumidification) in building applications is often as important as heat transfer, especially in warm, moist climates. The importance of moisture transfer is evident when the cooling of moist air is considered. For example, the ideal cooling of air from 35°C and 60% relative humidity (RH) to 25°C and 50% RH requires four times as much energy as cooling air from 35 to 25°C with no change in moisture level (i.e., humidity ratio). Moisture transfer in air-to-air energy wheels can significantly reduce the dehumidification and humidification loads of buildings. This reduces the energy consumption, as well as the size of the cooling equipment needed in the building.[12]

Desiccant Drying Wheels

Desiccant drying wheels are very similar to energy wheels in that they transfer both heat and moisture between two air streams. The main difference is that desiccant drying wheels are designed with an emphasis on air-drying, rather than energy transfer. To maximize moisture transfer, desiccant drying wheels use thick desiccant coatings, slow rotational speeds (<1 rpm), and external heat sources to dry the wheel and remove as much moisture as possible from the moist air stream (supply air for buildings).[13,14] Energy wheels, on the other hand, are passive devices that transfer heat and moisture with minimal external energy input.[15]

CONSTRUCTION AND MATERIALS

Heat/energy wheels come in many different sizes and are constructed with many different materials. The core of the wheel, known as the wheel matrix, permits heat and moisture transfer between the two airstreams. One of the most common matrix materials is aluminum because of its high thermal conductivity and thermal capacitance; however, other matrix materials, such as ceramics, stainless steel, plastics, paper, and a wide range of desiccants and desiccant coatings, are also utilized. Some desiccant coatings include: zeolites, molecular sieves, silica gels, activated alumna, titanium silicate, synthetic polymers, lithium chloride, and aluminum oxide. Each matrix material and desiccant coating has a specific range of applications, performance, and limitations. For example, high temperature and corrosive applications may favor the use of stainless steel and ceramic materials, while paper and some plastics may be limited to low temperature applications.[16,17]

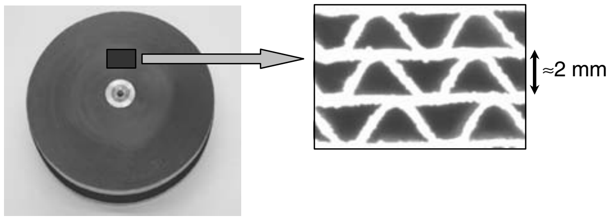

Fig. 2 A picture of an energy wheels with a typical corrugated matrix.

A common matrix arrangement is where the matrix material is corrugated to form small flow channels (e.g., sinusoidal, as in the end view of cardboard, triangular, or hexagonal) with a height of about 2 mm (Fig. 2). These small flow channels result in a large surface area for heat and mass transfer. The effectiveness of heat/energy exchangers is strongly dependent on the heat/mass transfer surface area—the larger the surface area, the greater the effectiveness. Therefore, heat/energy wheels are characterized by high heat and moisture transfer effectivenesses[15,17] because of their high heat transfer surface area to volume ratios, which result from these small flow channels. Commercial heat/energy wheels often have heat/mass transfer surface area to volume ratios of about 1000–5000 m^2/m^3. This means that for each cubic meter of exchanger, there are 1000–5000 m^2 of surface available to transfer heat and moisture. The net result is that it is possible to transfer a lot of energy with very compact wheels.

OPERATION

In a majority of installations, the two air streams flow through the heat/energy wheel in a counterflow arrangement to ensure the maximum possible heat/moisture transfer between the air streams. To explain how heat/energy wheels transfer heat and moisture between two air streams, Fig. 3 shows a side view of one of the flow channels in both a heat wheel and an energy wheel. For this example, the supply air stream is assumed to be hot and humid, while the exhaust air stream is assumed to be cool and dry. These conditions are representative of an air conditioned building during summer operating conditions.

As the hot supply air flows through the flow channel of a heat wheel, heat is transferred from the hot air to the cooler wheel matrix (Fig. 3). During this part of the wheel

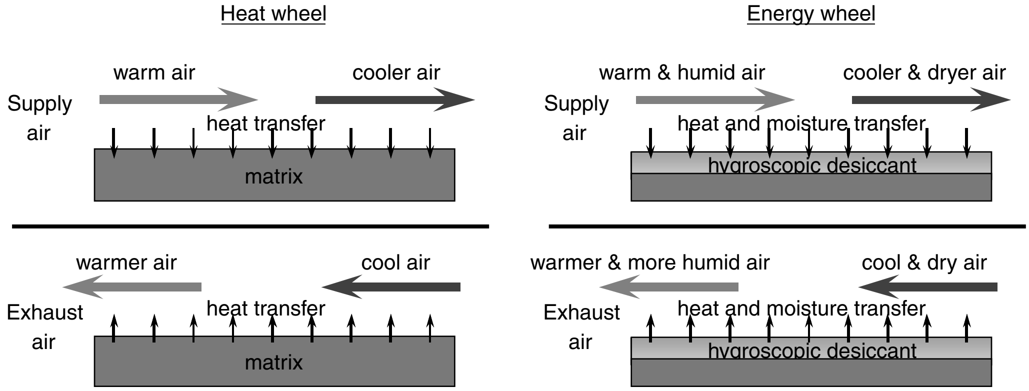

Fig. 3 A side view of a heat wheel and energy wheel matrix. Heat and moisture are transferred to the matrix from the supply air and removed from the matrix by the exhaust air.

cycle, the air stream is cooled and the wheel matrix is heated. As a result, the air leaving the wheel on the supply side is cooler than the air entering the wheel on the supply side and therefore less auxiliary energy is required to cool it for use in the building. During the other half of the wheel rotation, the cool exhaust air flows through the wheel. Here, heat is transferred from the warm matrix to the cool exhaust air. This cools the matrix and heats the air. The warm air is exhausted out of the building and the cooled matrix rotates back to the supply side, where it can cool the supply air again. This cycle repeats as the wheel continually rotates between the supply and exhaust air streams. For a typical wheel speed of 20 rpm, each flow channel in the matrix stores heat from the hot supply air and releases it to the cool exhaust air once every 3 s. Therefore, the matrix is exposed to hot air for 1.5 s followed by cold air for 1.5 s. The rotational speed of the wheel and the thermal capacity of the matrix are key parameters that affect the ability of the heat wheel to store and transfer heat between the two air streams. Other important parameters are the air flow rate and the heat transfer surface area.

The operation of an energy wheel is very similar to the operation of a heat wheel. The only difference is that the matrix of the wheel is also coated with a desiccant that stores moisture. Fig. 3 shows that moisture is transferred from the humid air stream to the hygroscopic desiccant on the supply side and removed from the desiccant by the dry air stream on the exhaust side. Here, the moisture storage capacity is an important parameter that affects the moisture transfer performance of the energy wheel. There are many types of commercial desiccants, but two of the most common are molecular sieve and silica gel. The equilibrium moisture content of silica gel is almost linearly dependent on RH and, therefore, silica gel is better-suited for applications of air-to-air energy wheels in buildings. Molecular sieve desiccants, on the other hand, are often favored in desiccant drying wheels.[18]

PERFORMANCE FACTORS

Effectiveness

Effectiveness is the most important parameter for quantifying the performance of energy exchangers, including heat/energy wheels. It is the prime factor that determines the economic viability or feasibility of an energy exchanger. Since the inlet operating conditions (temperature, humidity, and air flow rate) usually change quite slowly in typical building and other applications, the effectiveness, determined at steady-state test conditions, is used to characterize the performance of energy exchangers. The effectiveness can be measured using steady-state[19,20] or transient test methods,[21,22] but care must be taken to ensure that the uncertainty in the reported effectiveness value is low.[20,23] In most cases, it is advisable to use third-party certified wheels because the effectiveness may be verified with greater confidence and lower uncertainty.[24,25] The following equations define the three different effectiveness values for heat/energy wheels, which can range from 50 to 85% for commercial wheels.[15,17]

Sensible effectiveness for heat and energy wheels:

$$\varepsilon_s = \frac{\text{actual heat transfer}}{\text{maximum possible heat transfer}} = \frac{\dot{m}_s (T_i - T_o)|_s}{\dot{m}_{min}(T_{s,i} - T_{e,i})}. \quad (1)$$

Latent (or moisture transfer) effectiveness for energy wheels:

$$\varepsilon_l = \frac{\text{actual moisture transfer}}{\text{maximum possible moisture transfer}} = \frac{\dot{m}_s (W_i - W_o)|_s}{\dot{m}_{min}(W_{s,i} - W_{e,i})}. \quad (2)$$

Total energy transfer effectiveness for energy wheels:

$$\varepsilon_t = \frac{\text{actual energy transfer}}{\text{maximum possible energy transfer}} = \frac{\dot{m}_s(h_i - h_o)|_s}{\dot{m}_{min}(h_{s,i} - h_{e,i})} \quad (3)$$

where: ε_s is the sensible effectiveness of the heat/energy wheel; ε_l is the latent or moisture transfer effectiveness of the energy wheel; ε_t is the total effectiveness of the energy wheel; $\dot{m}$ is the mass flow rate of dry air (kg/s); T is the temperature of the air (°C or K); W is the humidity ratio of the air (kg/kg); h is the enthalpy of the air (kJ/kg); $\dot{m}_{min}$ is the minimum of the supply ($\dot{m}_s$) or exhaust ($\dot{m}_e$) air mass flow rates; and subscripts i, o, s, and e represent the inlet, outlet, supply, and exhaust sides of the heat/energy wheel.

In comparing the energy efficiency of heat/energy wheels and chillers, the recovered efficiency ratio (RER) is useful. The RER is defined in a similar manner to the energy efficiency ratio (EER) used for chillers—that is, RER equals the recovered energy rate for the exchanger at Air-Conditioning and Refrigeration Institute (ARI) test conditions[24] divided by the sum of the electrical power input for the fans to overcome the pressure drop across the wheel and the electrical power input for the motors to rotate the wheel. Values of RER range from 10 to 60 for heat wheels and from 40 to 100 for energy wheels.[15]

Pressure Drop and Leakage

All heat exchangers cause pressure losses in the fluid streams and are subject to possible leakage between the fluid streams. These factors should be considered and quantified in every design. The pressure drop across a heat/energy wheel is typically quite low compared to other air-to-air heat exchangers, with typical values ranging from 50 to 200 Pa in each air stream.[15,17] Depending on the location of the supply and exhaust fans and dampers, the pressure difference between the two air streams may be higher and result in small leakage flows and cross contamination between the supply and exhaust air streams. In addition, there is carryover of exhaust air into the supply air stream each time the wheel rotates and carries the entrained gas within the flow channels into the supply air stream. These effects can be minimized by positioning the fans so that leakage is from the fresh air on the supply side to the stale air on the exhaust side. This can be accomplished by applying good seals and installing a purge section, which uses the supply air to purge the exhaust air from the wheel before the wheel rotates into the supply air steam (Fig. 1). For some applications, toxic or hazardous contaminants in the exhaust gases will suggest that the heat/energy wheels may not be an appropriate selection, even when a purge section is used to reduce cross contamination to less than 1% of the flow rate. In other applications, large pressure differences between the exhaust and supply air ducts suggest that heat/energy wheels (as well as plate heat exchangers) will experience excessive leakage.

The ARI rating standard[24] specifies two factors that characterize the leakage between supply and exhaust air streams: the exhaust air transfer ratio (EATR) and the outside air correction factor (OACF). The EATR represents the fraction of exhaust air that is transferred (recirculated) into the supply air through the exchanger and typical values are from 1 to 10%. This means that from 1 to 10% of the exhaust air is transferred to the supply air stream and delivered to the space. The OACF represents the increase in outdoor ventilation rate required because of leakage between the supply and exhaust air streams. Typical values of OACF are from 1.0 to 1.1. An OACF of 1.05, for example, means that 5% of the supply air is transferred from the supply inlet side to the exhaust outlet side and not delivered to the building space. Therefore, the supply air flow rate must be increased by 5% to provide adequate outdoor ventilation to the building space.

Frosting

Condensation and/or frosting can occur in any air-to-air heat/energy exchanger under cold weather operating conditions. As the warm moist air passes through the exchanger, it can be cooled to the dew point temperature. Water will begin to drain from the exchanger if the temperature is above freezing, while frost will begin to accumulate within the exchanger if the temperature is below freezing. If condensation is to occur under system design conditions, a condensation drain should be provided. Excessive condensation may degrade the desiccant coating used in energy wheels. If frosting would unacceptably compromise ventilation, or if equipment would be damaged by frost, a frost control scheme should be provided. Frost control of heat/energy wheels can be achieved using several different methods, including supply air bypass or throttling, preheating the supply or exhaust air inlet flow, and wheel speed control. The manufacturer should address the issue of frost control for units intended for use in cold climates.

Energy wheels are much less susceptible to condensation and frosting than heat wheels and other sensible heat exchangers because they simultaneously transfer heat and moisture. Therefore, as the warm moist air passes through the energy wheel, it is simultaneously cooled and dried. As a result, the air is less likely to reach saturation (100% RH or dew point temperature). For many applications, outdoor temperatures as low as −30°C will not cause frosting in energy wheels, while heat wheels may experience frosting at outdoor temperatures as high as 10°C.[26,27]

Reliability

Heat wheels have a long history of very good maintenance and reliability characteristics. The experience with energy wheel applications is much shorter, which may cause some reservations about their long-term performance. Nevertheless, there are long-term experiences with desiccant drying wheels used as supply air dryers. Provided the desiccant coatings of these desiccant dryer wheels are not contaminated by solvents or excessive amounts of organics or dust, or eroded by particulates, they can have the same long-term performance characteristics as heat wheels. Although energy wheels operate at much lower temperatures than desiccant drying wheels and may use slightly different desiccant coatings, it is expected that they will have the same long-term reliability and vulnerability to airborne contaminants. The risk of such exposures will be small for well-designed systems, with correct filters being a key component.[17]

ECONOMIC AND ENVIRONMENTAL FACTORS

Economic and environmental considerations are the stimuli for the application of heat/energy wheels. This section will summarize some studies in the literature that demonstrate the payback, life cycle costs (LCC), and environmental impact of heat/energy wheels in the HVAC systems of buildings.

Payback

The time required to pay back the initial investment (payback period) depends on whether the heat/energy wheel is installed during the design and construction of a new building or the retrofit of an old building. In a new building, the size of the heating and cooling equipment can be reduced substantially when heat/energy wheels are applied. In many cases, the capital cost savings realized by downsizing the heating and cooling equipment are greater than the cost of the heat/energy wheel. This results in an immediate payback, with future energy savings realized from essentially no investment. In some cases, the cost of the new system will be greater with a heat/energy wheel than without a wheel. For these cases, payback periods of less than one year can be expected for a climate with significant heating and cooling loads, such as Chicago, Illinois.[28]

If a heat/energy wheel is to be retrofitted into a building with existing heating and cooling equipment, there is little or no possibility of reducing the size of the heating and cooling equipment unless they need replacing. In these retrofit cases, payback periods will be longer. The payback period depends strongly on the ventilation air flow rate, as well as the local climate and energy costs. Payback periods may range from two years for heat wheels to one and a half years for energy wheels in Chicago, for example.[28] Payback periods will be shorter in more severe climates (i.e., climates with more heating and cooling degree days) and will be longer in milder climates.

Life Cycle Costs

For longer life cycles (e.g., ten years for heat/energy wheels), the costs over the entire life cycle provide a more meaningful economic assessment. In fact, large savings may be lost when design decisions are based only on short-term objectives, i.e., the payback period, instead of long-term objectives, i.e., LCC.[28,29] The LCC are almost always lower for buildings with heat/energy wheels than those without heat/energy wheels. The LCC associated with supplying and conditioning outdoor ventilation air for a 120-person office building in Chicago over a ten-year life cycle are about 25%–50% lower with a heat/energy wheel than without one.[28] The energy savings over the life cycle exceed the capital costs by a factor of five. The LCC can be further reduced by about 10% by applying both a heat wheel and an energy wheel in the same system.[29] In this dual wheel system, the life cycle savings in energy exceed the capital costs by a factor of seven to eight and additional heating of the ventilation air may not be needed, even for a reasonably cold climate like Chicago, Illinois.[15]

Life Cycle Analysis

The environmental impact of many products can be assessed using the life cycle analysis (LCA) method. Life cycle analysis considers the impact of a product on the environment during its entire life cycle—from production to disposal. This includes the extraction of basic and energy raw materials, the production processes of materials and products, transportation, utilization and recycling. Life cycle analysis is similar to LCC analysis in that both address issues over the life of the product or system, rather than basing decisions on the first capital cost. However, LCA and LCC differ in their measuring metric; LCC uses money as the comparison scale, while LCA uses environmental indicators, such as carbon dioxide emissions (indicating climate change), sulfur dioxide emissions (indicating acidification potential), ethene or ethylene emissions (indicating ozone formation), and others. For many building service components, such as heat/energy wheels, the main consumption of raw materials occurs during production and the main consumption of energy occurs during use.[30–32]

Research[30–32] demonstrates that energy recovery from the exhaust air of office buildings and single-family residences is clearly an environmentally friendly solution in a cold climate (Helsinki, Finland). Energy recovery totally compensates for the harmful environmental impacts that arise from the manufacture, maintenance, and operation of the heat/energy wheel and the entire air-handling unit. A ventilation unit, with its function of providing outdoor ventilation air, but not heating the air, has a net positive impact on the environment when it includes a heat/energy wheel with an effectiveness over 20%. The greater the effectiveness, the greater the positive impact on the environment. For typical effectiveness values of 70%–75%, the emissions reduction as a result of energy recovered by the heat/energy wheel exceeds the total emissions of the air-handling unit by five to ten times. These reduced emissions result in reduced potential harmful changes to the environment. The reduction in environmental impacts due to heat/energy recovery exceeds the total impacts of the air-handling unit by two to ten times. Similar conclusions are expected in most locations, but the magnitude of the environmental benefits from heat/energy wheels will depend mainly on the local climate, energy sources, efficiencies, hours of operation, and ventilation rate. Therefore, a building with a highly effective heat/energy wheel and a higher outdoor ventilation rate may have the same environmental impact as a building with a heat/energy wheel of a lower effectiveness and lower ventilation rate. Since ventilation, indoor air quality, and health are closely related,[4] heat/energy wheels are healthy for occupants and the environment.

CONCLUSIONS

Heat wheels are rotating heat exchangers that transfer heat between two air streams. They are found in thermal power plants and the HVAC systems of buildings. Energy wheels are also rotating exchangers, but transfer both heat and moisture between two air streams and are mainly found in HVAC systems. Heat/energy wheels are distinguished from other air-to-air heat/energy exchangers because of their high effectiveness values and large internal surface areas. When properly applied, heat/energy wheels are cost-effective and reduce energy consumption and environmental impacts. In new buildings, heat/energy wheels often have an immediate or very short (less than one year) payback period, while in the retrofit of existing buildings, the payback period will be a little longer (e.g., two to four years). In nearly all cases, the total life cycle costs will be lower when heat/energy wheels are applied. The reduction in life cycle costs may be in the order of 25%–50% and the energy savings may exceed the capital costs of the exchanger by an order of magnitude. An additional benefit of heat/energy wheels is that they generally have a positive impact on the environment because they reduce energy consumption and the harmful emissions associated with energy production.

Heat Exchangers and Heat Pipes

Greg F. Naterer
University of Ontario Institute of Technology, Oshawa, Ontario, Canada

Abstract
This entry provides an overview of the design and opertion of heat exchangers and heat pipes. Different types of heat exchangers are discussed, including concentric-tube, cross-flow, and shell-and-tube heat exchangers. Methods of analysis are briefly discussed, with correction and geometrical factors for complex configurations. Condensers and evaporators are described in more detail. Heat pipes are additional types of heat exchange devices that use a porous wick material in a tube structure. The performance and operation of heat pipes are discussed. Limitations of wicking, entrainment, sonic, and boiling conditions are outlined, with respect to their effects on heat pipe performance.

INTRODUCTION

Heat exchangers are devices allowing energy exchange between fluid streams at different temperatures. They are commonly used in many applications, including power generation, energy storage, air conditioning systems, materials processing, and various others. Some common configurations include concentric-tube, cross-flow, and shell-and-tube heat exchangers (see Figs. 1 and 2). Another widely used device for heat exchange is a heat pipe, for applications such as spacecraft thermal control and thermal energy management in microelectronic assemblies. This entry explains the fundamental operating principles of heat exchangers and heat pipes.

In a concentric-tube heat exchanger, an internal fluid flows through the inner tube, and an external flow passes through the annular region between the inner and outer tubes. In a parallel-flow configuration, the outer fluid flows in the same direction as the inner flow. Otherwise, if the outer fluid flows in a direction opposite to the inner flow, then it is called a counter-flow heat exchanger. Analysis of heat exchangers usually requires empirical or advanced computer simulation techniques.

A cross-flow heat exchanger consists of an outer flow passing across tubes carrying fluid that flows in a direction perpendicular to the cross-flow. An example of this type of heat exchanger is found in a car radiator, where the outer and inner flows consist of air and water, respectively. The tubes are often covered with fins or other annular attachments to enhance the rate of heat transfer between the different fluid streams. For systems having fluid streams separated from one another by fins or baffles, the configuration is called unmixed, whereas a mixed configuration permits complete mixing of the fluid streams in the external cross-flow.

Another common type of heat exchanger is a shell-and-tube heat exchanger. In this case, the configuration consists of an outer shell pipe where fluid enters through one end, passes across internal tubes carrying a fluid at a different temperature, and exits through the other end. Baffles are often placed perpendicular to the inner tubes to enhance mixing and turbulence of the outer fluid stream. Baffles refer to perforated plates that obstruct some region of the outer flow while directing the flow around the remaining uncovered sections. Condensers in power plants are common examples of shell-and-tube heat exchangers. In these condensers, the outer flow is steam that condenses and leaves as water following heat exchange with the inner tubes carrying cold water.

Heat transfer occurs between fluids at different temperatures or phases. In the case of heat exchange between fluids of the same phase, but at different temperatures, the heat gained by the colder fluid stream balances heat lost by the hotter fluid stream, minus any external heat losses to the surroundings (often assumed negligible). Spacing and packing of tubes within heat exchangers varies with different applications. The surface area density of surfaces characterizes this packing, based on the number and diameter of tubes within the heat exchanger. The packing is often expressed in terms of a hydraulic diameter of tubes, D_h. A typical range is $0.8\ \text{cm} < D_h < 5\ \text{cm}$ for shell-and-tube heat exchangers, while $0.2\ \text{cm} < D_h < 0.5\ \text{cm}$ for automobile radiators and $0.05\ \text{cm} < D_h < 0.1\ \text{cm}$ for gas turbine regenerators. For heat exchange in biological systems (such as human lungs), the range is typically $0.01\ \text{cm} < D_h < 0.02\ \text{cm}$.

HEAT EXCHANGER ANALYSIS

Heat exchange between two fluid streams in a concentric-tube heat exchanger depends on the overall heat transfer

Keywords: Tubular heat exchanger; Cross-flow heat exchanger; Shell-and-tube heat exchanger; Condensers and evaporators; Heat pipe; Wicking limit; Entrainment limit; Sonic limit.

Heat–Inde

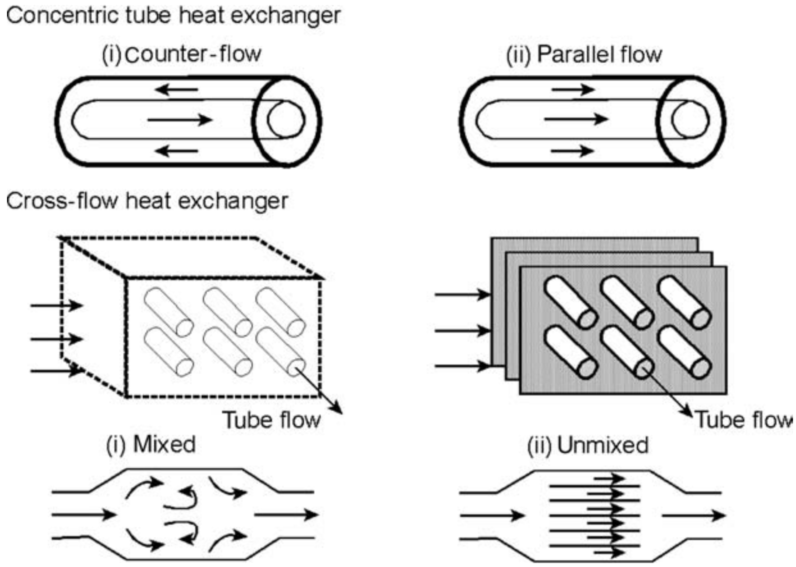

Fig. 1 Types of heat exchangers.

coefficient between both streams, including thermal resistances due to convection, fouling (due to fluid impurities such as rust formation), and conduction through the pipe wall. Frequent cleaning of the heat exchanger surfaces is needed to reduce and minimize the adverse effects of fouling, such as an increased pressure drop and reduced heat transfer effectiveness. Finned surfaces produce additional thermal resistances in a heat exchanger. These effects are often modeled based on the surface efficiency of a finned surface, which includes the efficiency for heat exchange through the fin, as well as heat transfer through the base surface (between the fins).

Using analytical methods for basic parallel-flow configurations of heat exchangers, the total heat transfer from a hot fluid stream to a cold stream between an inlet (1) and outlet (2) can be readily determined based on given (or measured) temperature differences, ΔT_1 and ΔT_2. A similar analysis can be derived for both parallel and counter-flow heat exchangers. In a parallel-flow heat exchanger, the highest temperature difference is encountered between the two incoming fluid streams. In the streamwise direction, heat transfer from the hot stream to the cold stream reduces the temperature difference between the fluids. But in a counter-flow heat exchanger, the temperature difference increases in the flow direction, since the temperature of the incoming cold fluid stream increases due to heat transfer from the hot stream flowing in the opposite direction. A counter-flow heat exchanger is generally considered to be more effective, since a smaller surface area is required to achieve the same heat transfer rate (assuming equivalent heat transfer coefficients between the fluid streams).

Predicted results for parallel-flow and counter-flow heat exchangers can be extended to more complicated geometrical configurations, such as cross-flow and shell-and-tube heat exchangers, after multiplying the heat transfer rate by a correction factor, F, which is usually based on experimental data to account for baffles and other geometrical parameters. The value of F depends on the type of heat exchanger. For example, $F=1$ for a one-shell-pass, one-tube-pass heat exchanger. For more complex arrangements, values of F are usually tabulated

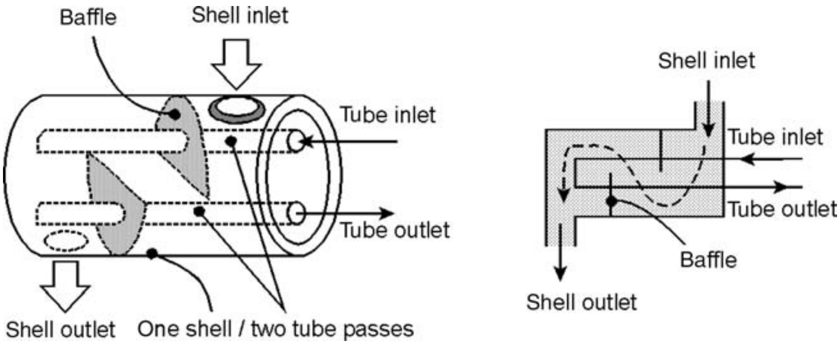

Fig. 2 Shell-and-tube heat exchanger.

and graphically depicted. For example, results of correction factors for a variety of heat exchanger configurations have been presented and graphically illustrated by Bowman et al.[1] Incropera and Dewitt,[5] and others. The *Standards of the Tubular Exchange Manufacturers Association* (6th edition, New York, 1978) provides additional results in terms of algebraic expressions or graphical representations.

The competing influences of pressure drop and heat exchange are important considerations in heat exchanger design. Larger rates of heat transfer can usually be achieved by increasing the packing of tubes within the heat exchanger or using baffles or other heat enhancement devices. But this comes at the expense of an increased pressure drop, which is disadvantageous due to additional pumping power required to move the fluid through the system at a specified mass flow rate. On the other hand, fewer heat exchange tubes can lead to a smaller pressure drop, but often at the expense of lower heat transfer, in comparison to a design with a high surface area density. Thus, optimization serves to provide an effective balance between the heat exchange and pressure losses. Empirical correlations are often used to predict the pressure drop in heat exchangers, in terms of additional parameters such as fluid velocity, the ratio of the free-flow area of the finned passages to the frontal area of the heat exchanger, friction factor, flow length, and flow passage hydraulic radius (total heat exchanger volume divided by the total heat transfer surface area). Values of friction factors have been documented extensively by Kays and London[6] for a variety of heat exchangers, including finned and various tubular configurations.

Plate-to-fin heat exchangers are commonly used in applications involving heat exchange between gas-to-gas streams. For example, air-to-air heat exchangers are typically based on plate-to-fin arrangements. These fins are classified into various types, such as plain fins, strip fins, pin fins, perforated fins, and others. Detailed design data involving these types of heat exchangers are outlined in Kays and London.[6]

CONDENSERS AND EVAPORATORS

Other common types of heat exchangers are condensers and evaporators, which are two-phase heat exchangers used in various engineering systems, such as power-generation and refrigeration systems. When a fluid stream evaporates or condenses within a heat exchanger and experiences a change of phase, then it is usually more useful to evaluate enthalpy (rather than temperature) in energy balances for heat exchanger analysis. The fluid temperature can remain nearly constant during the phase change, even though heat is transferred between the fluid streams. When calculating an enthalpy difference, the heat transfer analysis would include both the latent and sensible heat portions of the energy transfer between different fluid streams in the heat exchanger.

Unlike previously discussed heat exchangers involving single phase flows, a main difficulty in the analysis of condensers and evaporators is the range of phase-change regimes experienced by the fluid stream. The heat transfer coefficient depends on the local phase fraction, which varies throughout the flow path, so the heat transfer coefficient becomes position dependent. Unfortunately, the phase distribution is generally unknown until the flow field solution is obtained. Thus, a systematic procedure is needed to analyze heat transfer processes in condensers and evaporators.

The energy balances involve enthalpy to accommodate the latent heat of phase change, as well as sensible heat portions of the heat exchange. The fluid possibly undergoes various phase-change regimes, so the tube length is usually subdivided into discrete elements, and energy balances are applied individually over each element. After the enthalpy in a particular element is computed, its value may exceed the saturated vapor value of enthalpy at the flow pressure. In this case, the fluid enthalpy can be used to calculate the temperature of the superheated vapor based on thermodynamic property tables or computer-generated tabulation of the superheated property values. Alternatively, the specific heat of the fluid can be used to predict the temperature change corresponding to the enthalpy difference. This approach assumes a locally constant value of the specific heat, which requires a sufficiently small temperature change between elements. This method can be used when the fluid exists entirely as a superheated vapor, as the vapor specific heat at the mean temperature can be used.

However, if the enthalpy is computed to be less than the saturated vapor enthalpy, then the quality (mass fraction of vapor in the element) is needed. An updated estimate of the convection coefficient can be calculated based on the phase fraction and corresponding flow regime. Additional empirical factors (such as a transition factor) are often used to identify the flow regime and appropriate correlation for heat transfer. Then an updated overall heat transfer coefficient can be determined from the phase fraction and flow regimes.

A typical numerical procedure for analyzing two-phase heat exchangers can be summarized as follows: a boundary condition is first applied within the initial element of the tube. Then, a suitable forced convection correlation is used up to the element in which phase change is first realized. An appropriate heat transfer correlation can then be selected for that phase change regime. Near the points of saturated vapor or saturated liquid, a suitable single-phase correlation can be used with property values along the saturated liquid and vapor lines. Then, this procedure can be repeated for each element in the domain. For either condensing or boiling problems, a similar procedure can be adopted. In the latter case (boiling), a two-phase flow map would typically be utilized to identify the flow regime based on the computed phase fraction. This mapping would distinguish between flow regimes, such as the wavy, annular, and slug flow regimes.

Various design features and aspects of maintenance are important in terms of the effective performance of condensers and evaporators. Tubes should be readily cleanable on a regular basis, either through removable water heads or other means. Larger flow rates within the heat exchanger can reduce fouling (buildup of scale and dirt on the walls), reduce service, and extend the life of the heat exchanger. Furthermore, higher operating efficiencies can be achieved by placement of tubes in stacks with metal-to-metal contact between fins to permit better drainage of the condensate. Less thermal resistance occurs when less liquid accumulates on the fins, thereby improving the thermal efficiency of heat exchange. Also, a light and compact design is beneficial, as it requires less space and reduces difficulties in installation and moving, while often reducing costs associated with maintenance.

Another important factor in proper operation of condensers and evaporators is safety. For systems operating at pressures different from the surrounding ambient (atmospheric) pressure, leakage can occur. In maintenance procedures, the specific points of leakage can be detected and repaired by a basic method of soap or detergent brushed onto the surfaces where leakage is suspected, thereby generating bubbles to indicate leakage points. Alternatively, pressurizing the system and recording changes in pressure over time can indicate the tightness of a system (but not necessarily the location of leakage). Certain chemical leaks can be detected individually. For instance, sulfur dioxide can be detected by the white smoke forming when ammonia is brought into close contact with the leakage point.

Operating materials must be properly selected in conjunction with the working fluids. Most refrigerants can be used well under normal conditions with most metals (such as steel, aluminum, and iron), but some materials and liquids should never be used together. An example is methyl chloride fluid with aluminum shells and tubes, which can produce flammable gas byproducts. Also, the tensile strength, hardness, and other properties of exposed materials must be fully considered under all operating conditions. Effects of certain plastic materials on refrigerant liquids can often be difficult to predict, particularly due to the rapid rise in the number and types of polymer materials. An effective overall design of condensers and evaporators requires a thorough investigation of both thermal and materials engineering aspects.

HEAT PIPES

A heat pipe is a closed device containing a liquid that transfers heat under isothermal conditions. It operates through vaporization of liquid in an evaporator, transport and condensation of the vapor, and return flow of liquid by capillary action through a wick structure back to an evaporator. Due to geometrical requirements, the adiabatic section is designed to fit within spacing limitations of the heat pipe. Adiabatic implies zero heat transfer, as in a well-insulated section. Thermal energy from the external source is transferred to the working fluid in the heat pipe at the evaporator section. At the end of the heat pipe, a buffer volume may be constructed to enclose a non-condensable gas (such as helium or argon) for controlling the operating temperature, based on control of pressure within the inert gas. Flow of vapor occurs through the core interior region of the heat pipe at high velocities to the condensing section (up to 500 MPH in some cases).

Along the inner wall of the container of the heat pipe, a porous wick material with small, random interconnected channels is constructed for capillary pumping. The pores in the wick act as a capillary "pump," which acts analogously to regular pumping action on fluids in pipes by pumps. The wick provides an effective means of transporting liquid back to the evaporator through surface tension forces acting within the wick. Also, it serves as an effective separator between vapor and liquid phases, thereby allowing more heat to be carried over greater distances than other pipe arrangements (Fig. 3).

Various applications utilize heat pipes, including heating, ventilating, and air conditioning (HVAC) heat recovery systems; microelectronics cooling; and spacecraft thermal control. Heat pipes in air-to-air HVAC heat recovery systems allow effective storage of thermal energy contained in exiting combustion gases. Heat pipes offer key advantages over conventional techniques, including low maintenance (no moving parts), long life, and cost savings. Another example involves microelectronics cooling. Heat pipes can be up to 1000 times more conductive than copper (at the same weight). Examples include laptop computers, as well as telecommunications equipment, which have adopted heat pipes with success in their thermal designs. Also, heat pipes appear in several spacecraft thermal control applications. Heat pipes have been used in satellites to transfer heat generated by electronic equipment to radiation panels that dissipate heat into space. Another application is tubing in satellites, which provides effective control of temperatures required for reliable performance of electrical components on the satellite.

In the evaporator section of a heat pipe, heat is transferred by conduction from the energy source through the container wall and wick-to-liquid matrix to the vapor-to-liquid interface. Then, liquid is evaporated at the vapor-to-liquid interface, and heat transfer occurs by convection of vapor (laminar or turbulent) from the evaporator to the condenser. The temperature of the vapor is approximately the average between the source and sink temperatures at the ends of the heat pipe. Following condensation of vapor

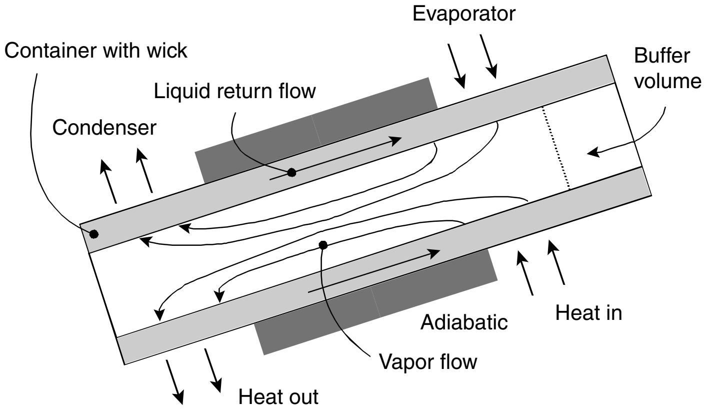

Fig. 3 Schematic of a heat pipe.

at the condenser end, heat transfer by conduction occurs through the wick-to-liquid matrix and container wall to the heat sink. Finally, liquid condensate returns to the evaporator through the wick structure (generally laminar) return flow.

The working fluid and wick type are important design factors in a heat pipe. The working fluid should have a high latent heat of evaporation, high thermal conductivity, high surface tension, low dynamic viscosity, and suitable saturation temperature. Also, it should effectively wet the wick material. Some typical examples of working fluids are water or ammonia at moderate temperatures, or liquid metals such as sodium, lithium, or potassium at high temperatures (above 600°C). In a typical example of a heat pipe with water as the working fluid and a vessel material of copper–nickel, an axial heat flux of about 0.67 kW/cm^2 at 473 K and a surface heat flux of about 146 W/cm^2 at 473 K are generated. For moderate operating temperatures (i.e., 400–700 K), water is the most suitable and widely used working fluid in heat pipes.

It is interesting to compare heat pipes with solid materials in terms of an effective thermal conductivity. Consider the axial heat flux in a heat pipe, using water as the working fluid at 200°C, in comparison with the heat flux in a copper bar (10 cm long) experiencing a temperature difference of 80°C. For the copper bar at 200°C, the heat flux per unit area can be estimated at about 0.03 kW/cm^2. In contrast, the axial heat flux for a water heat pipe under the given conditions is about 0.67 kW/cm^2, so the heat pipe transfers heat at a rate more than 20 times higher than a copper rod. This example indicates that heat pipes can be beneficial by providing a higher effective thermal conductivity of material.

In a heat pipe, proper liquid circulation is maintained within the heat pipe as long as the driving pressure (capillary forces) within the wick exceeds the sum of frictional pressure drops (liquid and vapor) and the potential (gravity) head of the liquid in the wick structure. Capillary action in the wick arises from surface tension forces at the liquid interface. In the wick structure, a liquid flow is generated by the capillary action due to liquid entrainment within the wick structure. Spatial differences of capillary pressure (due to different curvatures of liquid menisci) induce the capillary flow. Another pressure drop occurs when liquid flows (generally laminar) through grooves in the wick from the condenser back to the evaporator. This liquid flow can be analyzed through from Darcy's law for laminar flow in a porous medium. The wick structures can have a wrapped screen along the inner wall of the heat pipe or screen-covered grooves, in order to improve their operating performance. Examples of common wick materials are copper foam, copper powder, felt metal, nickel fiber, and nickel powder.

A vapor pressure drop arises since vapor drag in the core region may impede liquid flow in the grooves of the wick at high vapor velocities. An expression for this pressure drop can be determined from standard methods of fluid mechanics. This pressure drop is usually a small contribution to the overall force balance, since the vapor density is much smaller than the liquid density. Also, effects of vapor drag can be reduced by covering the grooves in the wick structure with a screen.

The equilibrium design condition of a heat pipe is determined from a balance of the previous pressure forces, including a gravity term, which can be positive (gravity assisted) or negative. A positive gravity head implies that the evaporator is above the condenser. The design condition is significant because operating beyond the maximum capillary pressure can dry out the wick and produce a "burnout" condition.

Wicking, entrainment, sonic, and boiling limitations have significant effects on the performance of heat pipes. A wicking limitation occurs on the axial heat flux, due to a maximum flow rate through the wick for a maximum capillary pressure rise. Entrainment refers to droplets entrained by the vapor from the liquid return flow. Under certain operating conditions, the vapor velocity may become sufficiently high to produce shear force effects on the liquid return flow from the condenser to the evaporator. It is possible that waves can be generated on the liquid surface and droplets may be entrained by the vapor flow, since there would be inadequate restraining forces of liquid surface tension in the wick.

Another factor is the sonic limitation. During conditions of startup from near-ambient conditions, a low vapor pressure within the heat pipe can lead to a high resulting vapor velocity. If the vapor velocity approaches sonic speed, a choked condition within the pipe limits the axial heat flux. This sonic limit and other previous depend on the fluid operating temperature. Heat flux limits generally increase with evaporator exit temperature due to the effect of temperature on the speed of sound in the vapor. For example, the heat flux limit for sodium increases from 0.6 kW/cm^2 at 500°C to 94.2 kW/cm^2 at 900°C. For liquid potassium, the heat flux limit is 0.5 kW/cm^2 at 400°C (evaporator exit temperature), and the limit increases to 36.6 kW/cm^2 at 700°C. In high-temperature applications, lithium can be used. Its heat flux limit ranges between 1.0 kW/cm^2 at 800°C and 143.8 kW/cm^2 at 1300°C.

In contrast to the limitations on the axial heat flux, the boiling limitation involves the radial heat flux through the container wall and wick. The onset of boiling within the wick interferes with and obstructs the liquid return flow from the condenser. Boiling within the wick may cause a burnout condition by drying out the evaporator containment. Recent advances in heat pipe technology are developing innovative techniques for dealing with this thermal limitation and enhancing the overall capabilities of heat pipes. Additional references in the topic of heat pipe analysis are given by Kreith and Bohn,[7] Hewitt et al.[4] Dunn and Reay,[3] and Chi.[2]

Abstract

Heat pipes have been known to be effective heat transfer devices for well over 70 years. They have been widely employed in various applications throughout industry. This article addresses various heat pipe applications in many disparate areas, such as aerospace, medicine, agriculture, transportation, and the automotive industry.

Examples in the application of heat pipe technology are given in heat exchangers, in electronic components, in medical devices, in ovens and furnaces, and in solar thermal applications.

INTRODUCTION

Heat pipes are heat transfer devices that have been widely used in numerous applications for at least 70 years. The concept of a "two-phase heat transfer device capable of transferring large quantities of heat with a minimal temperature drop" was first introduced by R. S. Gaugher in 1942. Since then, heat pipes have been employed in various industries, especially in the aerospace industry, in the various engineering disciplines, in medicine, in transportation, and in agriculture. The use of heat pipe technology is ubiquitous in heat exchangers, in the cooling of electronic components, and in solar thermal applications.

Heat pipes are essentially heat transfer devices, transferring heat from one area to another. In principle, heat pipes operate in a closed container, constituting a sealed environment lined with a wicking material saturated with working fluid. The pipes operate in a two-phase cycle in which the working fluid is either in a liquid state or exists in vapor form. Typically, in situations in which a cooling effect is desired, heat is absorbed in some manner at the evaporator end of the heat pipe and rejected or dissipated at the condenser end of the device as the vapor condenses to liquid. Contrariwise, when a warming or heating result is desired, heat is applied to the liquid at the condenser end of the heat pipe and released from the evaporator end, thus delivering heat or warmth at that point.

Heat pipe applications can be classified in four main categories: separation of heat source and sink, temperature equalization, temperature control, and thermal diode. Due to their high thermal conductivity, heat pipes can efficiently transport heat from source to sink without regard to heat sink space requirements. Another advantage of the high thermal conductivity is the ability to provide an effective method of temperature equalization. For example, a heat pipe located between two opposing faces of an orbiting platform can maintain constant temperature in both faces of the platform, thus minimizing thermally induced structural stresses. The resultant temperature control is the product of the capability of heat pipes to transport large quantities of heat without significant increases in the operating temperature of the heat pipe. A thermal diode is a heat pipe function for situations in which heat has to be transferred efficiently in one direction and heat flow in the reverse direction has to be prevented.

This entry will focus on the various areas of heat pipe applications. A brief account of various applications of heat pipe technology in each area will follow.

AEROSPACE

Heat pipes enjoy wide application in the area of spacecraft cooling and temperature stabilization. They enjoy the distinct advantages of low weight, essentially zero maintenance, and superior reliability over other devices. Structural isothermal operation is an important goal in aerospace operations. Thermal stress occurring from heat inequalities is a critical issue in many orbiting astronomical experiments. While in orbit, for example, an observatory may be fixed on a single point such as a star. Consequently, one side of the capsule will be subjected to intense solar radiation while the other is not. Heat pipes in this situation are used to transport heat from the side facing the sun to the cold side away from it, thus

Keywords: Heat pipe(s); Heat transfer; Heat sink; Heat pipe application; Heat-pipe heat exchanger; Heat pipe cooling; Heat pipe furnace; Heat pipe oven.

equalizing the temperature of the structure.[1] Because of the demand for reducing spacecraft costs while maintaining high-performance characteristics of the spacecraft bus, the mass of satellites has to be minimized. Thus, the reduction of space cooling by increasing heat density is an important challenge. To achieve this, heat pipes are commonly used to affect heat transfer and heat redistribution functions in the microsatellites.[2]

HEAT EXCHANGERS

Because of flexibility in design, heat pipes can easily be utilized as heat exchangers inside sorption and vapor-compression heat pumps, refrigerators, and other types of heat transfer devices. For example, heat pipe heat exchangers (HPHE) used for controlling humidity in air conditioning systems have been exhaustively researched.[3] The purpose of the HPHE is to recover heat from warm outdoor air to reheat the dewpoint airstream, thereby minimizing heating costs. Also, the evaporator of the HPHE acts as a precooler to the warm outdoor air before it reaches the air conditioner, thus enhancing the effectiveness of the cooling coil. When the condenser of the HPHE is used as a reheater to heat the airstream coming from the cooling coil, the relative humidity can more easily be reduced to the comfort zone, below 70%.

This HPHE concept can also be applied in various industries, such as metallurgy, power plants, and oil refining. For instance, in the thermal power industry, heat pipe air preheater/exchangers (see Fig. 1) are used to preheat the air used in the combustion of fuel in the boiler. This is achieved by retrieving the energy available in the exhaust gases. In this application, two ducts are held in parallel, with a common wall. Hot flue gases are made to flow through one duct while cold combustion air is directed through the other duct, causing the cold air to be "preheated."

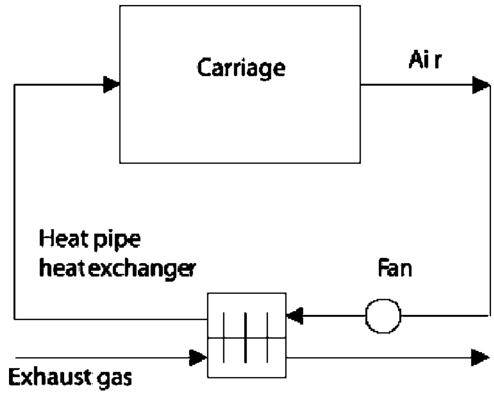

Fig. 2 Diagram of heating system.
Source: From Elsevier (see Ref. 5).

Heat pipe exchangers are also used to recover the thermal energy otherwise lost in exhaust gases of ground transportation vehicles—in buses, in vans and trucks, and in passenger cars. The heat thus recovered can be used for heating the cabins or the passenger areas in cold weather. The schematic diagram of the heating system used is in Fig. 2.

ELECTRONIC COMPONENTS

As of the present, one of the largest applications of heat pipe technology is the cooling of electronic components such as central processing units (CPUs), circuit boards, and transistors. For example, the CPU, one of the most important parts of any PC, is becoming increasingly more compact, faster, and more efficient. This leads to higher heat density, resulting in increasing CPU temperature, threatening a shortened life of the chip, or resulting in malfunction or failure. A conventional method used to keep a CPU from overheating is to use an extruded aluminum heat sink. This is an efficient method in terms of unit price, weight, and performance. However, as computers become smaller, the ability of

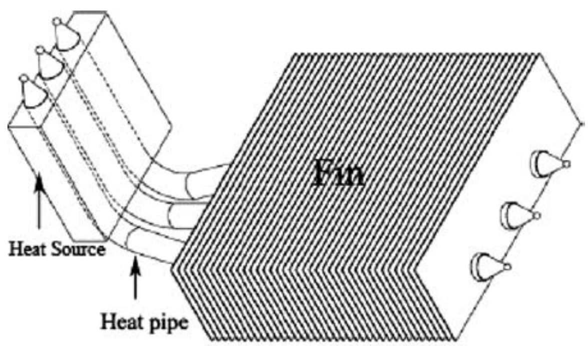

Fig. 3 Heat pipe cooling where heat source locates in the top and fin in the bottom.
Source: From Elsevier (see Ref. 6).

the heat sink to effect cooling becomes insufficient to meet demands, chiefly because of insufficient space. The use of heat pipes in such situations has marked advantages (see Fig. 3).

OVENS AND FURNACES

One of the earliest applications of heat pipe technology was in conventional baking ovens. Previously, flames were applied to the firebrick lining the oven which in turn transmitted the heat to the items baked in the oven. Unfortunately, the baked items were contaminated by smoke and soot and other combustion products produced by the flames.

In improved models using heat pipes, the transfer of heat to the oven was effectuated by the evaporation and condensation of the working fluid in the closed heat pipe system, which transferred the heat, but not the combustion products. The use of heat pipes conferred two other advantages: a more uniform oven temperature, and a savings of up to 25% of the fuel normally consumed.

Recently, in the fine-chemical industry, higher temperature requirements have been mandated for the spray-drying of powdered materials, which require a hot air temperature of 450°C–600°C or higher. It is difficult to heat the air to such high temperatures with conventional heat exchange equipment. Also, if the flue gas of the fuel were to be applied directly, pollutants might be carried with it, rendering the product quality unacceptable. Fig. 4 shows a newly developed heat pipe high-temperature hot air furnace that overcomes these objections.

SOLAR THERMAL APPLICATIONS

Due to a shortage in the supply of fossil fuel, renewable energy sources have become one of many alternative solutions. Solar energy is a renewable energy resource, and it is abundant. It has been used in a variety of applications in generating electricity, in cooling, and even in heating. The following solar applications employing heat pipe technology are discussed.

Solar Distillation

Recently, research has been directed to the discovery of alternative sources of energy. Ethanol is one of the key renewable fuels utilized to partially replace petroleum products. It is produced from agricultural products such as cassava, corn, sugarcane, molasses, and cereal grains. Solar distillation is one such technique. It is used to generate ethanol and results in the consumption of only a small amount of fossil fuel compared with conventional processes. Evacuated heat pipe collectors (see Fig. 5) are used in this system to generate the heat required for the distillation process.

Solar Cooking

Preparation of foods requires some amount of energy. Wood fuel and agricultural residues are the main energy sources for cooking in developing countries, normally accounting for 50%–90% of all energy consumed in those countries. However, the rate of wood fuel consumption exceeds its replacement, and this results in deforestation, pollution, soil erosion, global warming, and a worsening of the welfare of millions of people all over the world. Although electric cooking is comparatively convenient, its production from fossil fuel has cumulative consequences resulting in the emission of high quantities of carbon dioxide and sulfur dioxide into the atmosphere. The use of solar cooker technology is an alternative solution to the fuel problem. Heat pipes are utilized for solar cookers in transporting heat from the heat source to its destination, as shown in Fig. 6.

AGRICULTURE

In the process of agricultural production, a soil-free planting system is widely accepted as an efficient means of improving production. There are two types of soil-free planting systems: hydroponic and aeroponic systems. The aeroponic system is a soil-free system in which the roots of the plants are completely or partially exposed to air in a plant chamber. The plants are anchored in holes atop a panel of polystyrene foam. Inside the chamber, a fine mist of nutrient solution is sprayed onto the roots.

Evaporative cooling and refrigerant systems are frequently employed to control greenhouse and nutrient temperatures. For conventional aeroponic system, an exhaust fan and an evaporative cooling unit are used to control the greenhouse temperature. This is considered to be uneconomical due to their need for high electrical energy consumption, which accounts for 33% (fan) and 25% (cooling unit) of the total energy consumed. In addition, when the nutrient solution passes through the chamber, its temperature will be unavoidably increased due to the process of plant metabolism. Normally, a refrigeration system is needed to maintain the temperature of the nutrient solution at a specific level. This results in increased energy consumption. Thus, a device is needed to reduce the energy consumption that occurs during evaporative cooling of the greenhouse and the refrigeration process. The heat pipe is a good solution to the problem. Its application in an aeroponic system is shown in Fig. 7. The evaporator section of the heat pipe removes heat from the nutrient solution that flows out from the chamber. Therefore, the outlet temperature of the solution from the evaporator section is decreased, because heat is absorbed by the heat pipe. Similarly, the heat pipe can be used to reduce the heat generated in the greenhouse, thus reducing the cooling load of evaporative cooling.

MEDICAL APPLICATIONS

One of the more practical heat pipe applications in medicine is in the heat pipe cooler (see Fig. 8). This cooler has a copper–methanol heat pipe with a copper sintered powder wick and four Peltier elements, cooled by a water heat exchanger. It is used for noninvasive treatment of an inflamed vagina, rectum, or pelvis and for some common gynaecological and rectal conditions. The main component of the cooler used in this application is the heat pipe (1). The condenser of the heat pipe is thermally contacted with the cold surfaces of Peltier elements (2). The evaporator of the heat pipe is cooled by the water in the heat exchanger (3). Peltier elements and this heat exchanger are located inside the handle of the cooler (4). During the medical treatment, the heat pipe cooler is introduced into the rectum or vagina, cooling the mucous membrane. The cooling effect is not only positive for the above-mentioned organs, but also effective in the indirect cooling of reflex ganglions in conditions such as chronic gastritis, ulcerative colitis, acute gastritis, and gastric and duodenal ulcers.

Electrosurgery is commonly used to cauterize, cut, or coagulate tissue. In typical electrosurgical devices, Radio Frequency electrical energy is applied to the tissue being treated. Local heating of the tissue occurs. By varying the power output and the type of electrical waveform, it is

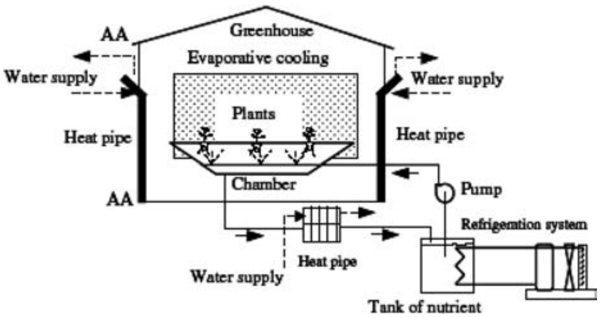

Fig. 7 Aeroponic system with heat pipe.
Source: From Elsevier (see Ref. 10).

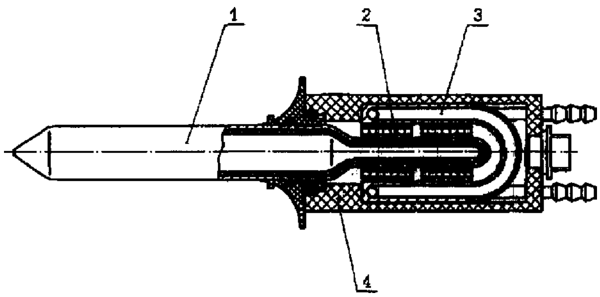

Fig. 8 Heat pipe cooler.
Source: From Elsevier (see Ref. 11).

possible to control the extent of heating and, thus, the resulting surgical effect. There are two types of electrosurgery: bipolar and monopolar. For bipolar, the device has two electrodes. The tissue being treated is placed between the electrodes, and the electrical energy is applied across the electrodes. In the monopolar device, the electrical energy is applied to a single electrode applied to the tissue, with a grounding pad placed in contact with the patient. The energy passes from the single monopolar electrode through the tissue to the grounding pad.

During this surgery, the tissue being treated tends to stick to the electrode, resulting in various complications. First, the tissue stuck to the electrode has a high resistance that hinders delivery of power to the tissue. While performing a procedure, a surgeon must periodically remove the device from the patient and clean it before continuing. Due to tissue's adhering to the electrode, when the electrode is removed, the portion of the tissue adhering to the electrode is torn away, resulting in bleeding. Therefore, cooling of the surgical site during electrosurgery is highly desirable. To achieve this, a heat pipe is introduced to maintain a constant temperature of 80°C at the electrode-tissue interface when the electrosurgical device is used.[12]

TRANSPORTATION SYSTEMS

Several heat pipe applications are used to improve the safety and reliability of air, surface, and rail transportation systems. In Siberia, during the long winter, snow may fall at the rate of 1000–1500 mm per day with the ambient air at −5 to −7°C. Heat pipe technology is used to heat the rails to prevent ice formation, as shown in Fig. 9. The condenser end of the heat pipe is located at the point of contact between the heat pipe and the rail.

In Virginia, a heated bridge[13] exists on Route 60 over the Buffalo River in Amherst County in the eastern foothills of the Blue Ridge Mountains. Road conditions during winter storms there can often be treacherous. An anti-icing heating system was designed and fabricated to obviate the situation. The system consists of approximately 2 mi of steel piping, including 241 heat pipes embedded in the concrete deck and the approach slabs. A propane gas-fired furnace is used to heat a mixture of propylene glycol and water. This antifreeze mixture circulates through a separate piping loop to the evaporators, heating the ammonia in the heat pipes. The bridge is tilted slightly on one end, so one end of the pipes is higher than the other. As the fluid boils, vapor rises in the heat pipes from the lower end to the higher and warms the bridge deck. As the vapor cools, it condenses and trickles back to the evaporators, where it is reheated (Fig. 10).

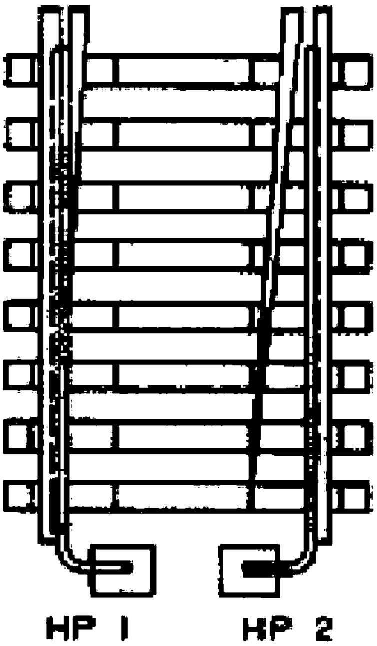

Fig. 9 Heat pipes for rail-point heating in winter.
Source: From Elsevier (see Ref. 11).

ENGINES AND THE AUTOMOTIVE INDUSTRY

Many sources of heat are available for low-temperature applications, including solar ponds, industrial waste, and geothermal energy. These sources of heat could be utilized for power generation. Many attempts to use this low-grade heat to produce electricity have been proposed. One of the attempts to integrate a turbine with a heat pipe was introduced in the Thermosyphon Rankine (TSR) engine for generating electricity. The heat pipe used in this application transfers heat from the evaporator through the turbine to the condenser. The schematic of the TSR engine is shown in Fig. 11. The working fluid located in the lower evaporator end of the pipe is evaporated and rises to the upper region with the application of the heat source. It is fed through the turbine, which in turn generates electricity.

This is an example of the conversion of kinematic energy to electrical energy.

OTHER HEAT PIPE APPLICATIONS

Cutting Tools

Cutting processes are being used in many factories. In the process, the energy supplied is converted to heat energy at the cutting zone. The heat generated in the tool and work piece is carried away by the working fluid. Three types of fluids[15] are commonly used: oil (with additives such as sulfur, chlorine, and phosphorus), emulsions, and synthetics. Although this cooling method shows some promise in increasing tool life, the exposure of the fluids to the working environment may cause significant contamination to the environment and increased health hazards to the workers. Currently, there is a strong worldwide trend toward minimizing the use of cutting fluids, as they have been shown to be a primary source of industrial pollution. For a cutting process to run without the use of fluids, alternative methods to remove the heat accumulated in the tool and the work piece had to be developed. Heat pipes provide an effective alternative solution to the problem, as shown in Fig. 12.

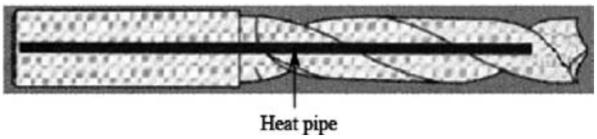

Fig. 12 Heat pipe cooling in drilling applications.
Source: From Elsevier Science (see Ref. 15).

CONCLUSION

Heat pipes have been used in many applications. This is because of their high thermal conductivity and their ability to maintain a constant temperature while heat flux varies. The ability to block heat flow when that is needed and the ability to dissipate heat from locations where cooling space is limited make the application of heat pipe technology indispensable.

Nowadays, gasoline poses a major expense in daily life. On hot summer days, while a car is parked, it will absorb a great deal of heating from solar radiation. The potential exists to use this heat in useful ways, rather than combating the heat by turning on the air conditioner. This is a situation in which established heat pipe technology can be applied effectively with little modification. If adopted, such application will also result in less gasoline consumption, thus helping keep the price of gasoline from rising even higher.

In medicine, heat pipes can also be introduced into back braces for use in people with back problems for which the application of constant heat affords some relief. After the acute phase of traumatic injury (e.g., a muscle tear or simple fracture), the application of heat using heat pipes will help reduce swelling and promote rapid healing.

Similarly, the application of heat pipe technology can make more efficient the application of constant low heat (presently achieved with cumbersome heat packs that have to be replaced every few hours), which can help relieve the aches and pains commonly seen in athletes and in members of the older generation.

Heat Pumps

Lu Aye
International Technologies Centre (IDTC), Department of Civil and Environmental Engineering, The University of Melbourne, Victoria, Australia

Abstract
Heat pumps capture heat energy from low-grade heat sources, such as ambient air and waste heat streams, and upgrade to a higher temperature level for useful applications. This entry includes a brief history, fundamentals, classifications, applications, and performance parameters of heat pumps. Working principles of the thermoelectric heat pump, the absorption heat pump, the gas compression heat pump, and the vapor compression heat pump are explained. Performance parameters of the heat pump systems are presented: coefficient of performance, energy efficiency ratio, primary energy ratio, and ambient energy fraction.

INTRODUCTION

This entry aims to provide foundation knowledge about heat pumps for both professional and nonprofessional readers. A brief history of heat pumps, basic terms used in the heat pump industry and research, and the fundamentals of heat pumps are presented. Working principles of the thermoelectric heat pump, the absorption heat pump, the gas compression heat pump, and the vapor compression heat pump are explained by using schematic diagrams. Performance parameters of the heat pump systems—coefficient of performance (COP), energy efficiency ratio (EER), primary energy ratio (PER), and ambient energy fraction (AEF)—are also discussed.

Major advances have been made in heat pump technologies over the past 30 years. Heat pumps in their various and diverse forms allow one to harness, in a cost-effective manner, solar energy that has already been stored in the atmosphere and biosphere. To make a fair systematic comparison with other systems that provide the same thermal output, AEF may be used. The concept and the method of estimating the AEF are discussed. The relationships among the AEF, the heating coefficient of performance (HCOP), and PER are also presented.

Brief History

Although most people are familiar with the common household refrigerator, the concept of using such a device to provide heating rather than cooling is less widely understood. The basic operational principle of this machine called heat pump, however, was laid down in thermodynamic terms by Lord Kelvin, the first professor of natural philosophy at the University of Glasgow, Scotland in the middle of the 19th century. Whereas the thermodynamic principle of the heat pump was found in 1852, it was not until 1855 that it was realized for producing heat by means of an open-cycle mechanical vapor recompression unit in Ebensee, Austria.[1] Much later, the closed vapor compression process was used for generating useful heat. After World War II, heat pump units for air conditioning homes and individual rooms became common. Now heat pump technology is well known as one of the energy conservation technologies.

Fundamentals

A heat pump is a thermodynamic system whose function is to heat at the required temperature with the aid of heat extracted from a source at lower temperature.[2] Heat pumps are devices designed to utilize low-temperature sources of energy that exist in atmospheric air, lake or river water, and in the earth. These sources are referred to as ambient energies. Heat pumps can also be operated using waste heat from commercial and industrial processes and thereby upgrading this to the required temperature level for some thermal process operations.[3]

The heat pump can be considered to be a heat engine in reverse.[4] A heat engine removes heat from a high-temperature source and discharges heat to a low-temperature sink, and in doing so can deliver work (see Fig. 1). Heat pumps capture heat energy from low-grade sources and deliver at a higher temperature. They require external work (W) to upgrade the heat absorbed (Q_L) (see Fig. 2). Note the heat energy flows from a low-temperature heat source to a higher application temperature. This is reverse to the natural flow direction of heat from a higher temperature to a lower temperature. For ideal conditions without heat losses the energy balance of a heat pump provides (Eq. 1):

$$Q_H = Q_L + W \tag{1}$$

Keywords: Heat pumps; Energy conservation; Heating; Energy recovery; Low-grade heat; Coefficient of performance; Energy efficiency ratio; Primary energy ratio; Ambient energy fraction.

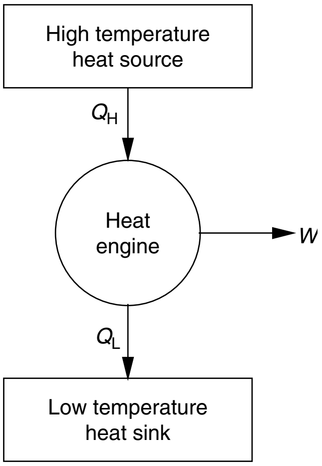

Fig. 1 Thermodynamic model of heat engine.

where Q_H, useful heat delivered; Q_L, heat absorbed; W, work input.

The useful heat delivered is always greater than the work input to the heat pump for ideal conditions.

The technical and economic performance of a heat pump is closely related to the characteristics of the heat source. Table 1 lists current commonly used heat sources. Ambient and exhaust air, soil, and ground water are practical heat sources for small heat pump systems, whereas sea/lake/river water, rock (geothermal), and waste water are used for large heat pump systems.[5]

The fundamental theories of heat pumps and refrigerators are the same. In engineering practice, a distinction is made between heat pumps and refrigerators. The principal purpose of the latter devices is to remove heat from a low-temperature heat source, and the purpose of the former device is to supply heat to a high-temperature sink. In many practical devices, the heating and cooling elements are interchangeable. The term reverse cycle air conditioner is frequently applied to heat pumps with interchangeable heating and cooling elements. In Japan and in the United States, reversible air-conditioning units are called heat pumps, and in Europe, the term heat pump is used for heating-only units.[1]

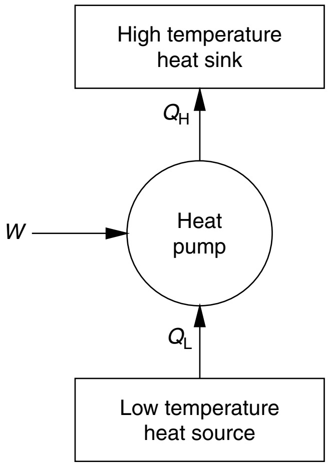

Fig. 2 Energy flow of a heat pump.

Table 1 Commonly used heat sources

Heat source	Temperature range (°C)
Ambient air	−10 to 15
Building exhaust air	15–25
Ground water	4–10
Lake water	0–10
River water	0–10
Sea water	3–8
Rock	0–5
Ground	0–10
Waste water and effluent	>10

Carnot Coefficient of Performance (Theoretical COP)

The heating performance of a heat pump is measured by HCOP. The HCOP is the ratio of the quantity of heat transferred to the high-temperature sink to the quantity of energy driving the heat pump (see Fig. 2).

$$\text{HCOP} = \frac{Q_H}{W} \tag{2}$$

In the Carnot ideal heat pump cycle, the heat is delivered isothermally at T_H and received isothermally at T_L. By using the laws of thermodynamics and definition of entropy, it can be shown that the Carnot heating coefficient of performance is given by Eq. 3.

$$\text{HCOP} = \frac{T_H}{T_H - T_L} = \frac{T_L}{T_H - T_L} + 1 \tag{3}$$

No practical heat pump constructed can have a better performance than this theoretical ideal HCOP. All that our practical heat pump cycles can do is struggle toward achieving this performance.[4]

Facts About Heating Relevant to Heat Pumps

It is argued that heat pumps are very energy efficient and, therefore, environmentally benign. The IEA heat pump centre provides the basic facts about heat supply and discusses the value of heat pumps.[6] The basic facts about heating explained are

- Direct combustion to generate heat is never the most efficient use of fuel.
- Heat pumps are more efficient because they use renewable energy in the form of low-temperature heat.

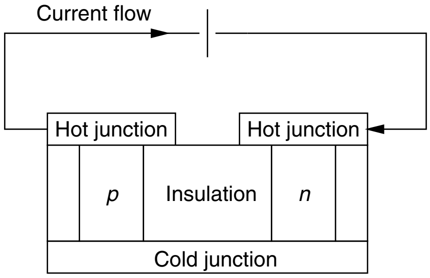

Fig. 3 Schematic of thermoelectric heat pump.

- If the fuel used by conventional boilers were redirected to supply power for electric heat pumps, about 35%–50% less fuel would be needed, resulting in 35%–50% less emissions.
- Around 50% savings are made when electric heat pumps are driven by combined heat and power (CHP) or cogeneration systems.
- Whether fossil fuel, nuclear energy, or renewable power is used to generate electricity, electric heat pumps make far better use of these resources than do resistance heaters.
- The fuel consumption and, consequently, the emissions rate of an absorption or gas-engine heat pump are about 35%–50% less than those of a conventional boiler.

Because heat pumps consume less primary energy than conventional heating systems, they are an important technology for reducing the unwanted air pollutants that harm the human environment, such as respirable particulate matters (PM), carbon monoxide (CO), nitrogen oxides (NO_x), sulphur dioxide (SO_2), and carbon dioxide (CO_2).

HEAT PUMP TYPES

Four major types of heat pumps may be identified in the literature.[7] These are

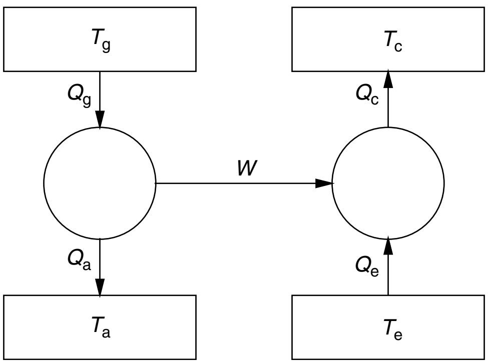

Fig. 4 Thermodynamic model of absorption heat pump.

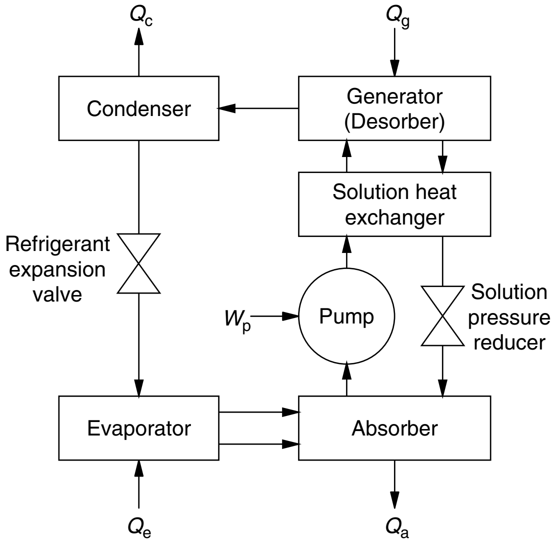

Fig. 5 Simple absorption cycle.

- The thermoelectric heat pump
- The absorption heat pump
- The gas compression heat pump
- The vapor compression heat pump

The Thermoelectric Heat Pump

The thermoelectric heat pump uses the Peltier effect. Two materials with different thermoelectric properties (p type and n type) are arranged to form hot and cold junctions, and are connected in series with a direct-current voltage source (Fig. 3). These devices do not have moving parts, and the cooling and heating elements may be reversed simply by changing the direction of the current.

The Absorption Heat Pump

All absorption cycles include at least three thermal exchanges with their surroundings (i.e., energy exchange at three different temperatures). For the system to operate, the generator temperature (T_g) must be greater than the condenser temperature (T_c) and the absorber temperature (T_a), which in turn must be greater than the evaporator temperature (T_e). An absorption cycle is a heat-activated thermal cycle. The absorption heat pump can be considered as a heat engine driving a heat pump (see Fig. 4).

The components of a simple single-effect absorption system are

- Generator (desorber)
- Condenser
- Refrigerant expansion valve
- Evaporator

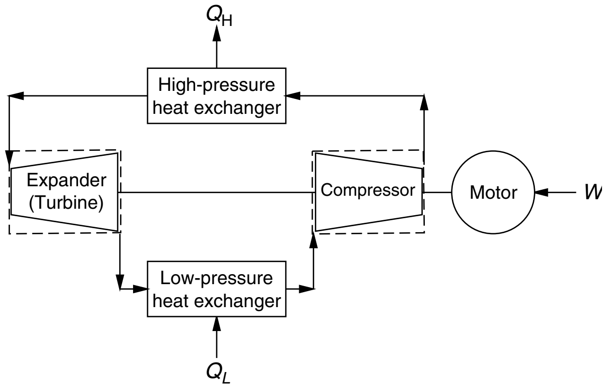

Fig. 6 Schematic of gas compression heat pump.

- Absorber
- Pump
- Solution heat exchanger
- Solution pressure reducer
- Connecting pipes

The absorption system utilizes a sorbent–refrigerant pair. The widely used pairs are Lithium-bromide and water, and water and ammonia. A schematic of the continuous absorption heat pump system is shown in Fig. 5. An absorption cycle is a heat-activated thermal cycle. The major exchanges with its surroundings are thermal energy. A small amount of mechanical work is required at the pump to transport the working fluids.

A high-temperature heat source supplies heat to the generator to drive off the refrigerant vapor from solution. The condenser receives the refrigerant vapor from the generator. In the condenser, the refrigerant changes phase from vapor to liquid, and heat is rejected at a medium temperature. The refrigerant expansion valve reduces the pressure of the refrigerant from the condensing pressure to the evaporating pressure. In the evaporator, the liquid refrigerant collects the low-temperature heat and changes to vapor phase. In other words, the working fluid (refrigerant) provides the cooling effect at the evaporator, and the vaporized refrigerant enters the absorber. The strong-concentration sorbent absorbs the refrigerant vapor and becomes a weak solution. Note the heat rejected at the absorber. The low-pressure weak solution (refrigerant and sorbent) is pumped to the solution heat exchanger to exchange heat with the strong-concentration sorbent. The solution pressure reducer accepts the high-pressure strong solution from the generator and delivers low-pressure strong solution to the absorber. The generator receives the high-pressure weak solution from the solution heat exchanger, and separates the refrigerant and sorbent.

The Gas Compression Heat Pump

Gas compression heat pumps use a gas as the working fluid. Phase changes do not occur during the cycle of operation. Major components of a gas compression heat pump system are:

- Gas compressor
- High-pressure heat exchanger
- Gas expander (or turbine)
- Drive motor
- Low-pressure heat exchanger

A schematic of a gas compression heat pump is shown in Fig. 6. The gas is drawn into the compressor and heated. The heated high-pressure gas delivers heat at the high-pressure heat exchanger. At the expander (turbine), high-pressure gas does the expansion work that helps drive the compressor. In general, the external work input to the compressor is provided by a drive motor.

The Vapor Compression Heat Pump

Almost all heat pumps currently in operation are based on either a vapor compression or an absorption cycle.[8] Heat pumps and refrigerators of the vapor compression type utilize a working fluid that undergoes phase changes during operation. The phase changes occur principally during the heat collection and rejection stages of the cycles. The phase-changing processes occurring in the vapor compression heat pumps are accompanied by extremely favorable heat transfer conditions. Boiling agitation in evaporators and dropwise condensation in condensers make the heat transfer rates very high. To carry out evaporation and condensation, any practical heat pump uses four separate components, as illustrated in Fig. 7:

- Compressor
- Condenser
- Expansion device
- Evaporator

The compressor is the heart of the vapor compression heat pump system. By using mechanical power, the compressor increases the pressure of the working fluid vapor received from the evaporator and delivers it to the condenser. The working fluid condenses and provides useful heat at the condenser. The pressure of the liquid working fluid coming out of the condenser is reduced to the evaporating pressure by an expansion device. The low-grade heat is collected at the evaporator, and the phase of the working fluid changes from liquid to vapor. The working fluid enters the compressor in vapor form to repeat the cyclic flow.[9]

Compressors used in practical units are generally of the positive displacement type: either reciprocating or rotary vanes. In practice, nearly all vapor compression heat pumps use thermostatic expansion valves (T-X valves) because of the availability of the valve to handle a wide range of operating conditions and because of the fact that

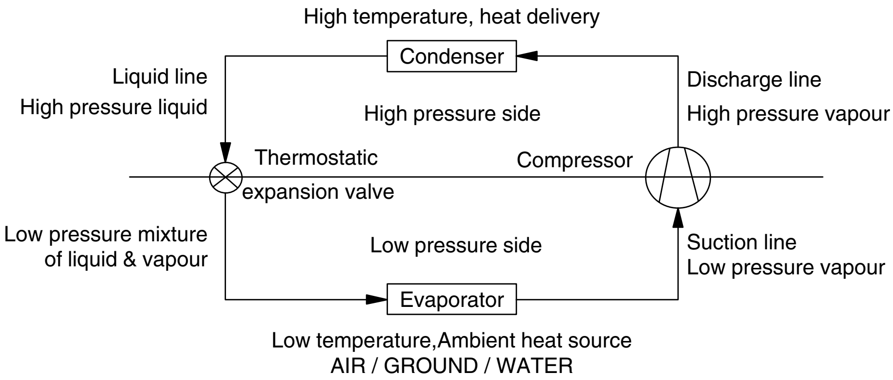

Fig. 7 Schematic diagram of vapor compression heat pump.

the pressure reduction is essentially isenthalpic. These valves, which are relatively low-cost devices, control the liquid working fluid flow to the evaporator by sensing the superheated condition of the working fluid leaving the evaporator. Such control ensures that nearly all the available evaporator surface is covered with a forced convection nucleate boiling film with consequential excellent heat transfer characteristics in the evaporation process.

Reversible circuit heat pumps for building cooling and heating are equipped with a four-way exchange valve that can be operated automatically or manually. This valve enables the normal evaporator to become the condenser and the normal condenser to become the evaporator so that the machine can be made to operate in reverse fashion. This arrangement is often incorrectly called a reverse-cycle operation because of the end effect achieved—i.e., the interchange of roles for the cooling and heating parts of the circuit. It would be better to call this a reverse-flow operation, as the basic thermodynamic cycle remains the same for each mode of operation.

In general, vapor compression heat pumps are classified in many ways. One method commonly used distinguishes among air, water, and ground sources of low-temperature energy and also between the high-temperature energy delivery medium (i.e., air or water). In such a classification, the most common types of heat pump units would include air to air units and water to water units. Solar energy could also be captured at the evaporator as a heat source. These types of heat pumps are called solar-assisted and sola-boosted heat pumps.[10]

Changes in condensing and evaporating temperatures affect the work done at the compressor, and, consequently the COP. Decreasing the condenser or increasing the evaporator temperatures will decrease the compressor work and increase the COP. Fig. 8 shows the effect of condensing temperature on COP for a fixed evaporator temperature. The effect of the evaporating temperature on the COP for a fixed condenser load temperature is shown in Fig. 9. For simplicity, these curves have been obtained assuming operation on the ideal heat pump cycle—i.e., the Carnot cycle of two isothermal and two isentropic (reversible adiabatic) processes not allowing any practical deviations. Although the COP values for real machines will be substantially lower, the trend will be the same.

PERFORMANCE PARAMETERS

This section defines and explains some performance parameters that are used to compare various heat pumps

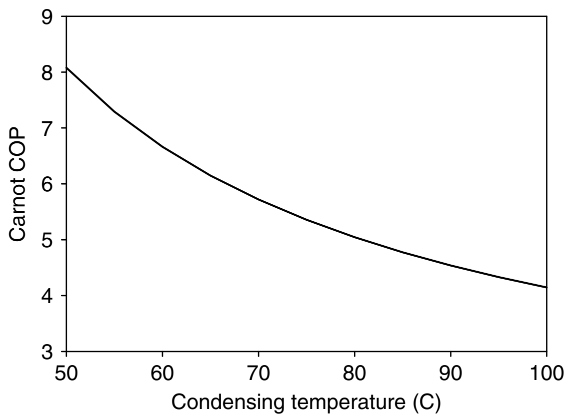

Fig. 8 Effect of condensing temperature on ideal COP (evaporating temperature = 10°C).

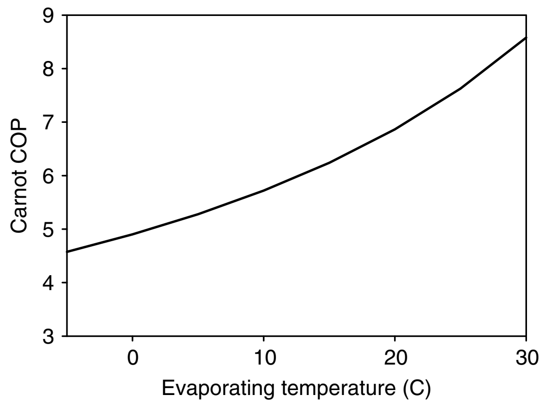

Fig. 9 Effect of evaporating temperature on ideal COP (condensing temperature = 70°C).

Heat–Inde

for a particular application, and also presents the relationships among them.

Coefficient of Performance and Energy Efficiency Ratio

System coefficient of performance (SCOP) is defined as output heating capacity per unit of power input to the system (see Eq. 4).

$$\mathrm{SCOP} = \frac{\text{Heating capacity(W)}}{\text{Power input(W)}} \tag{4}$$

System coefficient of performance is a dimensionless number that measures the performance of a heat pump. If the heating capacity is expressed in units other than W, it is called the heating energy efficiency ratio (HEER). Heat pumps sold in the United States are often stated in terms of EER (see Eq. 5).

$$\mathrm{HEER} = \frac{\text{Heating capacity(Btu/h)}}{\text{Power input(W)}} \tag{5}$$

In the equation described, EER has a unit of Btu/h per W. It should be noted that 1 Btu/h = 0.2928 W. Therefore, the relationship between EER and COP can be expressed as in Eq. 6.

$$\mathrm{COP} = \mathrm{EER} \times 0.2928 \tag{6}$$

Primary Energy Ratio

The HCOP provides a measure of the usefulness of the heat pump system in producing large amounts of heat from a small amount of work. It does not express the fact that energy available as work is normally more useful than energy available as heat. To assess different heat pump systems using compressor drives from different fuel or energy sources, the PER is applied. The PER takes into account not only the heat pump COP, but also the efficiency of conversion of the primary fuel into the work that drives the compressor. Primary energy ratio is defined as in Eq. 7.[4] This also can be expressed as in Eq. 8,

$$\mathrm{PER} = \frac{\text{Useful heat delivered by heat pump}}{\text{Primary energy consumed}} \tag{7}$$

$$\mathrm{PER} = \frac{Q_H}{E_{pe}} = \frac{Q_H}{W} \times \frac{W}{E_{pe}} = \mathrm{HCOP} \times \eta_{pp} \tag{8}$$

where Q_H = load, E_{pe} = primary energy used by the heat pump system, and η_{pp} = power plant efficiency.

The drive energy of heat pumps is most commonly electricity. "Ideally, a heat pump where free work is available should be contemplated, e.g., wind or water power."[4] Consider an electric heat pump powered by a

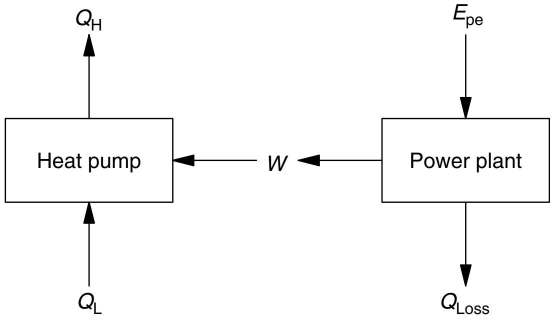

Fig. 10 Energy flow of a conventional electric heat pump.

conventional power plant fuelled by a nonrenewable energy source (see Fig. 10). The power-plant efficiency, η_{pp}, is up to 58% for oil- or gas-fired combined-cycle power plants currently available on the market. The PER is equal to the HCOP for direct power generation from renewable ambient energy sources, such as solar and wind.[1] This concept is illustrated in Fig. 11.

The amount of renewable or ambient energy spent (used up) to produce work for the heat pump is equal to the amount of work (i.e., $E_{re} = W$)—for this case, by definition $\eta_{pp} = 1$.[1] It should be noted that unlike the losses in a fossil-fuel power plant, the unused ambient energy passing through the renewable power plant is still in the form of ambient energy, and it is available to be used.

Ambient Energy Fraction

To make a fair systematic comparison of heat pumps and other systems that provide the same heat output, the term AEF was developed by Aye et al.[11] The term solar fraction is widely understood, accepted, and used in the solar energy field. It is defined as the fractional reduction of purchased energy when a solar energy system is used.[12] It is the fraction of the load contributed by the solar energy, which can be calculated by Eq. 9,

$$f = \frac{L - E}{L} = \frac{L_s}{L} \tag{9}$$

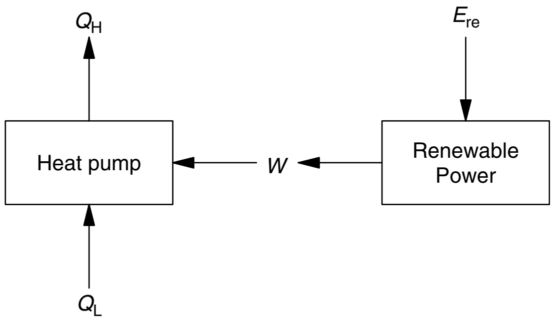

Fig. 11 Energy flow of a renewable electric heat pump.

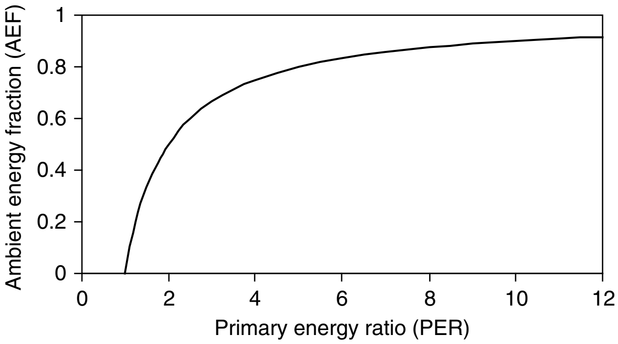

Fig. 12 The ambient energy fraction vs the primary energy ratio.

where L, the load; E, the auxiliary energy supplied to the solar energy system; and L_s, the solar energy delivered.

Similar to the solar fraction of a solar system, the term AEF of a heat pump can be defined as the fraction of the load contributed by the ambient energy, which may be calculated as in Eq. 10.

$$\mathrm{AEF} = \frac{Q_H - E_{pe}}{Q_H} = 1 - \frac{E_{pe}}{Q_H} = 1 - \frac{1}{\mathrm{PER}} = 1 - \frac{1}{\mathrm{HCOP} \times \eta_{pp}} \tag{10}$$

Fig. 12 illustrates the relationship between the AEF and the PER.

Table 2 shows the AEFs of a heat pump, which has an HCOP of 3.5, for various electric power plants. Table 2 clearly shows that for the same heat pump, the AEF may vary from 1 to 71%, depending on how electricity is generated for driving the heat pump compressor. The AEF for the renewable electricity-driven heat pump is the highest (71%). The renewable energy used is only 29% (i.e., 100%–71%) of the total thermal load. The energy use of the brown-coal electricity-driven heat pump is 99% of the total thermal load (i.e., 0.99 MJ of brown-coal energy is required for 1 MJ of thermal load). Table 3 shows the effect of heat pump COP on the AEF of a heat pump powered by a renewable source.

HEAT PUMP APPLICATIONS

Heat pumps have been used for domestic, commercial, and industrial applications.

Domestic applications are:

- Provision of space heating
- Provision of hot water
- Swimming-pool heating

Table 2 Ambient energy fractions of a heat pump powered by typical power plants

Power plant	Brown coal	Nuclear	Black coal	Gas-fired combined-cycle	Renewable
Power plant efficiency, η_{pp}	0.29[a]	0.33[b]	0.35[a]	0.58[b]	1.00
HCOP of heat pump	3.50	3.50	3.50	3.50	3.50
Primary energy ratio, PER	1.02	1.16	1.23	2.03	3.50

Ambient energy fraction, AEF	0.33	0.60	0.71	0.78

Commercial and industrial applications are

- Space heating
- Water heating
- Swimming-pool heating
- Drying and dehumidification
- Evaporation and boiling
- Desalination

CONCLUSION

The fundamentals of heat pumps were presented together with the working principles of the thermoelectric heat pump, the absorption heat pump, the gas compression heat pump, and the vapor compression heat pump. It should be noted that vapor compression heat pumps driven by electricity dominate the current market. Heat pumps are very energy efficient and, therefore, environmentally benign compared with other available heating technologies. The technical and economic performance of a heat pump is closely related to the characteristics of the heat source.

Various performance parameters are available for comparisons of heat pumps; HCOP and energy efficiency ratio are the most widely used. Primary energy ratio and AEF can be used to compare various heat pump systems systematically and fairly. The AEF of an electric heat pump depends on the HCOP and the power plant efficiency based on the primary energy used. The AEF is highly dependent on the type of power plant used to generate the electricity that drives the heat pump compressor. Heat pumps driven by renewable electricity offer the possibility of reducing energy consumption significantly. In the future, the AEF may be used widely as a performance parameter of heat pumps, because energy-resource issues are becoming more important.

ACKNOWLEDGMENTS

I wish to thank Emeritus Professor William W.S. Charters, former Dean of Engineering at the University of Melbourne, who introduced me to heat pump technology and for supporting my career and research in heat pumps.

Heat Transfer

Yunus A. Cengel
Department of Mechanical Engineering, University of Nevada, Reno, Nevada, U.S.A.

Abstract
Heat can be transferred in three different modes: conduction, convection, and radiation. All modes of heat transfer require the existence of a temperature difference, and all modes are from the high-temperature medium to the lower-temperature medium. Conduction is the transfer of energy from the more energetic particles of a substance to the adjacent, less energetic ones as a result of interactions between the particles. Convection is the mode of heat transfer between a solid surface and the adjacent liquid or gas that is in motion, and it involves the combined effects of conduction and fluid motion. Radiation is the energy emitted by matter in the form of electromagnetic waves (or photons) as a result of the changes in the electronic configurations of the atoms or molecules. In this section, we present an overview of the three basic mechanisms of heat transfer and discuss thermal conductivity after giving some historical background.

INTRODUCTION

Heat or thermal energy is the form of energy that can be transferred to or from a system by virtue of a temperature difference. An energy interaction is heat transfer only if it takes place because of a temperature difference. Therefore, there cannot be any heat transfer between two systems that are at the same temperature.

The science of thermodynamics deals with the amount of heat transfer as a system undergoes a process from one equilibrium state to another and makes no reference to how long the process will take. But in engineering, we are often interested in the rate of heat transfer—the amount of heat transfer per unit time—which is the topic of the science of heat transfer.

Heat can be transferred in three different modes: conduction, convection, and radiation. All modes of heat transfer require the existence of a temperature difference and all modes are from the high-temperature medium to the lower-temperature medium. Conduction is the transfer of energy from the more energetic particles of a substance to the adjacent, less energetic ones as a result of interactions between the particles. Convection is the mode of heat transfer between a solid surface and the adjacent liquid or gas that is in motion, and it involves the combined effects of conduction and fluid motion. Radiation is the energy emitted by matter in the form of electromagnetic waves (or photons) as a result of the changes in the electronic configurations of the atoms or molecules. In this section, we present an overview of the three basic mechanisms of heat transfer and discuss thermal conductivity after giving some historical background.

HISTOPRICAL BACKGROUND

Heat has always been perceived to be something that produces in us a sensation of warmth and one would think that the nature of heat is one of the first things understood by mankind. However, it was only in the middle of the nineteenth century that we had a true physical understanding of the nature of heat, thanks to the development at that time of the kinetic theory, which treats molecules as tiny balls that are in motion and thus possess kinetic energy. Heat is defined as the energy associated with the random motion of atoms and molecules. Although it was suggested in the eighteenth and early nineteenth centuries that heat is the manifestation of motion at the molecular level (called the live force), the prevailing view of heat until the middle of the nineteenth century was based on the caloric theory proposed by the French chemist Antoine Lavoisier (1744–1794) in 1789. The caloric theory asserts that heat is a fluid-like substance called the caloric that is a massless, colorless, odorless, and tasteless substance that can be poured from one body into another. When caloric was added to a body, its temperature increased; and when caloric was removed from a body, its temperature decreased. When a body could not contain any more caloric, much the same way as when a glass of water could not dissolve any more salt or sugar, the body was said to be saturated with caloric. This interpretation gave rise to the terms saturated liquid and saturated vapor that are still in use today.

Keywords: Heat transfer; Thermal conductivity; Conduction; Convection; Radiation.

The caloric theory came under attack soon after its introduction. It maintained that heat is a substance that cannot be created or destroyed. Yet it was known that heat can be generated indefinitely by rubbing one's hands together or rubbing two pieces of wood together. In 1798, the American Benjamin Thompson (Count Rumford) (1754–1814) showed in his papers that heat can be generated continuously through friction. The validity of the caloric theory was also challenged by several others, but it was the careful experiments of the Englishman James P. Joule (1818–1889) published in 1843 that finally convinced the skeptics that heat was not a substance after all, thus putting the caloric theory to rest. Although the caloric theory was totally abandoned in the middle of the nineteenth century, it contributed greatly to the development of thermodynamics and heat transfer.

CONDUCTION

Conduction is the transfer of energy from the more energetic particles of a substance to the adjacent less energetic ones as a result of interactions between the particles. Conduction can take place in solids, liquids, or gases. In gases and liquids, conduction is due to the collisions and diffusion of the molecules during their random motion. In solids, it is due to the combination of vibrations of the molecules in a lattice and the energy transport by free electrons. A cold canned drink in a warm room, for example, eventually warms up to the room temperature as a result of heat transfer from the room to the drink through the aluminum can by conduction. A detailed study of these modes is given in Refs. 1–4.

The rate of heat conduction through a medium depends on the geometry of the medium, its thickness, and the material of the medium, as well as the temperature difference across the medium. We know that wrapping a hot-water tank with glass wool (an insulating material) reduces the rate of heat loss from the tank. The thicker the insulation is, the smaller the heat loss will be. We also know that a hot-water tank will lose heat at a higher rate when the temperature of the room housing the tank is lowered. Further, the larger the tank is, the larger the surface area and thus the rate of heat loss will be.

Consider steady heat conduction through a large plane wall of thickness $\Delta x = L$ and area A, as shown in Fig. 1. The temperature difference across the wall is $\Delta T = T_2 - T_1$. Experiments have shown that the rate of heat transfer $\dot{Q}$ through the wall is doubled when the temperature difference ΔT across the wall or the area A normal to the direction of heat transfer is doubled, but it is halved when the wall thickness L is doubled. Thus, we conclude that the rate of heat conduction through a plane layer is proportional to the temperature difference across the layer and the heat transfer area but is inversely proportional to the thickness of the layer. That is,

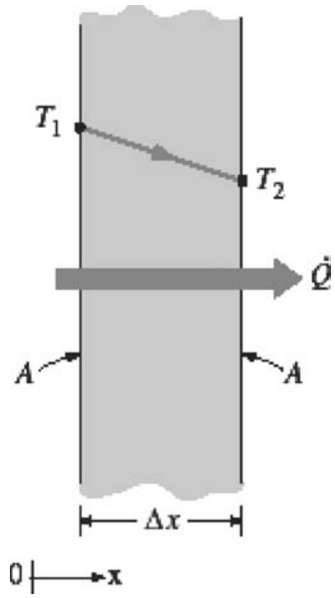

Fig. 1 Heat conduction through a large plane wall of thickness Δx and area A.

$$\text{Rate of heat conduction } \alpha \frac{\text{(Area)(Temperature difference)}}{\text{Thickness}}$$

or

$$\dot{Q} = kA\frac{T_1 - T_2}{\Delta x} = -kA\frac{\Delta T}{\Delta x} \quad (1)$$

where the constant of proportionality k is the thermal conductivity of the material, which is a measure of the ability of a material to conduct heat. The limiting case of $\Delta x \to 0$ reduces to the differential form:

$$\dot{Q} = -kA\frac{\mathrm{d}T}{\mathrm{d}x} \quad (2)$$

which is called Fourier's law of heat conduction after J. Fourier who expressed it first in his heat transfer text in 1822. Here $\mathrm{d}T/\mathrm{d}x$ is the temperature gradient, which is the slope of the temperature curve on a $T-x$ diagram (the rate of change of T with x), at location x. This relation indicates that the rate of heat conduction in a direction is proportional to the temperature gradient in that direction. Heat is conducted in the direction of decreasing temperature and the temperature gradient becomes negative when temperature decreases with increasing x. The negative sign in Eqs. 1 and 2 ensures that heat transfer in the positive x direction is a positive quantity.

The heat transfer area A is always normal to the direction of heat transfer. For heat loss through a 5-m-long, 3-m-high, and 25-cm-thick wall, for example, the heat transfer area is $A = 15\ \mathrm{m}^2$. Note that the thickness of the wall has no effect on A (Fig. 2).

Heat–Inde

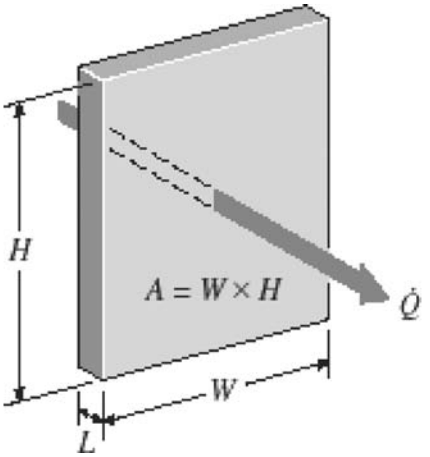

Fig. 2 In heat conduction analysis, A represents the area normal to the direction of heat transfer.

Example 1. The Cost of Heat Loss through a Roof.

The roof of an electrically heated home is 6 m long, 8 m wide, and 0.25 m thick, and is made of a flat layer of concrete whose thermal conductivity is $k = 0.8$ W/m K (Fig. 3). The temperatures of the inner and the outer surfaces of the roof one night are measured to be 15 and 4°C, respectively, for a period of 10 h. Determine the rate of heat loss through the roof that night and the cost of that heat loss to the home owner if the cost of electricity is $0.08/kWh.

Solution. Noting that heat transfer through the roof is by conduction and the area of the roof is $A = 6\text{ m} \times 8\text{ m} = 48\text{ m}^2$, the steady rate of heat transfer through the roof is determined to be

$$\begin{aligned}\dot{Q} &= kA\frac{T_1 - T_2}{L}\\ &= (0.8\text{ W/m K})(48\text{ m}^2)\frac{(15 - 4)^\circ\text{C}}{0.25\text{ m}} = 1690\text{ W}\\ &= 1.69\text{ kW}\end{aligned}$$

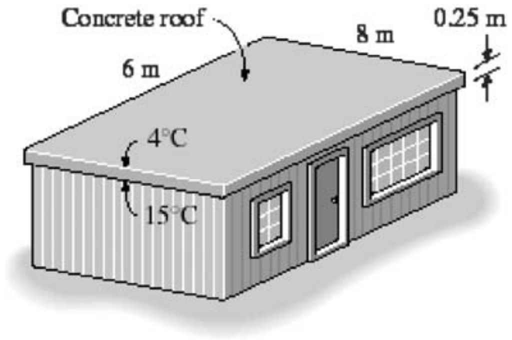

Fig. 3 Schematic for Example 1.

The amount of heat lost through the roof during a 10-hour period and its cost are

$$Q = \dot{Q}\Delta t = (1.69\text{ kW})(10\text{ h}) = 16.9\text{ kWh}$$

$$\begin{aligned}\text{Cost} &= (\text{Amount of energy})(\text{Unit cost of energy})\\ &= (16.9\text{ kWh})(\$0.08/\text{kWh}) = \$1.35\end{aligned}$$

Note that the total heating cost of the house is much larger than $1.35 because the heat losses through the walls are not considered. Also, for temperature differences, the units °C and K are identical.

Thermal Conductivity

Different materials store heat differently, and is defined as the property specific heat c_p is defined as a measure of a material's ability to store thermal energy. For example, $c_p = 4.18$ kJ/kg K for water and it is 0.45 kJ/kg K for iron at room temperature, which indicates that water can store almost 10 times the energy that iron can per unit mass. Likewise, the thermal conductivity k is a measure of a material's ability to conduct heat. For example, $k = 0.608$ W/m K for water and $k = 80.2$ W/m K for iron at room temperature, which indicates that iron conducts heat more than 100 times faster than water can. Thus we say that water is a poor heat conductor relative to iron, although water is an excellent medium to store thermal energy.

Eq. 2 for the rate of conduction heat transfer under steady conditions can also be viewed as the defining equation for thermal conductivity. Thus the thermal conductivity of a material can be defined as the rate of heat transfer through a unit thickness of the material per unit area per unit temperature difference. The thermal conductivity of a material is a measure of the ability of the material to conduct heat. A high value for thermal conductivity indicates that the material is a good heat conductor; and a low value indicates that the material is a poor heat conductor or an insulator. The thermal conductivities of some common materials at room temperature are given in Table 1. The thermal conductivity of pure copper at room temperature is $k = 401$ W/m K, which indicates that a 1-m-thick copper wall will conduct heat at a rate of 401 W through an area of 1 m^2 per °C or K temperature difference across the wall. Note that materials such as copper and silver that are good electric conductors are also good heat conductors and have high values of thermal conductivity. Materials such as rubber, wood, and Styrofoam are poor conductors of heat and have low conductivity values.

A layer of material of known thickness and area can be heated from one side by an electric resistance heater of known output. If the outer surfaces of the heater are well insulated, all the heat generated by the resistance heater

Heat–Inde

will be transferred through the material whose conductivity is to be determined. Then, measuring the two surface temperatures of the material when steady heat transfer is established and substituting them into Eq. 2 together with other known quantities give the thermal conductivity (Fig. 4).

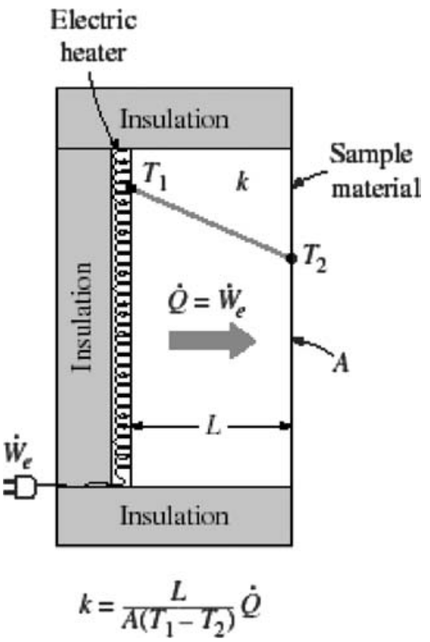

Fig. 4 A simple experimental setup to determine the thermal conductivity of a material.

The thermal conductivities of materials vary over a wide range, as shown in Fig. 5. The thermal conductivities of gases such as air vary by a factor of 10^4 from those of pure metals such as copper. Note that pure crystals and metals have the highest thermal conductivities and gases and insulating materials the lowest.

Temperature is a measure of the kinetic energies of the particles such as the molecules or atoms of a substance. In a liquid or gas, the kinetic energy of the molecules is due to their random translational motion as well as their vibrational and rotational motions. When two molecules possessing different kinetic energies collide, part of the kinetic energy of the more energetic (higher-temperature) molecule is transferred to the less energetic (lower-temperature) molecule, much the same as when two elastic balls of the same mass at different velocities collide—part of the kinetic energy of the faster ball is transferred to the slower one. The higher the temperature, the faster the molecules move, higher the number of such collisions, and the better the heat transfer.

The kinetic theory of gases predicts and the experiments confirm that the thermal conductivity of gases is proportional to the square root of the absolute temperature T and inversely proportional to the square root of the molar mass M. Therefore, the thermal conductivity of a gas increases with increasing temperature and decreasing molar mass. So it is not surprising that the thermal conductivity of helium ($M=4$) is much higher than those of air ($M=29$) and argon ($M=40$).

The mechanism of heat conduction in a liquid is complicated by the fact that the molecules are more closely spaced and they exert a stronger intermolecular force field. The thermal conductivities of liquids usually lie between those of solids and gases. The thermal conductivity of a substance is normally highest in the solid phase and lowest in the gas phase. Unlike gases, the thermal conductivities of most liquids decrease with increasing temperature, with water being a notable exception. Like gases, the conductivity of liquids decreases with increasing molar mass. Liquid metals such as mercury and sodium have high thermal conductivities and are very suitable for use in applications where a high heat transfer rate to a liquid is desired, as in nuclear power plants.

In solids, heat conduction is due to two effects: the lattice vibrational waves induced by the vibrational motions of the molecules positioned at relatively fixed positions in a periodic manner, called a lattice, and the energy transported via the free flow of electrons in the solid (Fig. 6). The thermal conductivity of a solid is obtained by adding the lattice and electronic components. The relatively high thermal conductivities of pure metals are primarily due to the electronic component. The lattice component of thermal conductivity strongly depends on

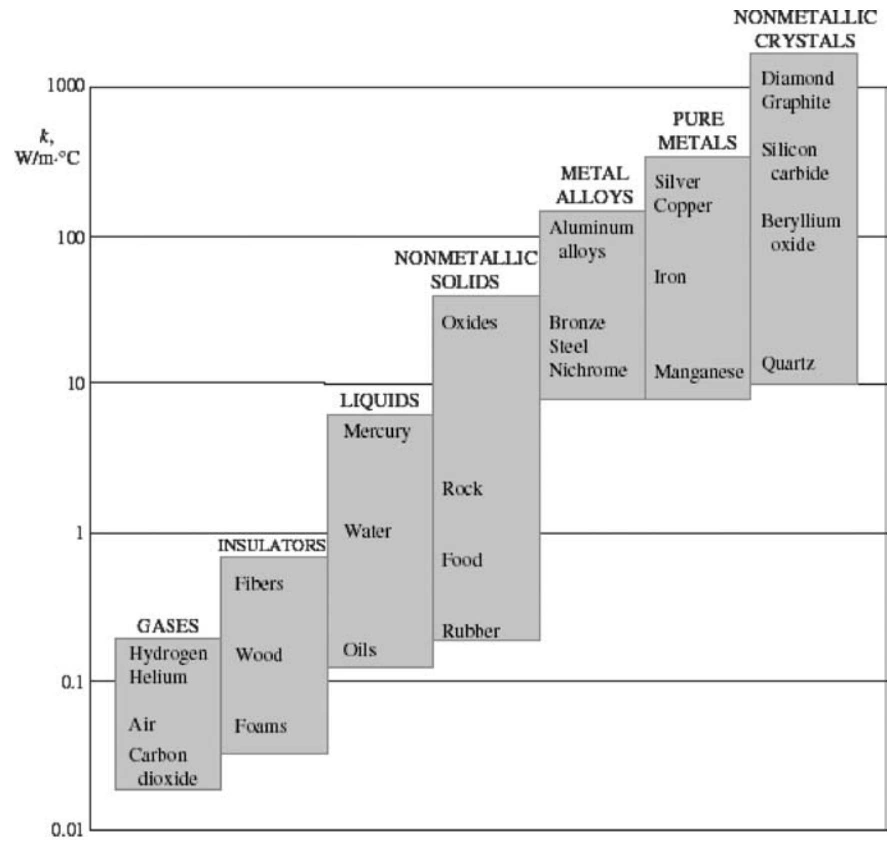

Fig. 5 The range of thermal conductivity of various materials at room temperature.

the way the molecules are arranged. For example, diamond, which is a highly ordered crystalline solid, has the highest known thermal conductivity at room temperature.

Unlike metals, which are good electrical and heat conductors, crystalline solids such as diamond and semiconductors such as silicon are good heat conductors but poor electrical conductors. As a result, such materials find widespread use in the electronics industry. Despite their higher price, diamond heat sinks are used in the cooling of sensitive electronic components because of the excellent thermal conductivity of diamond. Silicon oils and gaskets are commonly used in the packaging of electronic components because they provide both good thermal contact and good electrical insulation.

Pure metals have high thermal conductivities, and one would think that metal alloys should also have high conductivities. One would expect an alloy made of two metals of thermal conductivities k_1 and k_2 to have a conductivity k between k_1 and k_2, but this turns out not to be the case. The thermal conductivity of an alloy of two metals is usually much lower than that of either metal. Even small amounts in a pure metal of "foreign" molecules that are good conductors themselves seriously disrupt the flow of heat in that metal. For example, the thermal conductivity of steel containing just 1 percent of chrome is 62 W/m K while the thermal conductivities of iron and chromium are 83 and 95 W/m K, respectively.

The thermal conductivities of materials vary with temperature. The variation of thermal conductivity over

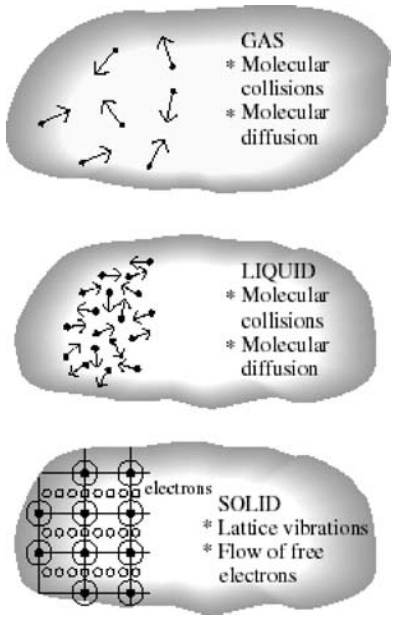

Fig. 6 Mechanisms of heat conduction in different phases.

certain temperature ranges is negligible for some materials, but significant for others. The thermal conductivities of certain solids exhibit dramatic increases at temperatures near absolute zero, when these solids become superconductors. For example, the conductivity of copper reaches a maximum value of about 20,000 W/m K at 20 K, which is about 50 times the conductivity at room temperature. The temperature dependence of thermal conductivity causes considerable complexity in conduction analysis. Therefore, it is common practice to evaluate the thermal conductivity k at the average temperature and treat it as a constant in calculations.

In heat transfer analysis, a material is normally assumed to be isotropic—that is, to have uniform properties in all directions. This assumption is realistic for most materials, except those that exhibit different structural characteristics in different directions (such as laminated composite materials and wood). The thermal conductivity of wood across the grain, for example, is different than that parallel to the grain.

CONVECTION

Convection is the mode of energy transfer between a solid surface and the adjacent liquid or gas that is in motion, and it involves the combined effects of conduction and fluid motion. The faster the fluid motion, the greater the convection heat transfer is. In the absence of any bulk fluid motion, heat transfer between a solid surface and the adjacent fluid is by pure conduction. The presence of bulk motion of the fluid enhances the heat transfer between the solid surface and the fluid, but it also complicates the determination of heat transfer rates.

Consider the cooling of a hot block by blowing cool air over its top surface (Fig. 7). Energy is first transferred to the air layer adjacent to the block by conduction. This energy is then carried away from the surface by convection—that is, by the combined effects of conduction within the air that is due to random motion of air molecules and the bulk or macroscopic motion of the air that removes the heated air near the surface and replaces it by the cooler air.

Convection is called forced convection if the fluid is forced to flow over the surface by external means such as a fan, pump, or the wind. In contrast, convection is called natural (or free) convection if the fluid motion is caused by buoyancy forces that are induced by density differences due to the variation of temperature in the fluid (Fig. 8). For example, in the absence of a fan, heat transfer from the surface of the hot block in Fig. 7 will be by natural convection because any motion in the air in this case will be due to the rise of the warmer (and thus lighter) air near the surface and the fall of the cooler (and thus heavier) air to fill its place. Heat transfer between the block and the surrounding air will be by conduction if the temperature difference between the air and the block is not large enough to overcome the resistance of air to movement and thus to initiate natural convection currents.

Heat transfer processes that involve the change of phase of a fluid are also considered to be convection because of the fluid motion induced during the process, such as the rise of the vapor bubbles during boiling or the fall of the liquid droplets during condensation.

Despite the complexity of convection, the rate of convection heat transfer is observed to be proportional to the temperature difference, and is conveniently expressed by Newton's law of cooling as

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_\infty) \tag{4}$$

where h is the convection heat transfer coefficient in $\text{W/m}^2\text{ K}$ or $\text{Btu/h ft}^2\text{ R}$, A_s is the surface area through which convection heat transfer takes place, T_s is the surface temperature, and T_∞ is the temperature of the fluid sufficiently far from the surface. Note that at the surface, the fluid temperature equals the surface temperature of the solid.

The convection heat transfer coefficient h is not a property of the fluid. It is an experimentally determined parameter whose value depends on all the variables influencing convection such as the surface geometry, the nature of fluid motion, the properties of the fluid, and the

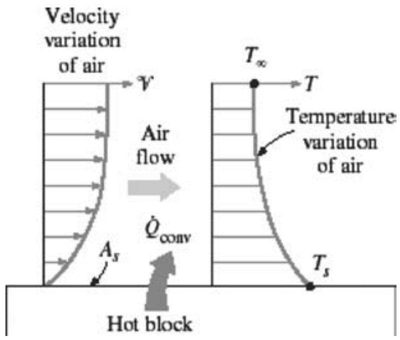

Fig. 7 Heat transfer from a hot surface to air by convection.

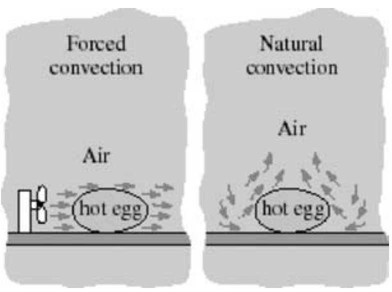

Fig. 8 The cooling of a boiled egg by forced and natural convection.

Heat—Inde

Table 2 Typical values of convection heat transfer coefficient

Type of convection	h, W/m² K[a]
Free convection of gases	2–25
Free convection of liquids	10–1000
Forced convection of gases	25–250
Forced convection of liquids	50–20,000
Boiling and condensation	2500–100,000

[a]Multiply by 0.176 to convert to Btu/h ft^2 R.

bulk fluid velocity. Typical values of h are given in Table 2.

RADIATION

Radiation is the energy emitted by matter in the form of electromagnetic waves (or photons) as a result of the changes in the electronic configurations of the atoms or molecules. Unlike conduction and convection, the transfer of energy by radiation does not require the presence of an intervening medium. In fact, energy transfer by radiation is fastest (at the speed of light) and it suffers no attenuation in a vacuum. This is how the energy of the sun reaches the earth.

In heat transfer studies, we are interested in thermal radiation, which is the form of radiation emitted by bodies because of their temperature. It differs from other forms of electromagnetic radiation such as x-rays, gamma rays, microwaves, radio waves, and television waves that are not related to temperature. All bodies at a temperature above absolute zero emit thermal radiation.

Radiation is a volumetric phenomenon, and all solids, liquids, and gases emit, absorb, or transmit radiation to varying degrees. However, radiation is usually considered to be a surface phenomenon for solids that are opaque to thermal radiation such as metals, wood, and rocks because the radiation emitted by the interior regions of such material can never reach the surface and the radiation incident on such bodies is usually absorbed within a few microns from the surface.

The maximum rate of radiation that can be emitted from a surface at an absolute temperature T_s (in K or R) is given by the Stefan-Boltzmann law as

$$\dot{Q}_{\text{emit,max}} = \sigma_s A_s T_s^4 \quad (5)$$

where $\sigma_s = 5.67 \times 10^{-8}$ W/m^2 K^4 or 0.1714×10^{-8} Btu/h ft^2 R^4 is the Stefan-Boltzmann constant. The idealized surface that emits radiation at this maximum rate is called a blackbody, and the radiation emitted by a blackbody is called blackbody radiation. The radiation emitted by all real surfaces is less than the radiation emitted by a blackbody at the same temperature, and is expressed as

$$\dot{Q}_{\text{emit}} = \varepsilon \sigma_s A_s T_s^4 \quad (6)$$

where ε is the emissivity of the surface. The property emissivity, whose value is in the range $0 \le \varepsilon \le 1$, is a measure of how closely a surface approximates a blackbody for which $\varepsilon = 1$. The emissivities of some surfaces are given in Table 3.

Another important radiation property of a surface is its absorptivity α, which is the fraction of the radiation energy incident on a surface that is absorbed by the surface. Like emissivity, its value is in the range $0 \le \alpha \le 1$. A blackbody absorbs the entire radiation incident on it. That is, a blackbody is a perfect absorber ($\alpha = 1$) as it is a perfect emitter.

In general, both ε and α of a surface depend on the temperature and the wavelength of the radiation. Kirchhoff's law of radiation states that the emissivity and the absorptivity of a surface at a given temperature and wavelength are equal. In many practical applications, the surface temperature and the temperature of the source of incident radiation are of the same order of magnitude and the average absorptivity of a surface is taken to be equal to its average emissivity. The rate at which a surface absorbs radiation is determined from (Fig. 9)

$$\dot{Q}_{\text{absorbed}} = \alpha \dot{Q}_{\text{incident}} \quad (7)$$

where $\dot{Q}_{\text{incident}}$ is the rate at which radiation is incident on the surface and ε and α is the absorptivity of the surface. For opaque (nontransparent) surfaces, the portion of

incident radiation not absorbed by the surface is reflected back.

The difference between the rates of radiation emitted by the surface and the radiation absorbed is the net radiation heat transfer. If the rate of radiation absorption is greater than the rate of radiation emission, the surface is said to be gaining energy by radiation. Otherwise, the surface is said to be losing energy by radiation. In general, the determination of the net rate of heat transfer by radiation between two surfaces is a complicated matter because it depends on the properties of the surfaces, their orientation relative to each other, and the interaction of the medium between the surfaces with radiation.

When a surface of emissivity ε and surface area A_s at an absolute temperature T_s is completely enclosed by a much larger (or black) surface at absolute temperature T_{surr} separated by a gas (such as air) that does not intervene with radiation, the net rate of radiation heat transfer between these two surfaces is given by (Fig. 10)

$$\dot{Q}_{rad} = \varepsilon\sigma_s A_s(T_s^4 - T_{surr}^4) \quad (8)$$

In this special case, the emissivity and the surface area of the surrounding surface do not have any effect on the net radiation heat transfer.

Radiation heat transfer to or from a surface surrounded by a gas, such as air, occurs parallel to conduction (or convection, if there is bulk gas motion) between the surface and the gas. Thus the total heat transfer is determined by adding the contributions of both heat transfer mechanisms. For simplicity and convenience, this is often done by defining a combined heat transfer coefficient $h_{combined}$ that includes the effects of both convection and radiation. Then, the total heat transfer rate to or from a surface by convection and radiation is expressed as

$$\dot{Q}_{total} = h_{combined}A_s(T_s - T_\infty) \quad (9)$$

Note that the combined heat transfer coefficient is essentially a convection heat transfer coefficient modified to include the effects of radiation.

Radiation is usually significant relative to conduction or natural convection, but negligible relative to forced convection. Thus radiation in forced convection applications is usually disregarded, especially when the surfaces involved have low emissivities and low to moderate temperatures.

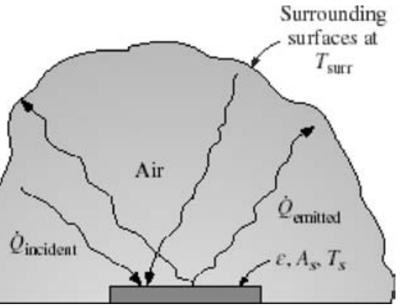

Fig. 10 Radiation heat transfer between a surface and the surfaces surrounding it.

CONCLUSION

There are three mechanisms of heat transfer, but not all three can exist simultaneously in a medium. For example, heat transfer is only by conduction in opaque solids, but by conduction and radiation in semitransparent solids. Thus, a solid may involve conduction and radiation but not convection. However, a solid may involve heat transfer by convection and radiation on its surfaces exposed to a fluid or other surfaces. Heat transfer is by conduction and possibly by radiation in a still fluid (no bulk fluid motion) and by convection and radiation in a flowing fluid. In the absence of radiation, heat transfer through a fluid is either by conduction or convection, depending on the presence of any bulk fluid motion. Convection can be viewed as combined conduction and fluid motion, and conduction in a fluid can be viewed as a special case of convection in the absence of any fluid motion.

High Intensity Discharge (HID) Electronic Lighting

Ken E. Patterson II
Advanced Energy Innovations—Bringing Innovation to Industry, Menifee, California, U.S.A.

Abstract
Electronic High-Intensity Discharge (E-HID) lighting systems are the "high frequency" wave of the future. Traditional and inefficient magnetic HID systems are increasingly being replaced by a new paradigm in lighting, E-HID. In addition to becoming a popular alternative in a lighting designer's arsenal of practical lighting solutions, E-HID has proven to be technologically feasible, economically justifiable, and extraordinarily versatile. However, the differences in E-HID power supplies (ballasts) that are "driving" the surge in new HID lamps, fixtures, and controls are significant. Just calling an HID ballast "electronic" can be misleading in relation to actual performance. Careful analysis is necessary in selecting the "best" E-HID system in terms of energy efficiency, lumens-per-watt (LPW) output, lamp compatibility, and dimming flexibility, as illustrated in this entry.

INTRODUCTION

After over a decade of promise, high intensity discharge (HID) electronic lighting has now become a practical alternative to traditional magnetic-based technology.[1] In particular, high-frequency electronic ballasts for HID lamps have proven to be technologically feasible and economically justifiable, while generating significant energy savings.[2] Because HID lighting systems consume $>4\%$ of our nation's energy, a viable efficiency solution is unfolding as an increasing number of energy efficient electronic ballasts replace old energy depleting magnetic ballasts, thereby reducing our per capita consumption of energy.

However, in addition to energy savings, electronic ballasts can change the entire operational standard for HID lighting. Using this technology, each of the many problematic issues (lumen depreciation, color shift, starts per day, hot restrike times, and lack of controllability) that have plagued HID in the past can be minimized if not totally eliminated.[3] Thus, the impact of electronic ballasts on HID lamps cannot be overstated as amplified in this study. The trend toward electronically ballasted HID lighting is a reality. Indeed, the growing awareness by government stakeholders that electronic ballast usage for every HID lamp should be mandated (as is now done for fluorescent ballasts) will only accelerate this trend.[4]

BACKGROUND

Electronic high-intensity discharge ballasts (E-HID) were introduced into the market in the early 1990s and have long since proven their worth in the market place.[5] Like any new advancement in electronics technology, electronic HID ballasts went through their growing pains—unit failures were rampant and caused many customers to shy away from this technology.

However, as we passed the mid-2000s, E-HID has established itself as a practical, cost-effective, and reliable alternative to traditional HID lighting systems.

The following discussion begins with a primer on electronic ballasts followed by an analysis of the performance of E-HID ballasts compared to magnetic HID ballasts. This comparison incorporates four different ballasts on the market today—Ballast A, an electronic sinusoidal high-frequency ballast with nonoptimal lamp compatibility; Ballast B, an electronic sinusoidal high-frequency ballast with nonoptimal lamp compatibility; Ballast C, an electronic high-frequency sinusoidal ballast with optimal lamp compatibility and avalanche enhanced ignition; and Ballast D, an electronic low-frequency square-wave ballast with nonoptimal lamp compatibility. The purpose is to prove that high-frequency E-HID is a viable and economical solution.

This discussion is also timely because a growing number of end-users are now evaluating the use of E-HID in their facilities and such information contained herein is not easily accessible or available to them.

Electronic Ballast Primer

Dimming Electronic Metal Halide (MH) and Ceramic MH (CMH) ballasts (E-HID) offer significant performance enhancements to virtually every aspect of HID lighting systems—lumen depreciation, color shift, starts per day, hot restrike times, and controllability. Electronic High-Intensity Discharge offers superior energy efficiency, lamp color conformity, lumen maintenance, and lamp

Keywords: Electronic lighting; High-intensity discharge; E-HID; High frequency; Electronic ballast; Sinusoidal; Dimming; Energy efficient; High lumen output; Avalanche ignition.

life. Quiet operation and control of the inherent stroboscopic nature of magnetic ballast and MH lamps are additional advantages.

As recent as 2005, many lighting "experts" thought high-frequency E-HID could not successfully "drive" the new CMH lamps. However, at least one E-HID ballast manufacturer has received certification to operate CMH lamps, opening the door to even greater innovation in ceramic ballasts and lamps in the future.[6]

Types of Electronic Ballasts

There are two types of electronic ballasts (E-HID) for HID lighting. The Low-Frequency Square Wave E-HID ballasts operate at relatively low frequency (100–200 Hz) and have efficiencies of 90%–93%. Although these ballasts offer improved efficacy and lumen maintenance over magnetic ballasts, the low frequency ballasts cannot be dimmed (operated at reduced power) and they consume more energy than High-Frequency E-HID Ballasts.[7] The High-Frequency Sinusoidal Wave E-HID ballasts operate above 100 kHz, offer improved lumen maintenance, can be dimmed (operated at reduced power levels) as low as 35%, and are 92+% efficient. The high- and low-frequency ballasts are suitable primarily for quartz Pulse Start (PS) MH lamps. Some E-HID ballasts are designed to also operate the new, highly efficient CMH lamps, offering the highest efficacy and CRI of all MH systems.

Lamp Ignition/Lamp Performance

Use of a high-frequency sinusoidal electronic ballast brings increased lamp life, improved color, lumen maintenance, and efficiency to HID lighting due, in part, to the characteristics of high frequency operation. The start-up is gentler on the lamp electrodes as the ballasts utilize an order of magnitude (approximately two-thirds) less energy than that of the conventional ballast ignition process. As a result, the life of the lamp and its color rendition will be greatly improved. The electronic ballast isolates the lamp from line voltage fluctuations, which, in-turn, eliminates these line variations as a source for lamp-life degradation.

Dimming and Controls

Lighting consumes close to 25% of our nations' energy. While purchaser's focus tends to be on the initial costs of a lighting system (costs of luminaire, lamp, ballast, and labor), an estimated 88% of the lighting system operating cost is the cost of the energy. As such, daylight harvesting, dimming/load shedding, and other means of controlling energy consumption are becoming popular and will be required by the utilities/regulators in coming years.[4] Because of their ability to be controlled, high-frequency E-HID ballasts are easily utilized in conjunction with dimmers, occupancy, and ambient light sensors to maximize potential energy savings. Most high-frequency E-HID ballasts are dimmable to 50% of lamp power. When dimmed, the light output ranges from 12 to 40%, depending upon the ballast, lamp, and luminaire. One manufacturer can even dim to 35% of lamp power with the backing of multiple lamp manufacturer warranties.[8]

Voltage

Most electronic ballasts have "auto-voltage" and do not need to be "tapped" to operate a particular voltage. They generally handle the range of 208–277, ±10%, 50–60 Hz, AC/DC. The "auto-voltage" feature simplifies and reduces the cost of installation. Most manufacturers also offer a 120 V version, as well. Because some E-HID ballasts hold the lamp to 0.5% of the wattage spec for each 10% variation in voltage, E-HID ballasts provide vastly improved lamp regulation compared to magnetic types.

Starting Behavior

Depending on the ignition process, E-HID ballasts can achieve full power within 45–300 s and full light output within 2–4 min.[9] The time that it takes to go from full power (or energy consumption) to full light output is wasted energy. Due to its proprietary avalanche enhanced ignition, the "C" sinusoidal E-HID ballast has superior time to full power, light output, and hot restrike faster than the standard PS–MH system or "other E-HID" systems.[10]

Efficiency and Operation

Due to the improved lumen maintenance, a facility utilizing E-HID ballasted PS–MH lamps can provide comparable light levels with up to 40% fewer fixtures than a magnetically-ballasted facility. Not only are the light levels and energy efficacy from a LPW (lumens-per-watt) perspective dramatically improved, but the prospect of future environmental waste is reduced due to fewer initial fixtures as well as less frequent relamping over the life of the facility. E-HID ballasts have a power factor (pf) ranging from 90 to 99% and reduced "power distribution losses" due to a much lower THD (Total Harmonic Distortion). Magnetic THD generally runs between 15 and 30% while electronic distortion can be less than 5%.

Electronic High-Intensity Discharge ballast efficiencies of 92%–96% compare favorably to that of reactor and CWA magnetic ballast efficiencies, which peak below 90% when new and become less efficient over life due to heat generation. Of the magnetic ballasts, the more efficient reactor type exhibits the most lamp variability to line voltage variations—for each 5% of line voltage variation the lamp wattage varies by as much as 10%.

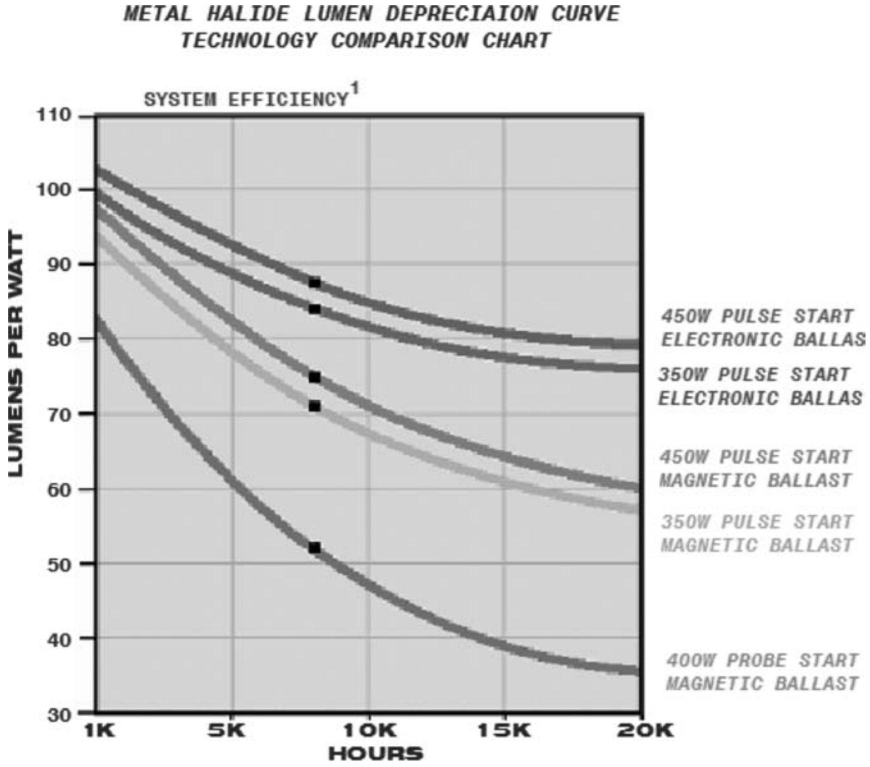

Fig. 1 System efficiency comparison.

As a result, color conformity suffers, lumen depreciation increases, and more regular relamping is required.

Efficacy Comparison

As an example, let's evaluate the number of lamps, lumens, and system watts required to generate 3.4 million mean lumens—enough to light a 60,000 ft^2. warehouse or retail facility at 50 fc. Fig. 1 compares E-HID Electronic Ceramic and Electronic PS systems to Electronic Fluorescent T5/HO, 400 W Magnetic PS and a conventional magnetic 400 W MH M/59 system. The CMH and PS systems light the warehouse using one-third fewer fixtures than the conventional M/59 system. The mean lighting efficacy (LPW) increased 76% with Electronic PS and over 105% with the Electronic CMH ceramic system.

E-HID: LIGHTING THE WAY

Today, many of the major ballast manufacturers are producing some sort of "electronic" HID ballast. However, all electronic ballasts are not alike and most of the manufacturers of electronic HID ballasts fall woefully short on how well their ballast treats the lamp on ignition, operation, dimming, acoustic resonance, and efficacy. In too many cases, promises do not meet expectations as manufacturers have hastened to get in on the flourishing E-HID ballast market. It appears the axiom of "anything is better than nothing" has prevailed.

When one compares costs, the first consideration is "installed costs." Installed costs should include rebates, HVAC savings, demand charges, and system watts at high power (using controls such as occupancy sensors, dimmers, and ambient light sensors), as well as the operating hours at high and low power levels. The incorporation of dimming, system watts (high and low), and percent of time at high and low levels are important drivers to the operating costs of the system.

The utilization of fewer fixtures using a high-efficiency ballast will result in other tangible benefits:

- Reduced HVAC costs due to less system watts and less cooling required; for each 3.4 W saved by the ballast there is a watt saved in cooling/chilling costs.
- Avoided utility company "demand charges" resulting from using controls, demand shedding, and more efficient fixtures.
- Less "power distribution losses" due to a much lower THD and therefore a more energy efficient system; magnetic THD is between 15 and 30%, while electronic is less than 5%.
- Less hazardous waste disposal costs from lamps as a result of less initial fixtures as well as a longer relamping schedule over the life of the facility.

Due to its improved ignition methodology, lumen maintenance, and increased operating efficiencies, high-efficiency electronic ballasts should be included as an option for every new or retrofit magnetic job. At full power, a high-efficiency dimming electronic ballast allows a facility lighting designer to drop down in lamp wattage (between 50 and 200 less lamp watts per fixture than a comparable magnetic system). More importantly, controls allow the system watts and light level to be even lower and fixed until the lamp ages or the luminaire dirt depreciation necessitates increasing power to the lamp. The low-frequency "square wave" ballast cannot offer this advantage because it typically cannot dim the HID lamp.[4]

LIFE EXPECTANCY

The electronic ballast can last as long as a conventional core and coil type (magnetic). At least one type of electronic ballast has a thermal transfer system that avoids the double thermal gradient that is typical in magnetic ballasts.

Most electronic ballast components must first transfer the heat to the air medium then to the housing and again to another air interface (ambient environment). This will lead to an internal thermal gradient of 20°C or higher above the external housing temperature.

However, at least one type of electronic ballast uses a special thermally conductive epoxy to transfer the heat to the housing with a thermal gradient of only 5°C above the housing temperature. It provides many other advantages as well, including vibration and moisture resistance.[6]

IGNITION METHODS

There is a way to start the lamp that is less stressful than ANSI pulse ignition. The ignition methodology of type of one electronic ballast commits a minimum of energy during the beginning of the avalanche process while the work function is low.[8] The lamp is then quickly pushed into thermionic operation in a fraction of the time of the magnetic ballast.

The intermix of the DC offset component and high frequency (3× operating frequency) is optimal to achieve the fastest ignition with the least net energy dump at first break over. Here, timing is everything—push too much, too soon, or too little and it will have the same negative effects on lamp life as a conventional ballast ignition method. Important factors are:

1. Low energy dump at first avalanche
2. Controlled limited crest factor from the start
3. Good dynamic impedance matching

How does this ignition technique of Ballast "C" compare to that of other electronic ballasts? There is a strong similarity in ignition types—certainly they know what works here. However, Ballast "A" and Ballast "B" suffer a delay between first avalanche and thermionic operation. As seen in Fig. 2, the delay in both "A" and "B" holds the lamp in its glow phase much longer than does the methodology inherent in Ballast "C."

With a typical E-HID ballast, the lamp is in glow phase conduction for 1.03 s before the thermionic conduction mode begins. This delay leads to electrode sputtering, blackening of the arc tube envelope, and thus higher lumen depreciation. Lumen depreciation would be exacerbated in

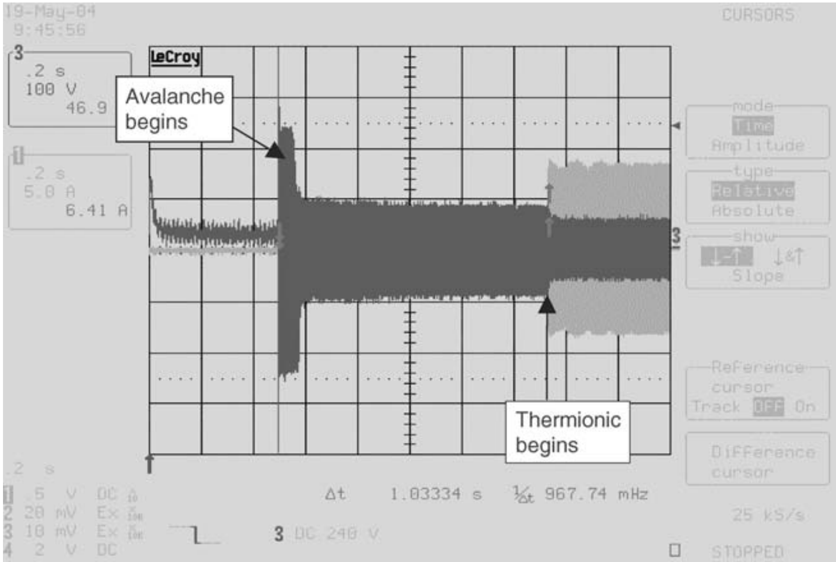

Fig. 2 Typical ballast "A" and "B" ignition @ 0.2 s. per section.

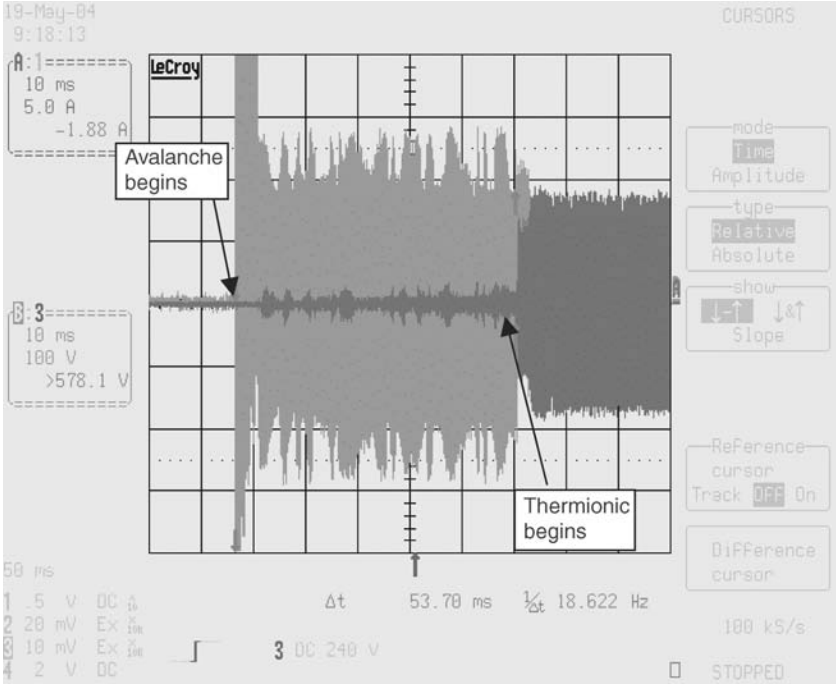

Fig. 3 Ballast "C" ignition @ 0.01 s per section.

applications where frequent on/off cycling is used for energy savings. Furthermore, a slow embedded microcontroller can also adversely affect lumen maintenance.

In Fig. 3, the glow to arc capture for the "C" ballast is 20 times faster than that of the "A" and "B" ballasts. Ballast "C's" glow to arc transition is 0.054 s compared to the "A" and "B" ballasts at 1.03 s each.

FULL-LIGHT OUTPUT

An electronic ballast with an optimized ignition, stabilization, operation, and dimming for HID will provide much better ramp-up/warm-up time while improving the lamp life.

The warm-up time for the "C" ballast is quicker when compared to the "A" and "B" ballasts. This ballast brings the lamp to an equilibrated condition in 30 s. However, the "A" ballast's final operating condition is still not attained at 100 s. It is important to note that this comparison is using the same lamp. Although the calculated current is lower (3.074 amps) for the "C" ballast as compared to Ballast "A" and Ballast "B" (3.192 amps), it comes to full power and light output faster. What's the secret? Better dynamic impedance matching.

MICROCONTROLLERS

Embedded systems have advantages in many applications. However, in HID applications, the lamp phenomena are far too fast and complex for low-cost embedded devices to optimally control. When one compares the time to glow-to-arc transition, the delayed response time of the "A" and "B" ballasts may be attributed to the microcontroller's lag in the acquisition of load data. The "C" ballast is a power supply designed to natively control the nonlinear lamp load and it is not a power supply that has been adapted by the application of external intelligence.

THERMAL CUT-OFF

The idea of a ballast that shuts down when the lamp goes bad sounds like a good idea, but the "C" ballast does not shut down. HID applications are typically critical ones and thus they require a ballast that can run continuously open-circuit without damage. Once a good lamp is placed in the socket, the ballast senses it and begins normal operations. The "A" and "B" ballasts have to shut down in order to save the ballast from damage.

SYSTEM EFFICACY

System efficacy is increased as the lamp is operated in a more ideal thermionic condition. However, this increase assumes that the power delivery does not have time variations in the delivered power to the lamp—something seen in the "A" and "B" ballasts.

When one compares the current and power envelope of the "A" ballast with that of the "C" ballast, the peak of the

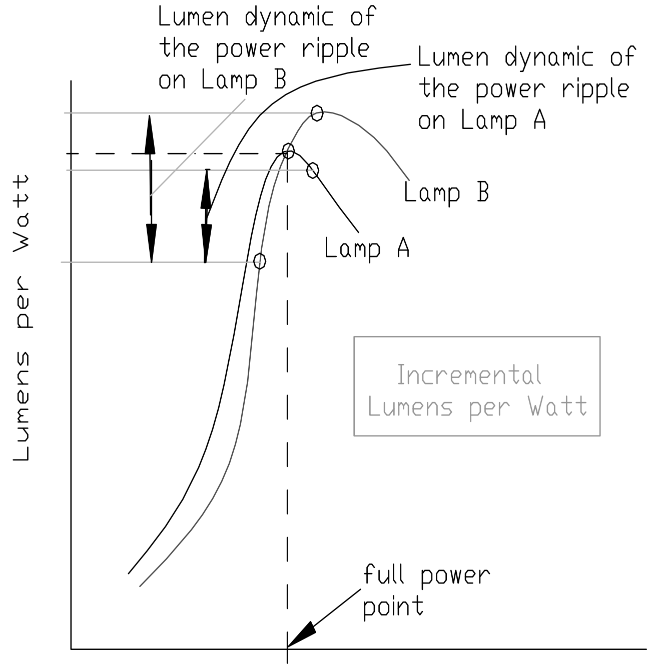

Fig. 4 Power dynamic chart.

power envelope is nearing 1.1 kW while the current peaks are 9+ amps. This methodology of using power pulsing will result in inconsistent performance that will vary depending on the lamp design. New high performance designed lamps, running near their peak LPW conditions, will be affected negatively. This can be better understood by examining the incremental LPW curve in Fig. 4 for two different lamp designs:

This figure shows the results of a power dynamic (change in LPW) analysis of the "C" ballast driving two different lamps. With existing E-HID ballasts (such as Ballasts "A," "B," and "D") the amount of light produced can vary unexpectedly from lamp to lamp. However, with the "C" ballast, there is a total lack of lumen output variation. The black dashed line is the "C" ballast imposed on the lamp curves A and B and yields identical light and LPW. Because the "C"-ballasted lamp has no power dynamic (change of power with time, as described above), a single line fully describes the lamp performance (on both lamps) as well as the expected outcome.

Thus, in the "A," "B," and "D" ballasts, the lumen outcome can vary due to the variation in the change in power over time. When we impose the power dynamic on lamp A, the peak of the RMS envelope exceeds the design point of the lamp. On this graph, the averaged level of the RMS power is still 400 W (on a 400-W lamp), although the peak may sometimes reach 700 W for a short interval. In this lamp, the maximum of the peak of the LPW curve was crossed during the power cycle.

After this peak point, increasing power produces less and less light for each watt increase in power. The net effect on the light output is a lower than expected performance. However, the outcome is very different if the lamp LPW curve peaks at a higher power level than the lamp's rating. Here, the outcome would be to produce more output than expected. The only remaining question is, at what cost? Effects of high power ripple are:

1. Inconsistent and unexpected lamp behavior by different lamp chemistries
2. Different X and Y color coordinates—color conformity dependant on lamp design
3. Different aging effects
4. Inferior lumen maintenance

ARE ALL BALLASTS CREATED EQUAL?

High frequency drives are not all the same at full power operation. There can be many unexpected problems if the ballast behaves in unusual ways.

When one compares one full high-frequency cycle of power delivered by the "A" and "B" ballasts, the energy transfer in the positive half-cycle is quantified at 2.014×10^3 J, while the power transfer in the negative half-cycle is 2.271×10^3 J. The result is a 13% difference in each half-cycle. If this phenomenon is allowed to continue, one electrode will increase in size due to a net transport of electrode material from the other electrode.

As a result of this mismatch in energy transfer from the positive to negative half, lamp performance will suffer

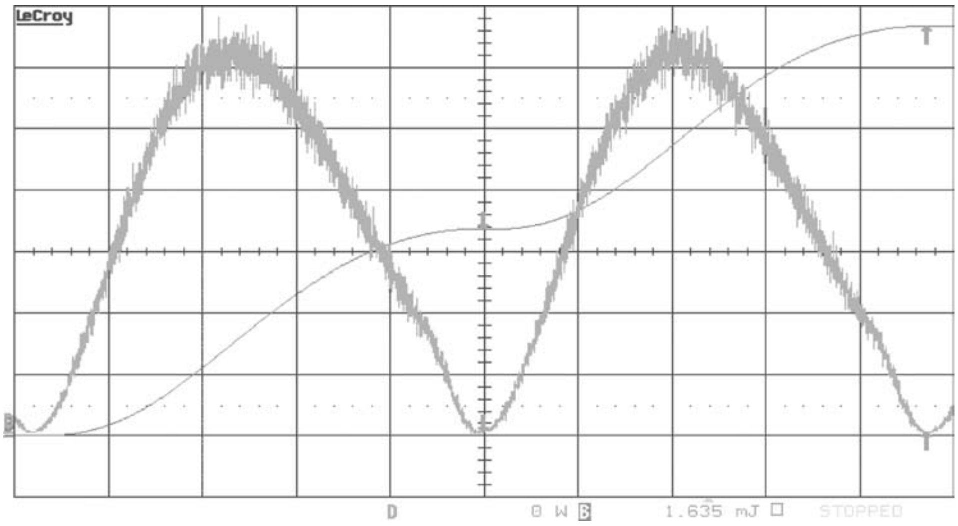

Fig. 5 Power cycle of "C" E-HID ballast.

over the lamp's thousands of hours of operation. An HID lamp operates at its best when there is uniformity and symmetry. Fig. 5 shows a positive and negative half-cycle on the "C" ballast that has mirror symmetry. This symmetry, in combination with the uniformity of the power envelope seen earlier, results in a lamp that will experience an ideal operating condition over its life.

LUMEN DEPRECIATION

As explained earlier, the "C" ballast appears to have been optimized to drive gas plasma loads while others have adapted existing power supply designs to operate lamps. The difference is a holistic system that interfaces with the lamp load during ignition, ramp-up, dimming, and full-power operation. Each one of these elements when precisely choreographed adds or subtracts from the life and performance of the HID lamp.

In Fig. 6, one can see the expected performance of the "C" ballast as compared to ballasts "A" and "B":

At the 8K-hour mark, a real divergence occurs. Ballasts "A" and "B" depreciated 16% at full power while the "C" ballast only depreciated 7.6% at full power. The low-frequency square-wave "D" ballast has an even greater variance than the electronic high-frequency "A" and "B"

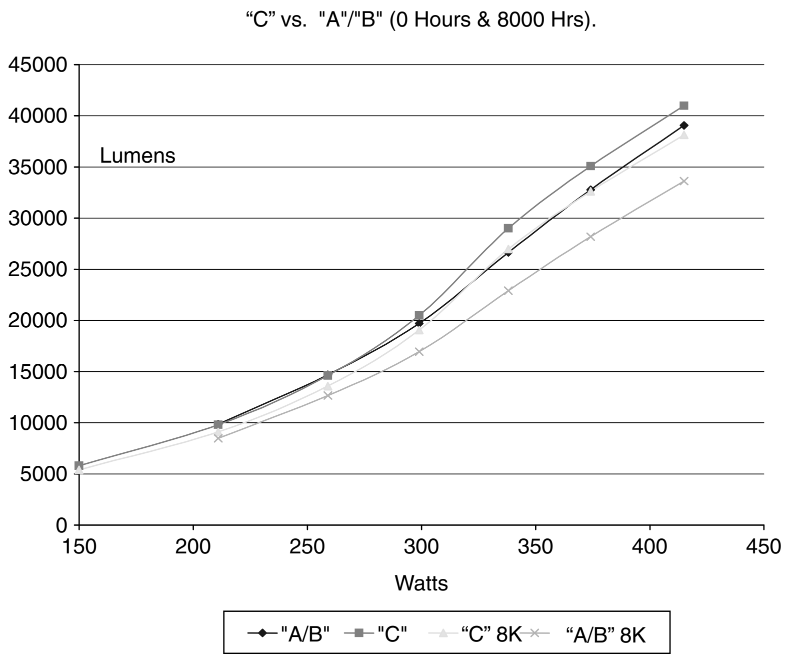

Fig. 6 "C" vs "A"/"B" (0 and 8000 h).

ballasts. The lower depreciation of the "C" ballast is a direct result of optimized operational conditions to reduce or eliminate the mechanisms that destroy the life and performance of HID light sources.

DIMMING LIMITS AND PERFORMANCE

Lamp manufacturers limit dimming to 50% in core-and-coil ballasts and "other electronic" ballasts. For the past decade, the Ballast "C" manufacturer has been working closely with major lamp manufacturers on certification, dimming warranties, and the research and development of new lamps. As a result, this ballast is the first electronic HID ballast to be warranted on both the PS and new ceramic lamp from Osram/Sylvania.

In addition, the "C" ballast is the only one that is warranted to dim to 35% of lamp power by the major HID lamp manufacturers.[6] Multiple lamp manufacturer warranties and an available mix of lamps and lamp types gives the designer options in lighting designs that are unmatched by any other ballast manufacturer. All other E-HID ballast manufacturers have single warranties and are permitted to dim only to 50%.

Also, electronic ballasts do not dim the same or have the same effect on the lamp. There are no standards when it comes to high-frequency dimming. However, there are good principals and practices that must be followed. Dimming has many design aspects that relate to both safety and customer satisfaction:

1. Dimming time should be controlled lest it stimulate the peripheral startle response. This would be dangerous to a machine/forklift operator who would then look to see what changed.
2. Dimming cannot be so slow that the end-user/owner cannot perceive a change. This is important for customer satisfaction and appreciation.
3. Dimming must ensure color uniformity in its transition over the lamp population.
4. Efficiency must be maintained when dimming to achieve and maintain energy savings.
5. Reduced power operation should not significantly degrade lamp color or lamp life.

All of the above design criteria are met in the "C" ballast design. The adaptive power control tracks the lamp throughout its transition through the plasma isotherms.

If the power supply is an adapted type, the dimming progress is achieved through a change-and-wait technique. This occurs when the dimming is artificially controlled for the worst-case lamp that may be experienced, because the dimming power control is not responsive. In other words, if one waits long enough with small transitions, negative resistance effects of the gas curves can be avoided and will never starve the lamp for voltage and extinguish. Ballasts "A" and "B" use this method.

It takes the "C" ballast about 10 s to achieve minimum power and about another five seconds to achieve minimum light. The dimming rate is below that which will stimulate the startle effect and fast enough to be perceived for use of manually operated controls.

Some studies have shown that dimming methodology can actually increase lumen maintenance. One caveat is freezer applications. At −20°C, care must be taken to avoid dimming so low that the freezer temperature has an appreciable effect on the lamp being cooled. This is a situation in which one will not want to dim to minimum power but rather regulate the light output at a predetermined level.

The way ballasts operate the lamp can lead to performance issues. The introduction of dimming electronic HID ballasts allows for a variety of control scenarios to further improve the efficacy of a lighting system and performance of an HID lamp.[11] The utilization of occupancy sensors, daylight harvesters, dimmers, and other energy management tools allows system watts and overall building lighting load to be reduced to as low as 35% of system watts. Table 1 provides the energy consumption (system watts) of the "C" E-HID ballast (full power/dim) as compared to a standard CWA ballasted system.

CONCLUSION

The intent of this entry was not to confuse anyone or to endorse any one manufacturer over another. The first intent was to point out the features, functions, and benefits of electronic HID.[12] The second intent was to show the differences among typical electronic ballasts that are on the market today. These differences are often vast, and just calling an E-HID ballast "electronic" can be misleading in

Table 1 System watts comparison chart between the "C" ballast and a CWA magnetic ballast

Electronic "C" ballast			CWA Ballast
Wattage/lamp: system watts (W)	**Full power (W)**	**Dim (W)**	**CWA (W)**
450	465	173	518
400	413	153	463
350	363	135	403
320	333	125	388
250	263	102	288
200	213	83	230
150	163	65	173

terms of actual performance characteristics as seen in this analysis.

Most consumers seeking a new car shop wisely and compare the features, functions, benefits, gas mileage, etc. before they make a decision. Why, then, should a lighting system end-user buy an E-HID ballast just because the label says "electronic"? As this discussion illustrates, there are significant differences between E-HID ballasts. What is on the inside is vastly more important than what it says on the outside.

HVAC Systems: Humid Climates

David MacPhaul
CH2M HILL, Gainesville, Florida, U.S.A.

Abstract
In humid climates, two of the functions of the heating, ventilation, and air conditioning (HVAC) system are essential—providing proper dehumidification and positive building pressurization—to prevent moisture problems. Although concepts for dehumidification are being discussed and taught to HVAC designers, the HVAC designer must always consider the impact of part-load conditions on the relative humidity levels in the building. The concepts for providing positive building pressurization are less well understood by the HVAC design community. Pressurization must be looked at in each pressure zone at the exterior of the building as well as from a whole-building perspective to ensure the success of the building.

Following a few simple rules when designing HVAC systems for humid climates can help prevent the catastrophic failures seen in such buildings as Florida's Martin and Polk county courthouses in the early 1990s. These buildings suffered rampant mold growth, complaining occupants, and escalating remediation costs because the HVAC system designers did not understand what is required to produce a successful building in a humid climate. Ultimately, the designers and contractors of these buildings were held liable for millions of dollars in remediation costs, which exceeded the original construction costs of the buildings.

INTRODUCTION

Following a few simple rules when designing heating, ventilating, and air conditioning (HVAC) systems for humid climates can help prevent the catastrophic failures seen in such buildings as Florida's Martin and Polk county courthouses in the early 1990s. These buildings suffered rampant mold growth, complaining occupants, and escalating remediation costs because the HVAC system designers did not understand what is required to produce a successful building in a humid climate. Ultimately, the designers and contractors of these buildings were held liable for millions of dollars in remediation costs, which exceeded the original construction costs of the buildings.

Understanding the Functions of the HVAC System

In any climate, the HVAC system designer must consider the four basic functions of the HVAC system:

- Comfort control (temperature, relative humidity, and air motion)
- Ventilation
- Contaminant control
- Pressurization

Keywords: HVAC; Humidity; Contaminant control; Pressurization.

By design, these functions overlap. Ventilation, for example, helps provide contaminant control and pressurization. In humid climates, two of these functions are essential—providing proper dehumidification (a component of comfort control) and positive pressurization—to prevent moisture problems.

DESIGNING FOR PROPER DEHUMIDIFICATION

Dehumidification, or removal of moisture from the supply air, is accomplished in most buildings by cooling the air below its dew point and condensing moisture from the air. In a typical building, the supply air is cooled to about 55°F at the air handling unit. When this air is provided to the occupied space and warmed to a room temperature of 74°F, the resulting relative humidity in the space is 55%–60%, which is comfortable for occupants and well below the 70% relative humidity threshold for mold growth. This process is illustrated in the psychrometric chart in Fig. 1.

Designing a system to handle both the latent (moisture) and sensible loads is taught to, but not necessarily well understood by, most HVAC system designers. However, much has been written recently to increase HVAC engineers' understanding of the problems typically associated with dehumidification in humid climates.[1] For example, discussed the problems that commonly used constant-volume air handling systems have with dehumidification in the Trane Co. *Engineer's Newsletter*.[4] In the *Dehumidification Handbook*,[3] Harriman describes the information HVAC system designers should know to

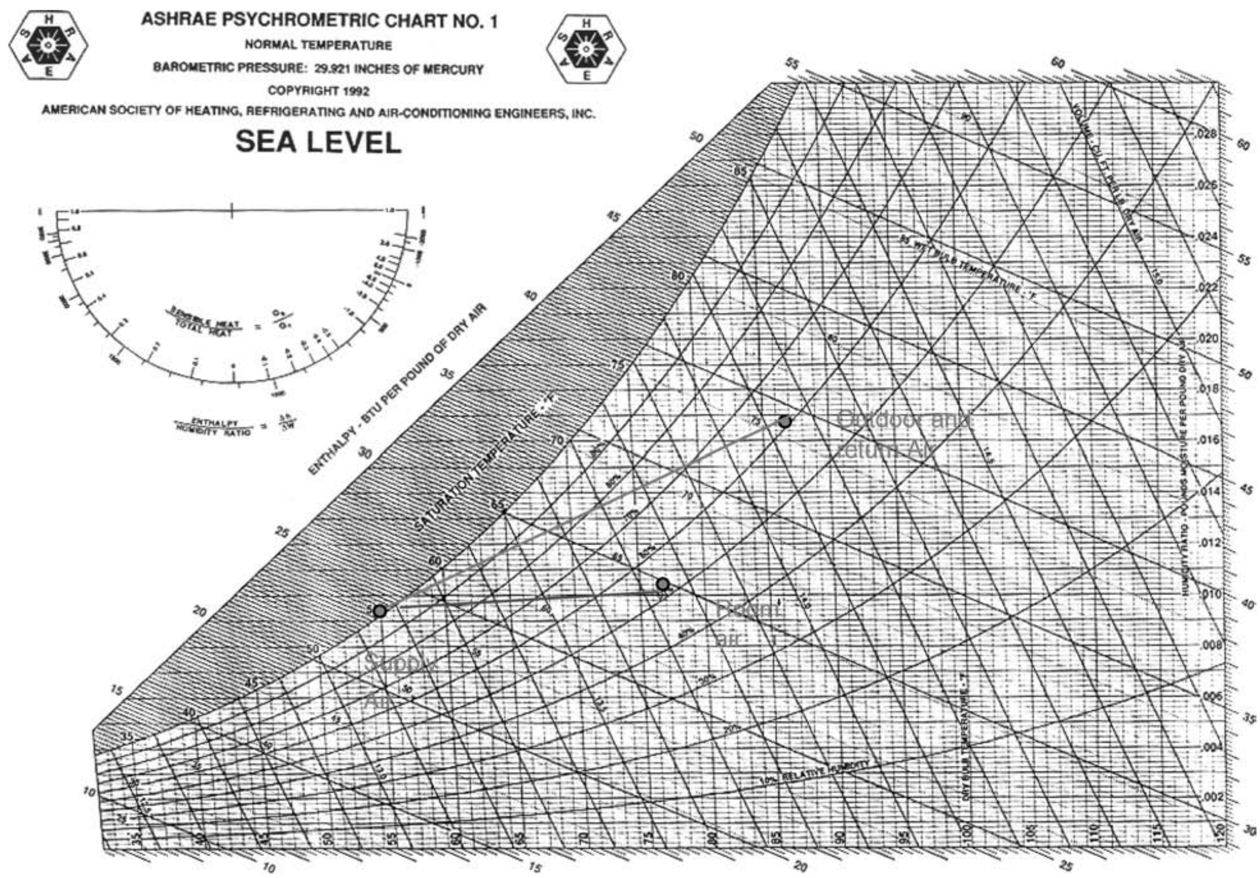

Fig. 1 A typical cooling process shown on the psychrometric chart.
Source: From ASHRAE (see Ref. 1).

prevent dehumidification problems in buildings. Dehumidification problems typically occur because these systems are controlled based on sensible loads, and under part-load conditions, moisture loads may be the largest cooling loads on the system.

CASE STUDY DEMONSTRATING POOR HUMIDITY CONTROL

Consider the vertical stacking fan-coil unit shown in Fig. 2. This type of unit is installed in thousands of hotel rooms throughout the world. In this case, the units were used in a hotel in Honolulu, Hawaii. The hotel owner was required to spend $5 million to remediate a $40 million addition within a year after construction.

As its name implies, a fan-coil unit consists of a supply fan and a cooling coil using chilled water to cool the supply air. As shown in the figure, the unit provides both cooling and ventilation, in this case bringing in 30 ft^3/min of outdoor air.

A simple wall-mounted thermostat controls the valve on the chilled water coil, opening and closing the valve in response to room cooling demands. This type of control responds only to room temperature, not humidity. Suppose that we set the thermostat to 74°F. When the room temperature is 73°F, the thermostat is satisfied even if the relative humidity in the room is 80%—well above the occupant comfort level of 60%. Therefore, the designer must be sure to prevent high relative humidity levels because the system does not actively control humidity; rather, it controls humidity passively as a byproduct of temperature control.

In Fig. 2, the system is providing cooling and removing moisture from the outdoor air. In Fig. 3, the thermostat is satisfied, and the outdoor air provided by the system is brought into the room unconditioned, containing large amounts of moisture. Depending on how long the unit is off, the room's relative humidity may exceed the 60% maximum for occupant comfort.

Fig. 4 shows the expected guest-room cooling loads, both sensible and latent, over the course of a typical day as determined by an off-the-shelf cooling load program typically used by HVAC system designers. Note that the sensible load varies by a factor of two, doubling from the early morning to the late afternoon. The latent cooling load, however, remains nearly constant throughout the day. The system designer must select a fan-coil unit with a cooling capacity at least equal to the worst case load expected. A fan-coil

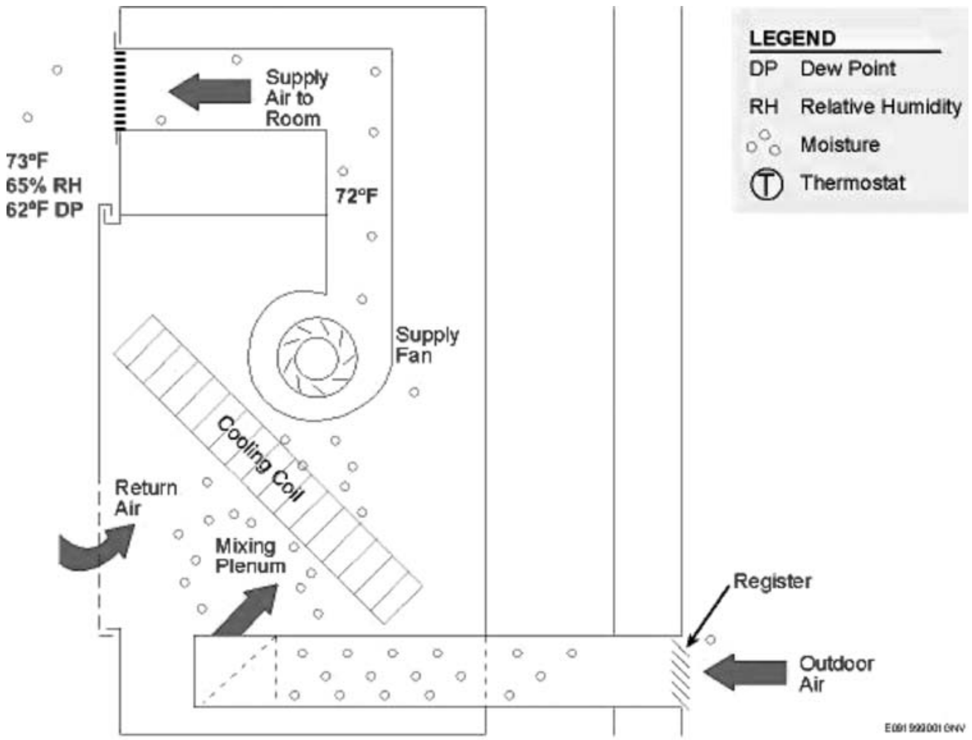

Fig. 3 The fan coil unit does not provide cooling or dehumidification when the thermostat is satisfied.

Heat–Inde

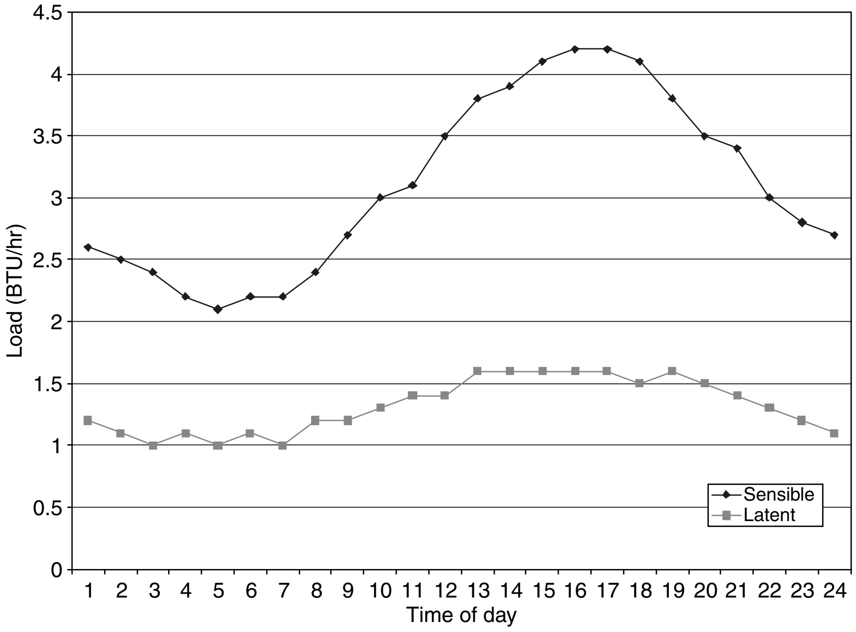

Fig. 4 Hourly cooling load requirements for a typical guest room, Honolulu, Hawaii.

unit with a capacity of approximately 6000 Btu/h is required to cool the room in the late afternoon. Unfortunately, the fan-coil units come in limited sizes, and the designer must select a unit with a higher capacity than needed—in this case, approximately 7500 Btu/h. The unit is oversize by approximately 25%.

To determine the run time (the amount of time the unit provides cooling) of the fan-coil unit for a typical guest room at the hotel, we can compare the sensible cooling required with the sensible cooling capacity of the fan-coil unit on an hourly basis. Fig. 5 shows that the run time ranges from 20 to 40 min/h over the course of a typical day in Honolulu.

In the early-morning hours, room cooling loads are low. The guest room still requires ventilation, and the outdoor air brought in through the fan-coil unit contains a high moisture load. However, the outdoor air is relatively cool—less than room temperature. In Honolulu at night, the outdoor air can actually provide a slight cooling effect even while bringing in large amounts of moisture. Based on the estimated run time of the fan-coil unit, we would expect difficulties controlling the relative humidity level in a guest room of the hotel.

To determine the actual relative humidity levels, data loggers were installed in the guest rooms to record the levels in the rooms over an extended period while guests occupied the room. Fig. 6 illustrates the relative humidity levels found in Room 544. In this room, the relative humidity ranges from 60% to more than 80%! The relative humidity cycles rapidly as the room thermostat opens and

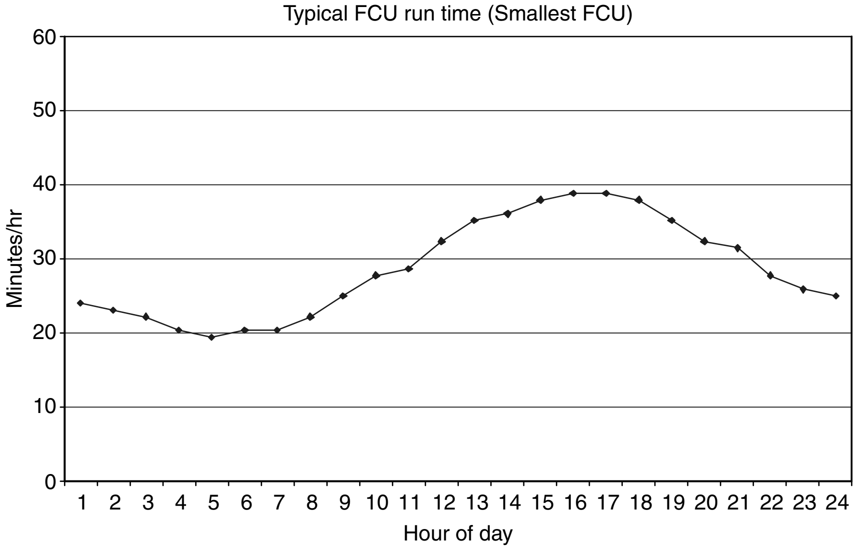

Fig. 5 Estimated fan coil unit run times for a typical guest room, Honolulu, Hawaii.

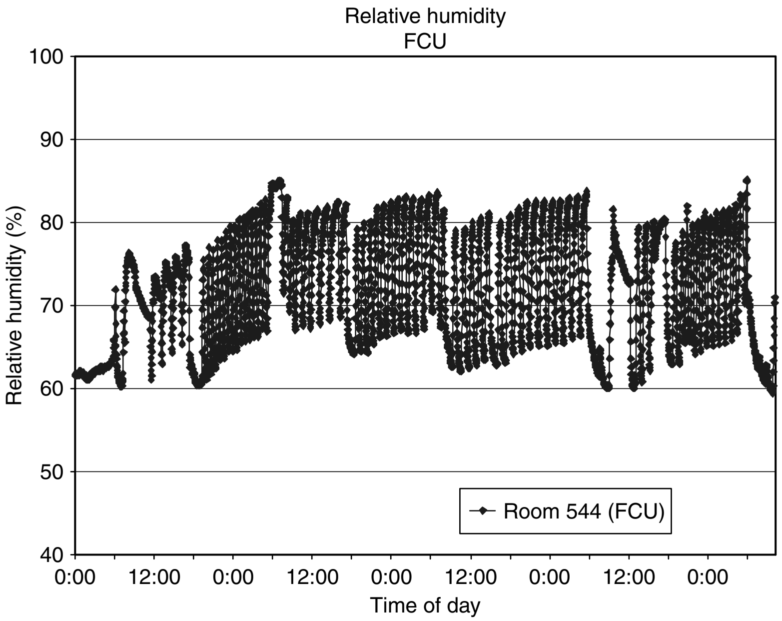

Fig. 6 Actual relative humidity levels in room 544, hotel, Honolulu, Hawaii.

closes the valve on the cooling coil. Needless to say, guests in these rooms found conditions very uncomfortable, and housekeeping staff spent additional time cleaning linens and drapes to remove mold growth caused by the high humidity levels.

In this case, the room's high relative humidity levels were entirely predictable. A simple comparison between the cooling load requirements (both sensible and latent) and the cooling capacity of the fan-coil unit immediately revealed that the unit would not run long enough to remove the required amounts of moisture from the air.

The remedy to this problem was relatively simple. A modified fan-coil unit, as shown in Fig. 7, was installed. In this fan-coil unit, the chilled water coil is separated into two parts. One portion continuously conditions the outside air; the other portion conditions the return air from the

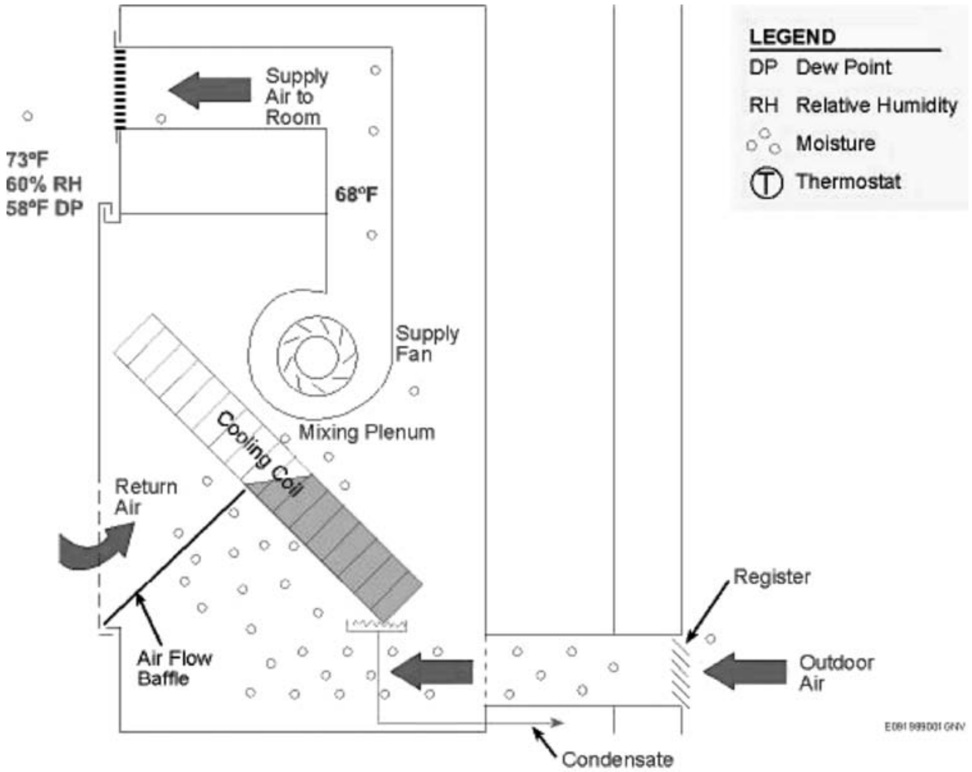

Fig. 7 Modified fan coil unit installed to provide humidity control, hotel, Honolulu, Hawaii.

room and is controlled by the thermostat. The coil itself is not physically separated; the piping providing chilled water is modified to provide the two parts of the coil. Separating the outside air from the return air separates the latent portion of the cooling (the outside air load) from the sensible portion of the cooling (the return air load from the room) and allows for proper humidity control in this small unit, even with the unit oversizing.

This fan-coil unit would have cost about an additional \$100 per room or approximately \$40,000 for the hotel if it had been installed as part of the original construction. Unfortunately, by the time the problem was corrected after construction, extensive remediation of mold growth was required, costing \$5 million.

DESIGNING FOR PROPER PRESSURIZATION

Pressurization in buildings is the second, yet equally important, key issue for producing successful buildings in humid climates. A building must be positively pressurized relative to the outside—that is, some conditioned air from inside the building must exfiltrate through the envelope to the outside. Unfortunately, the required methods for providing proper pressurization are not well understood among the HVAC design community.

Positive pressurization is normally achieved by providing more outdoor, or makeup, air to a building than is exhausted from the building. An HVAC designer typically provides 10%–15% more outdoor air to a building through the air handling units than is exhausted through restroom, kitchen, or laboratory exhaust systems.

Heating, ventilation, and air conditioning designers often treat the building as one large open vessel where air can move freely between zones, believing that the makeup air will go where it is needed in the building. Fig. 8 illustrates the common understanding of pressurization in buildings.

In reality, buildings do not function as open areas at all. Firewalls, floors, shafts, and other full-height walls create a series of pressure zones or vessels within a building. Depending on how the makeup air and exhaust air is distributed throughout the building, most buildings function similarly to the building shown in Fig. 9, containing both positively and negatively pressurized areas relative to the outside, and infiltration and exfiltration are rampant.

The Florida Solar Energy Center (FSEC), in *Uncontrolled Air Flow in Non-Residential Buildings*,[2] coined the term "the smart-air syndrome," describing the belief that air will go where it is needed rather than where it is distributed.

Areas that are positively pressured tend to exfiltrate excess outside air, and areas of negative pressurization have large amounts of infiltration. At best, this infiltration and exfiltration can cause a tremendous energy waste to cool and dehumidify the extra outside air. In the case of infiltration, when moist outside air comes into contact with

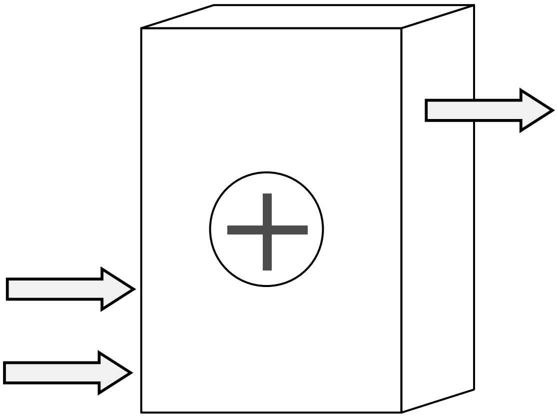

Fig. 8 The common understanding of building pressurization.

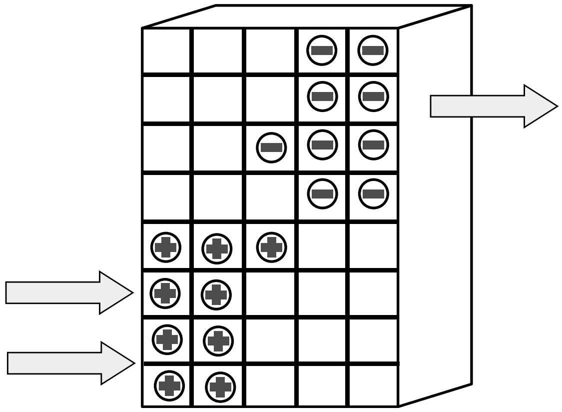

Fig. 9 The actual pressurization in most buildings.

cool building surfaces inside the wall cavity, condensation and moisture accumulation will occur. The amount of moisture accumulation can be quite large. The infiltration of 1 ft^3/min (cfm) of outdoor air in Orlando, Florida, can bring in nearly 20 gal of unwanted moisture per year. In its worst case, infiltration will create severe humidity problems, mold growth, and deterioration of building materials.

When designers refer to the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) *Handbook of Fundamentals*[1] about pressurization in humid climates, they find that it states, "Negative pressures of the indoor space should be avoided." For designers in humid climates, negative pressurization relative to the outside, with its resultant infiltration, must be prevented.

CASE STUDY DEMONSTRATING POOR PRESSURIZATION

The following case study of a hotel in south Florida illustrates what happens when the rules for proper

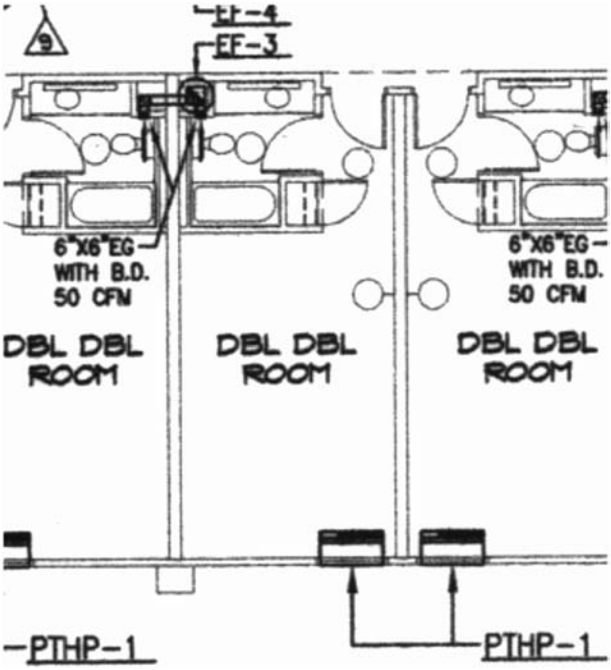

Fig. 10 The layout of the hotel HVAC system.

pressurization are not followed. Hotels are excellent examples because they contain a large number of pressure zones (each room in a hotel is surrounded by fire-rated full-height walls) and generally contain their HVAC systems within the room. In this case, a hotel began to suffer from mold growth, and odors were noted soon after construction was completed.

Fig. 10 shows the design of the hotel HVAC and exhaust systems. The guest room is served by a packaged terminal air conditioner (PTAC) installed in a sleeve through the outside wall. A continuous toilet exhaust fan serving a pair of rooms on each floor is located on the roof. The PTAC unit is scheduled to provide 70 cfm of outdoor air, and 50 cfm is exhausted through the bath fan.

Also, 25 cfm of makeup air per guest room is provided through the air handling system serving the corridor. This makeup air provided to the corridor is intended to serve as a safety factor. Assuming that at least half of the PTAC units would be in operation at any given time, 50 cfm of corridor makeup air would be available to transfer under the guest room door undercut into a guest room with the PTAC unit off, providing the makeup air required for the exhaust system.

To test the designer's assumption, after the hotel began to develop humidity and mold problems, we measured pressures relative to the outside in the guest room and corridor while sequentially shutting down the rooftop-mounted bath exhaust fans. Fig. 11 shows the pressures in the corridor and the guest room. The relative pressure is graphed against the ratio of corridor makeup air to exhaust air.

In this case, the corridor reached a neutral pressurization when the ratio of makeup air to exhaust air is 1.7. The guest room never reached a positive pressurization, even when the ratio of makeup air to exhaust air was nearly 3. Upon further examination, although the test-and-balance report indicated that the exhaust system was properly balanced, significant leakage of air into the exhaust ducts was occurring. Unfortunately, this problem is typical in many buildings. Even with the leakage, the final ratio of corridor makeup air to guest room exhaust air was above 2, and positive pressurization was not achieved as required.

In this case, the owner responded to the humidity problems as soon as they began occurring, and problems were limited through short-term corrective actions.

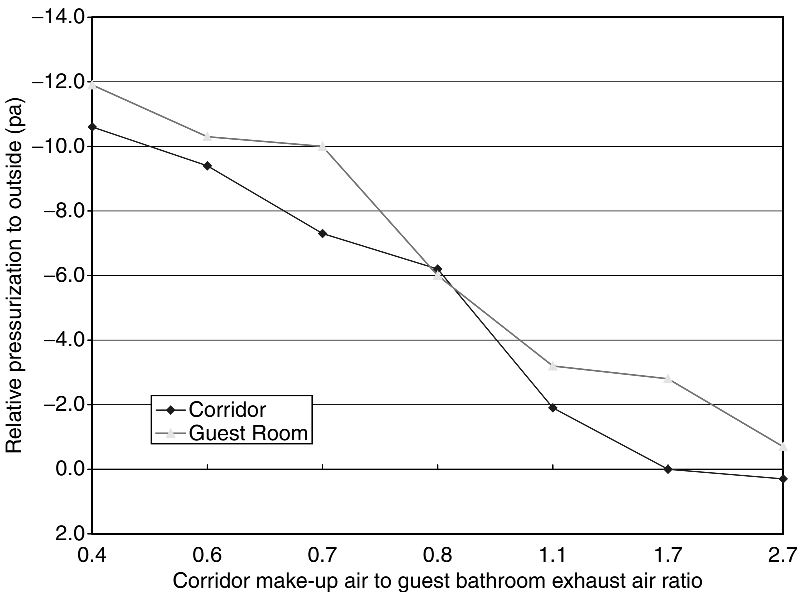

Fig. 11 Relative pressurization of the guest room and corridor.
Source: From CH2M HILL, Feburary 1, 2002.

Fig. 12 Mold growth caused by infiltration in a hotel room.

If the owner had waited to correct these problems, serious mold growth and damage could have occurred. Fig. 12 shows the result of waiting through one summer season before correcting the problems: large amounts of mold growth on the back side of the gypsum wallboard. This piece was removed from the partition wall between rooms approximately 4 ft from the perimeter wall. Extensive and costly remediation work was required at this hotel.

CONCLUSIONS

Providing proper dehumidification and maintaining positive pressurization in all zones of a building is critical to ensuring the success of the building in a humid climate. Although methods for dehumidification are being discussed and taught to HVAC designers, the designer must always consider the impact of part-load conditions on relative humidity levels. For designers, the concepts for providing positive building pressurization are less well understood. Pressurization must be looked at in each pressure zone at the exterior of the building as well as from a whole-building perspective to ensure the success of the building.

Hybrid-Electric Vehicles: Plug-In Configuration☆

Robert E. Uhrig
University of Tennessee, Knoxville, Tennessee, U.S.A.

Vernon P. Roan
University of Florida, Gainesville, Florida, U.S.A.

Abstract

The introduction of and wide-scale utilization of specifically designed plug-in hybrid vehicles has the potential to reduce the use of petroleum for the production of gasoline fuel by 50%–75%. Further, this can be accomplished without significantly degrading vehicle performance and operability compared to similar conventional automobiles and light truck vehicles (sport utility vehicles (SUVs), pickup trucks, minivans, panel trucks, etc.). The large-scale substitution of electricity produced by pollution-free power plants (nuclear, wind, solar, or renewable biofuels) for gasoline fuel could drastically reduce oil imports, balance-of-payment deficits, and tailpipe emissions. Whether the life-cycle cost of introducing plug-in hybrids on such a massive scale is balanced by the benefits is dependent upon factors beyond the scope of this analysis. However, intuitively, any large-scale reduction in the use of petroleum-based fuels would be expected to improve the energy security as well as the economic and political well-being of the United States. The plug-in hybrid vehicle approach discussed here is one of very few paths forward that appears feasible to begin implementation in the relatively near term with cumulative benefits as the technology penetrates the light vehicle market. The benefits and challenges of using hybrid automobiles to drastically reduce hydrocarbon fuel consumption are discussed below in both qualitative and quantitative terms with the view to show that the proposed approach is feasible, practical, compellingly rational, and thus worth immediate and serious consideration for implementation on a significant scale within a decade.

BACKGROUND

The hybrid vehicle is not a new concept. Hybrids were first conceived and constructed about 100 years ago. Even though they were demonstrated to be a viable concept technically, hybrid vehicles received relatively little attention until the late 1960s when they were considered by some to be a possible way of meeting the newly established emission reduction requirements for automobiles. Early research programs showed that vehicle tailpipe emissions could be dramatically reduced (even for nonplug-in designs) by using hybrid vehicles. However, the real stimulus for pursuing hybrids with an organized effort and significant funding came as a result of the petroleum embargo and resulting energy crisis of 1973–1974. Congress passed Public Law 94-413, the Electric and Hybrid Vehicle Research, Development, and Demonstration Act of 1976, which directed the newly established Department of Energy (DOE) to pursue, among other activities, the technologies associated with electric and hybrid vehicles. Through subsequent DOE funding, many studies were performed and many experimental components, systems, and vehicles were built and tested. However, even as these activities were underway, the energy crisis subsided simultaneously with automobile manufacturers making dramatic improvements in conventional vehicle fuel mileage and tailpipe emission. The introduction and widespread deployment of engine-controlling microprocessors along with continued improvements in exhaust after-treatment led to a near doubling of Environmental Protection Agency (EPA) fuel mileages and more than an order of magnitude reduction in exhaust emissions. As a result, there has been little corporate interest in pursuing the heavier, more fuel-efficient, less polluting, more complex, and more expensive hybrid vehicles. Even so, the considerable work that had been completed showed that hybrids could simultaneously improve fuel efficiency and greatly reduce tailpipe emissions compared to even the dramatically improved conventional vehicles. Consequently, DOE continued supporting some hybrid-oriented research activities as did the not-for-profit Electric Power Research Institute (EPRI) of the electric-utility industry. Electric Power Research Institute is one of the few organizations that has continued an extensive research program for hybrids, with special

emphasis on plug-in hybrid vehicles using batteries that are charged primarily with electricity generated by utilities.

WHAT MAKES HYBRID VEHICLES BOTH RESPONSIVE AND EFFICIENT?

The reason that hybrid vehicles can be designed to accelerate so well is that torque provides acceleration. Torque produced by a gasoline engine increases with engine speed from a low value at low rpm to a maximum (depending on the engine design) perhaps in the 3000–5000 rpm range, after which it falls off somewhat. However, in an electric motor of the type typically used in electric and hybrid vehicles, torque can be quite large, with maximum values occurring at zero rpm and remaining relatively constant during acceleration. Hence, in hybrids, the combination of an electric motor and a gasoline engine together can provide higher torque and better acceleration than would be available in comparable conventional vehicles of equal horsepower. This can occur even though the hybrids usually weigh more and have smaller gasoline engines than the conventional version of similar class vehicles.

The reason all hybrids are so fuel efficient is that the amount of fuel consumed per unit of energy output (specific fuel consumption—pounds or gallons per horsepower-hour) generally decreases with the power level until it reaches a minimum at 65%–85% of maximum power. Thus, a smaller engine running at the optimal percentage of its full power is more efficient and more economical for a given power than a larger, heavier gasoline engine operating at a lower percentage of its maximum power. Some hybrid vehicles also use continuously variable drives that are electronically controlled to operate the gasoline engine at its most efficient conditions over a wide speed range. Furthermore, regenerative braking is used on all types of hybrids. Regenerative braking uses electronic controls to temporarily switch the electric drive motor to an alternator (or generator). The resulting alternator then converts some of the kinetic energy of the decelerating vehicle to electrical energy and stores it in a battery for later use rather than converting it to wasted heat by friction between the brake discs and brake pads.

TYPES OF HYBRID-ELECTRIC VEHICLES

Historically, it was generally recognized that there were two primary power structures for hybrid vehicles—series hybrids and parallel hybrids. However, the evolution of microprocessors and power electronics—allowing virtually unlimited control of the engine and electric drive motor, simultaneously—has tended to blur this distinction. Today, four general types of hybrid-electric vehicles are commonly recognized: Fig. 1, micro hybrids (sometimes called start–stop hybrids); Fig. 2, mild hybrids; Fig. 3, full hybrids; and Fig. 4, plug-in hybrids. These have many common features and similar components, such as regenerative braking, gasoline or diesel engine, electric motor, alternator, battery pack, and central digital-control system. In the diagrams of the four types of hybrids, the size of the schematic representations of the primary components indicates their relative size. As we move from Figs. 1 to 4, the size of the electrical components become larger and their use increases, the gasoline engine becomes somewhat smaller, the performance (acceleration) typically increases, and the onboard fuel economy increases. However, larger electrical components are heavier, more complex, and more expensive. Furthermore, the decrease in the size of the gasoline engine is usually less than the increase in size of the electrical components because the engine must still have sufficient power for acceptable performance after the battery energy is depleted. For these reasons, hybrids can almost always out-accelerate conventional vehicles, especially at relatively low speeds. Drivers generally expect their automobiles to accelerate rapidly yet be economical, and hybrids can provide the desired combination of performance and economy.

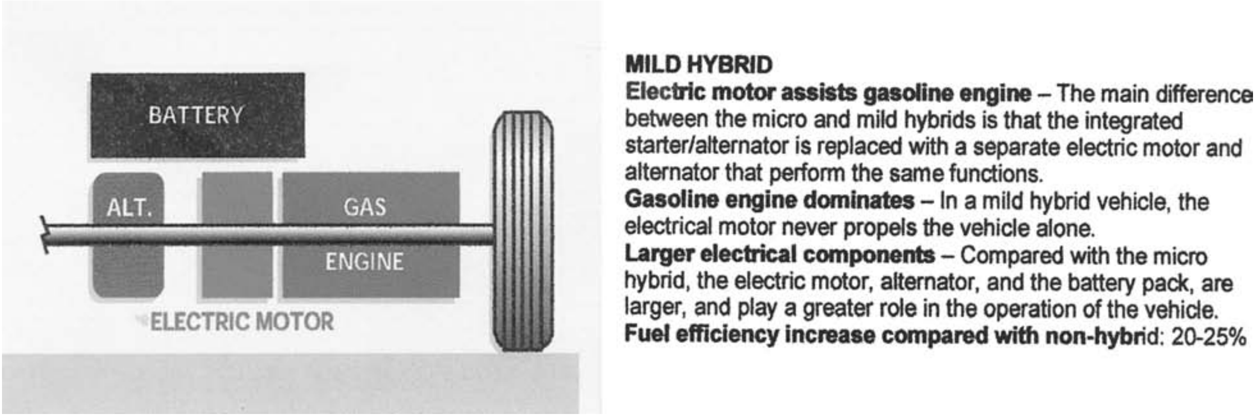

Fig. 2 Mild hybrid.

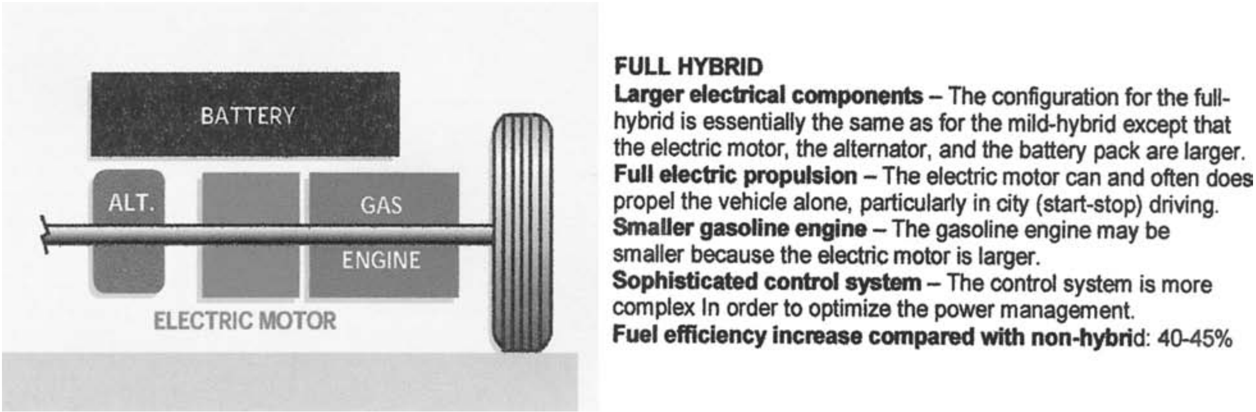

Fig. 3 Fully hybrid.

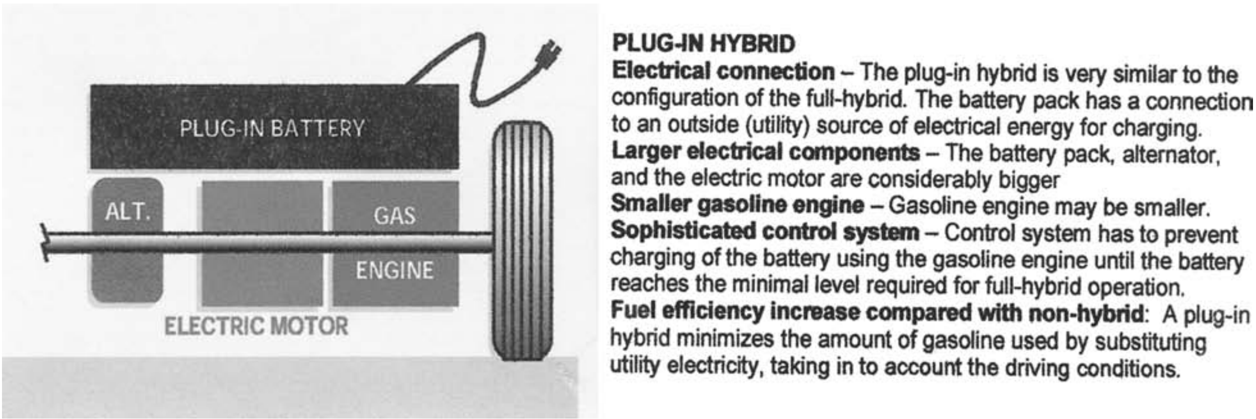

Fig. 4 Plug-in hybrid.

TODAY'S HYBRID VEHICLES

The first modern production hybrid-electric vehicle was introduced to the American public as the Toyota Prius, with the Honda Civic and Insight hybrids following close behind. The success of the Prius, as evident by the long waiting time for delivery, has convinced Toyota to schedule 100,000 Prius models for the U.S. market in 2005 and to introduce two additional hybrid models—the popular light SUV, the Highlander, and a premium SUV, the Lexus RX400h. Toyota and Honda have clearly established that there is a market for hybrid automobiles in the United States. The Prius and the new Ford Escape hybrid are full hybrids. The Civic and Insight models introduced in the late 1990s, the Honda Accord hybrid, and the Dodge RAM Diesel light-truck hybrid scheduled to be introduced in 2005 are mild hybrids. The Chevrolet Silverado and GMC Sierra are micro hybrids that are to be introduced in 2005.[1]

From the standpoints of fuel economy and tailpipe emissions, a somewhat counterproductive trend has appeared with some of the more recent hybrids. In contrast with the Prius that has a 1.5 l, I-4-cylinder 76-hp engine and provides EPA city/highway mileages of 60/51 mpg, the new Honda Accord and Toyota Highlander have 3.0 l, V-6-cylinder 255-hp and 3.3 l, V-6-cylinder, 268-hp gasoline engines, respectively, that provide EPA city/highway mileages of 30/37 and 32/27 mpg, respectively.[5] These large engines, enhanced by the high torque of the electric motors, can accelerate these vehicles from 0 to 60 MPH in 6.7 and 7.3 s, respectively compared to 10.0 s for the Prius (Vehicles with this kind of acceleration are generally considered "muscle" or "hot rod" vehicles, concepts totally inconsistent with the national need for reducing fuel consumption and oil imports). Current advertising for these vehicles emphasize "the high performance with the gas mileage of smaller cars." Assuming the need to reduce use of petroleum-based fuels, a more appropriate theme would be to emphasize "maintaining good performance with much higher fuel mileage." Realistically, however, even large numbers of optimally designed full hybrids will not solve our petroleum import problems.

Full hybrids significantly improve fuel mileage but tend to cost 10%–15% more than other hybrids and somewhat more relative to conventional vehicles. Independent testing by *Consumer Reports* indicates overall fuel mileages of 44 mpg for the Prius, 36 mpg for the comparable-sized Civic, and 51 mpg for the small two-seat Insight, all somewhat less than the EPA-mileage numbers on their window stickers.[1] While these gasoline mileage increases are impressive—typically 40%–45% for full hybrids, 20%–25% for mild hybrids, and 10% for micro hybrids—the differences are not sufficient to have a dramatic impact on the national consumption of petroleum-based fuels. However, a different mode of operation and some redesign of full-hybrids offers a possible means of saving much greater quantities of petroleum. The mode of operation is to utilize battery stored energy until it is nearly depleted without using the engine for recharging. The batteries would receive most or all of their recharging from grid electricity. The redesign involves a larger capacity battery, capable of providing an all-electric range of at least 35 mi. The redesign would also require a larger electric drive motor capable of providing adequate performance without utilizing the engine and an engine capable of providing adequate performance without the electric motor. The control strategy could still use both engine and electric motor for higher performance demands.

One manufacturer, DaimlerChrysler, in cooperation with EPRI, is testing the first of five "plug-in" hybrids (versions of their Dodge Sprinter vans) that are designed for the batteries to be charged by connecting to a grid-based electrical supply.[4] Two gasoline versions will be tested in California and a diesel version will be tested in Kansas.[2] As will be shown below, this approach, if implemented widely, could drastically reduce both fuel consumption and pollution emissions while reducing the cost of fuel for the average automobile owner. Perhaps most important, the widespread deployment of hybrid vehicles would not require changes in driver behavior nor would it require changes in fuel delivery infrastructure. As shown later, large scale use of the plug-in hybrid vehicles would require additional electric power plants and transmission/distribution facilities to deliver additional electrical power throughout the United States.[4]

U.S. LIGHT-VEHICLE TRANSPORTATION STATISTICS

Estimates based on extrapolated DOE–EIA data (unless otherwise indicated, data on U.S. vehicles are from the DOE Energy Information Administration's (EIA) statistics, available on the Internet) from the 1990s indicate that in 2004 there were 225 million light-transportation vehicles in the United States; 133 million were passenger automobiles and 92 million were light trucks (including SUVs, passenger minivans, pickup trucks, and delivery vans). It is further estimated by EIA that on any given day, on average, 50% of U.S. vehicles are driven less than 20 mi. Using these estimates, we can develop a simple model to calculate the potential saving of fuel by the use of hybrids operating in plug-in mode. The model assumes that only the electric motor, operating on batteries charged from electric-utility sources, is used to power a vehicle until the battery has discharged to about one-third of its full stored energy level (assumed to be 35 mi). Beyond that point, the gasoline or diesel engine and electric motor would operate together in the normal full-hybrid mode.

PLUG-IN MODE OF OPERATION

For purposes of this assessment, the standard automobiles and light truck vehicles are grouped and assumed to achieve an overall average of 20 mpg of gasoline or diesel fuel (DOE EIA data shows that in 2003, automobiles averaged 22.3 mpg and light trucks averaged 17.7 mpg; hence, 20 mpg is a reasonable weighted-average value). Let us assume that all of the above vehicles are hybrids capable of the plug-in mode of operation in about three decades i.e., 2035 (this assumption was made in order to evaluate the total potential savings of fuel associated with using hybrid vehicles operating in the plug-in mode. Fuel savings will be reduced in relation to the percent of light vehicles that are not plug-in hybrids). This mode involves charging the batteries of a hybrid overnight, using electricity from an electrical outlet typically in the owner's garage. We assume that when batteries are fully charged, these hybrids can operate using only the electric motor for at least the first 35 mi. For this type of operation, the controls of current full hybrids would need to be modified so as to not use the gasoline engine to recharge the batteries beyond the level necessary to sustain normal hybrid operation. The vehicles envisioned by the authors for plug-in operation are those manufactured by companies to today's standards equipped with normal features such as automatic transmission, air conditioning, and power steering. Hence, a larger electric motor and larger batteries probably would be required, which could possibly lead to the use of a smaller gasoline or diesel engine. Solid-state digital controls capable of optimizing performance and economy while minimizing the use of fuel should make the performance of these vehicles more than competitive with comparable standard vehicles.

MODEL USED TO CALCULATE FUEL SAVED BY PLUG-IN MODE OF OPERATION

The model assumes that each day, one-half of the 225 million light hybrid vehicles operate only for 15 mi on batteries alone while the other half operate on batteries alone for their first 35 mi and then automatically switch to normal full-hybrid mode, in which gasoline powers the vehicles for the remaining miles that day. This means that electrical energy provided to recharged batteries would fuel these vehicles for a grand total of 5.625 billion miles per day (supporting calculations for this and all other derived quantities are available upon request from the author at ruhrig@utk.edu). If the comparable standard (nonhybrid) light vehicles average 20 mpg, then the 225 million light vehicles would use 281 million gallons of fuel to travel 5.625 billion miles per day. Hence, it is theoretically possible (with 100% market penetration), based on this simple model, to replace 281 million gallons (6.7 million barrels) of fuel per day with electricity by using hybrid vehicles operating in the plug-in mode. This represents 74% of the estimated nine million barrels of oil per day now used to produce gasoline for standard automobiles and light truck-based vehicles. Tinkering with assumptions in the model will give slightly different numerical results but will not impact the overall conclusion that it is possible to save a large majority of the petroleum fuel used for light vehicles today through the wide-scale use of plug-in hybrid vehicles.

Recent graphical data attributed to EPRI and Daimler-Chrysler support this quantitative result.[4] Clearly, reductions in both imported oil for transportation fuels and vehicle-emitted atmospheric pollutants would be dramatic with widespread implementation of such full hybrids operating in the plug-in mode. However, realistically, some of the saved fuel would still be needed because in the minimum of three decades needed for full implementation, the number of vehicles and the number of miles driven per vehicle in the United States could increase significantly—perhaps 25%–50%.

FUEL-COST SAVINGS

At a price of $2.00 per gallon, the fuel cost is $0.10 per mile for standard light vehicles averaging 20 mpg. Because a gallon of gasoline contains 36.65 kWh of thermal energy, 1.833 kWh is used per mile. However, the efficiency of an internal combustion engine operating over a range of speeds plus energy losses in the transmission, drive, and tires results in an "overall average gasoline thermal energy to miles traveled efficiency" of about 20%. Hence, the mechanical energy expended at the pavement driving the vehicle is only about 0.37 kWh per mile. If the overall efficiency of the electric drive, including charger, batteries, motor, generator, and drive, is assumed to be 70%, the electrical energy purchased from the utility is about 0.52 kWh per mile. Because the proposed plug-in mode of operation would probably require larger batteries and a larger electric motor, adding several hundred pounds of weight to the vehicle, this value will be increased by 15% to 0.60 kWh per mile. At a price of $0.06 per kWh, the cost of electricity to drive a mile in a hybrid is only $0.036. On average, each vehicle would be driven by electricity 15 miles per day for half the year and 35 miles per day for the other half. Hence, each vehicle would be driven 9125 miles per year on electricity at a electricity cost of $328. Using gasoline at $0.10 per mile would cost $912 per year, so the "fuel" saving for the average hybrid vehicle would be $584 per year.

ELECTRICITY TAX IMPACT ON COST PER MILE

It is inevitable that if electricity becomes a significant source of energy for automotive and light-truck travel it will be taxed by an amount sufficient to recover the tax revenue lost on petroleum-based fuels by governmental authorities at the national, state, and local levels. If we assume that the total tax on these fuels is about $0.35 per gallon and the estimated total consumption of fuel is 103 billion gallons per year (281 million gallons per day), the total tax would be $36 billion per year. Using information provided earlier, the calculated total kWh of electricity consumed in the plug-in mode would be 1238 billion kWh per year. The equivalent tax is about $0.029 per kWh, thereby increasing the cost of electricity used on the road from $0.060 to $0.089 per kWh. Hence, the fuel cost per mile for the light-hybrid vehicles increases from $0.036 to

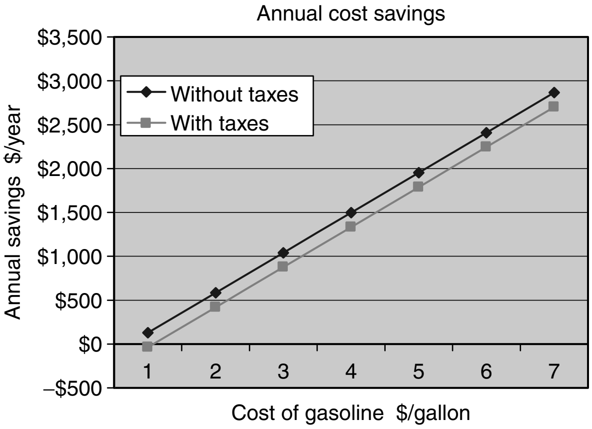

Fig. 5 Annual cost savings using hybrid vehicles.

$0.054 per mile, still little more than half the $0.10 per mile for standard vehicles using $2 per gallon gasoline. Adding this tax would increase the annual cost of electricity from $328 to $493, thereby decreasing the annual savings to $419.

The annual savings for gasoline at $2 per gallon are substantial, but they may not be large enough to justify the additional cost of a plug-in hybrid vehicle. However, if the cost of gasoline increases to $4 or $5 per gallon—prices that are common in Europe today and a realistic possibility in the United States if oil imports are not drastically reduced—the savings become much larger. These annual savings with and without taxes for gasoline prices ranging from $1 to $7 per gallon are shown in Fig. 5.

HOME ELECTRICAL SERVICE REQUIRED

Now let us look at the electrical supply aspects of this system. Light hybrid vehicles that travel 35 mi per day on electricity would use 21.1 kWh per day. If batteries are to be charged in 8 h at night using a 220-V system, the required capacity would be about 12 A. However, charging batteries requires more current initially, when the batteries are deeply discharged, so the peak currents could be double this value. While most modern homes with 200 A electrical service would probably have adequate spare capacity to provide 24 A at 220 V during the night, older homes might require additional electrical capacity. Furthermore, there would be need for plug-in facilities for car owners living in apartments and homes without garages.

ELECTRICAL GENERATION CAPACITY

Even though it is anticipated that battery charging would occur at night when we expect to have excess electrical generating capacity (an expectation that proves to be false), it is important to know the total electrical generating capacity required. Multiplying the 5.625×10^9 mi per day for all the light hybrids using electricity times the 0.603 kWh per mile results in 3.39 billion kWh per day. Charging the batteries in 8 h would require 424 million kWe or 424 GWe. This equals the output of 424 power plants of 1000 MWe size. Because the entire U.S. generating capacity today is about 850 GWe, it is clear that there would not be sufficient spare capacity available at night or any other time to charge the batteries of all the hybrids projected in 2035. Increasing the time for charging to 16 h (including the 3-h span of the three U.S. time zones) would cut the new generating capacity needed to 212 GWe. Hence, some 200 new 1000 MWe nuclear or other nonpolluting plants would have to be built to charge the batteries. New transmission and distribution lines and substations would also be needed to deliver the electrical power. Building 200 new 1000 MWe power plants and associated power delivery facilities in three decades would be a daunting task, but possibly feasible.

UTILITY ISSUES

Clearly, utilities have a key role in the implementation of the proposed plug-in hybrid electric-vehicle transportation system because they must generate and distribute the needed electrical energy. A study by Atomic Energy of Canada Limited[3] of the cost for electricity on the Alberta open market for 2002 showed an average price of $0.0293 per kWh with peaks as high as $0.600 per kWh. Further study showed that the price was less than $0.06 per kWh for 95% of the time and that the average price was $0.0224 per kWh. These prices would probably be lower in the United States, where about 80% of electricity is produced by coal, hydro, and nuclear energy. These competitive costs are low because the capital costs are ignored and the fuel costs for coal, hydro, and nuclear power are quite low. Such a situation is well suited for an interruptible supply mode of operation in which the utility could interrupt the supply of electricity to charge batteries for short time periods (not more than 5% of the time) in exchange for a reduced price for the customer. In most cases, the customer's additional cost, if any, would be the cost of a small amount of fuel. The utility would be relieved of meeting peak demands to recharge batteries when traditional peak utility loads such as air conditioning and heating are high. This means that a utility could delay adding additional generating capacity until its average load increases. It is a win–win situation because hybrid vehicle owners would get reduced electric rates that offset the costs of any extra fuel needed.

INCENTIVES FOR HYBRID VEHICLE OWNERS AND OTHERS

Current Internal Revenue Service (IRS) and some state regulations provide several tax incentives for buyers and operators of hybrid and electric vehicles. Given the large petroleum fuel and pollution reductions of the plug-in hybrids described above, additional incentives such as reduced or no taxes on electricity used to charge batteries at home would seem appropriate—at least in the early years of implementation. The federal government has a large vested interest in promoting any technology that drastically reduces the consumption of transportation fuels, thereby reducing importation of petroleum. Governmental agencies with fleets of light vehicles could be required to increase their percentage of plug-in hybrid electric vehicles on a progressive schedule during a phase-in period, thereby providing a market and incentive for manufacturers to develop and continuously improve plug-in hybrids.

PROBLEMS WITH IMPLEMENTATION

Current full-hybrid designs would require modifications for the proposed plug-in mode of operation for several reasons: (1) current hybrid vehicle electric motors are not powerful enough for satisfactory performance under battery power alone, (2) present hybrid vehicle batteries do not have sufficient capacity to provide the desired power and range for operation with only the electric motor, (3) larger electric motors and batteries will increase the cost and weight of a hybrid vehicle, (4) most batteries are designed for operation in a near fully charged condition and deeper discharge might harm them, (5) battery life (for current batteries) would almost surely be shortened under the proposed mode of operation, and (6) adequate power will be needed for desired accessories of today's light vehicles—air conditioning, automatic transmission, and power steering. These are engineering problems that may be a significant challenge to the manufacturers, but they do not appear insurmountable.

A human-factors issue to be addressed is connecting an electrical source to a vehicle every time it enters a garage or charging station. It is unlikely that a tired worker returning home from a long day at the office will give top priority to reconnecting the power cord to the vehicle. Hence, an automatic docking station that engages an electrical connection would undoubtedly be an desirable feature. Furthermore, an inductive coupling device that avoids mechanical contact would also seem to be a reasonable and appropriate feature of a docking station. Perhaps the biggest impediment to the proposed implementation of plug-in hybrids is time. It takes time to design and introduce even the relatively simple, but needed, changes in the current full hybrids. It takes time for people to accept the changes in operating hybrids compared to their current vehicles. It will a decade or more for a majority of the vehicles in the United States to be replaced. Higher sticker costs are impediments to purchasing new vehicles, even when life-cycle costs may actually be lower. The 30-year period used in this analysis for complete conversion may be unrealistic unless the cost of imported oil remains stable. Temporary reductions of imported oil prices in the past three decades have impeded relatively successful efforts to increase mileage, such as the CAFÉ (corporate average fuel economy) standards for automobiles.

CONCLUSIONS

Given the projected uncertainty in both cost and availability of petroleum, the possibility of replacing up to three-quarters (or even half) of the gasoline and diesel fuel needed for automobiles and light trucks in the United States with electricity by 2035 is extremely compelling. This proposed approach to reducing America's need for petrochemical fuel appears to be significantly simpler and could probably be accomplished sooner and much more inexpensively than any other approach presently under consideration. Indeed, it is probably the only technology that could be implemented quickly enough to have a significant near-term impact on oil imports—e.g., perhaps 10%–20% reduction within a decade relative to business-as-usual.

While the 30 years of the next three decades may seem like a long time, we are reminded that the 1973 Organization of Petroleum Exporting Countries (OPEC) oil embargo and subsequent energy crisis occurred more than 31 years ago and that little has been done since then to resolve the oil supply situation. Indeed, imports have doubled from about one-third to two-thirds of our total needs in this period. Unless the United States moves ahead decisively to reduce our use of petroleum by all practical and reasonably economic means, our importation of petroleum-based energy that is a critical driving force in our economy will be a far greater problem in 2035 than 2005. The use of hybrid vehicles operating in the plug-in mode is a rational and reasonable alternative that could be implemented in less time than almost any other alternative and it should be explored with deliberate speed. Nothing less than the economic well-being and security of the United States are at stake.

Independent Power Producers

Hemmat Safwat
Project Development Power and Desalination Plants, Consolidated Contractors International Company, Athens, Greece

Abstract
The historical evolution of the independent power producers (IPPs) is reviewed. The stakeholders of a typical IPP under a long-term power purchase structure are described. The roles of the various participants in a project of this type are summarized. The various stages of an IPP—from development to plant construction and plant operation—are described.

INTRODUCTION

An independent power producer (IPP) is a result of privatization and economy liberalization in infrastructure in various parts of the world that started in the early 1980s. Since that time, IPPs have taken various forms as the electricity markets evolved in various countries and regions. The evolutions are closely related to dynamics of structural/regulatory, economic/financial, technological, and environmental conditions. Thus, in planning and implementing an IPP, a multitude of considerations have to be thoroughly attended to.

Historical

Historically in the United States, utilities have operated under a regulated environment. Under this regime, a municipal, cooperative, or privately owned company had a monopoly on the supply of electricity to all customers in a specific region or area. Customers paid tariffs set by regulatory bodies that used review processes that essentially allowed the utilities to earn set returns above their reasonable costs. As a result of deregulation in several industries in the 1980s (e.g., the breakup of AT&T, the deregulation of the airlines, etc.), electricity regulation was criticized, and claims of large inefficiencies in the electricity industry were voiced. Various moves to encourage/introduce incentives for the nontraditional generation started to come about. For instance, in cogeneration plants where a producer in an industrial/agricultural setting could produce electricity, the utility serving the area where the producer built the plant would be obliged to buy the extra electricity that the producer generated under set rules. The trend expanded, and the small cogeneration plants got bigger and spread across the country, accompanied by changes in state laws. These led to the introduction of IPPs that would primarily generate electricity for sale as their main business.

An IPP is a nonutility power-generating entity that typically sells the power it generates to electric utilities or large users at wholesale prices. IPPs are unlikely to be franchised to distribute electricity or to own transmission lines for transmitting their generated power. The IPPs usually sell their power under a power purchase agreement (PPA) with the incumbent utility, the single purchaser, or large customers. It is common to see the PPA take the form of build own operate transfer (BOOT), which permits an investor to "build," "own," and "operate" the generation facilities and then "transfer" them to the host purchaser upon the termination of the contract. In fully restructured markets, IPPs may also operate on a purely commercial basis in which generators can offer their production in the daily wholesale energy markets. In either case, there is a tacit assumption that the IPPs are assured access to the transmission system on a nondiscriminatory basis.

The contribution of IPPs to the energy market can be huge. For example, IPPs owned and operated approximately 40% of U.S.-installed generating capacity in 2003.

It is noteworthy that in the U.S. context, the term IPP excludes qualifying facility (QF) from the definition. QFs are also nonutility power producers that meet certain operating, efficiency, and fuel-use standards set forth by the Federal Energy Regulatory Commission (FERC). They are relatively small power producers that use renewable and alternative energy resources like hydro, wind, solar, geothermal, municipal solid waste, or landfill gas to generate power. QFs, which may also include cogenerators, sell their output to the electric utilities, which must purchase this power at prices approved by the relevant state regulatory bodies. The price that the utilities pay is based on the cost that the utilities avoid by purchasing QF-produced power instead of generating or procuring it from third parties. These arrangements are governed by the Federal Public Utility Regulatory Policies Act (FPURPA) of 1978, which was enacted to stimulate the

Keywords: Independent power producer (IPP); Build own operate (BOO); Build own operate transfer (BOOT); Private power.

use of alternative and renewable energy sources in the generation of electric power.

Outside the United States, the liberalization of the economies of various countries led to a trend of shifting electric utilities from public (government) ownership to a private or mixed (government-private) ownership structure.

In the Middle East, because of the lack of water, the emergence of independent water and power producers (IWPPs) is noted. The IWPPs have grown to megaprojects involving large-capacity "power and seawater desalination."

It is noted that electricity service involves three basic elements: generation, transmission, and distribution. This section is concerned primarily with generation (i.e., the IPP is part of electricity generation). An IPP builds and operates a generation asset, and the electricity generated flows through other transmission/distribution systems owned/operated by others to reach the end consumers: bulk users such as large industries, industrial/commercial users, and households.

IPP PERSPECTIVE

From the perspective of an IPP, its interest starts in recognizing an opportunity to build a power plant or, in some cases, acquire a generation facility. The demand for the electricity to be produced is of paramount importance. This, coupled with the ability of the IPP to produce electricity at a competitive price while earning acceptable returns on its investments, all within a risk posture that is acceptable to those involved in the ownership of the enterprise, provides the impetus for starting a project. The perspective considers the various stages of the project, including the planning, the building of the facility, and the operating of the facility when it reaches commercial operation for the duration of the planned term or life of the facility.

In some instances, the opportunity starts from a competitive bidding process initiated by a government agency in a specific country. In other instances, directly negotiated arrangements are followed.

VARIATIONS IN IPPS

Two distinctive forms of IPPs are found—long-term power purchase (LTPP) and merchant (M) types—as well as mixes of the two types (LTPP+M). In the former, the IPP enters into an exclusive arrangement with an off taker who purchases all the electrical energy that the IPP produces. The two sides enter into a PPA that sets the obligations/rights of the two sides. Agreements in addition to the PPA involve other stakeholders beside the IPP and the off taker. This arrangement is generally followed where a single-buyer model is in effect and this single buyer is the off taker, as designated by law in the jurisdiction.

In the case of a merchant-type IPP—generally found in fully restructured markets—the IPP builds and operates a power plant that is dispatched or that is responding to market demand as it decides in accordance with economic merits of its own choice. In a mixed-type IPP (LTPP+M), the IPP commits to sell part of its production under a long-term arrangement, and with the other part, it exercises its own prerogative to generate or sell as market conditions meet its economic criteria.

THE IPP AND STAKEHOLDERS

An LTPP-type IPP is chosen for the purpose of introducing typical stakeholders associated with a project, referred hereafter as building a power plant and operating it for the duration "term."

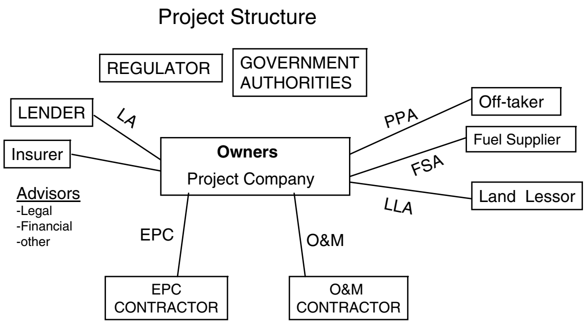
Fig. 1 depicts the stakeholders typically involved in the project. The figure also shows the agreements that are typically entered into for a LTPP.

Project

For the purposes of the discussions introduced hereafter, a project is defined as the execution of all the planned activities, starting from the idea of building a power plant to completing the plant, operating the plant, and selling the electricity generated from the plant.

The sections titled "Project Development", "Plant Construction", and "Plant Operation" provide further insights into the stages of the project.

As noted above, a number of agreements are completed for a project. These are referred to as the project agreements.



Project Agreements
PPA: Power Purchase Agreement, FSA: Fuel Supply Agreement, LLA: Land Lease Agreement
LA: Loan Agreement
EPC: Engineering, Procurement and Construction, O&M: Operation and Maintenance

Fig. 1 Stakeholders and project agreements.

Owner/Developer

The owner is the investor who will own the plant. Typically, the owner/investor invests in the form of equity as a portion of the total investment in the project. The other portion is a debt portion. The owner/investor may be a single entity, but typically the owner is a group of investors with different equity sharing. There also may be principal investors, together with investors with minority shares.

The developer is the manager of the effort to realize the project from its inception to (typically) the financial close, which triggers the start of construction of the facilities for the project.

Quite often, the principal investors act as the developer, though in some projects the developer may be a nonowner who acts independently until a certain stage in the development and then sells the work up to that point to a prospective owner; the developer may or may not continue to manage further the remaining development for the owner.

The owners form a project company that undertakes the project when necessary agreements among the various concerned stakeholders are completed and are in force, as applicable.

The project company is the special-purpose company that is formed by the owners/investors that undertake the project in accordance with the owners' shareholder agreement.

Off Taker

In a typical LTPP, the IPP enters into a long-term PPA in which the IPP is the seller of the electricity it generates in its facility and the off taker is the buyer of the electricity from the project company.

The PPA addresses the obligations and the rights of the two parties. Fig. 2 lists the key topics typically covered under the PPA.

Generally speaking, the owners/investors prepare the PPA and negotiate its terms on behalf of the project company (until it is formed) with the off taker. After the project company is formed, it becomes the responsible party as the seller of the electricity or the IPP.

Fuel Supplier

For a fossil plant, the owners/investors—and, upon financial close, the project company—enter as a buyer from a fuel supplier into a fuel supply agreement (FSA). For a LTPP, the items listed in Fig. 3 typically are addressed in the FSA.

Regulator and Governmental Authorities

Prior to the formation of the project company, the owners/investors and developer undertake all necessary steps to obtain all necessary permits, licenses, and consents from the government authorities in accordance with all applicable laws. They prepare and file the applications, and participate as needed in the presentations and reviews of the government bodies for these applications. When the permits/licenses/consents are granted, the project company acts in accordance with the specifics of the permit/license and takes steps to renew them in accordance with the conditions of the permit/license.

Environmental Agencies

The owners/investors initially and upon formation the project company have to attend to all of the requirements of the applicable laws and the related procedures, as dictated by the environmental agency. These relate to emissions, waste, and noise. The World Bank guidelines have emerged as the standard that is used in most countries, and these guidelines now serve as the generally accepted standard.

Lenders

Typically, nonrecourse financing is followed. Generally, the owners/investors contribute part of the total cost CAPEX (Capital Expenses) in the project, that is the investment, this could be of the order of 20%–30%, and hence the owners/investors raise the remainder through debt finance. Depending on how large the debt is, there may be a number of lenders, and there may be multiple debt tranches with different lenders and different conditions: term, interest rate, start of repayment, and fees. The lenders require a guarantee; hence, the project agreements are typically reviewed and will include appropriate clauses to protect the lenders' rights. The lenders request appropriate protection for their rights through the loan's life.

Advisers

In the various stages of the project, when the various stakeholders do not have the appropriate experiences in house, they engage advisers. These can be technical (e.g., engineering), environmental [for preparing or reviewing the environmental impact study (EIA)], or financial (including modeling and loan arrangers, legal, insurance, and tax advisers).

Contractors

Generally speaking, the project company deploys two main contractors: the engineering, procurement, and construction (EPC) contractors, and the operation and maintenance (O&M) contractors. The EPC contractor undertakes the execution of the project facilities per the EPC contract it enters into with the project company. Typically, the EPC contractor starts from site preparation. The EPC contract typically addresses the items covered in Fig. 4.

The project company deploys an O&M contractor, which handles the operation and maintenance of the plant upon its completion. Fig. 5 shows items typically covered under an O&M contract.

Payment Structure

Generally, an IPP entering into a PPA with an off taker under a LTPP scheme expects to get a reasonable return on its equity or an IRR (Internal Rate of Returns) for the project. Thus, the IPP weighs the expected revenue vs. the expenses through the life of the PPA or the term. The revenue side is established in the PPA and is generally broken into two types of charges: fixed charges and variable charges.

The fixed charges are in turn broken into two categories: capacity charge and O&M fixed charge. The capacity charge is meant to recover the capital costs initially invested in the project, including development costs, EPC costs, the

financing of the loans for the loans duration, and other applicable capitalization expenditures.

The fixed O&M charge relates to the fixed expenditures that the IPP encounters irrespective of how the plant was run (e.g., the cost of the O&M staff deployed to operate and maintain the plant on a continuous basis).

The capacity charge and the fixed O&M charge represent a payment stream that is paid by the off taker periodically (in most cases, monthly), provided that the IPP has what is termed declared capacity available for dispatch by the off taker. These charges are generally based on the declared capacity, in terms of kilowatt; thus,

the charge is specified in X \$/kW per month for the capacity charge and Y \$/kW per month for the fixed O&M charge.

On the other side, the variable charges—generally termed energy charges—relate to the net electrical energy taken by the off taker; thus, these charges are based on the electrical energy in kilowatt-hour per month.

These charges are broken into two types: fuel charges and O&M variable charges. The first charge relates to the costs of the fuel used to produce the electrical energy delivered by the IPP. The efficiency of the units in the plant, depending on the dispatch instruction subject to the technical specifications of the units, figures into the fuel consumption and, hence, the related compensation. The O&M variable charges are meant to address the expenses the IPP encounters as a result of running the units in the plant, such as the cost of consumables and maintenance related to wear and tear associated with the unit's operation. In some cases, the PPA takes the form of what is called an energy conversion agreement (ECA). Under such agreement, the off taker assumes the responsibility of the fuel. In this case, the fuel charges are not included in the off taker's payment.

The above payment structure gives the basic payment structure for a typical LTPP. In addition to the above, there may be ancillary payments/adjustments to account for, such as:

- Unit starts
- Shortfall in capacity/heat rate in tests compared with agreed specifications
- Shortfall in plant availability

In some PPAs, there may be allowances for bonuses if performance exceeds or falls short of the agreed-upon values.

For IPPs in countries other than the United States, the PPAs may use two components for these charges—one in U.S. dollars and another in the local currency.

Risks

The project agreements represent what the stakeholders have agreed upon in terms of the extent of the exposures that each party is willing to accept. The risk allocation for each project is quite complex. Exhibit 1 gives a simplified representation of the risk matrix from the perspective of the IPP and the off taker.

It is noted that the risk matrix takes into account the risks in each phase of the project (i.e., project development, plant construction, and plant operation). These phases are discussed in the following sections.

Referring to Exhibit 1, site conditions include but are not limited to archaeological material, buried objects, and soil characteristics. Environmental conditions include emissions, noise, and waste. Force majeure includes political and natural events.

As for the agreement on the tariff—i.e., the charges (referred to under the Payment Structure section above), escalation, and interest for delay in payment are generally agreed to.

Fuel-related risks—including quality, quantity, uninterrupted delivery, and backup fuel in the case of unavailability of the primary fuel—are of primary concern to the IPP. Fuel price is a major concern for the IPP.

In an international IPP setting, government guarantees are sought by the IPP for payments and other pertinent obligations for the off taker and the fuel supplier. In some instances, tax exemptions or holidays are offered by the host country. The currency exchange and local escalation are also addressed.

The lenders require many commitments to safeguard their interests until the loans are fully paid.

PROJECT DEVELOPMENT

For LTPP, the starting point may be a bid initiated by or on behalf of an off taker. Under such a case, the entity that wants to invite candidate bidders to undertake the project starts with steps to define the project and proceeds to qualify possible bidders and tenders the project. When the candidate bidders qualify and prepare their bids, they go through the development phases. This sequence is described below.

Project Definition

The entity that is undertaking the bidding on behalf of the off taker starts by evaluating the demand to establish the required capacity. It undertakes a feasibility study that compares options and alternative schemes for the project, including possible sites for the project. The feasibility study addresses the economics and the environmental impact. Based on the results of the feasibility study, the terms of reference for the project are prepared. These include the functional technical specifications. The site investigations are undertaken to complement the technical specifications. Then the request for proposal (RFP) is prepared, and the commercial conditions are spelled out. The RFP generally includes drafts for the project agreements. Further, the RFP addresses the evaluation criteria.

In parallel to the preparation of the RFP, the qualification of candidate bidders is completed.

When the RFP is issued to the qualified bidders, each of the candidate bidders initiates its development activities (refer to the next section).

Development Phases

The sponsors forming the group that is to bid for the project agree on the roles each group member is to undertake, and, on the sharing among them, this generally takes the form of a joint development agreement. The sharing of external costs for consultants retained by the group is addressed in this agreement.

The preparation of the bid in response to the RFP is the focus of the first phase of the development.

During this phase, the technical activities focus on the selection of the plant configuration and conclude with an EPC agreement with the EPC contractor.

The EPC agreement represents the basis on which the group bids in terms of the plant performance at site conditions and at different loads/dispatch. Technical considerations also cover the degradation in the performance with time. The technical considerations also extend to address the anticipated O&M. The technical data is then used as input to the financial model that the group formulates to simulate the finances of the project over the term.

The financial model is a key tool that the group uses to simulate the financing according to the equity sharing and the loan conditions. The financial model simulates the revenue streams and the expenses over the term of the project.

With the aid of the financial model, the group establishes the bidding tariff it is going to offer.

As part of the bid preparation, the group, with the aid of its advisers (consultants), establishes the loan agreements and the acceptable terms and conditions for its bid.

If the group's bid is selected, the second phase of the development proceeds. During this phase, negotiations of all the project agreements are completed, leading to initialing the project agreements.

In parallel, the group completes its negotiations with the EPC contractor and the O&M contractor. It also completes key steps with the lending institutions to reach agreement with the lenders for project financing.

With the initialization of the project agreements, the group completes the negotiation/finalization of the loan agreements and all necessary documentation to reach financial close. All activities to secure necessary permits and consents, including preparation of the EIA, are also completed.

In parallel, the group completes the formation of the project company. When financial close is reached, project implementation by the project company occurs as the IPP commences. Initial funding of the EPC contractor takes place; notice to proceed is given; and plant construction starts.

PLANT CONSTRUCTION

Upon financial close, the EPC contractor is given notice to proceed by the project company. The project execution commences. The EPC contractor proceeds with engineering. The project company may engage an owner's engineer to oversee the execution of the EPC contract. The EPC contractor submits a detailed schedule for the project. The various drawings and specifications are completed by the EPC contractor; they are reviewed and approved as applicable by the project company. Procurement of long-lead items is initiated, and site preparations get under way. Then construction proceeds with civil works, and the mechanical and electrical erection of equipment. Then comes commissioning. Finally, the testing, including reliability and performance tests, ends with the completion certificate. This marks the commercial operation date.

During this phase, meeting schedule milestones are monitored. Delay liquidated damages are effected as applicable, and everyone involved should avoid delays because of the economic and financial consequences. Equally important is meeting all performance guarantees specified in the EPC contract.

PLANT OPERATION

During the plant construction phase, the O&M contractor proceeds with various mobilization activities. These include hiring personnel; training; reviewing procedures and documentation; and receiving and storing spare parts, tools, consumables, etc.

From the start of commercial operation, the O&M staff takes charge of the operation and the maintenance. The operation means responding to the dispatch orders, monitoring, and reporting on plant performance. The maintenance includes the regular and planned maintenance, and responding to forced outages that may be encountered.

The O&M staff ensures conditions that attain maximum availability and optimum performance for the most economical operation under high reliability. The O&M staff also ensures the completion of all regular inspections and tests in accordance with operation manuals and the requirements of the project agreements. Ensuring the highest levels of safety and operating the plant in accordance with the environmental permits are essential. Testing for the verification of degradation also is performed per the PPA requirements.

CHANGING WORLD

Although the discussions presented in the previous sections give reasonable representation of many of the various aspects of the IPP world, the dynamics in world economy, and the oil and fuel markets, environmental concerns continue to affect the electricity industry.

Competitive forces in any market have major influence. The growth of major companies specializing in deregulated power generation and the entry of newcomers to the IPP world continue to be influenced by evaluating the individual opportunity and the risks involved. The expertise accrued and the previous experience/record enable adjustment to new conditions in a market the company is already in or a new market.

Changing regulations also has its impact. The perception of societies of deregulated power generation continues to be debated between advocates of privatization and proponents of public/regulated electricity.

Technology

The advances in gas turbine and combined cycle technology have propelled the growth of IPPs around the world, particularly with the increased use of natural gas to fuel many IPPs. Renewable IPPs are also gaining a larger share due to increased awareness of using cleaner power generation to protect the environment. As this trend continues to emerge, hydro and wind power are seeing steady growth.

CONCLUSIONS

In this entry, the history of how IPP came about was reviewed, and the stakeholders for a typical LTPP-IPP were presented. Through this discussion, the roles of the various participants were presented. Then the typical stages for an IPP project were discussed.

The discussions in the previous sections provide general information, yet this information should be a good basis to use in varied situations.

The IPP industry continues to grow with improvements in technology and the emergence of new technologies.

ACKNOWLEDGMENTS

The author wishes to acknowledge the very valuable information and knowledge acquired through participation in numerous IPPs/IWPPs while at Enron and since joining Consolidated Contractors International Company in 2001. Through extensive exposure to and interfacing with outstanding and experienced developers, advisers/consultants, original equipment manufacturers (OEM), and O&M principals as well as clients, the author has accumulated extensive experience. For the purpose of preparing this entry, the author opted to write it from this perspective rather than depending on citations. The author hopes that its contents will be useful to the reader, particularly to a novice interested in a comprehensive introduction to IPPs.

In the discussions of this entry, the author opted not to get into material that is covered in other sections of this encyclopedia. Further, the reader will find many sources of information on IPPs on the Internet.

The author also wishes to acknowledge the valuable input received from the reviewers of this entry.

Industrial Classification and Energy Efficiency☆

Asfaw Beyene
Department of Mechanical Engineering, San Diego State University, San Diego, California, U.S.A.

Abstract
In this article, energy consumption data for 300 manufacturing plants in Southern California are collected and analyzed by standard industrial classification (SIC) code. The results show that in order of magnitude, combined heat and power (CHP), variable speed drive (VSD), and compressed air systems offer the largest opportunities to reduce energy use in small and medium sized manufacturing plants. It also follows that the SIC is not a convenient tool to classify energy use, and in fact, to date there is no such convenient code to sort manufacturing plants by their energy intensity. The energy use profile cannot be systematically fitted to existing industry classification for the group of targeted plants. Opportunities and challenges related to capturing the potential energy savings in small and medium sized plants are also summarized.

BACKGROUND

The subjects of this article are data collected over several years through the Industrial Assessment Center (IAC) (The center is funded by the Office of Industrial Technology (OIT) in the U.S. Department of Energy (DOE), which is responsible for promoting and funding research for energy efficiency in industrial sectors.) at San Diego State University (SDSU) from 300 plants in 18 major standard industrial classification (SIC) (the North American Industrial Classification Standard (NAICS) has replaced the SIC code. Both classifications will be used in this article although most of the study was conducted for the latter) categories. It is believed that these data from diverse manufacturing plants can provide a generalized hint to better serve manufacturing and also develop better research strategies and funding policies. It can also be duplicated elsewhere as a useful measure to promote energy efficiency and link academia with industry. Although most energy efficiency strategies and technologies are applicable to manufacturing plants regardless of their sizes, there are issues unique to small and medium size plants such as those targeted by IACs that limit the abilities of these plants to identify and implement energy efficiency measures. This program is funded by the DOE to defeat these limitations.

Small and midsized plants are defined initially by the Organization for Economic Cooperation and Development (OECD), established on December 14, 1960, in Paris to promote sustainable economic growth. Members of OECD include Australia, Japan, U.S.A., Turkey, Canada, Greece, Iceland, New Zealand, and countries of Western Europe. The group formally associated sustainable growth with small and midsized plants and addressed the issue of charting industrial policy. The OECD committee addressed the diffusion of technology, and creation of new firms, supportive networks, financial incentives, and regulatory framework for target industries. Small and medium firms were recognized and encouraged as a component of sustainable growth. Department of Energy's support to such industry sectors stems from this early recognition of the role of these industry sectors in the larger scheme of economic growth.

ENERGY SAVING OPPORTUNITIES

Among the 300 plants analyzed, 19% are rubber and plastic manufacturing starting with SIC code of 30, whereas 15% are fabricated metal products starting with SIC code of 34. These two manufacturing groups, accounting for about one-thirds of the total, deal with some sort of molding process. The nature of the variable load in molding machines typically offers great opportunities for variable speed drive (VSD) application. Among the remaining plants surveyed by IAC/SDSU, electrical and electronic plants starting with SIC code of 36 comes third. Eleven percent of this group of plants was surveyed. Rubber and plastic plants are concentrated in Southern California as evidenced by the ratio of plants assessed, but the high number of metal manufacturing reflects more IAC's and DOE's emphasis on Industries Of the Future (IOF) (IOFs are defined by DOE, and the list can be viewed at DOE's web site.) in the late 1990s and early 2000s than the statistical concentration of the metal industry in Southern California. The plants analyzed here are mostly in the counties of San Diego, Orange,

Riverside, and Los Angeles. The NAICS code has been suggested to replace the SIC code (Table 1).

The combined electric consumption of the 300 surveyed plants was 1318 GWh/year 14% of the plants used no natural gas or used a negligible amount. A total of 1996 energy conservation opportunities (ECOs) were recommended, where 61% of the plants did not offer natural gas savings. The remaining 39% made a combined total gas savings of 16,101,416 therms/year The total savings are about $19 million for electric and about $8.5 million for natural gas, which results in about $27.5 million for both, about 20% of the total energy use. The payback period is calculated as the total implementation cost divided by the total annual cost savings. A summary of the energy use profiles and costs of the assessed plants are shown in Table 2.

Plotting the annual total cost of energy ($/year) of the 300 plants as a function of their recommended annual cost savings establishes a somewhat linear relationship between the two parameters; the higher the energy use the higher the gross savings (Fig. 1). The linear graph further shows that a plant may save about $0.28 for every dollar spent on conservation. The coefficient of variation, $R2=0.59$ suggests about 60% confidence in a linear relationship between energy cost and saving potentials. However, higher savings are accompanied with higher implementation cost. On the average, about $1.36 will be spent for every dollar savings. With $R2=0.449$, the relationship between energy saving ($/year) and implementation cost has about 45% confidence to have a linear relationship (Fig. 2). The most common recommendations for energy saving strategies are shown in Table 3.

Quantitatively, lighting retrofits (30%) and air leak repair (14%) constitute the top two energy saving opportunities. Heating, ventilating, and air conditioning (HVAC) (3%) and fuel switch from electric to natural gas (3%) are the least recommended (Fig. 3). Combined heat and power (CHP), although only 10% by quantity recommended, offers the largest cost savings at 56% total. Consequently, although CHP is not frequently recommended, it provides the largest cost and energy savings (Fig. 4).

Based on the analyzed data, CHP offers the largest opportunity for cost saving. Fuel switch offers the second largest cost savings but often comes at the cost of increased energy use. Fuel switch entails replacing

Table 2 Energy use summary of surveyed plants

Total electric use	1,318 GWh/year
Total cost of electric energy	$107,481,270/year
Total electric energy savings	307,784 MWh/year
Total electric cost savings	≈$19 million
Average electric use	4,438 MWh/year
Average electric energy savings	1,036 MWh/year
Total natural gas use	71,767,530 therms/year
Total cost of natural gas	$33,092,324/year
Total natural gas savings	16,101,416 therms/year
Total natural gas cost savings	≈$8.5 million
Average natural gas use	241,642 therms/year
Average natural gas savings	54,214 therms/year
Total energy (electric and gas) cost	$140,573,594/year
Total cost savings (electric and gas)	≈$27.5 million
Total implementation cost (electric and gas)	$45,802,482
Average payback period	18 months

electricity with natural gas burners where the technology allows. Switching the energy source is known to save large amounts in Southern California because of the high cost of electricity and demand charges. This may continue to be the case unless the price of natural gas rises sharply relative to the price of electricity. Variable speed drives offer the third largest energy saving opportunity. Nine of the 20 largest energy saving opportunities in all the survey are related to CHP, eight to VSD, and three to compressor systems. Thus, excluding fuel switch, the largest opportunities for energy savings can be summarized as:

- Waste heat recovery and CHP
- Variable speed drive in metal industry and other variable load applications
- Compressor systems
- Modernizing aging equipment.

Waste Heat Recovery and CHPs

Combined heat and power applications constitute qualitatively the single most prominent opportunity for industrial energy savings, mainly because properly designed CHP systems offer superior efficiencies, at times exceeding 80%. Combined heat and power is so rewarding because the source of energy is often waste heat, and there would often be no net emission addition at the site.[1]

Among the 300 plants discussed here, almost all savings amounting to one million or more kilowatt per year come from CHPs. The few exceptions are VSDs on injection and die-cast processes when the plant in question has several large machines. The CHP installation also includes incineration exhaust heat recovery.

In spite of such great opportunities emanating from use of available waste heat, and in spite of the fact that CHP enjoys some level of support through state incentives, its implementation has been slow, even for cases where the savings are large and the payback is short. The market has not yet developed the necessary confidence, mainly due to regulatory and technical challenges. The main support for

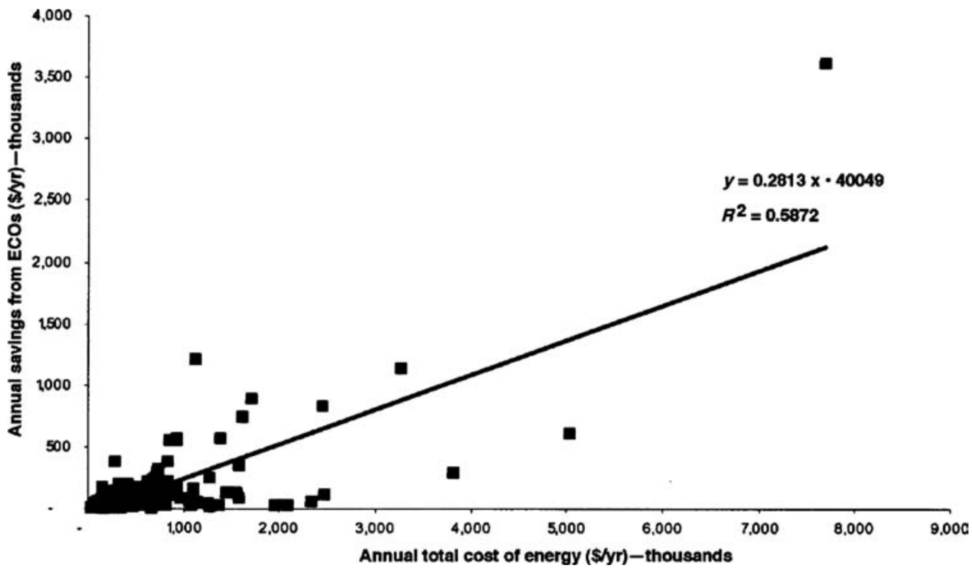

Fig. 1 Annual total cost of energy ($/year) vs their respective annual cost savings.

CHPs in the United States started in 1978 when the U.S. Public Utilities Regulatory Policy Act (PURPA) was formulated, allowing excess energy produced by CHPs to be sold back to the main grid. These guidelines gave impetus to increased use of CHPs, which until then was restricted by rules that favored a tight monopoly in the power market. According to Energy Information Agency (EIA), by 1996, the United States had an estimated 51 GW of installed CHP capacity, about 6% of the total U.S. electric generation.[2] But unresolved issues related to technical and connection standards remained, and the growth of CHP was hampered. As a result, the 6% still remains lower than that of Europe, which has 9% CHP, and much lower than that of Denmark, at 40%. Estimates of future growth of CHP in the United States have been inconsistent. According to EIA,[2] at most a 6 GW increase can be expected by 2010. A more recent report suggests up to 31 GW of CHP additions by 2010.[3] Other estimates of potential for additional CHP capacity by 2010 vary from as low as 7.1 GW to as high as 60 GW.[4] Despite this disagreement on estimated growth, there is consensus on at least doubling the current CHP output by 2010. This is also consistent with DOE's challenge made to the CHP industry to double the U.S. CHP generation capacity by 2010.[5] But the inconsistency also points to a lack of accurate market data, especially on smaller CHP units, and the inability to anticipate regulatory and policy trends.

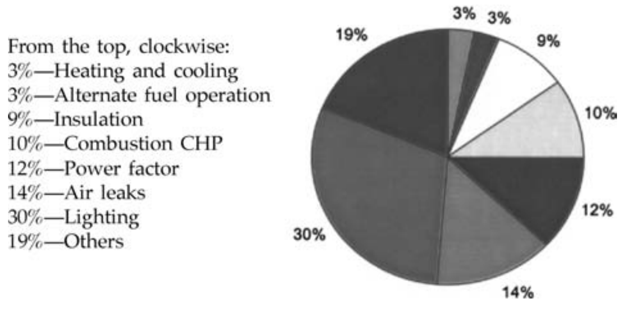

Fig. 3 Graphical representation of energy saving recommendations by category.

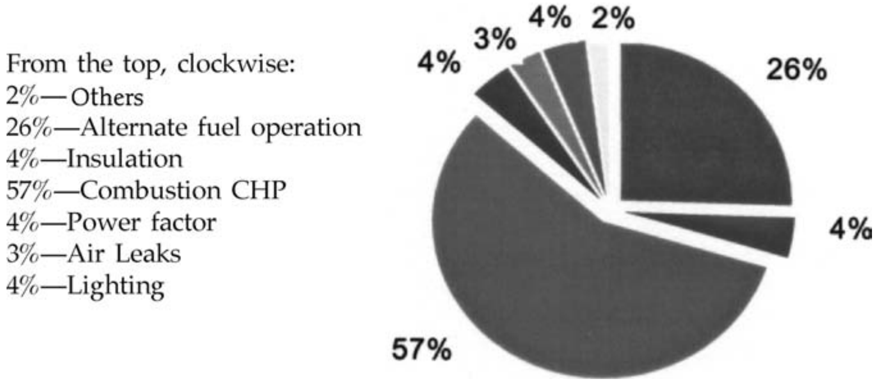

Fig. 4 Graphical representation of energy saving recommendations by cost savings.

Energy Information Agency conducts a survey of nonutility power generators on a yearly basis to collect data on CHPs exceeding 1 MW. Other data collected by DOE and independent research institutes are sporadic, fragmental, and limited in their outreach.

The most difficult regulatory hurdle is probably the new source review (NSR) and the prevention of significant deterioration (PSD), particularly in nonattainment areas, cities where pollutant levels exceed the national air quality standard. The NSR requires that facilities obtain a permit before beginning construction of a new facility or before significantly increasing emissions. In nonattainment areas, the installation of a new CHP, even if it is proven to reduce global emissions, may still be in violation of PSD. Outside nonattainment areas, new installation will mean new sources of emission, adding to existing emission levels, but the new sources would still be much lower than what would have been emitted from the electricity supplying power plant. Since electricity is usually distributed from central plants over long distances, a CHP may increase on-site emissions at the local level, and therefore trigger NSR even if it displaces emissions from the remote fossil fuel combustion power plant that supplies electricity to the facility. This means an overall reduction in emissions as a result of new CHP installation is not only ignored in assessing global pollutions, but locally it also triggers expensive and time-consuming regulatory processes. The lack of clear understanding of such complex rules has more often forced plant managers to take a safe route, which is to avoid facing regulatory bureaucracy by avoiding CHPs altogether.

Interconnection standards for back-up capacity from utility and off-site sale of excess electricity is locally regulated or left for negotiations, at times resulting in unfair market competition that suppresses CHPs. There is no single and simple stream of process to ease and simplify existing complex permit procedures well-discussed by Kolanowski.[6] Even systems with very high efficiencies have no blanket regulatory support.

In the United States, federal support for CHP has been increasing in recent years. One such major development is the 2004 report of the National Energy Policy Development (NEPD) Group. The group recommended that the president direct:

- The secretary of the treasury to work with congress to encourage increased energy efficiency through CHP projects by shortening the depreciation life for CHP projects or providing investment tax credits.
- The Environmental Protection Agency (EPA) to work with local and state governments to promote the use of well-designed CHP and other clean power generation at brownfields sites, consistent with the local communities' interests. Environmental Protection Agency will also work to clarify liability issues if they are raised at a particular site.
- The EPA administrator to promote CHP through flexibility in environmental permitting.
- The administrator of EPA to issue guidance to encourage the development of well-designed CHP units that are both highly efficient and have low emissions. The goal of this guidance would be to shorten the time needed to obtain each permit, provide certainty to industry by ensuring consistent implementation across the country, and encourage the use of these cleaner, more efficient technologies.

These recommendations have been praised for legitimately embracing the CHP technology. They are important steps towards rewarding high efficiency systems with investment credits, tax incentives, exemption from fees, shorter depreciation tax life, and blanket regulatory support. But critics also say they have not gone far enough to establish parallels between efficiency and pollution reduction by, for example, linking emission limits to the amount of net power output from the plants, not to the amount of fuel required to run a generating plant. In the current scenario, less efficient plants requiring more fuel input will be allowed more polluting emissions than efficient plants requiring less fuel for the same power output. However, there is a general consensus that the NEPD recommendations are necessary steps to advocate and promote the environmental benefits of CHPs. The impact of these recommendations on the overall progress of the CHP market and technology remains to be seen. To foster CHP, interconnection standards must be better regulated and a single and simple stream of process to ease and simplify existing complex permit procedures should be established.

VSD for Variable Load Applications

Synchronous motors are powered from a fixed-frequency electrical source, i.e., they turn at a fixed rounds per minute (RPM). If such machines always operated at full capacity there should be no reason to employ VSDs. However, they often run at part-loads, giving an opportunity to save energy with reduced speed when the load drops. This is possible due to advances in the electronics industry that now offer accurate and reliable breeds of new motor control devices. The a.c. inverter or VSD is placed between the motor and its power source to collect a signal indicating the load of the motor. The signal is then used to vary the frequency of a.c. electrical power to match the load, which results in power savings by running the motor at all part-load speeds without significant penalty to the efficiency.

Variable speed drives are commonly used in injection molding machines, HVAC systems, conveyers, packaging lines, and many other processes with variable load. For injection molding machines, research has shown that 20%–40% energy savings are possible. A field test conducted by the author in air-handler fan applications has also confirmed savings of the same magnitude.[7] The 30% range saving is generally applicable to cycling machines with similar intervals to injection machines. The idea is also valid for mixers with varying density and viscosity of the mixed medium, an application still requiring research. Mixing is common in paper and cellulose byproducts, chemical, and food industries. The amount of energy depends on such mixing characteristics as the density, viscosity, batch, composition, and required consistency of the final mix. This is also the case in paint mixing and liquid food processing such as ice cream and soup. Since one or more of characteristics of the mixture almost always varies in time, it is advisable to vary the input energy to match it to the load, and as a result, reduce energy use.

A large percentage of the mixing energy in these processes is dissipated as heat, usually requiring cooling of the mixing tank. This may require additional chilled water or tower cooling with pumps and fans, involving other lateral capital and maintenance costs. This means, in addition to energy savings anticipated as a result of the matched energy input to the actual variable load, VSDs have several other related applications. Reducing the input energy also means reducing the generated heat, and therefore, less energy load on the cooling system.

Advantages of VSDs can be more than simple savings, and may include reduced utility peak demand charges, a lessened space cooling load required to remove the energy dissipated in the form of heat, less noise, and reduced tear and wear problems on motors and other parts. The ability of digitally administering the RPM can also improve product quality by allowing more accurate control of the process. It can save time by better synchronizing the starting and ending time, and possibly even using the change in RPM at constant input power to signal the change in viscosity or other fluid properties.

Compressor Systems

Compressed air systems offer the third largest energy saving opportunity, but generally have the quickest payback period. In the United States, compressors alone use 18% of plant energy consumption.[8] Virtually all manufacturing plants assessed have compressors, and almost all compressed air systems had leaks. It can be argued that air leaks are the most common waste of energy in compressed air systems. In many cases, compressed air is supplied at much higher pressure to be throttled down to the required set point. Some plants need different levels of pressures in different parts of the plant, forcing the compressor to work for the highest pressure output needed by one or few machines. The following is a list of the most common sources of energy waste in compressed air system.

- Air leaks.
- Over-compression.
- Running the compressor when not needed, time-clocks to shut off at night and weekends.
- Expensive condenser cooling.
- Oversized compressors.
- Wrong application, such as using compressed air where blowers could do the job.
- Mismatch of process and compressor hours, for example, solenoid valve could be used to shut off compressed air supply from machines that need it only when operating.
- Cooler outside air intake.
- Use of compressor waste heat.

Measures that could reduce or eliminate energy waste in compressed air systems are typically less complicated and inexpensive. Air leaks can be repaired; compression can be reduced to match the site need, and in cases where the pressure demand varies, multiple compressors can be installed to isolate and serve the peak areas with dedicated compressors. Because of the prevalent use and associated presence of energy waste so common to air compressors, more serious regulatory and research attention to these systems would be productive.

Modernizing Outdated Equipment

The typical small or medium-sized plant has no in-house expertise for energy management. Such a plant, therefore, has to rely on expensive audits which can be biased if the vendors have a motive and market interest in their ideas. More aggressive training programs and workshops can help in technology awareness and transfer of efficient technologies to the manufacturing floor. More creative ways of distributing incentives to aggressively promote replacement of aging and inefficient equipment will also help small and medium sized manufacturing plants that often lack funding to modernize their plants. Low interest rate financing for proven technologies or concepts and promotion of not-for-profit institutes that promote efficiency will help build a good case for energy savings.

Visits to hundreds of manufacturing plants proved that equipment in old neighborhoods is also relatively old, especially noticeable in large and capital intensive blocks such as the metal industry, which are also relatively expensive to retrofit. The forging and casting industries are very energy intensive, with obsolete ovens and heat transfer control systems in most cases. This will be discussed, taking aluminum forging as an example.

Of the several process variables controlling closed-die aluminum forging deformation characteristics, die temperature is widely recognized as the most critical. For the majority of aluminum alloys forged, optimal die temperature for die lubricant performance and work-piece deformation characteristics is around 700°F. Consequently, on-press die heating is an essential thermal process for successful, cost efficient, and high quality aluminum forging manufacture. However, current on-press die heating systems are inefficient, with poor control systems. Process parameters, such as air–gas mixture and volumes are typically manually controlled. There is no research-driven knowledge base and understanding of the on-press die heating process. Most of the technologies currently in use, including burner, air–gas mixture systems, and controls, are over 30 years old.

Billet heating is the second largest energy user, as well as the second most important forging process variable controlling aluminum forging deformation. Required input billet temperatures are in the range of 700°F–850°F. Commonly, billet heating is accomplished by direct-fired natural gas conveyor ovens, which suffer from large thermal losses. Forging stock is charged in one end and exits the other through openings or open doors. Furnace and combustion systems have burner blowers with heat input ducted directly into the working zone.

Solution heat treatment (SHT) and aging thermal processes for aluminum alloy forgings impart the final mechanical properties at 890°F–995°F to achieve metallurgical objectives, and therefore, are very critical processes in the manufacturing flow. Because of the high-SHT temperatures, aluminum's affinity for hydrogen and rapid quench requirements, SHT furnaces are indirect fired (radiant tube), natural gas drop bottom batch furnaces. Required SHT practices for aluminum alloys necessitate precise control of the work piece temperature (±10°F or better) and time-at-temperature.

Artificial aging of aluminum alloys is a single- or multiple-step thermal process conducted at temperatures in the range of 200°F–400°F for times from 10 to 24 h Furnaces employed for artificial aging are car bottom, batch, and natural gas direct-fired aging types. Aging also requires precise control of the work piece temperature (±10°F or better) and time-at-temperature.

Sometimes dies are preheated prior to installation in the press in car bottom natural-gas fired ovens to temperatures of 600°F–800°F. The ovens are constantly opened, exposing the load to ambient temperature with attendant thermal losses. Research would help investigate the use of multicompartment ovens to reduce thermal losses. There remains a lack of fundamental understanding of the optimum and most efficient technology for die preheating that will support a large number of presses. A significant opportunity exists to effect reductions in energy use through capture of existing energy conservation or alternate heating technologies. Some of these energy saving opportunities include [9]:

- die and billet coatings to enhance heat transfer
- flat flame and/or rotary burner systems
- electric and/or gas infrared high energy flux heating systems
- state-of-the-art furnace burner and combustion systems
- high velocity recirculating air gas-fired furnace systems
- closed-loop and microprocessor control of thermal processes

Industry Classification and Energy Savings

To assess the relationship between energy consumption and industrial classification for small and medium sized plants, the following parameters were further calculated for each SIC code of the assessed plants:

- Gross annual sales ($/year).
- Number of employees.
- Electrical energy consumption (kilowatt per year).
- Gas usage (therms/year).
- Electric rates paid ($/kilowatt hour).
- Gas rates paid ($/therms).
- Energy conservation opportunities savings ($/year).
- Energy conservation opportunities implementation costs ($).
- Types of recommended energy saving opportunities.
- Energy savings (kilowatt hour and therms).
- List of energy consumed by services.
- Energy saving recommendations implemented.
- The total energy consumed per employee.

- The gross annual sales per plant annual energy consumption.
- The total annual sales per employee.

These values were calculated and graphed as a function of the SIC code. In addition, the last three values were plotted for four SIC codes of 3089, 3672, 3679, and 3728, which are the four most frequently surveyed plants by SDSU/IAC. The graphs showed that they vary drastically for each SIC group. Only a few plants have fairly consistent energy use per employee. Standard industrial classification 33 has somewhat consistent annual sales per energy use. Other plants have striking deviations suggesting gross variations in energy intensity even within the same SIC classification. For instance, the three parameters for 25 plants with SIC 3089 have gross annual sale/MMBtu (1 MMBtu = 0.293 MWh) varying from as low as about 500 to as high as about 4500.

All calculated values proved that the industry classification standards do not reflect the energy consumption, i.e., SIC and NAICS offer little hint to make pertinent conclusion regarding the energy consumption profile for any group of manufacturing plants defined by these codes. Graphs plotted with SIC codes on the *X*-axis and other relevant parameters such as kilowatt hour, cost savings, implementation cost, etc. on the *Y*-axis showed no readable uniformity per SIC or NAICS code and such graphs offered no unique features that can be generalized for each SIC or NAICS group. Thus, the SIC may be very useful for industry manufacturing classification by product output, but it does not mark or represent any energy use profile for the coded group in the manufacturing class. Even within one SIC group, the energy intensity is drastically different depending on the building type, equipment age, personnel awareness, utility incentives, regulatory codes, etc. For example, more SIC 3089 plants have been surveyed by SDSU/IAC than any other plant. These plants, however, have drastically different levels of energy and cost intensity for virtually the same product. Simply stated, no energy parameter is consistent per SIC, even for plants manufacturing the same final products. This can be explained by inconsistencies in management skills and tolerance to aging equipment of the manufacturing floor. Furthermore, the industry concentration in California and any other part of the U.S. is uneven, with some specific process types more concentrated than others.

The IAC data are not even by region and industry type, and this probably impacts the quality of the analyses. For example, miscellaneous plastics (SIC 30), fabricated metal products (SIC 34), and electrical–electronic equipment (SIC 36) constitute about one thirds of the plants surveyed. This ratio will certainly vary in other regions of California or the United States.

Heat recovery depends on process, not output classification. Processes such as melting, incineration, heat treating, heating, and drying often have high stack temperature, i.e., there is a possibility to recover large amounts of waste heat.

CHALLENGES

Industrial Assessment Center has extensive experience in recommending energy efficient devices and measures that save millions of kilowatt hour per year. Most, if not all, such recommendations are mature technologies that have been in the market for years. And yet, IAC reports are received as a promotion of new technologies and concepts. This is because of poor technology transfer, particularly in small and medium sized plants that do not have in-house expertise to adopt efficient and innovative energy management systems.

The relatively low price of electricity and the general industry understanding of energy expenses as a small part of the production agenda that has to be paid without much of a fuss has led to a general acceptance of energy costs as an essential expense, and efficiency as an extravagance to be thought of at times of energy crisis or diminishing profit. This is a serious problem to promoting energy efficiency. During the 2001 energy crisis, the IAC received several phone calls from industries looking for ways to reduce the cost of energy. The voluntary calls completely disappeared by the winter of the same year when talk of the crisis receded. During the crisis, reaction to IAC offers was almost immediate, much faster than later or during the years that preceded the crisis. The conclusion is obvious: a rising cost of energy critically narrows the profit margin to a level where energy cost becomes a serious matter. A 15% profit for a plant with $30 million total annual sales results in $450,000 in net profit. Paying $100,000/year for utility bills still would leave $350,000 profit. It can easily be seen why the plant cannot tolerate a doubling or tripling energy cost.

Industrial Assessment Center data suggest that unless an idea represents large cost savings of, say, over $100,000, industry reaction to ideas of payback in more than 2 years is cautiously enthusiastic or casual. Ideas that are commonly known, such as T-8 lighting, or ones with which the plant personnel are very familiar, have better chance of implementation. This explains why the implementation rate for great conservation opportunities such as CHPs offering millions of dollar savings is generally not as high as expected.

Lack of monitoring and recording energy consumption of individual processes is another major problem. For example, there is no tradition of kilowatt per ton monitoring of large chiller systems, which means ongoing energy efficiency of such systems, once installed, is not known. Few plants have consistent monitoring of air/fuel ratios for combustion, and air flow rates of high-temperature ovens have to be estimated from oven design capacity, since flow rates are rarely monitored. Without fairly accurate knowledge of the airflow rate, it is not possible, for example, to size the heat exchanger for heat recovery.

Another area of challenge is the complexity of control systems. For example, VSDs offer significant savings in areas where the load varies considerably, by matching the energy input to the load instead of supplying a constant amount of energy above the maximum point of the cycle. However, VSDs require thorough expertise in selecting the signal input to the device, protecting the system from disturbing signals, and also assuring a clean environment for its operation. This is overwhelming for most small and medium sized plants that have no on-site expertise. Variable speed drive vendors do offer expertise to install the VSD in most cases, but plant engineers in general tend to be uncomfortable using a device whose internal working mechanisms they don't understand and whose service is totally independent of their employees; i.e., production may be at the mercy of an external expertise who may not be available when called for.

Limited application of some energy saving devices is also a problem. This is true for lighting where, for example, reflectors and skylights may not be useful in a dusty manufacturing environment. Retrofitting 12-ft lamps with T-8 is almost always too expensive for buildings that are not lit for long hours. Caution must be taken when recommending VSDs to a very dusty and oily environment, unless the VSD can be placed in a suitable environment and a remote control system can be afforded. One common problem of energy use in industry is the selection of either the wrong device or the wrong size for the same job. An example is the use of compressed air as an agitator, as a blower, or for low-pressure control systems. These are all cases where a fan can be used. Plants also use large compressors for small operations during the weekends and third shifts even though the plant is mostly closed during these hours. A proper measure would be to purchase a small compressor for small operations and also to serve as a lead unit where only part of the manufacturing is running.

Implementation of CHP systems involves complex engineering and permit processes to account for the several variables impacting the system sizing and equipment selection. Such variables include the site energy use, demand charges, excess energy price, and steam need. To date, there has been an attempt to enlist detailed input data required for a typical CHP plant.[6] A CHP mathematical model has also been suggested to calculate investment returns.[10] A simple, free, web-based and user-friendly procedure to assist in feasibility analysis of CHP sizing and selection has also been developed.[11] However, there are still interconnection issues and regulatory obstacles to CHP implementation such as the NSR and the PSD, particularly in nonattainment areas. Under the NSR, facilities are required to obtain a permit before beginning construction of a new facility or significantly increasing emissions. This means overall reduction in emissions as a result of new CHP installation triggers expensive and time-consuming regulatory processes. Interconnection standards and existing complex permit procedures[6] remain as obstacles to CHP. The lack of clear understanding of such complex rules has more often forced plant managers to take a safe route, which is to avoid facing regulatory bureaucracy by avoiding CHPs altogether.

The parallel between efficiency and pollution reduction is not supported by the current U.S. emissions standards because emission limits are based on the amount of fuel required to run a generating plant, not on the amount of net power output from the plant. Less efficient plants requiring more fuel input will be allowed more polluting emissions than more efficient plants requiring less fuel for the same power output. A more equitable emission calculation equation rewarding high efficiency has been discussed.[11]

For lighting, replacing T-8 offers an opportunity to replace ballasts and insert reflectors which could cut as much as 50% of the light energy consumption. Reflectors may not offer large enough savings to be undertaken as a separate measure. The implementation cost is much more affordable if replacing bulbs, ballasts, and inserting reflectors are conducted all at once. Some plants stagger this process, ending up paying a high-implementation cost.

Other challenges include:

- Long payback period caused by short operating hours, resulting in low kilowatt hour.
- Unfavorable past experience with a new technology, such as harmonic feedback in VSDs.
- Lack of awareness and time, inability to reach decision makers in the plant.
- Inaccurate data reading resulting in exaggerated savings or undermined implementation cost.
- Lack of awareness about various opportunities, such as availability of incentives, existence of new technology.
- Sizing and purchasing errors resulting in hiring unqualified or inexperienced contractors.
- Code limitations such as the number of skylights on a roof.

CONCLUSION

The IAC experience suggests that there is a tremendous opportunity to recover the large amount of industrial waste heat lost through stacks and exhaust systems. Even low-grade heat, such as from compressor motor cooling, can be used for various applications such as space heating or sludge drying. Innovative technologies, such as oscillating combustion, control system, and new alternative energy sources can be promoted with energy efficiency, eliminating the need for new fossil-fuel power plants. Legislation can be designed to better serve energy efficiency by limiting maximum stack temperature. This will "force" industry to reclaim high-temperature waste heat and also eliminate the hazardous nature of such high temperature exhaust. More research on VSD applications in other areas can also expand its applications. Regulatory supports like emission credits for all documented energy savings or developing a methodology to assess and quantify the environmental impact of energy saving measures in terms of NO_x and CO_2 reductions can also be very useful to reduce the energy intensity of manufacturing plants.

The SIC classification may be useful to compare products and industry profiling; it is less than useful for energy analysis. This is because energy intensity is more a function of the process, not the industry type. Such industry process, for example, includes melting, heat-treating, forging, etc. These are energy intensive processes that may or may not be present in the given SIC code.

ACKNOWLEDGMENTS

The author greatly appreciates Department of Energy's Office of Industrial Technology for the several years of funding granted to the Industrial Assessment Center at San Diego State University. Great thanks also go to the California Energy Commission and Mr. Pramod Kulkarni specifically, for supporting the data analysis.

Industrial Energy Management: Global Trends

Cristián Cárdenas-Lailhacar
Department of Industrial and Systems Engineering, University of Florida, Gainesville, Florida, U.S.A.

Abstract
This entry details energy usage and savings in industry are areas of interest, particularly for large energy users. This interest becomes more important when the associated costs of energy rise at values larger than expected, making it a concern for all size and types of facilities. Therefore, the goal becomes to reduce energy costs while keeping or improving the quality of the manufactured goods, which is not an easy task.

In light of the energy and environmental problems that our industrial society is facing today, energy conservation and environmental protection through good energy management (EM) practices appear to be a natural path. Recently, great effort has been devoted to developing computational tools that can help energy managers save energy. In this regard, the U.S. Department of Energy (DOE) has devoted great efforts to developing a series of programs, such as the Best Practices program, the Federal Energy Management Program (FEMP), and the Industrial Assessment Center (IAC) program. Support for industries and federal facilities (like FEMP) and some software developed by the best practices (BP) and IAC programs are discussed here. Others have recently been created by the author and his collaborators. The use of these packages can greatly improve your chances of exploring common and new energy-saving opportunities. Numerical examples of their use are given, and their features are discussed.

Many publications based on case studies on energy efficiency, recommendations, new technology that consider reductions of energy consumption, electric regulatory issues, energy forecasting, and energy purchase exist. With all of this information, it is hard for industries to decide what steps to take or what strategy to follow. Saving energy while maintaining product quality will have a significant impact on their bottom line. In this framework, this entry will show current and new trends for energy savings, encompassing an energy assessment of the facility that cannot be conceived without an energy balance (EB) and its added value.

The importance of the consequences of energy efficiency and its environmental impact are discussed in this entry. Current procedures, techniques, and results through a case study, the introduction of the concept of energy descriptors (a mathematical representation of the energy consumption of equipment that are major energy users), which passes through an inevitable EB, are analyzed. We will show that there is a correlation between energy consumption and potential energy savings and implementation that is not only intuitive, but can be quantified.

In this entry, we discuss the energy–environment relationship from a global (worldwide) and local perspective in terms of its importance in the development of countries and personal welfare. As we move toward the local influence, we discuss these effects through a case study by reviewing the current energy usage patterns of a number of Florida citrus juice facilities.

INTRODUCTION

In today's energy-addicted world, the efficient use of energy, savings, and research on new fuels and their use is becoming a daily concern almost all over the world. As discussed in other entries, countries rich in nonrenewable energy resources today should administer them wisely, particularly those coming from fossil fuels. Nowadays, every country is affected by energy issues. Our industrialized world requires more and more energy every day, which, among its many consequences, means more environmental problems.

Keywords: Energy balance; Energy assessment; Energy and environment; Energy and development; Energy descriptors; Energy software; Energy analysis; Alternative fuels; Symbiotic energy.

At the governmental level, the responsibility for the way and fashion in which energy is generated and consumed is tremendous, particularly from the most industrialized countries. The provision of policies and regulations that should be in place as national energy management (EM) policies are of primary importance (rates, taxes, incentives, etc.). However, governments are not the only players in the energy efficiency and conservation endeavor.

Facilities (industries, buildings, commercials, etc.) that usually were not concerned about their energy consumption now pay close attention and dedicate time and effort to reduce it. In the United States, federal buildings are not exempt; Executive Order 13,123 mandates that by year 2005, energy consumption should be reduced by 20% as of that one consumed in 1990, and by 25% by 2010. In the chain of energy usage, energy savings are affecting our lives and our environment. Specifically, each time that energy (or water) is consumed, some fuel has been burned, and some pollutants are released into the atmosphere. These pollutants, whatever their origin and concentration, are moved around the globe through the atmosphere via jet streams that do not exclude any countries or people; rather, they affect the planet as a whole. For some years now, research has shown an increase in the amount of acid rain, and the effect of some pollutants in producing depletion (a hole) in the ozone layer, which protects us from being burned by ultraviolet rays coming from the sun. The increase in pollution can have catastrophic consequences, and it is a continuous threat to our presence on the planet.[1]

Saving energy has additional benefits. It certainly allows for economic competitiveness as production costs are reduced, along with the intensity in industrial energy. Moreover, energy efficiency allows for fuel independence by reducing oil imports, which, in turn, reduces our vulnerability to oil embargos. In addition, it reduces the negative balance of trade as imported oil bills are also reduced, directly affecting payment balances.

Although energy has to be consumed in order to produce the goods and services that we need, we can certainly imagine that facilities (manufacturing, buildings, hospitals, etc.) can continue their process with less, more efficient-energy consumption through the implementation of EM programs. This is the use of engineering and economic principles to control the cost of energy so as to provide needed services in buildings and industries and reduce energy costs and pollution. Among the rainbow of proactive facilities for energy savings, two extreme types can be considered, and they do exist, with the majority sitting in between. On one end is the somehow appealing choice for some companies to do nothing about it; their reasons are that they have no time (they are too busy), no qualified in-house personnel to undertake an energy program/audit, no funds available to hire the services of an external consultant, or that energy is a minor fraction of their operations cost, and, of course, the golden rule that "If it's not broken, then don't fix it!" The other end of the spectrum is represented by well-known companies around the world that have made tremendous changes in their energy consumption with teams of energy managers. 3M and Walt Disney World are just two examples.[2] These teams are constantly performing internal energy assessments that recommend and implement energy conservation opportunities, allowing them to continue manufacturing their goods and providing services with the same high quality, but optimum energy consumption; that is, they use their energy in the most efficient manner possible. This translates to resource savings that positively impact the bottom line of these companies. Needless to say, the savings obtained by implementing the ideas recommended by these EM teams have greatly exceeded their salaries (i.e., "Work smart, but not hard"). Unfortunately, this second type of facility is not very common; however, their example should be our ultimate goal. What we learn from this is that those facilities employing an energy engineer or manager certainly reduce their production costs and are more successful. We shall return to this topic in the next section.

The way to achieve this goal does not seem elementary, as much needs to be accomplished in new technology through research and development. Partnership between academia, the government, and facilities (industrial or federal) is very appealing. In this regard, the U.S. DOE has devoted an enormous amount of effort to help industries and federal buildings, as well to reduce energy consumption. The Office of Industrial Technologies (OIT)[3] and the Office of Energy Efficiency and Renewable Energy,[4] with programs like the Best Practices (BP) program, the IAC program, and the FEMP,[4] are examples of how the U.S. government is becoming more and more a partner in energy conservation.

A case study will be presented in this entry to show current energy (heat and power) usage patterns' associated costs, energy indicators, and previously recommended energy savings measures. We propose a set of energy savings measures outlining some energy indicator values and benchmarks, which will reduce production costs ($/unit). Finally, key energy end uses and innovations are explored.

In the upcoming sections, we also discuss the effect of energy use on the environment and development of affected countries and their industries. Within this framework, we will discuss the importance of an EM program from the financial standpoint. This will be discussed in more detail through the use of an industrial case study, where we address current and new trends in energy auditing. Later, we discuss the use of current and newly developed software, and address alternative sources of energy in a symbiotic fashion. Finally, we draw some conclusions regarding the importance of energy savings and environmental conservation.

ENERGY, ENVIRONMENT, AND DEVELOPMENT

Per our previous discussion, it is easy to see that hiring an energy manager will probably not happen in many industries unless required by law. In other words, there are a few countries whose governments have understood the importance of energy consumption efficiency and reduction, and that this is not a government problem only, but everyone's problem. Hence, they require that, by law, every facility that manufactures a product must have an energy engineer/manager in the plant as part of their permanent staff. An example is Japan, whose manufacturing industry has reached impressive international levels of excellence.

Some countries in Latin America and the Caribbean, like Chile, are taking similar steps through their national energy agencies, as is their Comision Nacional de Energia (CNE), and its Ministry of Energy and Mines, which promotes energy savings and incentives to install cogeneration systems, for example. The same is true for Colombia. Other nations in this region, like Ecuador, promote energy research and offer companies the option of donating 25% of their taxes on power to institutions (including educational and research institutions), with obvious beneficial consequences. Peru offers tax reduction incentives for international companies that want to establish operations in the country, etc. At a local level, in states like Florida, for example, there are tax incentive programs for discounts on up to 100% of taxes paid on electricity.[5] All of these incentives have tremendous impacts on the economy of local industry and the country itself.

The economic costs associated with implementing environmental protection ranges from the conclusions drawn by scholars such as Porter,[6] who believe that environmental standards will increase business competitiveness, to scholars who find no empirical evidence of this through statistical, economic analysis. The Kuznets Curve is an inverted-U relationship that suggests that in the beginning stages of industrialization, environmental conditions tend to deteriorate because the country is focused on economic development. This trend, however, is predicted to reverse once basic needs are met and nations reach middle-income levels per capita Gross Domestic Product (GDP) of US \$5000–\$8000.[7] According to Yandle et al.[7] and other scholars, countries will take more interest in cleaning up their environments once GDP reaches a certain level. This is the turning point when the line begins to fall (see Fig. 1). The curve differs according to the pollutant,[7] but there is no single environmental Kuznets Curve that fits all pollutants for all places and all times. The conclusion is that once some environmental degradation is accepted during industrialization, economic growth can be the force that helps undo previous environmental damage.

The economic perspective of this analysis concludes by stating that if economic growth is good for the environment, policies that stimulate growth (economic restructuring, trade liberalization, and price reform, for example) should be good for the environment. Overall, the conclusion is that once a country reaches a certain level, pressure will build up to protect the environment via policy measures and consumer behavior.[7]

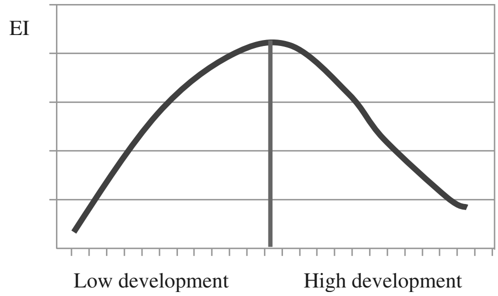

Fig. 1 Kuznet's curve for environmental impact (EI) as a function of development.

ENERGY PROJECTS MANAGEMENT

One of the most important aspects of an EM project is strong support from upper management. If this is not in place, the program will most certainly fail. The literature is full of companies that have illustrated their experiences with such programs, which are all total successes. Many companies find it difficult to pay for energy-efficient measures, even though they will save a significant amount of money in the long run. Below we summarize a set of opportunities to finance the implementation of energy savings projects, which are also discussed in other chapters in this energy encyclopedia.

In-house capital	
Utility incentive programs	
Debt financing/loans: (government loans)	The State of Florida Energy Loan Program (FELP)[6] requires that the interested party have 200 employees or less and have made a profit for the past two consecutive years
Commercial lending institutions	
Leases	Capital leases
	Operating leases
Performance contracts	Shared savings
	Performance contract for energy services (ESCO)
	Insurance guarantee of energy savings

THE ENERGY MANAGEMENT PROGRAM AND THE AUDIT PROCESS

No matter the type of facility, an energy audit program will always find savings through more efficient means of manufacturing and operations—the cost of the projects being the key point. To save energy, isolated projects are usually undertaken. However, such an endeavor should adhere to an energy program that must consider an energy assessment at the facility that will quantify energy and money savings to be obtained through a thorough engineering evaluation. To achieve these goals, this

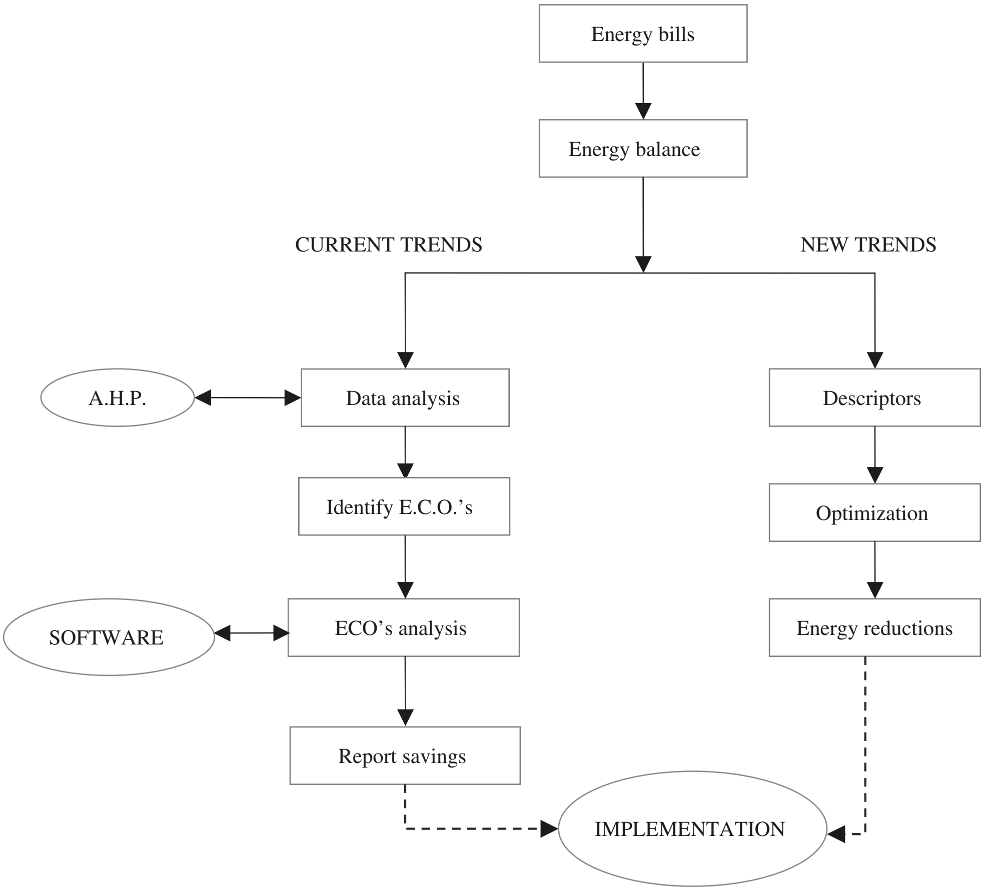

Fig. 2 The energy management (EM) program, including current and new trends. Notice that both encompass an EB.

chapter will show the importance of an energy balance (EB) in the EM program. The EM program scheme shown in Fig. 2 considers the analysis of current energy bills (to seek patterns and obtain real costs of demand and energy), an EB and, from there, the options for proceeding through current and/or new trends to pursue and implement energy savings projects. No matter the route followed, both consider the EB to be mandatory.

It must be pointed out that both trends pass through an EB and consider the implementation of the ECOs. It is an extra step to iterate again so as to improve until satisfaction levels are reached according to a pre-established energy conservation master plan.

Energy Balance: its main goal is to account for the electric energy consumed by each piece of equipment in a facility. This, in turn, allows for the performance of EM studies that track energy consumption for lighting, air compressors, air conditioning, motors, and any other piece of equipment. The energy consumed by each piece of equipment is then balanced against the facility's overall energy consumption (this allows the researcher to look for trends). The importance of an EB has been stressed in a set of published papers.[8–13] Recently, an EM program that does the balancing has been created in the form of software.[10–13] The software generates a report with the balance, graphs, and pie charts, and a set of ECOs that can be quickly evaluated. The importance of the EB is based on avoiding the not-uncommon situation of having a project that saves more energy than what the equipment currently requires. We shall return to the EB and its importance when we discuss some frequently used software.

Current Trends: today, no serious energy assessment can be completed without an EB that, through an Assisted Hierarchical Process (AHP), emphasizes the analysis of equipment efficiency and its loads. Then, as an inspection of the current process is performed, ECOs are identified and analyzed with the help of some software (to be discussed later). Finally, those ECOs of interest are reported.

New Trends: these are initiatives that come into place from an operations perspective so as to secure further savings. They are a function of the EB, and comprise a good procedure if the current trends ECOs have already been explored. Through a set of indicators, which we call descriptors,[14] we will discuss new trends that can, in turn, be used as benchmarks.

ENERGY SAVINGS: A CASE STUDY

We will consider Florida orange and grape industry—one of the largest manufacturing sectors in this state—energy usage[14] as a case study. The cost of manufacturing citrus juice depends on the cost of growing and picking the fruit from the groves, extracting fresh juice, and producing concentrate. We will show that a review of operations can help to improve procedures, and efficiency, and generate interesting savings. In this study, we analyze the general background of these facilities, their energy usage patterns, and the recommendations made to reduce energy consumption and production costs, as well (less manufacturing cost per unit). The citrus juice manufacturing processes performed in these facilities is succinctly illustrated in Fig. 3. Rather, we concentrate on the processes with a focus on energy usage requirements, although waste management and productivity issues should also be included.

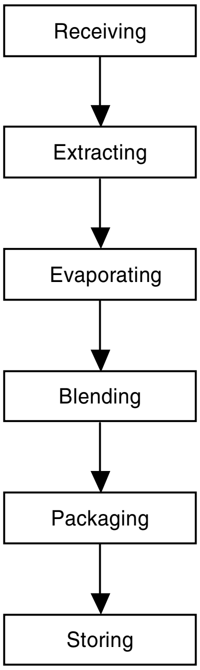

Fig. 3 Citrus juice manufacturing process.

Citrus Juice Production

In general, as well as after receiving, the fruit is washed with a soap solution while on the conveyors. The quality of grapefruits is tested by the U.S. Food and Drug Administration (FDA) through an on-site office. The FDA officers test the quality of fresh fruit coming into the facility. There is also some visual inspection, which is a crucial part of the process not only from the perspective of quality control, but also from the regulatory stand point.

In Table 1, we present the profile of four facilities with Standard Industrial Classification (SIC) code 2033,[15] sales figures, annual production, facility size, production cost, and number of employees. All four facilities participate in the State of Florida Electricity Tax Exemption program.[5] Also displayed are the energy savings (the number in parenthesis indicates the number of ECOs made during the assessment). The process is briefly pinpointed in Fig. 3. Finally, the percentage that these ECOs represent with respect to total electric energy consumption is also displayed. Other related citrus industries have been examined, too (SIC 2037 and 2087), and we refer the reader to the literature.[14]

Energy Consumption

The energy consumption of the facilities differs from one to the other, even if they manufacture the same product. Nevertheless, a closer look at their energy consumption reveals some trends. It also allows the relative merits of energy conservation and load management to be assessed. In this section, we will discuss these trends in terms of the energy used by type of equipment, and other features, like energy costs. An energy profile of the four facilities studied is shown in Table 1.

The Utility Company

While most of the large utilities offer good financial incentives to companies that install energy and demand saving equipment, midsize utilities offer little incentive for the adoption of new technology (like solar energy for water heating), and small utilities offer no incentives. It is

Table 1 Energy profile of four citrus companies

			Production area					
Plant	Sales ($/year)	Annual production	ft^2	\$/ft^2	EMPs	Taxes prog.	E. savings ($/year)	% of E savings
A	45,000,000	7,000,000 cases	142,283	316.27	175	Yes	86,741 (6)	10.83
B	50,000,000	25,000,000 lbs of Conc.	300,000	166.67	150	Yes	216,126 (5)	26.98
C	100,000,000	14,000 boxes fruit juice	645,712	154.87	150	Yes	124,460 (8)	15.54
D	140,000,000	3,400,000 gals of Conc.	100,341	1,395.24	140	Yes	189,709 (9)	23.68

Table 2 Energy profile prior to energy audits

	Electricity					Natural gas		Energy costs
Plant	KW	kWh	$/kW/month	$/kWh no demand	$/kWh with demand	MMBtu/year	$/MMBtu	per sales (%)
A	3,656	21,904,186	2.17	0.041	0.045	13,863	5.60	2.35
B	4,674	15,754,599	2.45	0.041	0.061	269,913	2.65	3.28
C	6,689	33,301,959	1.66	0.043	0.047	241,438	7.83	15.19
D	2,125	10,079,587	8.59	0.064	0.083	234,553	1.10	0.80
Average	4,286	20,260,083	3.72	0.047	0.059	189,942	4.295	5.40

indeed a very good practice to stay in close touch with the utility company and its available programs.

Energy Data

Table 2 shows energy usage and the cost of electricity and natural gas for the same four facilities. It becomes clear that, on average, the cost of electricity is very reasonable. However, there are still some exceptions due to small electric utilities, as shown by the rates of plant D. This difference sometimes cannot be changed by the facility, as it is geographically dependant. Would de-regulation help to reduce these values? At the end of 2002 and the beginning of 2003, the cost of natural gas increased about 300%, which resulted in a lagging cost increase in electricity. Now, a day's natural gas has practically the same cost as electricity in terms of dollars per MMBtu. Would a combined heat and power system[12] be a more attractive solution, particularly to serve end-of-the-line areas? This question will remain an issue.

The average values for demand and energy costs are shown in Table 2 under demand and energy costs. These costs are used in the economic analysis of the ECOs. These costs include taxes and are all based on a 12-month period, and, consequently, they differ from those shown on energy bills because ours include all other charges as applicable taxes, fuel cost adjustments, etc.

ENERGY BALANCE AND ENERGY COST DISTRIBUTION

As a regular practice, and to identify electric energy usage by equipment type, we developed EB software.[8–13] Fig. 4 shows the average equipment energy usage distribution from where it becomes clear that chillers, motors, air conditioners, and ammonia compressors are the main electric energy consumers. These facilities are much larger electric energy consumers than related industries (SIC 2037 and 2087, for example) by approximately a factor of five. As noted above, the inconsistent cost of natural gas makes it rather difficult to attempt to procure averages. Therefore, we concentrate our analysis on electrical energy consumption only. In this type of industry, natural gas is mostly used by kilns for the drying process.

CURRENT TRENDS: ECOs

As the energy assessments were performed, many of the recommendations summarized in Table 3 were made for each plant. These facilities have energy usage seasonal

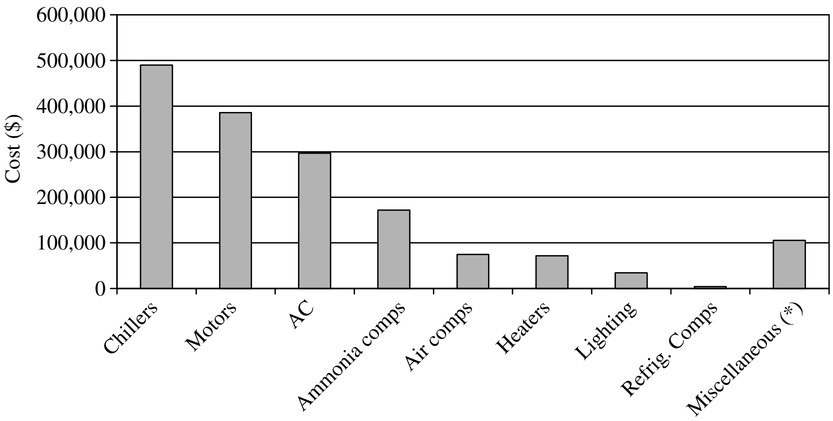

Fig. 4 Average equipment energy usage. (*Miscellaneous considers all minor equipment as computers, copiers, printers, desk-lamps, etc.).

Indu–Inter

Table 3 Energy conservation opportunities

Assessment recommendations	
Install high efficiency lighting	Repair steam leaks
Install combined heat and power system	Recover waste/exhaust heat
Install new refrigeration system	Insulate facility roof
Install high efficiency motors	Insulate roof of tank farms
Replace V belts with cogged V belts	Turn off lights and AC
Turn off unused equipment	
Install occupancy sensors	
Repair compressed air leaks	Remove unnecessary lights
Provide cooler air for air compressor	Schedule freezers lights use
Reduce compressed air pressure	Turn off outside lights
Reduce lighting in selected areas	Install skylights and sensors
Retrofit gas fired system	Implement a lights management system
Adjust boiler air/fuel ratio	Change feed mill schedule
Increase frequency of boiler tune-up	Install a light-bulbs recycling unit, etc.

fluctuations due to the nature of their business. Additional savings recommendations, which are not listed here, were made in the areas of waste handling and productivity enhancement.

Data Analysis

Based on the data shown, we are now in a position to estimate potential savings for the type of facilities considered, with the caveat that they are suggestions that show trends (and that they represent a fraction of this Florida industry). To show potential savings, we consider the average of energy savings and the fraction that corresponds to the energy usage for each type of equipment listed.

Consequently, we can write the fraction of savings $F_{i,j}$ as follows:

$$F_{i,j} \;=\; \langle S_j \rangle \left[C_j / \sum_{j=1} T_j \right]$$

where $F_{i,j}$ = Counters: i is for kWh = 1; kW = 2; cos t ($/year) = 3, j is for the type of piece of equipment. It runs from 1 to 11 as of the sequence shown in Table 4 (first column). $\langle S_i \rangle$ = Average of Savings (kW, kWh, cos t), C_j = Current Consumption (kW, kWh, cos t), T_j = Total Current Distribution according to piece of equipment.

In this fashion, we see how the energy is being distributed, and hence, we obtain proposed energy, demand, and associated cost savings that we can now directly compare with current usage. We perform our analysis by type of energy consumers that are typically present in most manufacturing facilities, listed in Table 4. Also listed are the average proposed energy (kWh), demand (kW), cost ($/year) savings (used to compute the associated cost savings), associated implementation cost, the expected simple payback period (SPP), and the return on investment (ROI), all of which are a consequence of the energy savings and demand reduction (DR).[14]

Table 4 Savings from the energy assessments

	Savings					
	kWh	kW	$/year	Implementation cost ($)	SPP years	ROI %/year

NEW TRENDS: DESCRIPTORS FOR ENERGY SAVINGS

In this section, we analyze how electric energy is used by different pieces of equipment in the facilities. Obviously, some consume more energy than others and, as a consequence, are more relevant for an energy conservation study, and to describe energy consumption in the plant. Accordingly, we recognize this by first classifying the energy consumers by the kind of equipment, as we did in Table 4 (1=Lighting; 2=motors, 3=AC, etc.), and shown in Table 5. Secondly, we assign them a specific weight, whose value will serve to describe the electric energy consumption; we will call them electric energy usage descriptors.[14]

We compute these descriptors ($f_{i,k}$) by taking the average consumption value of a given type of equipment $\langle L_{i,k} \rangle$ and dividing it by the sum of all. This is:

$$f_{i,k} = \langle L_{i,k} \rangle / \sum_{i=1}^{11} L_{i,k}$$

Notice that the counter i runs for all equipment considered and shown in Table 5. The counters are for demand ($k=1$), energy ($k=2$), and cost savings ($k=3$). These descriptors must satisfy the following necessary condition:

$$\sum_{i=1} f_{i,k} = 1$$

The calculated values of computed descriptors for demand, energy, and costs are shown in Table 5. The highlighted values again indicate the major contributors that better describe the energy usage in the plants studied. Motors, air conditioning, chillers, and compressors are the big consumers. On average, this equipment represents 87, 73, and 82% of all the electric demand, energy, and associated manufacturing costs.

These descriptors multiplied by the demand, energy, or cost associated with the equipment (lights, motors, chillers, etc.), account for the total electric energy use. However, and as discussed above, there are some particular pieces of equipment that account for most of the descriptor (demand, energy, and cost savings).

For this case, the demand, energy, and cost descriptors are (from Table 5):

Demand ($k=1$):

$$f_{i,k} = f_{i,1} = f_{2,1} + f_{3,1} + f_{5,1} + f_{8,1}$$
$$= 0.255 + 0.209 + 0.107 + 0.298 = 0.869$$

Energy ($k=2$):

$$f_{i,k} = f_{i,2} = f_{2,2} + f_{3,2} + f_{8,2}$$
$$= 0.185 + 0.197 + 0.344 = 0.726$$

Cost ($k=3$):

$$f_{i,k} = f_{i,3} = f_{2,3} + f_{3,3} + f_{5,3} + f_{8,1}$$
$$= 0.236 + 0.182 + 0.105 + 0.300 = 0.823$$

These descriptors describe the parameter of interest (demand, energy, and cost savings). The advantage is that we focus only on a few types of equipment. Notice that here only those components bigger or equal than 0.100 are considered.

Table 5 Descriptors distribution

	kW	kWh	Cost ($)

SOME AVAILABLE SOFTWARE

In this section, we provide a very simple, quick review of relevant software, as provided by the U.S. DOE Best Practice program. The different software are useful in helping the user make energy conservation decisions in the areas of motors, pumps, compressed air, steam, etc. (these program packages are free to download from the Web).[16] They are very versatile and easy to use. Data entries like location, utility details (energy costs), the system itself, efficiency, maintenance, life cycling, etc. are required. They are as follows.

Motor Master (MM+4.0)

Motor Master is a package designed to help utility auditors and industrial energy coordinators support motor improvement planning by identifying the most efficient action for a given repair or motor purchase action.

It contains an amazing amount of information for over 10,000 inventory motors from 15 different motor manufacturers.

Air Master +1.0.9

Air Master has a large suite of compressed air offerings that allow the user to explore possibilities for improving the compressed air system performance and operation through energy efficiency measures.

PSAT: Pumping Assessment Tool

Being very thorough software, PSAT will compute, according to input data, the optimal energy-efficient pump motor for the user, given a user optimization rating (input).

Steam System Assessment Tool 1.0.0

Through the analysis of operational steam-systems data, the auditor can examine possible savings in energy, cost, and emissions.

Steam System Scoping Tool 1.0d

Designed to be used by steam systems operations personnel for large industrial plants, this package offers good operational benchmarking, and it comes in the form of an Excel spreadsheet that allows the user to establish a record of what is currently being done in the steam system so as to show potential opportunities for improvement, evaluate current operational procedures, and compare steam systems with those of other facilities.

3E Plus

3E Plus is a very useful industrial insulation evaluation tool for exploring the best economic alternatives.

Process Heating Assessment and Survey Tool (PHAST 1.1.1)

This is a very valuable tool that helps to improve thermal efficiency on process heating equipment. For example, it allows for the investigation of cascading possibilities for process heat.

Industrial Energy Management Software

In a previous work, we described the new interactive EB software.[8–13] The package offers an easy way to account for energy bills, working equipment, and their energy operating characteristics: lighting, air conditioning, refrigeration compressors, air compressors, motors, and others. The electric energy consumed by all pieces of equipment is balanced against the energy bills. The corresponding energy costs, graphs, pie charts, and free format reports are automatically generated and show paths and trends of energy consumption. A "Recommendations" section allows for a quick, but beyond-the-back-of-the-envelope type of calculation, initial analysis of potential energy improvement projects associated with current equipment, and/or for the installation of new ones. After entering electric bills and equipment data, it performs an EB for the user.[10] This is a list of all the equipment that utilizes electricity as well as consumption operational patterns. The total is finally compared with the actual electric energy bills (usually from the previous 12 months), requiring a deviation of less than or equal to 2%.

To deal with other important pieces of equipment, we refer the reader to other chapters in this encyclopedia and other references, as well.[17–22]

DISCUSSION

From the proposed 7,460,625 kWh/year savings for these industries, we realize that not only is the bottom line affected, but the environment is, as well. Taking an optimistic perspective, let us assume that this electricity was generated with an efficiency of 40%, and an implementation rate of the same fraction, meaning that about 25,500 MMBtu/year of fuel are to be saved. To put this in the proper context, this represents, on an annual basis, unburned fuel equivalent to 255,000 therms of natural gas, or 5000 barrels of crude oil, or 1020 ton of coal. This is just the good news; the bad news is that 1.5 times thisamount is sent to the atmosphere, with all of the associated pollutants. This phenomenon is happening constantly all over the world in a kind of export fashion of the nontraditional type. Some utilities do have the appropriate required filters (such as scrubbers), but they are not enough.

NEW AND ALTERNATIVE SOURCES OF ENERGY

Today, the high costs of energy call for new sources of energy that pass through renewables and alternative fuels that are not generally considered, but that are sometimes process-dependent. Some of these are cars and trucks tires, which burn in an oven that handles them in a fork display; industrial oils, which can be further treated to eliminate their excess of water; and chemicals like sulfur, which, when burned, generates power and, as a by-product, provides sulfuric acid with many applications (manufacture of fertilizers, for example).

Another use of energy is symbiotic—this is a partnership between different types of industries in which one

Table 6 Compare demand, energy and cost descriptors distribution for related SIC codes 2037 and 2087

		2037			2087

TOTAL	1.000	1.000	1.000	1.000	1.000	1.000

generates waste that is fuel for the other. An example is biogas, where the manure (waste) generated on an animal farm can become the fuel source (biogas) of any facility that can use gas in its process. In this case, symbiosis has the added value of solving a health problem that results from piling-up excreta. These symbiotic possibilities should be explored thoroughly by energy managers.

CONCLUSIONS

We have presented a review of the current energy usage patterns of a number of Florida juice (orange and grapefruit) manufacturing facilities at which the University of Florida IAC has performed energy audits. Their current energy (heat and power) usage patterns, associated costs, energy indicators, and recommended energy savings measures have been discussed.

Through an analysis of the available data, we have presented a consistent set of measures that can be applied to reduce the production cost of citrus juice through the establishment of energy-saving measures or simple energy cost reduction. Moreover, and for the SICs considered, we have identified the areas that should be prioritized through a descriptors approach.

In our study, we have proposed the use of descriptors, whose advantages include narrowing down the areas in which an EM program should concentrate. In other words, we have made a Pareto identification of energy consumption areas to which priority should be given. Moreover, we believe that through this process we are also providing a tool for benchmarking the considered SIC codes. In essence, we foresee that facilities with SIC codes, like those considered here, can easily identify savings possibilities and, by comparison, benchmark their operations. Tables 5 and 6 provides the necessary information for this task, for different but related Standard Industrial Classification (SIC) codes (2033, 2037 and 2087, respectively).

Heat recovery is an attractive idea, as the cost per MMBtu coming from electricity is currently approximately (average) 2.5 times higher than the one from natural gas. As discussed at the very beginning of this entry, the cost of natural gas has gone up, but we believe that this fact should encourage heat recovery opportunities, as recommended to practically all the plants considered here. Finally, energy conservation opportunities do provide pollution reduction in a somewhat direct mode. Indeed, electricity is an on-time commodity, hence each time a plant reduces its electric energy consumption, the corresponding utility company burns less fuel with the consequent pollution reduction. Hence, this work, like others in EM, has a dual purpose—energy savings and environment conservation.

Abstract
This study examines data from 41 industrial motor system optimization projects implemented between 1995 and 2001 that were developed into Department of Energy (DOE) case studies to determine the effect of the energy savings brought about by such projects. The study calculates aggregate energy savings, the net present value (NPV) of project savings, and the internal rates of return of project cash flow (IRR) for each project, as well as for all projects aggregated together and for projects having large capital expenditures vs. those in which the systems were optimized primarily with engineering changes. Finally, the study makes some rough estimates of possible energy savings throughout U.S. industry.

For this study, projects are considered financially worthwhile if the NPV of the project savings over a 10-year project life is greater than the project cost. Because the simple payback criterion is the norm in the DOE case studies, it is used as a complementary measure of success.

The initial results suggest that the NPV for most of the projects' savings in the sample are positive with 10- and 15-year project lives, and that many are even positive with 5-year project lives. For projects involving large capital purchases, a project life of 10 years is required for a positive NPV, while for projects that primarily involve engineering changes, a positive NPV was achieved with a 5-year project life. This suggests that motor system optimization projects do not necessarily require large capital expenditures to achieve substantial energy savings.

INTRODUCTION

Since the mid-1990s, manufacturing plants in the United States have undertaken measures to reduce energy consumption. One of the primary types of these measures has been to increase the efficiency of their motor systems. These efforts have been encouraged by the U.S. DOE Office of Energy Efficiency and Renewable Energy (EERE) through its Best Practices program. The Best Practices program includes the publication of case studies and similar documents (approximately 150 since 1995) on industrial energy efficiency projects to raise awareness within industry of the benefits of such projects.

This study explores the effect of such projects by examining data from 41 separate projects that were developed into DOE case studies. Through this review, it is expected that a better understanding of the impact of industrial motor system improvement projects will be achieved.

This article is organized in the following manner. The first part defines and discusses the methodology of the study. Next, the analytical tools employed are discussed, along with the data and the selection criteria. In the next section, the results are presented, discussed, and interpreted. Finally, some concluding remarks are presented.

Methodology

The main objective of this study is to estimate the impact of motor system optimization on industrial competitiveness and to provide insights into the mechanisms by which such benefits are delivered to industry. Specifically, it is expected that the study will (1) provide planning-relevant information on the nature and magnitude of the financial impacts from industrial motor system optimization, and (2) convey to the policy process, the rates of return to U.S. industry from expenditures on such efforts. The data from the 41 projects are aggregated to provide a collective estimate of their impact and extrapolated to estimate potential industry-wide energy savings, which will allow the results of this assessment to feed back into DOE's strategic planning process.

Empirical Measures

The primary quantitative measures employed in this study are NPV, IRR, and simple payback. The NPV is used

☆ This entry originally appeared as "Industrial Motor System Optimization Projects in the U.S." in *Energy Engineering*, Vol. 102, No. 1, 2005. Reprinted with permission from AEE/Fairmont Press.

Keywords: Energy efficiency; Industrial; Productivity; Motor systems.

because it is an absolute measure of the value or expected value of an investment in constant dollar terms. It therefore portrays the annual energy savings from the projects as interest payments on a bond, and can be used to compare the performance of expenditures on motor system improvement projects to the performance of other potential uses of financial capital. If the 10-year NPV of project savings exceeds the project cost, the project will be considered successful.

The IRR of project cash flow is the compound rate of return paid by an investment. In this study, the project cost is the investment and the IRR of project cash flow gives each project's total return on its project cost. By providing a rate of return measure, the IRR of project cash flow allows comparison with a designated opportunity cost of the funds being considered for the projects. For this study, an IRR of project cash flow that is greater than 50% will constitute a rate of return that makes a project successful. For the aggregate data, the IRR will be labeled the CRR of project cash flow (collective rate of return).

The simple payback is a complementary measure that serves as a modified benefit-cost ratio. According to the U.S. Industrial Motor Systems Market Opportunities Assessment (MSMOA), many firms use only the simple payback as a decision tool (MSMOA, P. 54), and DOE uses it in all of its case studies, making it relevant for this study. Although the MSMOA applies a 3 year simple payback to energy efficiency measures, some of the firms whose projects are used in the study report using a financial hurdle rate of 2 years or less on the simple payback to obtain project approval. Therefore, projects having a simple payback of 2 years or less will be considered successful in this study.

In addition to energy savings, many of the projects in the study have led to important non-energy benefits such as maintenance savings, increased or improved production, and lower emissions. These additional benefits are in effect positive externalities of motor system improvements. With these methods, this study provides both qualitative assessments and quantitative estimates of the net financial benefits resulting from industrial motor system optimization.

Data

The data used in the study come from 41 separate motor system optimization projects that were implemented in manufacturing plants in the United States between 1995 and 2001 and cover seven different motor systems across 17 industries. The 41 projects were selected because they all provided the following data: energy savings in U.S. dollars, energy savings and consumption in kilowatt-hours (kWh), project cost, and power cost ($/kWh). These projects are not a random sample; nor do they present the largest or smallest energy savings among motor system projects. However, in many cases their manner of implementation is consistent with best industry practices for motor system optimization.

Along with the above-mentioned attributes, additional assumptions in the study include a discount rate of 5%, and a project life of 10 years. The 5% discount rate is used because that rate approximates the average yield on the 10-year U.S. Treasury bond between 1995 and 2001. The 10-year project life is the typical life span reported by various consultants, manufacturers, and personnel involved in many of the study's projects. Because a 10-year project life may not be universal, results for 5- and 15-year project lives are also presented to see how the results differ with time periods that are 50% shorter and 50% longer than the selected baseline.

Results

The aggregate results show positive values for each of the measurement tools applied to the data. The aggregate project costs for all 41 projects total $16.8 million, and the aggregate savings sum is $7.4 million and 106 million kWh. Using these figures, the NPV of project savings for the baseline analysis is $39,572,000, which exceeds the aggregate project cost. The CRR of project cash flow in this analysis is positive at 41% and the simple payback is 2.27 years. These results are summarized in Table 1. Fig. 1 shows energy consumption before and after the projects. The initial aggregate results are skewed by two projects that were implemented with the intent of improving process reliability rather than saving energy. For these two projects, the costs vastly exceed the energy savings, and they are viewed as outlyers. When these two projects are taken out of the sample, the NPV of project savings

Table 1 Aggregate data

Aggregate data	$N=41$	Without outlyers ($N=39$)
Total costs	$16,772,740	$15,072,740
Total savings	$7,401,700	$7,303,700
Median cost	$240,000	$188,000
Median saving	$115,000	$108,000
Kilowatt-hour	106,483,517	104,544,517
Simple payback	2.27	2.06
Collective rate of return	41%	46%
Present value	$56,344,762	$55,598,746
Net present value 5-year	$13,913,292	$15,207,003
Net present value 10-year	$39,572,022	$40,526,006
Net present value 15-year	$61,975,378	$58,200,783

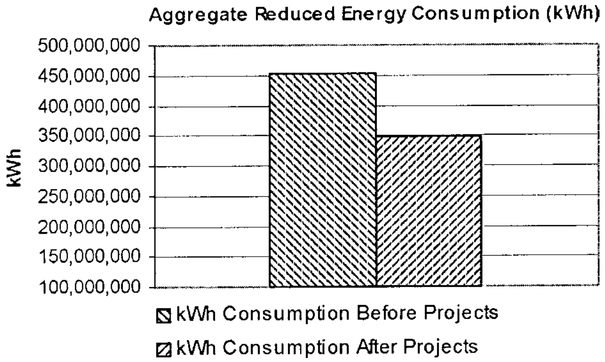

Fig. 1 Aggregate energy consumption before and after projects.

becomes $40,526,000, the CRR of project cash flow is 46%, and the simple payback is 2.07 years. Because of the outlyers, median rather than average values of project costs and savings are provided in Table 1. Using the aggregate data, the NPV and CRR are also calculated for 5- and 15-year project lives. For the 5-year project life, the NPV figure is positive but smaller than the total project cost. The CRR figure reduces to 32% and the simple payback stays the same. In the 15-year project life, the NPV greatly exceeds total project cost and the CRR of project cash flow is 43%.

Once the initial aggregate results were calculated, the data were divided according to two main sets of features. The two main sets of features were plants belonging to the industries of the future (IOF) or non-IOF companies, and projects involving much capital spending vs. others that depended primarily on re-engineering.

Projects at IOF vs. Non-IOF Industrial Facilities

Of the 41 projects in the study, 21 occurred in plants of companies that fall under DOE's IOF (mining, forest/paper products, steel, glass, metal casting, agriculture, petroleum, chemicals and aluminum.) designation, while 20 were implemented in facilities of non-IOF firms. Industries of the future companies are considered to have the most energy intensive industrial processes, and it was expected that motor system optimization projects in such facilities would have the greatest energy savings and highest returns. The results for the projects at IOF companies bear this expectation out and are displayed in Table 2, which shows that the NPV of project savings and IRR of project cash flow for the IOF facilities' projects are greater than those of the non-IOF firms. The before and after energy consumption patterns are shown in Fig. 2.

Table 2 Industries of the future (IOF) vs. non-IOF energy consumption

	IOF companies $N=21$	Non-IOF companies $N=20$
Total costs	$7,266,740	$9,506,000
Total savings	$4,182,700	$3,219,000
Median cost	$240,000	$219,000
Median saving	$120,000	$99,000
Kilowatt-hour	66,993,517	39,490,000
Simple payback	1.74	2.95
Internal rates of return	55%	31%
Present value	$31,840,420	$24,504,342
Net present value 5-year	$10,073,934	$3,839,358
Net present value 10-year	$24,573,680	$14,998,342
Net present value 15-year	$37,233,815	$24,741,564

Because the NPV and IRR figures of IOF facilities' projects are greater than those of non-IOF facilities, this suggests that motor system improvement projects in such facilities are desirable. The non-IOF facilities' lower NPV, IRR, and simple payback is partly because many of their projects incurred higher equipment costs than did the IOF

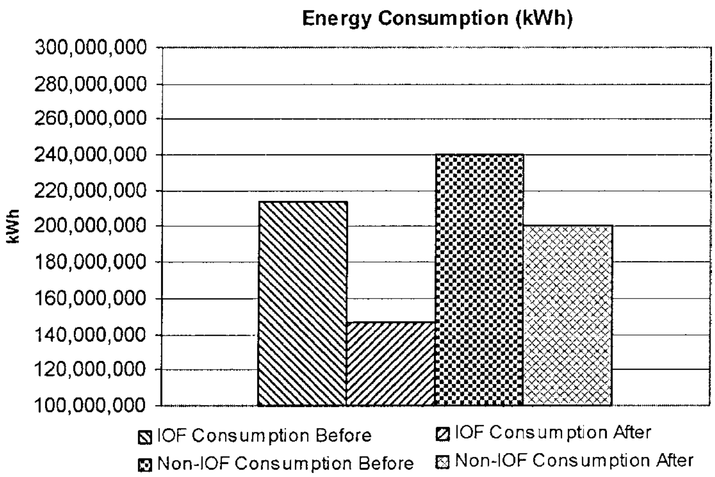

Fig. 2 Energy consumption before and after projects for industries of the future (IOF) and non-IOF companies energy consumption (kilowatt-hours).

Indu–Inter

Table 3 Capital spending vs. re-engineering

	Capital spending $N=35$	**Re-engineering** $N=6$
Total costs	$16,533,740	$239,000
Total savings	$6,999,700	$402,000
Median cost	$264,000	$35,000
Median saving	$115,000	$44,500
Kilowatt-hour	102,523,517	3,960,000
Simple payback	2.4	0.6
Internal rates of return	40%	164%
Present value	$53,284,574	$3,060,188
Net present value 5-year	$12,485,677	$1,427,615
Net present value 10-year	$36,750,834	$2,821,188
Net present value 15-year	$57,937,423	$4,037,956

facilities' projects. This higher cost is reflected by the fact that the weighted average of the non-IOF facilities' project costs is over 25% greater than that of the IOF facilities' projects.

Capital Spending vs. Re-engineering

The other salient feature about many of the projects in the study was the degree to which equipment replacement and spending on capital equipment was significant in many projects. Spending on capital equipment was equal to or greater than 70% of the total project cost in 31 of the study's 41 projects. Furthermore, the main features in 35 projects included the replacement or addition of OEM (original equipment manufacturer) devices such as pumps, fans, compressors, VSDs (variable speed drives), and control systems.

The projects were divided into two categories: capital spending and re-engineering. Projects that fell into the capital spending category were those for which most of the project cost was on new equipment or that were characterized by equipment replacement. The re-engineering category included projects in which capital equipment purchases were small relative to the projects' costs or in which new equipment did not significantly contribute to the projects' results. Of the 41 projects in the study, 35 were classified as capital spending and six as re-engineering.

The analysis for the two categories of projects produced vastly different results, which are shown in Table 3. Fig. 3 shows both groups' energy consumption before and after the projects. While the NPV of capital spending projects' savings makes them successful according to the study's criteria, their IRR of project cash flow and simple payback are below the study's criteria for success. This category contains the two outlyer projects, and when they are subtracted, the IRR of project cash flow and simple payback for the category remain below those criteria at 43% and 2.18 years. By contrast, the projects in the re-engineering category are successful according to all three metrics. Also, the NPV of project savings for the re-engineering projects is greater than the total project costs under the 5-year scenario.

While the data from the re-engineering projects in this study show that higher rates of return were obtained through reconfiguration of or adjustments to existing motor systems, this does not indicate that equipment replacement is not justified. In many of the capital spending projects, the new OEM equipment was smaller than the devices it replaced. Also, the new equipment was more technologically advanced or contributed to more efficient operation of the motor systems involved, which

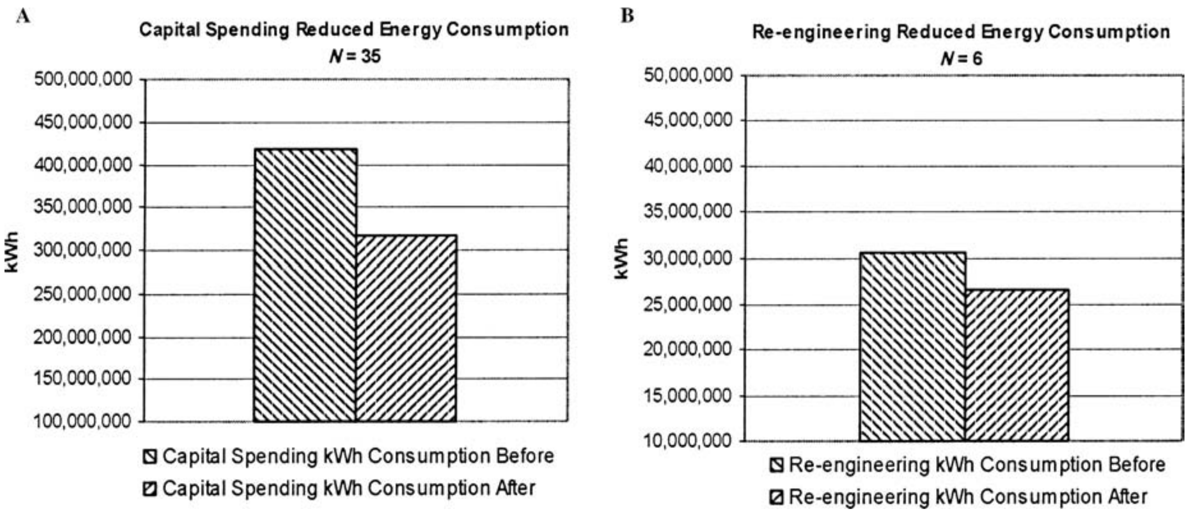

Fig. 3 (A) Energy consumption before and after projects; (B) Capital spending and re-engineering.

obviated the need for previously anticipated equipment purchases. However, the re-engineering projects' results do suggest that large capital equipment expenditures are not a necessary condition for energy efficiency.

The results in Table 3 display the NPV of project savings for 5- and 15-year project lives to show how the rates of return differ with time periods that are 50% shorter and 50% longer than the 10-year baseline project life. However, these time frames may not be appropriate. The 5-year scenario is very short for the capital spending projects, and the 15-year project life may be unrealistic for the projects that fall under the re-engineering category because it is unlikely that the results will persist for that length of time. Therefore, the more appropriate time-frames to view the NPV of project savings for the capital spending projects are the 10- and 15-year ones, while for the re-engineering projects, the 5- and 10-year NPVs would be more realistic and reflective of the findings obtained in the study.

Individual Project Results

All 41 projects were individually analyzed under 5-, 10-, and 15-year project lives. Table 4 shows the results along with the percentages that those results represent.

As Table 4 shows, the NPV of project savings exceeds the project costs in a majority of the 41. The IRR of project cash flow is greater than 50% in each project life scenario. This is also true for the projects that fell under the capital spending label, and particularly so for the re-engineering projects.

Indirect Impacts

While the vast majority of the projects provided measurable energy savings, some yielded unanticipated benefits that can be seen as positive externalities. Typically, many additional improvements or savings were generated in one or more of the following areas: productivity (production and/or product quality), maintenance, emissions, ancillary products, plant safety, and avoided equipment purchases. In addition, some firms received rebates or incentive payments for implementing their projects. Because not every project in the study resulted in all of the above-mentioned benefits, they are considered more ad hoc and should not be expected each time that a motor system is optimized. Of the 41 projects, 22 resulted in reduced maintenance requirements on the motor systems involved. Twelve of these 22 plants were able to quantify their maintenance savings, which together total $900,000. Improvements in productivity in the form of production increases or better product quality were reported in 14 projects, three of which were able to quantify annual revenue increases that total $568,000. Others reported percentage increases in production or decreases in product reject rates. Lower emissions or purchases of ancillary products such as treatment chemicals were reported in eight projects, and two projects resulted in improved plant safety. Also, six projects forestalled equipment purchases and one project averted an expensive asbestos abatement campaign. Together, these seven projects' avoided costs total $770,000. Finally, 10 projects resulted in incentive payments to the firms that

Table 4 Individual project results of 41 total projects

	5 year project life		10 year project life		15 year project life	
	Number of projects	Percentage of projects	Number of projects	Percentage of projects	Number of projects	Percentage of projects
All projects						
Net present value < project cost	27	66	34	83	39	95
IRR > 50%	22	54	24	59	26	63
Simple payback > 2 years	27	66	27	66	27	66
Capital spending						
Net present value > project cost	21	58	28	78	33	92
IRR > 50%	18	50	19	53	20	56
Simple payback < 2 years	21	58	21	58	21	58
Re-engineering						
Net present value > project cost	6	100	6	100	6	100
IRR > 50%	5	83	5	83	6	100
Simple payback < 2 years	6	100	6	100	6	100

performed them that total $1.2 million. When the incentive payments were factored out of the results, the average simple payback for these 10 projects increased by 28% to 6.5, and the IRR of project cash flow decreased by an average of 33% to 46%. When added to the total energy savings achieved, the indirect benefits from motor system optimization projects present a compelling case for their implementation.

Drivers of Motor System Projects

Although each of the projects in the study yielded energy savings, not all of them were implemented with such savings as their primary objective. A review of the reasoning behind each project's implementation revealed a range of drivers for the projects. These motives can be divided into five separate categories: production issues, energy savings, motor system effectiveness, plant expansion, and process reliability. The production issues category refers to projects that were implemented because a motor system was unable to support production processes effectively and the plant was experiencing severe production stoppages and/or high product reject rates. The energy savings group represents plants in which there was recognition that a particular motor system was wasting energy and that optimizing it to capture energy savings was a worthwhile pursuit. The motor system effectiveness label describes motor systems that were able to support production equipment but that operated erratically or unsatisfactorily. The plant expansion category includes plants that underwent an expansion of production equipment and optimized a motor system to support the expansion. Finally, two projects in the study were undertaken with the primary aim of ensuring process reliability. The five categories and the numbers of projects performed according to each are shown in Table 5.

Potential Industry-wide Energy Savings

To provide planning-relevant information useful for strategic planning, the study extrapolates energy savings for U.S. industry based on estimates of annual energy consumption by industrial motor systems. Ballpark estimates of potential industry-wide energy savings were calculated using data from two separate sources: the United States Industrial Motor-Driven Systems Market Assessment, written by the U.S. DOE's EERE, and the EIA's Manufacturing Energy Consumption Survey (MECS) from 1998.

According to EERE's assessment, U.S. industry consumed 691 billion kWh in process motor-driven systems in 1994. The MECS industrial end-use consumption figures reveal that direct industrial uses and processes in U.S. manufacturing plants consumed over 711 billion kWh in 1998. The aggregate pre-project power consumption by the motor systems in the study's 41 plants is 453 million kWh. The energy savings by the plants in the study (106 million kWh) represent a 23% reduction in their aggregate energy consumption. Whether all industrial facilities in the U.S. would achieve similar energy savings rates from implementing projects aimed at improving motor system efficiency is not evident. However, because many of the projects in the study employed best practices in industry for motor system optimization, it is not too far-fetched either. Therefore, a range is presented in Table 6 that indicates how much energy and money could be saved under various implementation rates based on the 23% energy savings rate achieved in this study.

As shown in Table 6, manufacturing plants in the United States could potentially save as much as 83 billion kWh and $4 billion if manufacturing plants that account for 50% of industrial energy consumption would implement projects of similar quality as those in this study. While these sets of figures are tentative, they provide a rough estimate of the range of industry-wide energy savings that industrial motor system optimization projects might achieve in the United States. Additional savings can also be obtained by improving other industrial systems such as steam and direct-fired process heating systems.

Table 5 Drivers of motor system projects

Category	Number of projects	Percent of total
Production issues	8	20
Energy savings	14	34
Motor system effectiveness	15	37
Plant expansion	2	5
Process reliability	2	5

Table 6 Total U.S. energy savings from potential motor system optimization projects (figures are in millions of kilowatt-hours and U.S. dollars)

Energy efficiency and renewable energy assessment			
Implementation rates	10%	25%	50%
Kilowatt-hour	16,228	40,570	81,139
Dollars	779	1,947	3,895
Manufacturing energy consumption survey data			
Implementation rates	10%	25%	50%
Kilowatt-hour	16,698	41,744	83,488
Dollars	801	2,004	4,007

CONCLUSION

This study's intent has been to estimate the impact on industrial competitiveness resulting from motor system optimization projects. The impact of 41 motor system optimization projects was evaluated individually and collectively using three metrics: NPV, IRR, and simple payback. The main findings are that:

- A majority of the 41 projects was successful according to the study's criteria.
- Projects that were implemented in energy intensive manufacturing plants obtained a greater rate of success and a higher rate of return.
- Projects involving large expenditures of capital achieved lower rates of success and return, than projects characterized primarily by engineering or process changes.
- Many projects resulted in positive externalities such as maintenance savings, better productivity, lower emission levels, reduced purchases of ancillary products, improved plant safety, and avoided purchases of plant capital or other costs.

The important finding is that motor system optimization is an underrated source of productivity. Many of the 41 projects were performed in response to production problems. Once the projects were complete, the production problems went away and the plants began to notice the energy savings. Improvements in production occurred in 34% of the plants in this study, and while many of them could not quantify the production impact of their project, they recognized that production increased or that production equipment operated more effectively after the project completion. Instead of re-allocating resources, motor system improvements cause specific systems to use fewer resources (namely, energy) while allowing for a desired production level or standard of quality. Because of this, such projects increase industrial competitiveness and productivity. To view some of the case studies whose data were used in this report, please visit: http://www1.eere.energy.gov/industry/bestpractices/case_studies.html.

Insulation: Facilities

Wendell A. Porter
University of Florida, Gainesville, Florida, U.S.A.

Abstract
In this entry, insulation materials and techniques are described in detail. The advantages and disadvantages of the most popular materials and their manufacturing processes are discussed. Information concerning new and emerging techniques and materials is also included. The concept of a building envelope is explained and descriptions of each major building component, such as floors, ceilings and walls, are illustrated in detail.

The proper installation methods for each major type of insulation are explained in both the text and in illustrations. These methods are repeated for the different types of wall construction, frame, masonry, and insulated concrete. The concept of a radiant barrier is also explained, along with related installation instructions.

INTRODUCTION

Insulation is rated in terms of thermal resistance, called *R*-value, which indicates the resistance to heat flow. Although insulation can slow all types of heat flow—conduction, convection, and radiation—its greatest impact is on conduction.

The higher the *R*-value is, the greater the insulation effectiveness is.[1,2] The *R*-value of thermal insulation depends on the type of material, the thickness, and the density. When calculating the *R*-value of a multilayered installation, the *R*-values of the individual layers are added.

The effectiveness of an insulated wall or ceiling also depends on how and where the insulation is installed. For example, compressed insulation will not give its full rated *R*-value. The overall *R*-value of a wall or ceiling will also be somewhat different from the *R*-value of the insulation itself because some heat flows around the insulation through the studs and joists thermal bridging. With careful design, this short-circuiting can be reduced.

The key to an effective insulation system is proper installation of quality insulation products. A building should have a continuous layer of insulation around the entire building envelope (Fig. 1). Studies show that improper installation can cut performance by 30% or more.

INSULATION MATERIALS

The wide variety of insulation materials makes it difficult to determine which products and techniques are the most cost effective (Table 1). Whatever product is chosen, install it per the manufacturer's specifications.

Here are short descriptions of a few of the insulation products available today:

- Fiberglass insulation products come in batt, roll, and loose-fill form, as well as a semirigid board material. Many manufacturers use recycled glass in the production process of fiberglass building insulation, with most using between 20 and 30% recycled glass in their product. Fiberglass is used for insulating virtually every building component—from walls to attics to ductwork.
- The term mineral wool refers to both slag wool and rock wool. Slag wool is manufactured from industrial waste product. It is primarily (~75%) produced from iron ore blast furnace slag, a by-product of smelting. Rock wool is fireproof and produced from natural rocks—basalt primarily—under high heat. Mineral wool insulation is available as a loose-fill product, batts, semirigid, or rigid board. Usage of this product has decreased as more and more building codes require active sprinklering of buildings.
- Cellulose insulation, primarily made from post-consumer recycled newsprint with up to 20% ammonium sulfate and/or borate flame retardants, is installed in loose-fill, wall-spray (damp), dense-pack, and stabilized forms. Because of its high density, cellulose can help reduce air leaks in wall cavities, but air sealing other areas of air infiltration, such as under wall plates and band joists, must be performed to obtain an effective air barrier. However, given certain conditions and applications, cellulose may hold moisture.
- Molded expanded polystyrene (MEPS), often known as beadboard, is a foam product made from molded beads

Keywords: *R*-value; Insulation; Radiant barrier; Ventilation; Batt insulation; Loose-fill insulation; Wall insulation; Floor insulation; Attic insulation.

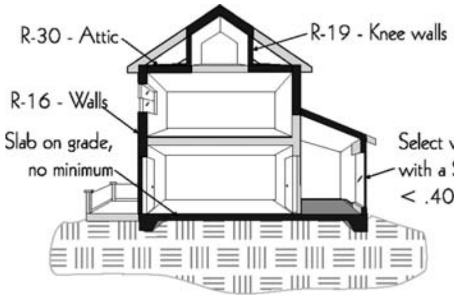

Fig. 1 Building envelope insulation.

of plastic. MEPS is used in several alternative building products discussed in this chapter, including insulated concrete forms and structural insulated panels (SIPs).

- Extruded polystyrene (XPS), also a foam product in rigid board form, is a homogenous polystyrene produced primarily by three manufacturers with characteristic colors of blue, pink, and green.
- Polyisocyanurate, foil-faced rigid board, is insulating foam with one of the highest available *R*-values per inch.
- Closed-cell, high-density spray polyurethane is used both for cavity insulation and as insulating roofing materials [often referred to as spray polyurethane foam (SPF)]. It has structural properties, good adhesive properties, and good compressive strength.

Table 1 Comparison of insulating materials

Material	Typical *R*-value (per inch)
Batts, blankets, and loose-fill insulation	
Mineral wool and fiberglass	2.2–4.0
Cellulose (loose-fill)	3.0–3.7
Cotton (batts)	3.0–3.7
Perlite (loose-fill)	2.5–3.3
Foam insulation and sheathing	
Polyisocyanurate	6.0–6.5
Closed-cell, spray polyurethane	5.8–6.8
Open-cell, low-density polyurethane	3.6–3.8
Extruded polystyrene	5.0
Molded expanded polystyrene (beadboard)	4.0
Fiberboard sheathing (blackboard)	1.3
Air-krete	3.9
OSB sheathing (3/8 in.)	0.5
Foil-faced OSB	Depends on installation
Polyicynene	3.6

Determine actual *R*-values and costs from manufacturers or local suppliers.

- Open-cell, low-density polyurethane foam is used primarily to seal air leaks and provide an insulating layer. Produced primarily from petrochemicals, some of these products are now manufactured in part from soybeans.
- Aerated concrete, including lightweight, autoclaved (processed at high temperature) concrete, can provide a combination of moderate *R*-values and thermal mass for floors, walls, and ceilings, in addition to structural framing.
- Reflective insulation is often used between furring strips on concrete block walls to reflect the heat. Note that reflective insulation products differ from radiant barriers in that they include a trapped air space as part of the product. These trapped air spaces may be a result of the way the reflective insulation is manufactured or installed.

Note that many new types of insulation are rapidly becoming incorporated into conventional construction. However, always research a material's characteristics and suitability to a particular situation before buying any new product. For instance, many new insulation products require covering for fire rating.

Insulation and the Environment

There has been considerable study and debate about the potential negative environmental and health impacts of insulation products.[3] These concerns range from detrimental health effects for the installer to depletion of the earth's ozone layer.

- Fiberglass and mineral wool—questions about effects on health from breathing in fibers. In 2001, the International Agency for Research on Cancer changed its classification for fiberglass and mineral wool from "possible human carcinogen" to "not a known human carcinogen."
- Cellulose—concerns about dust inhalation during installation to VOC emissions from printing inks (these are now almost entirely vegetable-based) and limited evidence of toxicity of boric acid flame retardants. Long-term fire retardancy is unknown. Limited health and safety research has been performed on these products.
- Foam products and chlorofluorocarbons—for years, many foam products contained chlorofluorocarbons (CFCs), which are quite detrimental to the earth's ozone layer. The CFCs were the blowing agent that helped create the lightweight foams. Current blowing agents are:
  - Expanded polystyrene—pentane, which has no impact on ozone layer, but may increase the potential for smog formation.

— Extruded polystyrene, polyisocyanurate, and polyurethane—use primarily hydrochloro-fluorocarbons (HCFCs), which are 90% less harmful to the ozone layer than CFCs. Some companies are moving to non-HCFC blowing agents.
— Open-cell polyurethane, including the products made by Icynene, Inc. and Demilec, Inc., as well as the newer soy-based foams—use water, which is much less detrimental than other blowing agents (Table 2).

INSULATION STRATEGIES

In general, commonly used insulation products are the most economical. Prices can vary according to installer and location. Review all of the choices, as they offer different *R*-values, suggested uses, and environmental and health considerations.

Critical Guidelines

When installing any insulating material, the following guidelines are critical for optimum performance[4]:

- Seal all air leaks between conditioned and unconditioned areas
- Obtain complete coverage of the insulation, especially around doors and windows
- Minimize air leakage through the material with air sealing measures
- Avoid compressing insulation
- Avoid lofting (installing too much air) in loose-fill products

Foam Insulation Strategies

Foam products are primarily economical when they can be applied in thin layers as part of a structural system or to help seal air leaks. Examples include:

- Exterior sheathing over wall framing
- Forms in which concrete can be poured
- As part of a structural insulated panel for building walls
- Spray-applied foam insulation

FLOOR INSULATION

Slab-on-Grade

Slab-on-grade floors consist of a concrete slab poured over at least four inches of compacted gravel or sand and a layer of 10-mil polyethylene used as a vapor barrier. In hot, humid climates, most buildings are built with concrete slab-on-grade.

For colder climates, slabs lose energy as a result of heat conducted outward toward the perimeter of the slab. Insulating the exterior edge of the slab with R-10 rigid insulation can reduce winter heating bills by 10%–20%.

Raised Floor

Raised floor systems (wood and concrete) have specific requirements depending on climate zones. Consult the local building code for specific details.

WALL INSULATION

Walls are the most complex component of the building envelope to provide adequate thermal insulation, air sealing, and moisture control.

Concrete Wall Insulation

Foundation walls and other masonry walls are usually built of concrete block or poured concrete. Insulating concrete block walls is more difficult than insulating framed walls.

Insulating Concrete Block Cores

Builders can insulate the interior cores of concrete block walls with insulation such as:

- Vermiculite R-2.1 per inch (See Fig. 2)
- Polystyrene inserts or beads R-4.0–5.0 per inch
- Polyurethane foam R-5.8–6.8 per inch

Unfortunately, as shown in Fig. 2, the substantial thermal bridging in the concrete connections between cores continues to depreciate the overall *R*-value. This approach is only a partial solution to providing a quality, well-insulating wall. Other techniques, as explained in the next few pages, provide more cost-effective solutions.

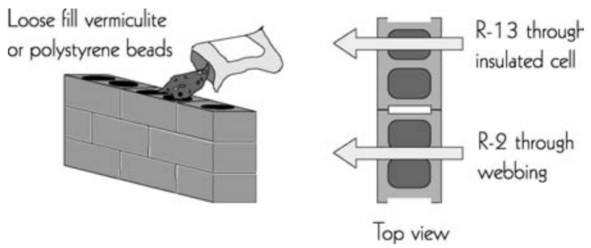

Fig. 2 Insulating concrete block cores (R-4–R-6 overall).

Table 2 Comparison of insulation materials (environmental characteristics and other information)

Type of insulation	Installation method(s)	*R*-value per inch (RSI/m)[a]	Raw materials	Pollution from manufacture	Indoor air quality impacts	Comments
Fiber insulation						
Cellulose	Loose fill; wall-spray (damp); dense-pack; stabilized	3.0–3.7 (21–26)	Old newspaper, borates, ammonium sulfate	Vehicle energy use and pollution from newspaper recycling	Fibers and chemicals can be irritants. Should be isolated from interior space	High recycled content; very low embodied energy
Fiberglass	Batts; loose fill; semi-rigid board	2.2–4.0 (15–28)	Silica sand; limestone; boron; recycled glass, phenol formaldehyde resin or acrylic resin	Formaldehyde emissions and energy use during manufacture; some manufactured without formaldehyde	Fibers can be irritants, and should be isolated from interior spaces. Formaldehyde is a carcinogen. Less concern about cancer from respirable fibers	
Mineral wool	Loose fill; batts; semi-rigid or rigid board	2.8–3.7 (19–26)	Iron-ore blast furnace slag; natural rock; phenol formaldehyde binder	Formaldehyde emissions and energy use during manufacture	Fibers can be irritants, and should be isolated from interior spaces. Formaldehyde is a carcinogen. Less concern about cancer from respirable fibers	Rigid board (e.g., Roxul) can be an excellent foundation drainage and insulation material
Cotton	Batts	3.0–3.7 (21–26)	Cotton and polyester mill scraps (especially denim)	Negligible	Considered very safe	Two producers; also used for flexible duct insulation
Perlite	Loose fill	2.5–3.3 (17–23)	Volcanic rock	Negligible	Some nuisance dust	

[a]RSI/m: The standard unit of measurement in the United States has been the Imperial unit. The country is converting to the International System (SI) unit—or metric standard—which predominates internationally. To differentiate like terms, you may find "SI" added to the term symbol. For example, RSI refers to the *R*-value in International System (metric) units.

Conversion factors

R-value conversions	To get	Multiply	By
Thermal resistance (*R*)	RSI (m^2 C/w)	R (ft^2 hF/Btu)	0.1761
Insulation *R*/unit thickness	RSI/mm	*R*/in.	0.00693
In the chart, the heading is *R*-value per inch (RSI/m); to obtain this number, the RSI/mm is divided by 1000.			

(Continued)

Table 2 Comparison of insulation materials (environmental characteristics and other information) (*Continued*)

Type of insulation	Installation method(s)	*R*-value per inch (RSI/m)[a]	Raw materials	Pollution from manufacture	Indoor air quality impacts	Comments
Foam insulation						
Polyisocyanurate	Foil-faced rigid boards; nail-base with OSB sheathing	6.0–6.5 (42–45)	Fossil fuels; some recycled PET; pentane blowing agent; TCPP flame retardant; aluminum facing	Energy use during manufacture	Potential health concerns during manufacture. Negligible emissions after installation	Phaseout of HCFC ozone-depleting blowing agents completed
Extruded polystyrene (XPS)	Rigid board	5.0 (35)	Fossil fuels; HCFC-142b blowing agent; HBCD flame retardant	Energy use during manufacture. Ozone depletion	Potential release of residual styrene monomer (a carcinogen) and HBCD flame retardant	Last remaining insulation material with ozone-depleting blowing agents
Expanded polystyrene (EPS)	Rigid board	3.6–4.4 (25–31)	Fossil fuels; pentane blowing agent; HBCD flame retardant	Energy use during manufacture	Potential release of residual styrene monomer (a carcinogen) and HBCD flame retardant	
Closed-cell spray polyurethane	Spray-in cavity-fill or spray-on roofing	5.8–6.8 (40–47)	Fossil fuels, HCFC-141b (through early 2005) or HFC-245fa blowing agent; nonbrominated flame retardant	Energy use during manufacture, global-warming potential from HFC blowing agent	Quite toxic during installation (respirators or supplied air required). Allow several days of airing out prior to occupancy	
Open-cell, low-density polyurethane	Spray-in cavity-fill	3.6–3.8 (25–27)	Fossil fuels and soybeans; water as a blowing agent; nonbrominated flame retardant	Energy use during manufacture	Quite toxic during installation (respirators or supplied air required). Allow several days of airing out prior to occupancy	
Air-Krete	Spray-in cavity-fill	3.9 (27)	Magnesium oxide from seawater; ceramic talc	Negligible	Considered very safe	Highly fire-resistant; inert; remains friable
Radiant barrier						

Bubble back	Stapled to framing	Depends on installation	Aluminum; fossil fuels	Energy use during manufacture	Minimal offgassing from plastic	Exaggerated *R*-value claims have been common
Foil-faced polyethylene foam	Stapled to framing; requires air space for radiant benefit	Depends on installation	Aluminum; fossil fuels; recycled polyethylene	Energy use during manufacture	Minimal offgassing from polyethylene	Exaggerated *R*-value claims have been common. Recycled content in some
Foil-faced paperboard sheathing	Stapled to framing; requires air space for radiant benefit	Depends on installation	Aluminum; fossil fuels; recycled paper	Energy use during manufacture	Considered very safe	High recycled content. Structural sheathing available (e.g., Thermo-Ply®)
Foil-faced OSB	Most common as attic sheathing	Depends on installation	Wood fiber; formaldehyde binder in OSB; aluminum	Energy use and VOC emissions during manufacture	Formaldehyde emissions	Primary benefit is reduced heat gain

Exterior Rigid Fiber Glass or Foam Insulation

Rigid insulation is generally more expensive per *R*-value than mineral wool or cellulose, but its rigidity is a major advantage (Fig. 3). However, it is difficult and expensive to obtain *R*-values as high as in framed walls.

Interior Foam Wall Insulation

Foam insulation can be installed on the interior of concrete block walls (Fig. 4); however, it must be covered with a material that resists damage and meets local fire code requirements. Half-inch drywall will typically comply, but furring strips will need to be installed as nailing surfaces. Furring strips are usually installed between sheets of foam insulation; however, to avoid the direct, uninsulated thermal bridge between the concrete wall and the furring strips, a continuous layer of foam should be installed underneath or on top of the nailing strips.

Interior Framed Wall

In some cases, designers will specify a framed wall on the interior of a masonry wall (Fig. 5). Standard framed wall insulation and air-sealing practice can then be applied.

Insulated Concrete Form Systems

Insulated concrete forms (ICFs) are permanent rigid plastic foam forms that are filled with reinforced concrete to create structural walls with significant thermal insulation (Fig. 6). The foam is typically either expanded polystyrene (EPS) or extruded polystyrene (XPS) and occasionally polyurethane, but it may also be made from a composite of cement and foam insulation or a composite of cement and processed wood.[5]

The concrete will be one of several shapes: flat, waffle- or screen-grid, or post-and-beam, depending on the specific form design. The Portland Cement Association (PCA) reports that in 1994, 0.1% of all new homes used ICFs in above-grade walls (about 1100 new homes). That number rose to 1.2% in 1999, 2.7% in 2001, and increased to 3.8% in 2002, which would be 50,639 homes, according to U.S. Census Data.

Above-grade ICF walls cost more to build than typical wood-framed walls. As wood-framed walls approach the thermal insulation value of ICFs, the cost differential will decrease. In most cases, materials' costs (concrete and forms) are primarily responsible for increased costs, while labor costs are often similar to wood framing. Cost premium depends on relative material prices, labor efficiency for each system, engineering necessity, and its effect on other practices or trades, among other factors.

The cost premium for ICF houses is smaller in areas such as high-wind regions, which require additional labor, time, and materials for special construction of

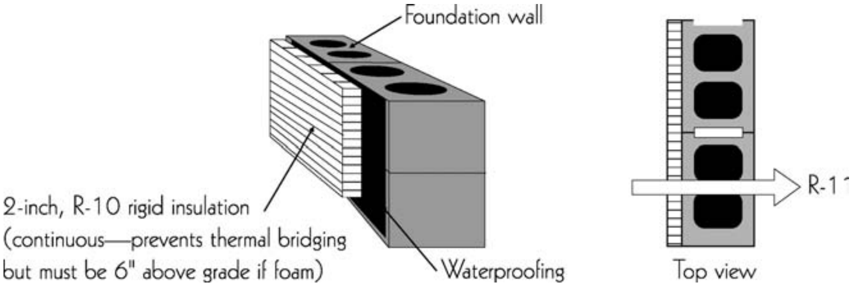

Fig. 3 Exterior foam insulation (R-11–R-12 overall).

wood-framed houses. According to an NAHB Research Center study, costs are estimated to increase by 1%–8% of total house cost over a wood-framed house.

Lightweight Concrete Products

Lightweight, air-entrained concrete is an alternative wall system (Fig. 7). Autoclaved aerated concrete (AAC), sometimes referred to as precast autoclaved aerated concrete (PAAC), which can be shipped either as blocks or panels, combines elevated *R*-values (compared to standard concrete) with thermal mass.

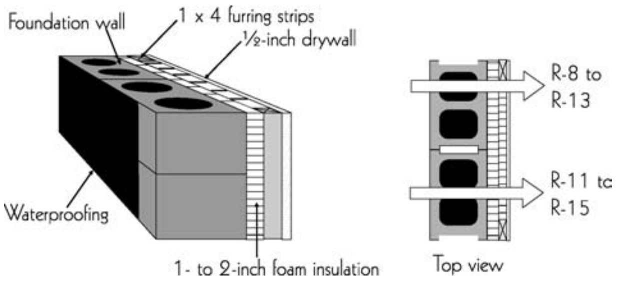

Fig. 4 Interior foam insulation (R-10–R-14 overall).

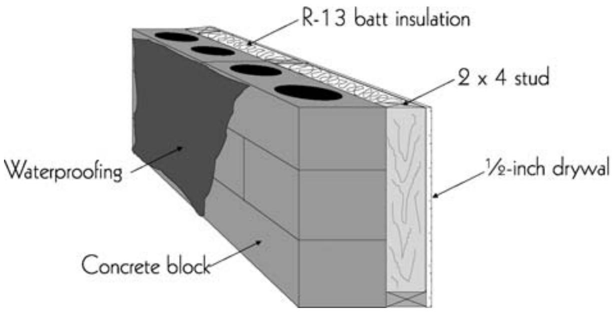

Fig. 5 Interior framed wall insulation (R-11–R-13 overall).

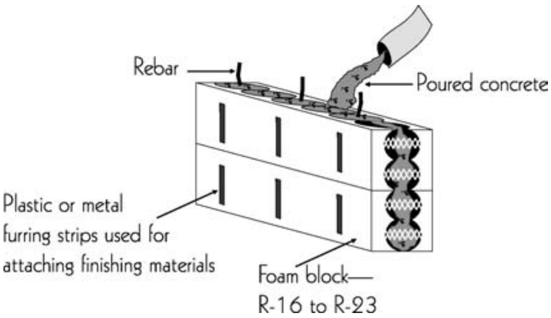

Fig. 6 Insulated concrete foam system (R-17–R-24 overall).

2×4 Wall Insulation

Throughout the United States, debates on optimal wall construction continue.[6] Table 3 summarizes typical problems and solutions in walls framed with 2×4 studs. In addition to standard framing lumber and fasteners, the following materials will also be required during construction:

- Foam sheathing for insulating headers.
- 1×4 or metal T-bracing for corner bracing (Fig. 8).
- R-13 batts for insulating areas during framing behind shower/tub enclosures and other hidden areas.
- From the Florida Building Code, Residential (FBC-R): "R307.2 Bathtub and shower spaces. Bathtub and shower floors and walls above bathtubs with installed shower heads and in shower compartments shall be finished with a nonabsorbent surface. Such wall surfaces shall extend to a height of not less than 6 ft above the floor."
- Caulking or foam sealant for sealing areas that may be more difficult to seal later.

Avoid Side Stapling

Walls are usually insulated with batts that have attached vapor retarder facing. Many builders question whether it is best to side staple or face staple batt insulation. The common arguments are that face stapling results in less

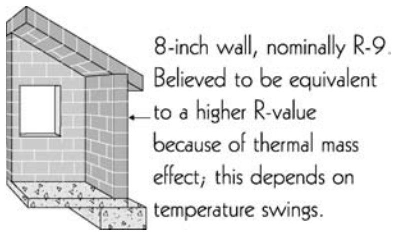

Fig. 7 Lightweight concrete products (R-1.1 per inch plus).

Table 3 2×4 Framed wall problems and solutions

Problem	Solution
Small space available for insulation	Install continuous exterior foam sheathing and medium (R-13) to high (R-15) density cavity insulation
Enclosed cavities are more prone to cause condensation, particularly when sheathing materials with low *R*-values are used	Install a continuous air barrier system. Use continuous foam sheathing
Presence of wiring, plumbing, ductwork, and framing members lessens potential *R*-value and provides pathways for air leakage	Locate mechanical systems in interior walls; avoid horizontal wiring runs through exterior walls; use air sealing insulation system

compression, while side stapling interferes less with drywall installation.

The ideal solution should focus on where the kraft paper (vapor retarder) is rather than on how it is installed.[7]

The face stapling question is an appropriate question in northern or "heating-dominated" climates. In northern areas, vapor retarders should be installed on the "warm" side of the wall cavity. In southern or "cooling-dominated" climates, the vapor retarder should be on the outside surface of the wall cavity. Because of this, the use of unfaced batts is recommended in hot-humid climates (Fig. 9).

Unfaced batts are slightly larger than the standard 16- or 24-inch stud spacing and rely on a friction-fit for support. Because unfaced batts are not stapled, they can often be installed in less time. In addition, it is easier to cut unfaced batts to fit around wiring, plumbing, and other obstructions in the walls.

Blown Loose-Fill Insulation

Loose-fill cellulose, fiberglass, and rock wool insulation can also be used to insulate walls. This insulation is installed with a blowing machine and held in place with a glue binder or netting (Fig. 10). This technique can provide good insulation coverage in the stud cavities; however, it is very important that excess moisture in the binder be allowed to evaporate before the wall cavities are enclosed by an interior finish. Keep in mind that insulation products are not replacements for proper air sealing technique.

Blown Foam Insulation

Some insulation contractors are now blowing polyurethane or polyicynene insulation into the walls and ceilings of new buildings (Fig. 11). This technique provides high *R*-values in relatively thin spaces and seals air leaks effectively. The economics of foam insulation should be examined carefully prior to their application.

Structural Insulated Panels

Another approach to wall construction is the use of structural insulated panels (SIP), also known as stress-skin panels (Fig. 12).[8] They consist of 4-inch or 6-inch thick

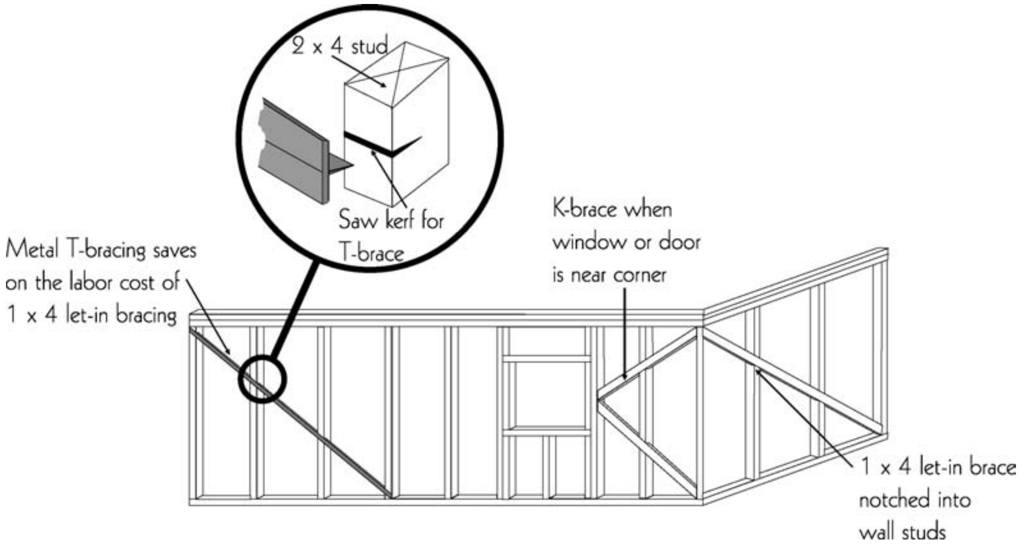

Fig. 8 Let-in bracing.

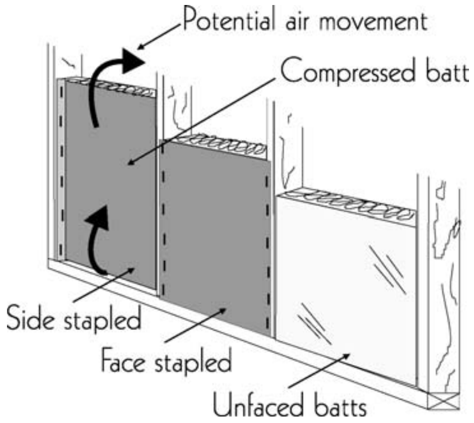

Fig. 9 Insulating walls with batts.

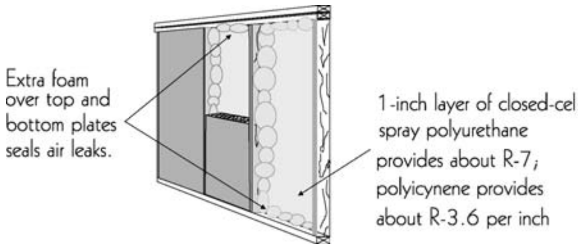

Fig. 11 Blown foam insulation.

foam panels onto which structural sheathing, such as oriented strand board (OSB), cement fiber board, or various types of metal have been attached. They reduce labor costs, and because of the reduced framing in the wall, they have higher *R*-values and less air leakage than standard walls.

SIPs are generally four feet wide and eight to twelve feet long. There are a wide variety of manufacturers, each with its own method of attaching panels together. Procedures for installing windows, doors, wiring, and plumbing have been worked out by each manufacturer. Some SIPs come from the factory with preinstalled windows. In addition to their use as wall framing, SIPs can also be used in ceilings, floors, and roofs.

While buildings constructed with SIPs may be more expensive than those with standard framed and insulated walls, research studies have shown that SIP-built buildings have higher average insulating values per inch than most commonly used insulation materials. Due to their typical modular style of construction, infiltration losses are also reduced. Thus, they can provide substantial energy savings. Be sure to follow local building codes with regard to termites, including leaving a 6” inspection zone above finished grade.

The performance of any SIP wall depends on its component materials and installation processes. There are a few important variables to take into consideration when building with SIP systems:

1. Panel fabrication (proper panel gluing, pressing, and curing) is critical to prevent delamination.
2. Panels must be flat, plumb, and have well-designed connections to ensure tightness of construction.
3. Though SIPs offer ease of construction, installers may need training in installing the system being used.
4. Fire rating of SIP materials and air-tightness of SIP installation affect the system’s fire safety.
5. There may be potential insect and rodent mitigation issues, depending on SIP materials and construction.
6. Proper HVAC design and installation must take the SIP system being used into account.

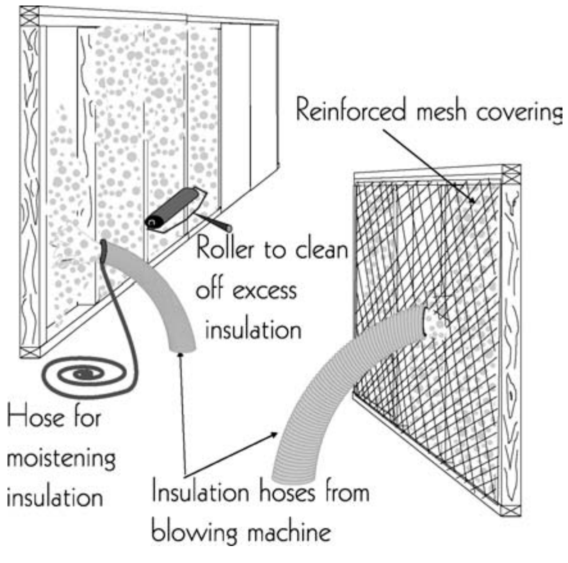

Fig. 10 Blown sidewall insulation options.

Metal Framing

Builders and designers are well aware of the increasing cost and decreasing quality of framing lumber. As a consequence, interest in alternative framing materials,

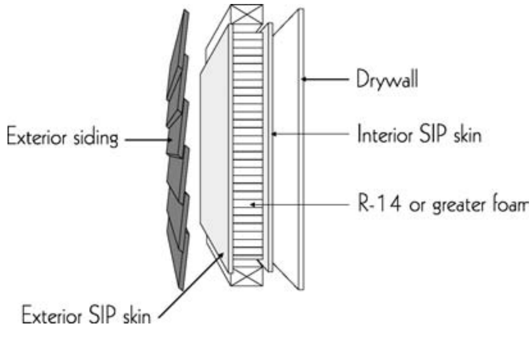

Fig. 12 Structural insulated panels (SIP).

such as metal framing, has grown. While metal framing offers advantages over wood, such as consistency of dimensions, lack of warping, and resistance to moisture and insect problems, it has distinct disadvantages from an energy perspective.

Metal framing is an excellent conductor of heat. Buildings framed with metal studs and plates usually have metal ceiling joists and rafters, as well. Thus, the entire structure serves as a highly conductive thermal grid. Insulation placed between metal studs and joists is much less effective due to the extreme thermal bridging that occurs across the framing members.

The American Iron and Steel Institute is well aware of the challenges involved in building an energy efficient steel structure. In their publication *Thermal Design Guide for Exterior Walls (Publication RG-9405)*, the Institute provides information on the thermal performance of steel-framed buildings. Table 4 summarizes some of their findings.

Moisture-related problems have been reported in metal frame buildings that do not use sufficient insulated sheathing on exterior walls. Metal studs cooled by the air conditioning system can cause outdoor air to condense, leading to mildew streaks (or ghosting), where one can see the framing members on the inside and outside of a home. In winter, studs covered by cold outside air can also cause streaking. Attention to proper insulation techniques can alleviate this problem.

2×6 Wall Construction

There has been interest in hot, humid climates in the use of 2×6s for construction. The advantages of using wider wall framing are:

- More space provides room for R-19 or R-21 wall insulation.
- Thermal bridging across the studs is less of a penalty due to the higher *R*-value of 2×6s.
- Less framing reduces labor and material costs.
- There is more space for insulating around piping, wiring, and ductwork.

Table 4 Effective steel wall *R*-values

Cavity insulation	Sheathing	Effective overall *R*-value
11	2.5	9.5
11	5	13
11	10	18
13	2.5	10
13	5	14

Disadvantages of 2×6 framing include:

- Wider spacing may cause the interior finish or exterior siding to bow slightly between studs.
- Window and door jambs must be deeper, resulting in additional costs.
- Walls with substantial window and door area may require almost as much framing as 2×4 walls and leave relatively little area for actual insulation.

The economics of 2×6 wall insulation are affected by the number of windows in the wall because each window opening adds extra studs and may require the purchase of a jamb extender. Walls built with 2×6s having few windows provide positive economic payback. However, for walls in which windows make up over 10% of the total area, the economics become questionable.

CEILINGS AND ROOFS

Attics over flat ceilings are usually the easiest part of a building's exterior envelope to insulate. They are accessible and have ample room for insulation. However, many homes use cathedral ceilings that provide little space for insulation.[9] It is important to insulate both types of ceilings properly.

Attic Ventilation

In the summer, properly designed ventilation reduces roof and ceiling temperatures, thus potentially saving on cooling costs and lengthening the life of the roof. In winter, roof vents expel moisture which could otherwise accumulate and deteriorate insulation or other building materials.

At present, several research studies are investigating whether attic ventilation is beneficial. For years, researchers have believed the cooling benefits of ventilating a well-insulated attic to be negligible. However, some experts are now questioning whether ventilation is even effective at moisture removal. The Florida Building Code, Residential now provides provisions for "conditioned attic assemblies" (Section R806.4) as long as certain conditions are met. When attic ventilation is provided, ventilation openings shall be provided with corrosion-resistant wire mesh with 1/8 in. minimum to 1/4 in. maximum openings. Total net free ventilation area shall not be less than 1–150 of the area of the space ventilated. An exception for 1–300 is provided in the code.

Vent Selection

The amount of attic ventilation needed is based on state building code requirements. If ventilating the roof, locate vents high along the roof ridge and low along the eave or

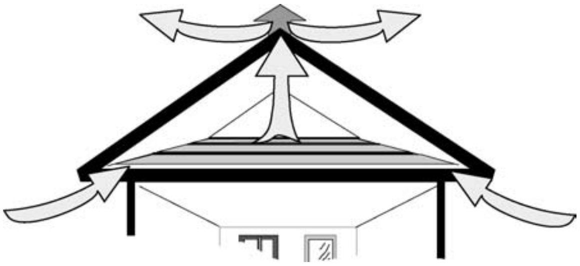

Fig. 13 Attic ventilation through soffit and ridge Vents.

soffit. Vents should provide air movement across the entire roof area (Fig. 13). There are a wide variety of products available, including ridge, gable, soffit, and mushroom vents.

To allow for proper airflow in attic spaces, it is common practice to install a rafter baffle at the soffit. This will prevent insulation from sealing off the airflow from the soffit vent to the attic space.

The combination of continuous ridge vents along the peak of the roof and continuous soffit vents at the eave provides the most effective ventilation. Ridge vents come in a variety of colors to match any roof. Some brands are made of plastic and covered by cap shingles to hide the vent from view.

Manufacturer or product testing is being performed by a variety of organizations to verify leak-free operation of continuous ridge vents in high wind situations. Care should be taken to ensure that the vents chosen are appropriate for hurricane-prone areas.

Powered Attic Ventilator

Electrically powered roof ventilators can consume more electricity to operate than they save on air conditioning costs and are not recommended for most designs. Power vents can create negative pressures in the home, which may have detrimental effects, such as (Fig. 14):

- Drawing outside air into the home
- Removing conditioned air from the home through ceiling leaks and bypasses
- Pulling pollutants, such as radon and sewer gases, into the home
- Backdrafting fireplaces and fuel-burning appliances

Attic Floor Insulation Techniques

Either loose-fill or batt insulation can be installed on an attic floor. Generally, blowing loose-fill attic insulation is usually less expensive than installing batts or rolls. Most attics have either blown fiberglass, rock wool, or cellulose. Ceilings with a rise greater than 5 and a run of 12 (5 over 12) should not be insulated with blown-in insulation.

Loose-Fill Attic Insulation

Steps for installing loose-fill attic insulation[10]:

1. Seal attic air leaks, as prescribed by fire and energy codes.
2. Follow manufacturer's and state building code clearance requirements for heat-producing equipment found in an attic, such as flues or exhaust fans. One example of attic blocking is shown later in this chapter.
3. Use baffles to preserve ventilation space at eave of roof for soffit vents.
4. Insulate the attic hatch or attic stair. Foam boxes are available for providing a degree of insulation over a pull-down attic stairway.
5. Determine the attic insulation area; based on the spacing and size of the joists, use the chart on the

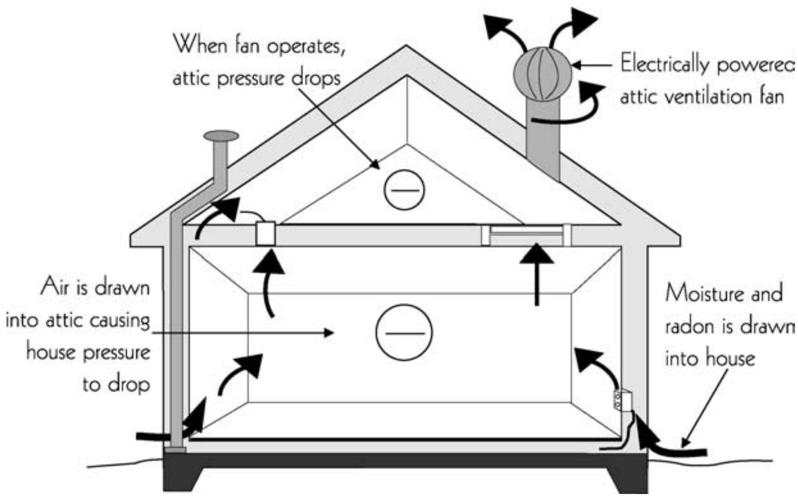

Fig. 14 Attic ventilation through powered ventilation.

Table 5 Blown cellulose in attics

			2×6 joists spaced 24 in. on center		2×6 joists spaced 16 in. on center	
***R*-value at 75°F**	**Minimum thickness (in.)**	**Minimum weight (lb/ft^2)**	**Coverage per 25-lb bag (ft^2)**	**Bags per 1000 ft^2**	**Coverage per 25-lb bag (ft^2)**	**Bags per 1000 ft^2**
R-40	10.8	2.10	12	83	13	77
R-32	8.6	1.60	16	63	18	56
R-24	6.5	0.98	21	48	23	43
R-19	5.1	0.67	37	27	41	24

insulation bag to determine the number of bags to install. Table 5 shows a sample chart for cellulose insulation. Cellulose is heavier than fiberglass for the same *R*-value. Closer spacing of roof joists and thicker drywall is required for larger *R*-values. Check this detail with the insulation contractor. Weight limits and other factors at R-38 insulation levels are shown in Table 5 for the three primary types of loose fills.

6. Avoid fluffing the insulation (blowing with too much air) by using the proper air-to-insulation mixture in the blowing machine. A few insulation contractors have "fluffed" (added extra air to) loose-fill insulation to give the impression of a high *R*-value. The insulation may be the proper depth, but if too few bags are installed, the *R*-values will be less than claimed.
7. Obtain complete coverage of the blown insulation at relatively even insulation depths. Use attic rulers (obtainable from insulation contractors) to ensure uniform depth of insulation.

Batt Attic Insulation

Steps for installing batt insulation:

1. Seal attic air leaks, as prescribed by fire and energy codes.
2. Block around heat-producing devices, as described in Step 2 for loose-fill insulation.
3. Insulate the attic hatch or attic stair as described in Step 4 for loose-fill insulation.
4. Determine the attic insulation area based on the spacing and size of the joists, order sufficient R-30 insulation for the flat attic floor. Choose batts that are tapered—cut wider on top—so that they cover the top of the ceiling joists. (See Fig. 15).
5. When installing the batts, make certain they completely fill the joist cavities. Shake batts to ensure proper loft. If the joist spacing is uneven, patch gaps in the insulation with scrap pieces. Try not to compress the insulation with wiring, plumbing, or ductwork. In general, obtain complete coverage of full-thickness, noncompressed insulation.
6. Attic storage areas can pose a problem. If the ceiling joists are shallower than the depth of the insulation (generally less than 2×10s), raise the finished floor using 2×4s or other spacing lumber. Install the batts before nailing the storage floor in place (see Fig. 16).

Note that often attic framing is not designed for storage. Check engineered loads of framing before increasing loads and piggy-backing ceiling joists.

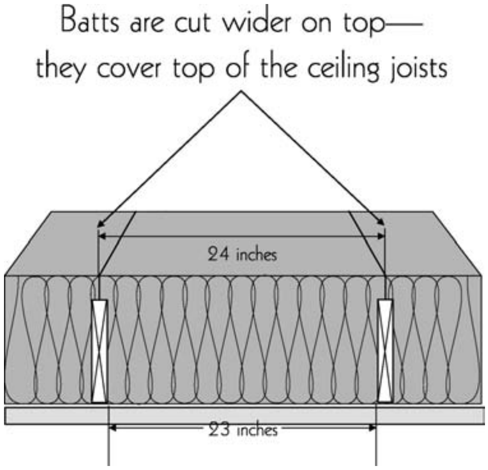

Fig. 15 Full-with ceiling batt insulation.

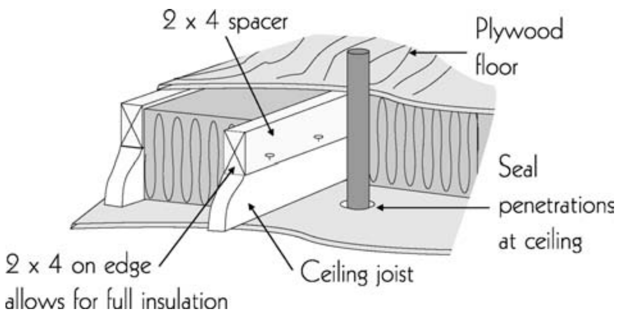

Fig. 16 Ceiling insulation under attic storage floor.

Indu–Inter

Preventing Air Flow Restrictions at the Eave

One problem area in many standard roof designs is at the eave, where there is not enough room for full R-30 insulation without preventing air flow from the soffit vent or compressing the insulation, which reduces its *R*-value. Figs. 17 and 18 show several solutions to this problem. If using a truss roof, purchase raised heel trusses that form horizontal overhangs. They should provide adequate clearance for both ventilation and insulation.

In stick-built roofs, where rafters and ceiling joists are cut and installed on the construction site, an additional top plate that lies across the top of the ceiling joists at the eave will prevent compression of the attic insulation. Note: This needs to be a double plate for bearing unless rafters sit directly above joists. The rafters sitting on this raised top plate allow for both insulation and ventilation.

Cathedral Ceiling Insulation Techniques

Cathedral ceilings are a special case because of the limited space for insulation and ventilation within the depth of the rafter. Fitting in a 10-in. batt (R-30) and still providing ventilation is impossible with a 2×6 or 2×8 rafter (R-19 or R-25, respectively).

Building R-30 Cathedral Ceilings

Cathedral ceilings built with 2×12 rafters can be insulated with standard R-30 batts and still have plenty of space for ventilation. Some builders use a vent baffle between the insulation and roof decking to ensure that the ventilation channel is maintained.

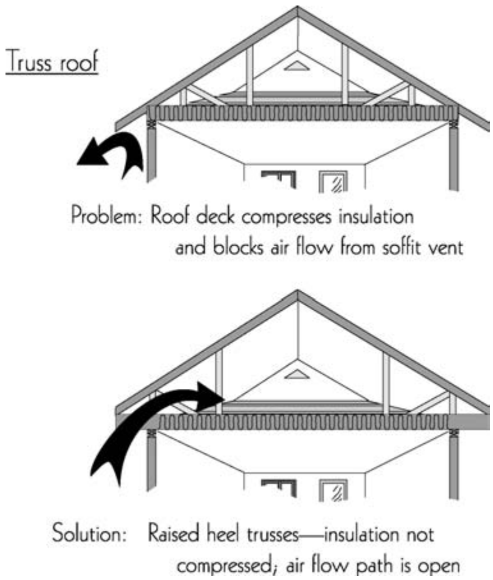

Fig. 17 Soffit air ventilation—raised heel trusses.

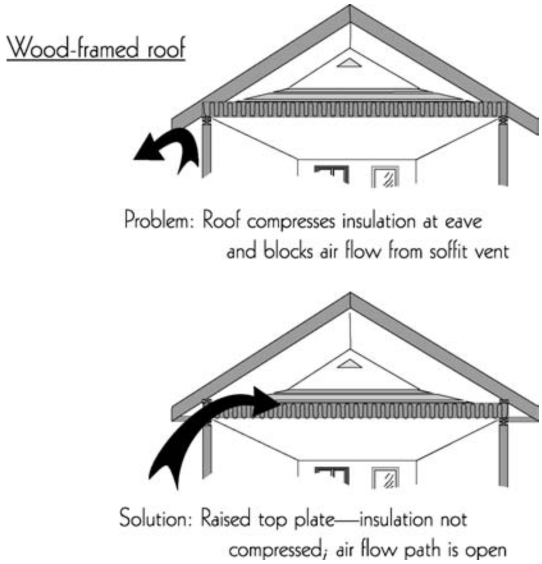

Fig. 18 Soffit air ventilation—raised top plate.

If 2×12s are not required structurally, most builders find it cheaper to construct cathedral ceilings with 2×10 rafters and high-density R-30 batts, which are 8¼ in. thick (Table 6).

Some contractors wish to avoid the higher cost of 2×10 lumber and use 2×8 rafters. These roofs are usually insulated with R-19 batts.

In framing with 2×6 and 2×8 rafters, higher insulating values can be obtained by installing rigid foam insulation under the rafters. Note that the rigid foam insulation must be covered with a fire-rated material when used on the interior of the building. Drywall usually meets this requirement.

Scissor Trusses

Scissor trusses are another cathedral ceiling framing option. Make certain they provide adequate room for both R-30 insulation and ventilation, especially at their ends, which form the eave section of the roof.

Difficulties with Exposed Rafters

A cathedral ceiling with exposed rafters or roof decking is difficult and expensive to insulate well. Often, foam

Table 6 Cathedral ceiling insulation options

Rafter	Batt
2×8	R-19
2×10	R-25
2×10	Moderate density R-30
2×12	Standard density R-30

Any sized rafter; blown-in cellulose, fiberglass, or rock wool held in place; provide 1 in. ventilation space above.

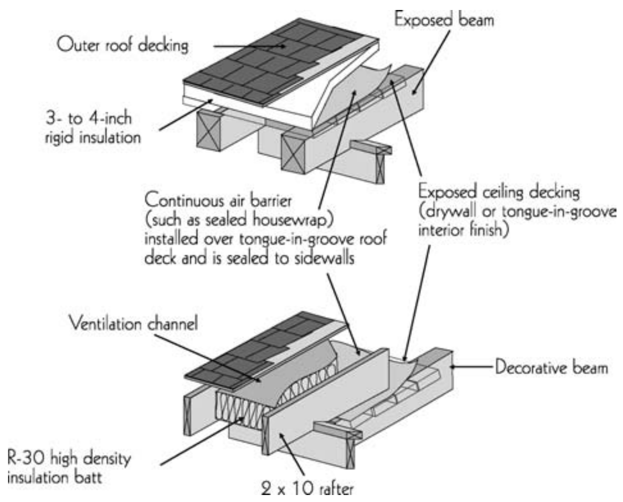

Fig. 19 Insulating exposed rafters.

insulation panels are used over the attic deck, as shown in Fig. 19. However, to achieve R-30, four to seven inches of foam insulation are needed. Ventilation is also a problem.

In homes where exposed rafters are desired, it may be more economical to build a standard, energy efficient cathedral ceiling, and then add exposed decorative beams underneath. Note that homes having tongue-and-groove ceilings can experience substantially more air leakage than solid, drywall ceilings. Install a continuous air barrier, sealed to the walls above the tongue-and-groove roof deck and held in place; provide 1 in. ventilation space above.

Recessed Lights

Standard recessed fixtures require a clearance of several inches between the sides of the lamp's housing and the attic insulation. In addition, insulation cannot be placed over the fixture. Even worse, recessed lights leak considerable air between attics and the home.

Insulated ceiling (IC) rated fixtures have a heat sensor switch that allows the fixture to be covered—except for the top—with insulation (see Fig. 20 for the proper insulation methods for these fixtures). However, these units also leak air. If you have to use recessed lights, install airtight IC-rated fixtures. There are alternatives to recessed lights, including surface-mounted ceiling fixtures and track lighting, which typically contribute less air leakage to the home.

RADIANT HEAT BARRIERS

Radiant heat barriers (RHB) are reflective materials that can reduce summer heat gain via the insulation and building materials in attics and walls. RHBs work two ways: first, they reflect thermal radiation well; and, second, they emit (give off) very little heat. RHBs should always face a vented airspace and be installed to prevent dust build-up. They are usually attached to the underside of the rafter or truss top chord or to the underside of the roof decking. Acceptable attic radiant barrier configurations can be found in Fig. 21.

How Radiant Barrier Systems Work

A radiant barrier reduces heat transfer. Thermal radiation, or radiant heat, travels in a straight line away from a hot surface and heats any object in its path.

When sunshine heats a roof, most of the heat conducts through the exterior roofing materials to the inside surface

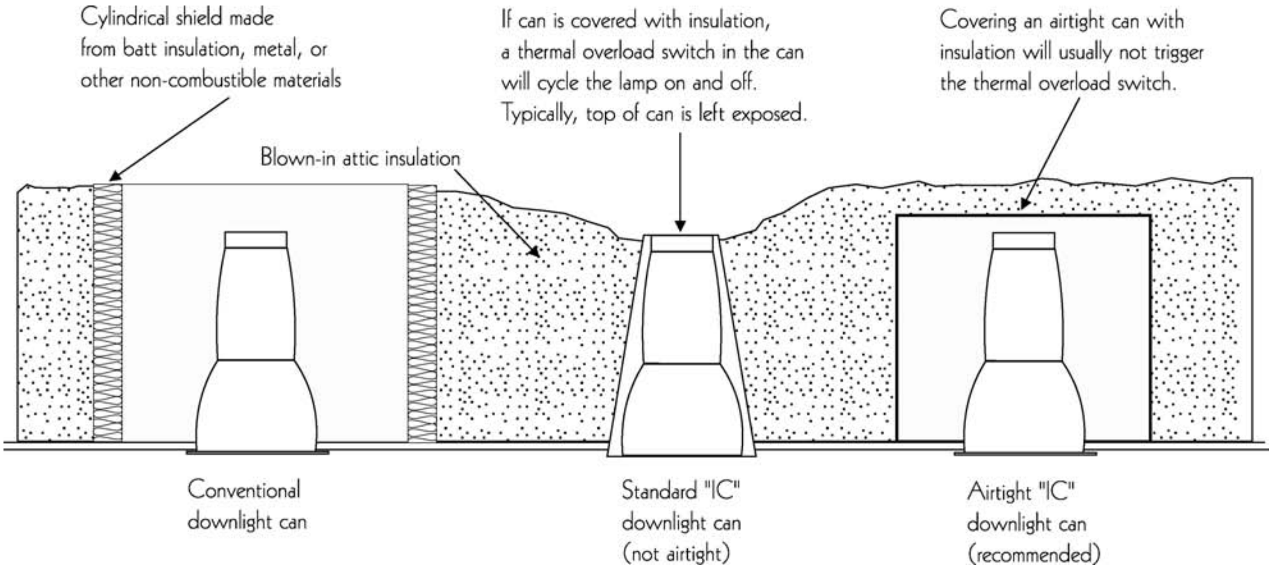

Fig. 20 Recessed lighting insulation.

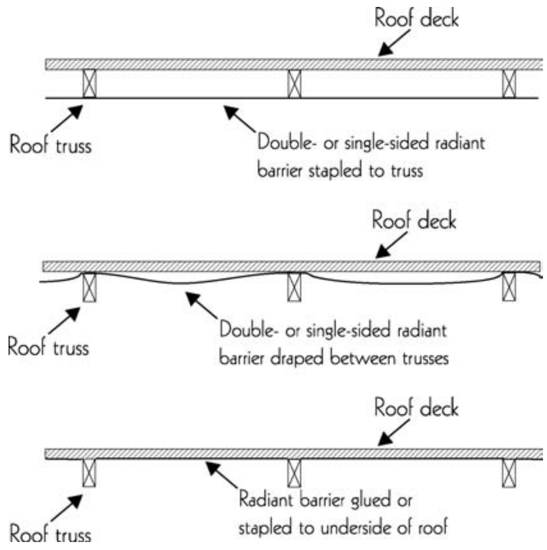

Fig. 21 Radiant Barrier Configuration.

of the roof sheathing. Heat then transfers by radiation across the attic space to the next material—either the top of the attic insulation or the attic floor. A radiant barrier, properly installed in one of many locations between the roof surface and the attic floor, will reduce radiant heat flow. Thermal insulation on the attic floor resists the flow of heat through the ceiling into the living space below. The rate at which insulation resists this flow determines the insulation's *R*-value. The amount of thermal insulation affects the potential radiant barrier energy savings. For example, installing a radiant barrier in an attic that already has high levels of insulation (R-30 or above) would result in much lower energy savings than an attic insulated at a low level (R-11 or less).

All radiant barriers use reflective foil that blocks radiant heat transfer. In an attic, a radiant barrier that faces an air space can block up to 95% of the heat radiating down from a hot roof. Only a single, thin, reflective surface is necessary to produce this reduction in radiant heat transfer. Additional layers of foil do little more to reduce the remaining radiant heat flow.

Conventional types of insulation consist of fibers or cells that trap air or contain a gas to retard heat conduction. These types of insulation reduce conductive and radiant heat transfer at a rate determined by their *R*-value, while radiant barriers reduce only radiant heat transfer. There is no current method for assigning an *R*-value to radiant barriers. The reduction in heat flow achieved by the installation of a radiant barrier depends on a number of factors, such as ventilation rates, roof reflectivity, ambient air temperatures, geographical location, the amount of roof solar gains, and the amount of conventional insulation present.

Several factors affect the cost effectiveness of installing a radiant barrier. You should examine the performance and cost savings of at least three potential insulation options: adding additional conventional insulation, installing a radiant barrier, and adding both conventional insulation and a radiant barrier.

In 1991 (revised June, 2001), the U.S. Department of Energy (DOE) published the Radiant Barrier Attic Fact Sheet, which shows how to calculate the economics of radiant barriers and added ceiling insulation. It includes an Energy Savings Worksheet with an example. The worksheet is part of the fact sheet and can be found at http://www.ornl.gov/sci/roofs+walls/radiant/rb_05.html.[11]

Because radiant barriers redirect radiant heat back through the roofing materials, shingle temperatures may increase between 1 and 10°F (0.6°C–5.6°C). This increase does not appear to exceed the roof shingle design criteria. The overall effect on roof life, if any, is not known.

Remember, radiant barriers are most effective in blocking summer radiant heat gain and saving air-conditioning costs. Although the radiant barrier may be somewhat effective in retaining heat within a cold-climate home, it may also block any radiant winter solar heat gain in the attic.

CONCLUSION

Buildings are insulated to help moderate the environment that we live and work in. As utility costs rise, this aspect of our constructed environment becomes more and more important. Many new materials have entered the market in the past few years, each having their own particular advantages and disadvantages. This article has described in detail the importance of installation practices and their effect on overall performance. Emphasis was placed on properly defining the building envelope and different methods and materials that can be used to effectively insulate and, therefore, thermally isolate the constructed environment from the daily extremes produced by local weather.

New techniques and materials will evolve; however, some guidelines will remain the same:

- Choose an insulation material with characteristics suitable for the climate region.
- Use the proper *R*-value for the climate region where each particular structure is being constructed.
- Apply the recommended thickness, or *R*-value, to each building component, such as ceiling, walls, and floors.
- Install each particular insulation product in a proper fashion, following the manufacturer's recommendations and instructions, leaving no voids, and filling each building cavity to the level required for the building site.

Insulation materials and techniques play a large part in minimizing energy consumption and maximizing human comfort. Recent advances in both materials and techniques will help further this trend.

ACKNOWLEDGMENTS

Many thanks to Kyle Allen, an engineering student at the University of Florida, because without his persistent efforts, the publication of this article would not have been possible.

Abstract
Gasification or partial oxidation in an integrated gasification combined cycle (IGCC) consists of converting an often "dirty" fuel, such as coal, biomass, or refinery residues that cannot be directly used in gas turbines, to a clean gaseous fuel that meets engine specifications and environmental emissions standards. Gasification itself has been in commercial use for more than fifty years; its first applications involved making "town gas" for heating and cooking purposes before large natural gas reserves were discovered and providing synthesis gas (or syngas) for production of chemicals. Valuable coproducts such as H_2 or Fischer Tropsch liquids can enhance IGCC economics.

INTRODUCTION

Conversion of gasification feedstock is accomplished in a "gasifier," where the feedstock is typically reacted with an oxidant (oxygen or air) under partially oxidizing conditions. The partial oxidation reaction for carbon is

$$C + 1/2\,O_2 = CO.$$

Because this reaction is exothermic, water is introduced as steam or a liquid to moderate reaction temperature by the endothermic reaction:

$$C + H_2O = H_2 + CO.$$

Other reactions that occur within a gasifier include the shift reaction

$$CO + H_2O = H_2 + CO_2$$

and the hydrogasification reaction

$$C + 2H_2 = CH_4.$$

Sulfur present in feed is evolved mostly as H_2S with some as COS. CS_2 and mercaptans are insignificant when gasification occurs at high temperatures (over 1800°F or 980°C).

Prior to gasification reactions, feedstock undergoes heat-up, drying and pyrolysis or devolatilization. Pyrolysis produces a number of components such as H_2, NH_3, HCN, H_2S, COS, CS_2, mercaptans, CO_2, H_2O, CH_4, and higher hydrocarbons, tars and oils. Depending on the temperature of the gases leaving the gasifier, decomposition or reforming of some of the pyrolysis products may occur.

Typical syngas compositions obtained by high temperature gasification are shown in Table 1.

Keywords: Gasification zero emission; Gasifier; IGCC; Integrated gasification combined cycle.

TYPES OF GASIFIERS

There are three major types of gasifiers:

- Moving bed gasifiers as exemplified by the Lurgi gasifier,[15] consists of introducing coarse solids at the gasifier top while oxidant and steam are introduced at the gasifier bottom. The gasifier may be divided into four distinct zones, from top to bottom: (1) the drying/preheating zone, (2) the devolatilization zone, (3) the gasification zone, and (4) the combustion zone. Gases leave the top at relatively low temperatures (under 1000°F or 540°C) and contain H_2, CO, CO_2, H_2O, CH_4, and other organic compounds including oils and tars; sulfur compounds such as H_2S, COS, some CS_2 and mercaptans; and nitrogen compounds such as NH_3 and HCN. The tars also contain some sulfur and nitrogen. Gasifier thermal efficiency is high while specific O_2 consumption is low, but since the process produces tars and oils, gas clean-up is more complex. Only a limited amount of fines in the feed can be handled. Coals with high Free Swelling Indices could plug up the bed and are not desirable feedstocks. The British Gas Lurgi gasifier,[3] which is similar to the original Lurgi in many respects, recycles tars and oils separated from the gas to the gasifier by introducing these into the bottom section of the gasifier along with fines.
- The fluidized bed gasifier as exemplified by the Advanced Transport Reactor[8] consists of introducing dried feed that is typically less than 0.25 in. (0.64 cm) near the bottom of the gasifier and accomplishing devolatilization and gasification in a bed fluidized by oxidant and steam. Recycled synthesis gas may also be used to maintain required gas velocity for fluidization of bed material. In the bottom section of the gasifier, the temperature is high enough to fuse ash

Table 1 Typical syngas compositions

Component (vol.% dry basis)	Air blown Biomass feed	High temperature entrained Oxygen blown High sulfur coal feed
CO	15	46.5
H_2	16	37.3
CO_2	18	13.5
CH_4	7	0.1
N_2+Ar	44	1.9
H_2S+COS	Trace	0.7
Total	100	100.0

particles together to form agglomerates; while in the top of the gasifier, where gasification reactions predominate, temperatures are lower (1800°F–1900°F or 980°C–1040°C). Gases leaving the gasifier are essentially free of hydrocarbons heavier than CH_4. Thermal efficiency of this type of gasifier tends to be lower since syngas carries more of feed (coal or biomass) bound energy as sensible heat than moving bed gasifiers, while specific O_2 consumption tends to be higher. Carbon conversion tends to be rather low with unreactive feedstocks, such as high-rank coals, and is more suitable to lower-rank coals (lignites and subbituminous) and biomass. This gasifier is especially suitable for biomass applications in which the feedstock also tends to be heterogeneous with respect to particle size and composition. Further, since a large inventory of bed material is maintained within the gasifier, the gasifier performance tends to be less susceptible to sudden changes in feedstock composition.

- Entrained bed gasifiers, as exemplified by General Electric[9] and Shell,[5] operate at temperatures typically in excess of 2200°F or 1200°C, with ash forming a slag, while syngas is essentially free of hydrocarbons heavier than CH_4. In the General Electric gasifier, solids are introduced in the form of water slurry (containing finely ground solids); while in the Shell gasifier, solid feed is fed, after drying and grinding, with steam used as a temperature moderator. Thermal efficiency for a given carbon conversion tends to be the lowest among the three types of gasifiers, since syngas carries a significant portion of feed-bound energy as sensible heat, while specific O_2 consumption tends to be the highest. This type of gasifier is more suitable to unreactive feedstocks, such as high-rank coals and petroleum coke. The E-Gas entrained bed gasifier[6] introduces coal as a slurry into two sections of the gasifier in order to increase its efficiency while decreasing the specific O_2 consumption.

Depending on the type of gasifier, feedstock, and end use for the syngas, the operating pressure may vary from near atmospheric to as high as 1200 psig (8400 kPag).

Novel types of gasifiers are being developed, such as those that react steam with feedstock while using heat provided by an inert solid-circulating medium heated externally.[10] Such gasifiers have the advantage of utilizing air in the process instead of oxygen; the circulating medium is heated externally by combusting the unreacted char with the air while producing syngas with a heating value similar to or greater than that obtained from Oxygen blown gasifiers.

FEEDSTOCKS

Feedstocks that may be converted to syngas by gasification:

- Coal
- Biomass
  - — Agricultural
  - — Municipal (Sewage Sludge, Solid Waste)
- Paper Mill Black Liquor
- Refinery Residues
  - — Petroleum Coke
  - — Asphaltenes, Visbreaker Bottoms
  - — Refinery and Petrochemical Wastes
- Oil Emulsion (Orimulsion)

Important feedstock characteristics to be taken into account for gasifier selection (Also dependent on ultimate use of syngas):

- Reactivity
  - — Limited carbon conversion for fluidized bed gasifiers with lower reactivity feedstocks.
- Moisture Content
  - — High moisture content a thermal penalty for dry pulverized feed gasifiers, as well as for slurry feed gasifiers when it is bound moisture.
- Ash Content
  - — High ash content a thermal penalty for slurry feed gasifiers.
  - — Low ash content a challenge for membrane wall gasifiers such as the Shell gasifier; these may require recycle of ash.
- Ash Fusion Temperature Under Reducing Conditions (typically lower than that under oxidizing conditions for coals, while higher for petroleum cokes)
  - — High ash fusion temperature a thermal penalty for slagging gasifiers while shortening refractory life for refractory lined gasifiers; may require fluxing agent.
  - — Low ash fusion temperature a challenge for non-slagging gasifiers; may increase gasifier steam consumption.

- Particle Size
  — Lower limit on fines fraction in feed to moving bed gasifiers; may require briquetting.
- Free Swelling Index
  — Can cause plugging in moving bed gasifiers; may require a stirrer.

SYNGAS TREATMENT

Raw gas leaving a gasifier is either cooled by heat exchangers while generating steam or directly quenched with water. The cooled gas is purified by further treatments to remove contaminants such as particulates, alkalis, chlorides, and nitrogen and sulfur compounds. Various contaminants that could be present in coal-derived raw syngas are listed in Table 2. The exact nature of contaminants and their concentrations is dependent on the type of feedstock and type of gasifier. For example, potassium salts can be in significant concentrations in the case of raw syngas derived by the gasification of agricultural products, while the chlorides can be in significant concentrations in municipal-solid-waste-derived syngas. An advantage with gasification is that sulfur may be recovered as salable elemental sulfur or sulfuric acid.

The following section describes "cold gas cleanup" technologies used for treatment of syngas before it can be fired in gas turbines. "Warm gas cleanup" technologies to clean gas at higher temperatures (570°F–750°F or 300°C–400°C) are being developed, and some of these are in the demonstration phase.[2,4,7] Syngas is kept above its water dew point, which eliminates extensive waste water treatment typically required by gasification using cold gas cleanup.

Acid Gas Removal

Acid gas removal processes available for capturing sulfur compounds from syngas include the following:

1. Selective Amine Scrubbing (aqueous methyl diethanol amine solvent with additives)
2. Rectisol (methanol solvent)
3. Selexol® (mixture of dimethyl ethers of polyethylene glycol solvent)

The amine solvent, being a chemical solvent, requires a significant amount of steam for its regeneration to release absorbed acid gases. Additives improve selectivity between H_2S and CO_2 absorption and are suitable for applications in which CO_2 capture is not required. Without good selectivity, a significant fraction of CO_2 is co-absorbed by the solvent. The loss of CO_2 from syngas has the detrimental effect of reducing the amount of motive fluid (available at pressure) for expansion in gas turbines while increasing the amount of diluent required for NOx control. Furthermore, solvent circulation rate and utility consumptions are increased. The efficiency and cost of downstream sulfur recovery units (SRUs) (for converting captured H_2S and any co-absorbed COS to elemental sulfur), and tail gas treating units (for hydrogenating trace amounts of elemental sulfur and its oxygen containing compounds and for recovery of the H_2S) are also negatively affected due to the presence of a large concentration of CO_2 in the acid gas.

The amine process is used both in the Polk County, Florida[9] and Wabash, Indiana[6] IGCC plants. In Wabash, tail gas is recycled to the gasifier after hydrogenation, instead of treating it in an amine unit to recover the H_2S for recycling to the SRU.

Both the amine and Selexol® processes require COS hydrolysis to convert COS to H_2S, since only a small fraction of COS is captured. Hydrolysis is accomplished by the catalytic reaction:

$$COS + H_2O = H_2S + CO_2.$$

Rectisol and Selexol® processes utilize physical solvents and work best when the syngas to be treated is at a high pressure, typically greater than 400 psi (2800 kPa) for Rectisol and greater than 600 psi (4100 kPa) for Selexol®. Refrigeration is required to cool the solvent to enhance solubility.

Rectisol is especially suitable when very low specification on syngas sulfur content is required. COS hydrolysis is not required since it is readily absorbed by the solvent. Selexol® is especially suitable in "Zero Emission" IGCC plants where CO_2 emissions are to be controlled.[11] Syngas is decarbonized and desulfurized in the same Selexol® unit to produce gas that is essentially H_2 for combustion in gas turbines. CO_2 is released from the solvent at pressures significantly higher than atmospheric to reduce the power consumption of compressors required to generate a high-pressure CO_2 stream for sequestration.

Table 2 Typical coal derived syngas contaminants

Particulates	Carbonyls	Sulfur compounds
Ash	Ni	H_2S
Soot	Fe	COS
		CS_2
		Mercaptans
Volatile metals	**Chlorides**	**Nitrogen compounds**
Hg	NaCl	NH_3
As	HCl	HCN
Cd		
Se		

Indu–Inter

Metal Carbonyls

Metal carbonyls may be captured by activated carbon. Carbon particles accompanying syngas, leaving the gasifier, and collecting in barrier filters located upstream of the raw syngas scrubber may also capture carbonyls. Rectisol solvent captures carbonyls by converting them into sulfides.

Mercury, Arsenic, Cadmium and Selenium

Mercury, arsenic, cadmium and selenium typically volatilize within the gasifier and leave with the raw syngas. Sulfided activated carbon has been used to remove mercury and arsenic from syngas at the Tennessee Eastman plant.[14] Calgon offers this activated carbon for removal of mercury, reducing its concentration to as low as 0.01–0.1 μg/Nm^3 Hg in syngas depending on operating temperature and moisture content. Mercury is captured predominantly as a sulfide, with some captured as elemental mercury. Its capture is reduced as syngas temperature and relative humidity are increased. Spent carbon is disposed of as hazardous waste, although attempts are being made to recover elemental mercury.

Experience at the Eastman plant indicates that activated carbon is more effective in capturing arsenic. Calgon's experience has shown that arsenic, if present as an arsine, is captured by this sulfided carbon. SudChemie offers activated carbons for removal of arsenic and its compounds. Copper-impregnated carbon is offered to capture arsenic if present as an organic compound. The capture of other volatile metal (cadmium and selenium) compounds by the activated carbon is also expected to occur.

AIR SEPARATION TECHNOLOGY

In high-temperature gasifiers, gasifier efficiency is increased and the size of downstream equipment is minimized when oxygen is used instead of air. If air is used, a significant portion of feed-bound "chemical energy" is degraded to thermal to heat the N_2 to gasifier effluent temperature. In plants where CO_2 capture is required or syngas is to be utilized for co-producing products such as H_2 or methanol, it is essential that the gasifier be oxygen blown. The use of air as an oxidant in a gasifier may be more attractive in certain cases:

- Smaller-scale plants (e.g., biomass applications) where the cost of producing O_2 at smaller scales becomes unattractive.
- Lower-temperature gasifiers such as fluidized beds, especially if limestone is utilized to capture significant portion of sulfur within the gasifier itself.

Cryogenic Technology

Conventional air separation technology for large-scale O_2 production consists of cryogenically separating air. For IGCC applications, an Elevated-Pressure (EP) Air Separation Unit (ASU) is preferred over Low-Pressure (LP) ASUs, because both O_2 (for gasifier) and N_2 (for NOx control and increased power output in gas turbine) can be utilized at elevated pressures. The distillation pressure within the ASU cold box affects the liquid bubble-point. As this pressure is increased, cold-box temperature increases, resulting in a reduced ratio of incoming air pressure to outgoing stream pressures (O_2 and N_2). Thus, if O_2 and N_2 can be utilized within the plant at the cold-box outlet pressure or higher, a net increase in the IGCC plant efficiency is realized. N_2 produced by an EP cold box is further compressed and fed to gas turbines.

The relative volatility between N_2 and O_2 approaches unity as this operating pressure is increased, requiring more stages in the distillation operation; thus, an optimum upper limit exists for the pressure.

Typically, a 2% reduction in plant heat rate and cost may be realized with EP ASU over LP ASU. Optimum O_2 purity for IGCC applications with cryogenic ASUs (with either EP or LP) is 95%. The number of distillation stages decreases steeply as purity is reduced from 99.5 to 95%, but remains quite insensitive as purity is further reduced. O_2 compression costs (both capital and operating) continue to increase as purity is decreased below 95%. The size of most equipment downstream of the ASU also increases slightly while efficiency of the gasification unit decreases as purity is reduced. Both the Demkolec[5] and Polk County IGCCs utilize an EP ASU (with 95% purity O_2). Higher-purity O_2 may be required in coproduction plants (e.g., coproducing H_2 utilizing pressure swing adsorption to limit its Ar content).

Feed air pressure for an LP ASU is in the range of 50–90 psig (350–600 kPag), while that for an EP ASU is typically set by the pressure of air extracted from gas turbines (to provide the portion of air required by the ASU). Extraction of air from the gas turbine compressor discharge increases commonality for the gas turbine (relative compressor/turbine size) between IGCC and natural gas applications. When extraction air pressure is very high, partial expansion may be required in order to limit the cold-box operating pressure so the relative volatility between O_2 and N_2 is not too close to unity.

High-Temperature Membrane Technology

Cryogenic ASU power consumption constitutes more than half of the total power consumed by the IGCC or 5%–10% of total power produced. Membranes (semi-conductor materials) are being developed that operate at temperatures around 1500°F–1600°F (800°C–900°C) for air separation with a goal of reducing power consumption and capital cost by about 30%. Integration of the membrane unit with a gas turbine capable of roughly 50% air extraction (not possible with current large-scale machines) is required for this technology to be economical, with the feed air to the membrane being the extracted high-pressure air (preheated by directly firing syngas). Gas turbines also capable of receiving depleted air from the membrane unit are required. A large-scale membrane unit with a capacity of 2,000 ST/D (1800 MT/D) is expected to be available for demonstration in 2012.[1]

OVERALL PLANT INTEGRATION

Fig. 1 depicts a coal-based IGCC consisting of slurry-fed, high-pressure entrained bed gasifiers. Cryogenic EP ASU supplies 95% purity O_2 to gasifiers and produces intermediate pressure N_2 for injection into gas turbines. Coal is wet ground in rod mills to form slurry and introduced into the gasifiers. The gasifiers generate hot gas (raw syngas), slag, and char particulates. Raw syngas is cooled while generating high-pressure steam in heat exchangers (radiant coolers followed by convective coolers). The gas is then wet scrubbed to remove entrained solids. Soluble alkali salts, hydrogen halides, and some NH_3 are also removed. The contaminated water is treated to remove fine slag and char particulates, and the remaining water is treated before discharge.

Scrubbed gas is preheated and then fed to a COS hydrolysis reactor. Effluent then enters a series of heat exchangers to generate steam, heat up circulating water for a syngas humidifier (to introduce water vapor into clean syngas for NOx control and increase motive fluid in the gas turbine), and vacuum condensate from the combined cycle unit. After cooling against cooling water, the syngas is superheated by about 20°F (11°C) to avoid condensation and then fed to activated carbon bed(s) to remove volatile metals and their compounds. The effluent gas is then cooled against cooling water and fed to an Acid Gas Removal Unit (AGRU). The high-temperature condensate separated from the gas is recycled to the scrubber while the colder condensate is fed to a sour water stripper to remove absorbed gases such as NH_3, HCN, and H_2S. The sour gases stripped from the water are routed to a Claus SRU.

The acid gas removal process consists of an absorber column where H_2S is removed. Rich solvent loaded with H_2S after preheating (against stripped solvent) is fed to a stripper to release a concentrated stream of H_2S along with co-absorbed CO_2. Stripping is accomplished using steam. After the heat exchange, stripped solvent is recycled back to the absorber. Acid gas mixture from the stripper is cooled, and the condensate is removed to be sent to the SRU (to produce elemental sulfur) and a Tail Gas Treating Unit.

Clean (treated) syngas, after humidification in a counter-current column (by direct contact with hot water) and preheating, is fed to gas turbines. Exhaust gas

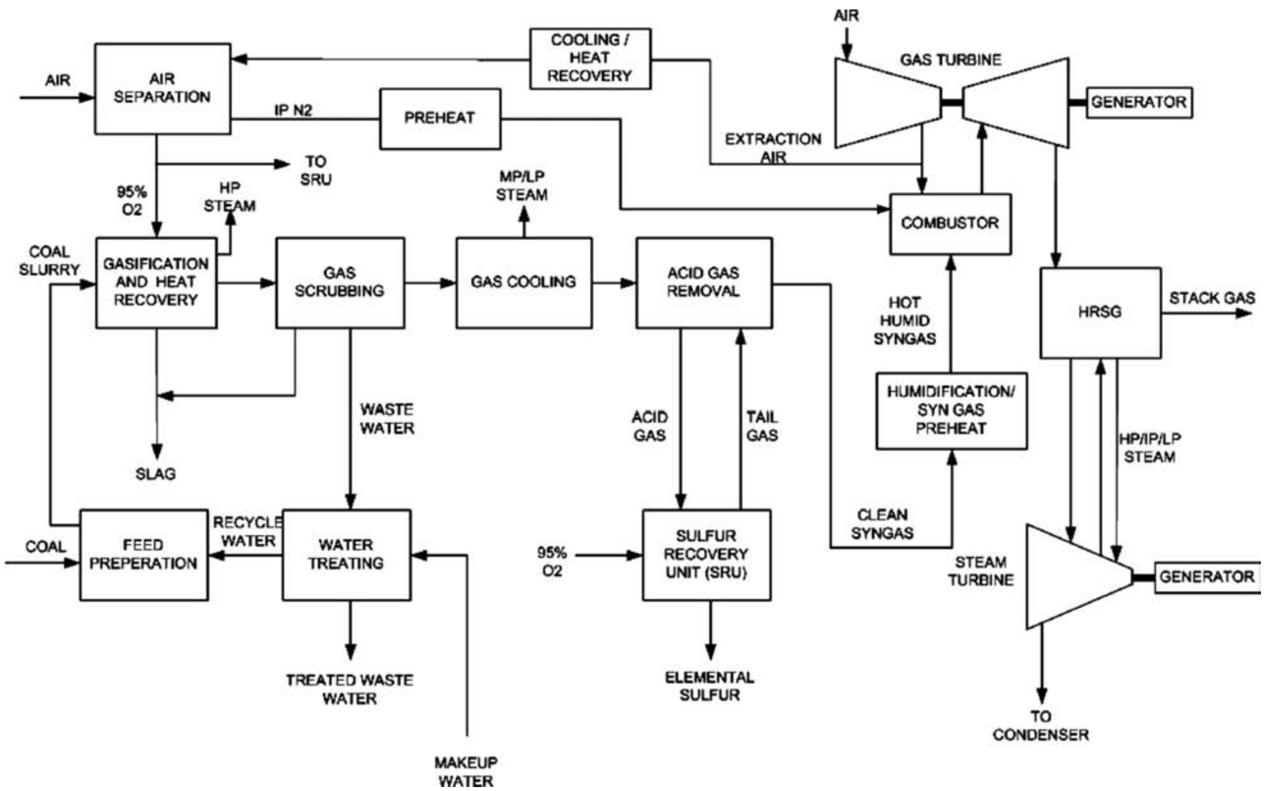

Fig. 1 IGCC overall block flow sketch.

from the gas turbines is fed to triple-pressure Heat Recovery Steam Generators (HRSGs), which provide superheated and reheated steam to a condensing steam turbine.

Necessary general facilities required include cooling water systems, instrument air, and flare.

Coproduction

A major advantage of an IGCC is that a number of co-products may be produced to improve process economics. Fig. 2 depicts various products and co-products that may be produced. Advantages include the following:

- Economies of scale of larger plants
- Efficient use of steam in a single large steam turbine
- Opportunity for load following
- Advantages specific to products such as methanol or Fischer Tropsch liquids:
  - — Reduced synloop recycle rate with unconverted purge gas fired in gas turbines
  - — Higher reactor throughput due to lessened buildup of inerts
  - — Reduction in diluent addition to gas turbines for NOx control due to low heating value of purge gas

Environmental Signature

Integrated gasification combined cycle is one of the most efficient, environmentally effective means of producing electricity. Air emissions from an IGCC are far below U.S. Clean Air Act standards. Reductions of emissions of SO_x, NOx, CO, volatile metals, and particulates can be significantly better than those obtained by scrubber-equipped pulverized, as well as circulating fluidized bed coal combustion plants.

Integrated gasification combined cycle's economic benefits will become more significant as air emission standards are made more stringent, since this technology can achieve greater emissions reductions at lower incremental costs.

Integrated gasification combined cycle plants can be designed to approach zero emissions, including CO_2 emissions.[12] Carbon is captured as CO_2 from syngas, such that a gas that is mostly H_2 is burnt in gas turbines. This pre-combustion capture may be combined with syngas desulfurization and may be accomplished in a physical solvent acid gas removal process (e.g., Selexol®). Major modifications to the process scheme described in the previous section include the following:

- Adding catalytic shift reactors to convert CO in syngas to CO_2 by the reaction

$$CO + H_2O = CO_2 + H_2.$$

- Use of a multi-column design in the AGRU to capture CO_2.

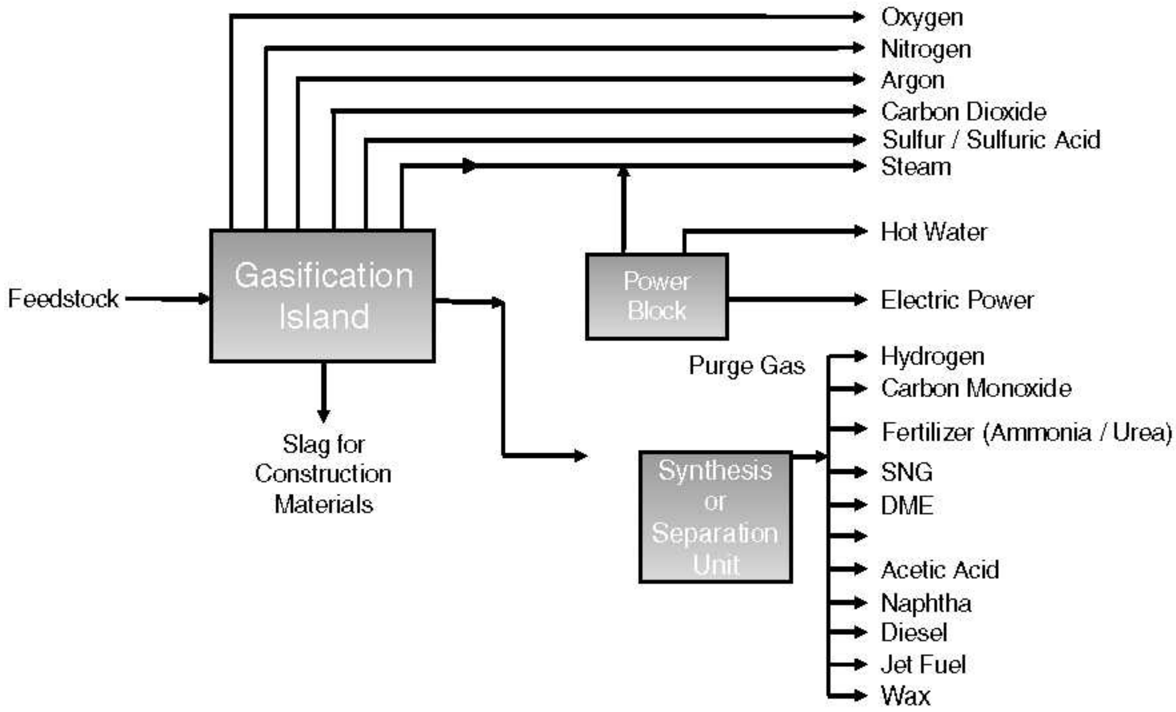

Fig. 2 Coproduction alternatives in an IGCC.

IGCC VERSUS PULVERIZED-COAL BOILER FUTURE TRENDS

In the case of high-rank coals, economics are typically in favor of an IGCC when compared to a supercritical coal-fired boiler plant, with environmental constraints very stringent. The cost of 90% or greater volatile mercury removal from a coal IGCC is about a tenth of that from a pulverized coal combustion plant.[13] In addition to lower cost, gasification-based mercury removal is more efficient than removal of mercury after combustion because the volume of pressurized syngas is much smaller than stack gas from the pulverized coal plant, which is at atmospheric pressure and diluted with N_2.

Technological advancements aimed at increasing plant thermal efficiency of both types of plants are taking place. Advanced gas turbines are being developed that will have a significant effect on both IGCC thermal efficiency and plant cost (Fig. 3). As power block efficiency increases, the amount of syngas required to generate a unit of electric power is reduced in direct proportion, which in turn reduces plant size and cost upstream of the power block.

ECONOMIES OF SCALE AND BIOMASS GASIFICATION

Plant size has a significant effect on IGCC economics. The typical size required for a commercial plant to take advantage of economies of scale is in excess of 400 MW, while smaller decentralized plants fit with the smaller biomass resources. Due to its low energy density, transportation of biomass collected from various locations over long distances to a central plant is economically prohibitive. The biomass facility has to be located in close proximity to the feedstock. Consideration should be given to building a larger IGCC fed by both biomass and coal (or petroleum coke). During seasons of low biomass feedstock availability, the plant would increase its coal usage to offset a decrease in biomass-derived syngas. In the case of co-feeding an IGCC with a high-rank coal or petroleum coke with biomass, two types of gasifiers may be required, one optimized for the coal or petroleum coke such as an entrained bed gasifier, and the other suitable for the biomass feedstock such as a fluidized bed gasifier.

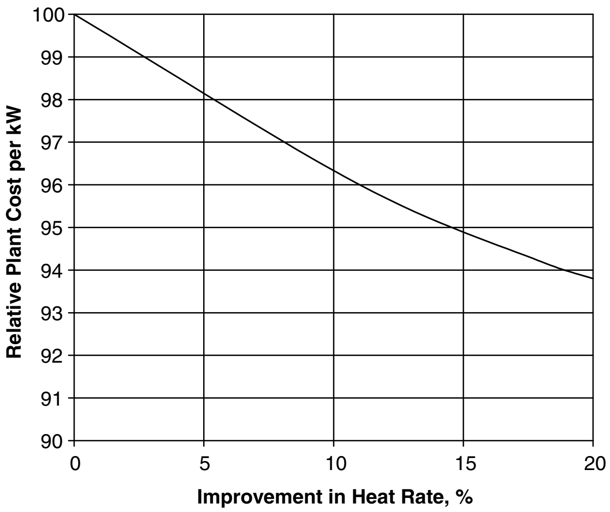

Fig. 3 Effect of power block efficiency on IGCC cost.

CONCLUSIONS

Integrated gasification combined cycle is commercially proven, and the gasification process itself has been in commercial use for more than 50 years. Valuable coproducts such as H_2 or Fischer Tropsch liquids may be co-produced to enhance economics. Integrated gasification combined cycle is one of the most efficient, environmentally effective means of producing electricity. Integrated gasification combined cycle plants can be designed to approach zero emissions.

Galvin Electricity Initiative, Palo Alto, California, U.S.A.

Abstract
The IntelliGrid (IntelliGrid is a service mark of the Electric Power Research Institute.) is a fully functional power delivery system that incorporates sensors, communications, enhanced computational ability, and electronic control. It delivers reliable, digital-grade power to meet the needs of an increasingly electronic society.

The IntelliGrid is a possible foundation for the intelligent electric infrastructure of the future and the platform for future technical, process, and service innovation in the energy sector.

INTRODUCTION

Today's electricity supply system is aging, under stress, often not well maintained, and being physically used in ways for which it was not designed.

Society has entered a new era of experience driven by digital technologies. The world is more interconnected than at any other time in history, utterly dependent on the integrity of a complex web of networks—both communications and electricity. The electric power system is the foundation of this interconnection. The lack of critical infrastructure investment and surging demand for electricity are taxing the electric power system to its limits. In the past ten years, growth in U.S. electricity demand has exceeded new transmission capacity by more than 15%. This occurs at a time when microprocessor-based technologies have radically altered the nature of the demand for electricity, resulting in demand that is compatible with a power system created to meet the needs of an analog economy. This has led to quality and reliability problems responsible for more than $100 billion in losses to U.S. industry and society annually.

A coordinated effort to upgrade and modernize the entire electric power system—from generation to transmission, distribution, and end use—is needed for the benefits or interconnection to be fully realized.

DESIGNING THE POWER SYSTEM OF THE FUTURE

The IntelliGrid Consortium is a broad-based collaboration of energy, high-tech, and government leaders working to address these technology issues and set us on a migration path toward the intelligent, self-healing power system of the future.

The foundation of this system is the IntelliGrid—an open systems-based comprehensive reference architecture for the energy enterprise of the future. IntelliGrid enables the integration of intelligent equipment and data communications networks into a managed enterprise and industrywide distributed computing system. It is the basis for enabling enhanced system capabilities, such as the self-healing grid, integrated consumer communications, and real-time energy information and power exchanges.

IntelliGrid applies the latest systems engineering methods and computing and communications tools to model the energy enterprise of the future. It expands traditional operating boundaries, promoting greater interoperability; enabling unprecedented improvement in performance and asset utilization; and ensuring desirable levels of robustness, responsiveness, and security.

The IntelliGrid is the basis of a "smart" power delivery system. It is an integrated, self-healing, self-diagnosing, electronically controlled electricity supply system of extreme resiliency and responsiveness, one that is fully capable of responding in real time to consumer needs.

The IntelliGrid will be an integrated electricity and information infrastructure that enables the next wave of technological advances to flourish. The system will be always on and "alive," interconnected and interactive, and merged with communications in a real-time network, sensing and communicating information and power exchange. The IntelliGrid will be a self-healing system that senses disturbances and corrects them, or reconfigures the flow of power to mitigate interruption and disturbance. The system will also be smart enough to integrate traditional power generation with distributed energy resources (DER) seamlessly.

Keywords: IntelliGrid; Smart power delivery system; Self-healing; Integrated consumer communications; Transmission; Distribution; Consumer portal; FACTS; Communications.

The goal of the IntelliGrid is to create a new self-healing paradigm for power delivery systems, with automated capabilities that can anticipate many potential problems, reduce recovery time when unexpected disturbances occur, and enhance performance of normal operations.

To reach this goal, three primary objectives of the self-healing grid need to be achieved:

- Dynamically optimize the performance and robustness of the system
- Quickly react to disturbances in such a way as to minimize impact
- Effectively restore the system to a stable operating region after a disturbance

The initial step in developing the IntelliGrid is to define clearly the scope of the requirements of the power system functions and to identify all the roles of the stakeholders. These then must be included in an Integrated Energy and Communications System Architecture. Many power system applications and a large number of potential stakeholders already participate in power system operations. In the future, more stakeholders—such as customers responding to real-time processes, distributed energy resource owners selling energy and ancillary services into the electricity marketplace, and consumers demanding high-quality power—will participate actively in power system operations. At the same time, new and expanded applications will be needed to respond to the increased pressures for managing power system reliability as market forces push the system to its limits.

Power system security has also been recognized as crucial in the increasingly digital economy. The key is to identify and categorize all these elements so that their requirements can be understood; their information needs can be identified; and eventually, synergies among these information needs can be determined. One of the most powerful methodologies for identifying and organizing the pieces in this puzzle is to develop business models that identify a straw set of entities and address the key interactions among these entities. These business models will establish a set of working relationships among industry entities in the present and the future, including intermediate steps from vertical operations to restructure operations. The business models will include, but not be limited to, the following:

- Market operations, including energy transactions, power system scheduling, congestion management, emergency power system management, metering, settlements, and auditing
- Transmission operations, including optimal operations under normal conditions, prevention of harmful contingencies, short-term operations planning, emergency control operations, transmission maintenance operations, and support of distribution system operations
- Distribution operations, including coordinate volt/var control automated distribution operation analysis, fault location/isolation, power restoration, feeder reconfiguration, distributed energy resource management, and outage scheduling and data maintenance
- Customer services, including automatic meter reading (AMR), time-of-use and real-time pricing, meter management, aggregation for market participation, power quality monitoring, outage management, and in-building services and services using communications with end-use loads within customer facilities
- Generation at the transmission level, including automatic generation control, generation maintenance scheduling, and coordination of wind farms
- Distributed resources (DR) at the distribution level, including participation of DR in market operations, DR monitoring and control by nonutility stakeholders, microgrid management and DR maintenance management

These business models will be analyzed and used to define the initial process boundaries for subsequent tasks. Business process diagrams will be used to illustrate the more complex interactions.

FAST SIMULATION AND MODELING

When the architecture begins to be deployed, the industry's computational capability must be enhanced. To enable the enhanced functionality of the power delivery system, a capability that allows fast simulation and modeling (FSM) will need to evolve to ensure the mathematical underpinning and look-ahead capability for a self-healing grid—one capable of automatically anticipating and responding to power system disturbances while continually optimizing its own performance. Creating a self-healing grid will require the judicious use of numerous intelligent sensors and communication devices that will be integrated with power system control through a new architecture. This new architecture will provide a framework for fundamentally changing system functionality as required in the future.

The FSM will augment these capabilities in three ways:

- Provide faster-than-real-time, look-ahead simulations and to avert unforeseen disturbances
- Perform what-if analysis for large-region power systems from both operations and planning points of view
- Integrate market, policy, and risk analysis into system models, and quantify their effects on system security and reliability

The next step in creating a self-healing grid will involve addition of Intelligent Network Agents (INAs) that gather and communicate system data, make decisions about local control functions (such as switching a protective relay), and coordinate such decisions with overall system requirements. Because most control agents on today's power systems are simply programmed to respond to disturbances in predetermined ways—by switching off a relay at a certain voltage, for example—their activity may actually make an incipient problem worse and contribute to a cascading outage.

The new simulation tools developed as part of EPRI's FMS project will help prevent such cascading effects by creating better system models that use real-time data coming from INAs over a wide area and, in turn, coordinate the control functions of the INAs for overall system benefit, instead of the benefit of one circuit or one device. As discussed later in this article, having such improved modeling capability will also enable planners to better determine the effects of various market designs or policy changes on power system reliability.

To reach these goals, the FSM project will focus on the following three areas:

- *Multiresolution modeling*. New modeling capabilities will be developed that provide much faster analysis of system conditions and offer operators the ability to "zoom" in or out to visualize parts of a system with lower or higher degrees of resolution.
- *Modeling of market and policy impacts on reliability*. The recent power crisis in the Western states dramatically illustrated how untested policies and market dynamics can affect power system reliability. The new modeling capabilities being developed in this project will allow planners and policymakers to simulate the effects of their activities before putting them into practice.
- *Validation of integrated models with real-time data*. Once the new, integrated models have been thoroughly tested offline, they will be validated and enhanced using real-time data from major power systems.

Unified integration architecture is the key enabler to deploying advanced functions successfully and inexpensively. This architecture must be robust enough to meet the numerous disparate requirements of power system operations and must be flexible enough to handle changing needs. The focus of this project is to identify and propose potential solutions for enterprise and industrywide architectural issues that will arise from the high levels of integration and management foreseen by this project.

The IntelliGrid will be constantly self-monitoring, communicating, and self-correcting to maintain the flow of secure, digital-grade quality, and highly reliable and available power.

The IntelliGrid concept includes a combination of enhancements to the power delivery infrastructure and consumer technologies to enable delivery of highly reliable digital-grade power. The IntelliGrid enhancements will result in very long mean time between failure (MTBF) rates, thereby maximizing reliability for digital devices, digital applications, and the digitally enabled enterprises they make possible.

The IntelliGrid architecture enables equipment manufacturers to design products to function at the reliability levels that they realistically encounter in the field. Manufacturers could embed resilience to degraded power quality and reliability into their products, provided that an industry consensus is reached and/or market forces motivate them to do so. The IntelliGrid is expected to be a key to economic prosperity at all levels of the economy.

The IntelliGrid architecture includes a window to the consumer referred to as the consumer portal or EnergyPort. The EnergyPort relieves the constraints provided by the meter, allowing price signals, decisions, communications, and network intelligence to flow back and forth through a two-way portal. The EnergyPort is the integration technology that leads to a fully functioning retail power marketplace with consumers responding to price signals. Capabilities of the EnergyPort can include the following:

- Real-time pricing
- Value-added services
- Building and appliance standards
- Consumer energy management
- Distributed energy resources (DER)
- Real-time system operations
- Short-term load forecasting
- Long-term planning

The IntelliGrid includes functional attributes that address the efficiency of electricity use. Advances in electrotechnologies, advanced motors, lighting, improved space conditioning, real-time energy management systems, automated recycling systems, and other technologies could encourage investment in energy-efficient technologies, reduce energy costs, stimulate the economy, and minimize the environmental impact of electricity generation and delivery. In addition, widespread use of electric transportation solutions can enhance energy balance.

The IntelliGrid will also encourage widespread deployment of DER.

Several critical enabling technologies will enable the IntelliGrid to evolve, including the following:

- Increased power flow
- Automation
- Communications architecture
- Distributed energy resources (DER)

- Power electronics-based controllers
- Power market tools
- Technology innovation
- The EnergyPort
- Value-added services

Increased Power Flow

Real and reactive power flows in large integrated power transmission systems are constrained by voltage and power stability criteria. In many cases, the limits dictated by these stability criteria are far below the "inherited" thermal capacity of transmission corridors. Even with the adoption of stability measures, power flow levels could still be below the thermal limit due to the "uncontrolled" flow levels as determined by the power transfer law, which is governed by the line impedance, voltage magnitudes, and angle difference at the transmission corridor ends.

This technological solution is named FACTS (Flexible AC Transmission Systems). The use of FACTS controllers helps preserve system integrity during the short-term major system disturbances or to direct and control real and reactive power flows fully on transmission corridors.

Automation: The Heart of the IntelliGrid

Automation will play a key role in providing high levels of reliability and quality. To a consumer, automation may mean receiving hourly electricity price signals, which can adjust home thermostat settings automatically. To a distribution system operator, automation may mean automatic "islanding" of a portion of the distribution system in an emergency. To a power system operator, automation means a self-healing, self-optimizing power delivery system. Through the EnergyPort, consumers will tie into the IntelliGrid to allow price signals, decisions, communications, and network intelligence to efficiently flow back and forth. The resulting retail marketplace will offer consumers a wide range of services, including premium power options, real-time power quality monitoring, and home automation services.

Communication Architecture

To realize the vision of the IntelliGrid, standardized communications architecture must be overlaid on today's power delivery system. An integrated energy communications system architecture is needed: a standards-based systems architecture for a data communications and distributed computing infrastructure. Several technical elements will constitute this infrastructure, including data networking, communications over a wide variety of physical media, and embedded computing technologies. The IntelliGrid will enable the monitoring and control of power delivery systems in real time; support deployment of technologies that increase the control and capacity of power delivery systems; enhance the performance of end-use devices that consumers employ; and enable connectivity, thereby revolutionizing the value of consumer devices.

Distributed Energy Resources

Distributed power generation and storage devices, integrated with the power delivery system, offer potential solutions to several challenges that the electric power industry currently faces. These challenges include the need to improve the power delivery infrastructure; provide high-quality power; enable a range of services to consumers; and provide consumers lower-cost, higher-quality power. A key challenge for DER will be to develop ways of integrating these devices seamlessly into the power delivery system, and then monitor and dispatch them that so they can contribute to overall reliability and power quality.

Power Electronics-Based Controllers

In addition to FACTS, other power electronics controllers, based on solid-state devices, offer control of the power delivery system with the speed of a microprocessor. These controllers allow operators to direct power along specific corridors. Power electronics-based controllers can increase power transfer.

Power Market Tools

Market-based mechanisms are needed that offer incentives to market participants in ways that benefit all stakeholders, facilitate efficient planning for expansion of the power delivery infrastructure, effectively allocate risk, and connect consumers to markets. Service providers need a new methodology for the design of retail service programs for electricity consumers, and consumers need help devising ways they can participate profitably in markets by providing dispatchable or curtailable electric loads. Market participants critically need new ways to manage financial risk.

Technology Innovation in Electricity Use

Technology innovation in electricity use is a cornerstone of economic progress. The growth in the gross domestic product over the past 60 years has been accompanied by improvements in energy intensity and labor productivity. Development and adoption of technologies in a number of areas are needed:

- Industrial electrotechnologies
- Indoor air quality

- Lighting
- Recycling processes

The EnergyPort

Assuming that electricity infrastructures are integrated and realizing the ability to connect electricity consumers more fully with electronic communications will depend on evolving a consumer portal to function as a "front door" to consumers and their intelligent equipment. The EnergyPort would sit between consumers and wide-area access networks. The EnergyPort would enable two-way communications between consumers' equipment and energy service entities.

Value-Added Electricity Services

There is enormous consumer advantage in developing and implementing technologies that will enable traditional and nontraditional energy providers and service providers, as well as their customers, to access a variety of electricity-related, value-added services opportunities, including real connecting to electricity markets.

Create ebusiness-enabled opportunities by providing time-saving onsite, online services, based on the integration of electricity with communication systems. These services can be offered by anyone and will improve the digital economy's competitiveness and performance through better integration of power, communications, and delivery of entertainment and emerging wireless communication technologies. Convergence of these technologies and capabilities will create new value within the traditional electricity industry, and remove delays and complexities in decision-making by transforming the current "getting connected" model into a fast and efficient online model. Consumers would enjoy a great deal of benefit if suppliers were able to offer a menu of services related to the "new" electricity.

Electric utilities will be able to expand the portfolio of their business services to include communication, Internet access, real-time online monitoring, and other associated services. The customers will gain real-time access to energy markets and thus better control energy cost and energy utilization. Integrated communication and control will be available to expedite data exchange.

CONCLUSION

There are profound opportunities for innovation to transform the reliability, quality, security, and value of electricity for the 21st century. Conversely, there is a large and growing gap between the performance capability of today's electricity power systems and the needs and expectations of tomorrow's world.

International Performance Measurement and Verification Protocol (IPMVP)☆

James P. Waltz
Energy Resource Associates, Inc., Livermore, California, U.S.A.

Abstract

It is in some ways a strange curiosity that the "microprofession" of measurement and verification has generally ignored the financial side of the question of demonstrating the performance of an energy retrofit project. That is, a component which is conspicuously absent from the International Performance Measurement and Verification Protocol (IPMVP) is any treatment of the conversion of units of energy into dollars saved or costs avoided. It is an unfortunate omission, as conspicuous as the "missing man" in a formation flyover at a memorial service.

This article attempts to fill that hole in the IPMVP by addressing at least five different treatments of establishing a realistic dollar value for the units of energy saved in a performance contract and which are potentially being documented in a measurement and verification process.

INTRODUCTION

The International Performance Measurement and Verification Protocol (IPMVP) is notable in its lack of addressing the valuation of energy savings. This situation may very well be the result of the fact that the vast majority of professionals involved in measurement and verification come from an engineering and/or academic point of view and perhaps have a predilection for dealing with engineering units only. This should probably be considered a significant weakness in IPMVP, as it has been our experience that building owners, in fact care very less about saving energy, but care very much about saving money.

An addition to the IPMVP has been proposed to the technical committee but, for the apparent reasons stated above, was not implemented in the 1997 IPMVP's successor, "IPMVP 2000." This article essentially presents that proposed addition "Valuing Energy Savings," and discusses many different ways of establishing the value of a kilowatt hour saved. In doing so, it will address the following concepts and methodologies:

"avoided cost"
average unit cost
weighted average unit cost
calibrated simulation
real time costing
rate application

Readers should realize that just as *all* methods of measurement and verification are imperfect, yet useful, the various methods of valuing energy savings presented herein are similarly flawed, but also useful.

AVOIDED COST

Facility managers can get into trouble if they do not address the mindset of the "audience" they are working for—generally upper management. As a general observation, upper managers tend not to understand, nor do they particularly care about, the intricacies of energy management and the "wonders" of the engineering world of Btus or kilowatt hours. Rather, they more characteristically tend to think and deal in economic units, i.e., dollars. As a result, trouble can occur due to this difference in mind sets.

As a simple but illustrative example, suppose that the facility manager has managed to decrease energy use by 10% from the prior year. Unfortunately, however, the energy supplier has simultaneously raised his rates by 10%—with the result that the *total cost of energy for the facility has remained the same*. Now, suppose further that upper management, based on what they thought were the promises made by the facility manager for his energy conservation program, decreased the budget for energy by 10%, and has now discovered that they are 10% over budget. Upper management cannot help but conclude that the facility manager has failed to produce the promised "savings" (after all, they paid a million last year and the bill this year is still a million—meaning that *there are no*

☆ This entry originally appeared as "Valuing Energy Savings: Finding the 'Missing Man' in the IPMVP 'Formation'" in *Energy Engineering*, Vol. 101, No. 2, 2004. Reprinted with permission from AEE/Fairmont Press.

Keywords: Performance measurement; International standards; IPMVP; Verification; Energy savings.

savings). The potential consequences for the facility manager are fairly obvious and ominous in this scenario and would be avoided by any facility manager with any sense at all.

Then the astute facility manager, will have educated upper management in such a way that they understand that total energy cost is a product of two components: consumption and *rates*, and that cost may stay the same or even increase at the same time that "savings," better known as "cost avoidance," is being achieved.

This "cost avoidance," then, is the difference between what the actual cost of energy is vs what the cost of energy *would have been* had no conservation actions been taken. In our illustration, while total cost remained the same, it would have increased by 10% had no energy management program been implemented. This concept is particularly poignant in facilities such as acute care hospitals, where a phenomenon known as "energy creep" is fairly common. In many acute care hospitals (and other types of complex facilities as well, of course), over time, more and more diagnostic and other types of electric and electronic equipment is brought into the facility. When this is combined with the natural "wearing down" of the facility's infrastructure systems (lighting, heating, ventilating and cooling (HVAC), etc.), it is not uncommon for a facility's energy use to gradually increase over time. In one specific case documented in the references, a 10-year pattern of growing energy use was observed, approximately 3% for electric and 5% for natural gas, during a period when no active changes to the energy management program were undertaken.

AVERAGE UNIT COST

This is the simplest method of valuing units of energy, and it may be applied to any of the four measurement and verification options (A–D).

This method simply takes the total cost of energy (from the utility bill) and divides it by the total number of units consumed, thereby producing an average unit cost for the units consumed. To set a value for energy units saved, this average unit cost for the current period (typically a month) is simply multiplied by the units of energy the measurement and verification procedures identified as having been saved.

This method is obviously very simple and (perhaps obviously) ignores the fact that energy use often has a time-related value, as embodied, e.g., in time-of-use (TOU) electric rates. Just as some believe that Option A in its simplest form (where few or no actual measurements are made) is a "bogus" measurement and verification (M&V) methodology, the use of average units costs may similarly be disparaged. However, if the energy management program being employed is a broad program that affects energy use in a generally uniform manner over all time periods, then it may well be a perfectly suitable and acceptable methodology to the parties of a performance contract.

WEIGHTED AVERAGE UNIT COST

This is a fairly simple method, which is also applicable to all methods of measurement and verification. It is, however, perhaps best suited to Option A.

This approach makes a number of thoughtful assumptions about the time-occurrence of energy use (or energy *savings*) and performs calculations which apply the appropriate rate schedules to the assumptions to determine a weighted average unit cost for the energy units.

While it is based on assumptions, it may be updated or "calibrated" to actual experience if a time-related energy use pattern data are available (say, in a 15-min demand profile).

Tables 1–3 show three examples of a spreadsheet which performs the calculation of weighted average unit cost. Note that the examples show three different patterns of energy use, and produce distinctly different results based on those patterns. Keeping in mind that the analysis assumes that the load being evaluated is a nominal 1 kW load, then the calculation of annual kilowatt hour, e.g., also equals the equivalent full load operating hours (EFLH—please see the American Society of Heating Refrigeration and Air Conditioning Engineers (ASHRAE) handbook for a discussion of this term if it is one with which the reader is unfamiliar). While a complete explanation of the details of the spreadsheet has not been provided, the majority, if not all, of the calculations can be understood by observation. The author will assist those in need of explanation as required.

REAL TIME COSTING

This method is a bit more rigorous than those discussed above, and is generally oriented towards Option B.

This approach consists of building the rate schedule into the monitoring system and applying the rate schedule "on the fly" as energy savings are (or were) actually occurring.

For example, if a variable frequency drive was applied to a motor which previously operated fully loaded all the time, then the instrumentation, data gathering, and data reduction measurement and verification "package" applied to this retrofit would, during each operating time window (perhaps an hour), measure the then-current

energy use of the motor, when compared with the original or baseline energy use, calculate the energy units saved, and apply the rate schedule applicable during that window of time.

If a real-time system of data gathering and analysis is employed, then this valuing of energy units saved would also be in real time. However, the approach is just as effective in valuing the energy units saved even if it is applied after the fact to energy data gathered in real time, but analyzed at a later time.

Table 4 shows a sample spreadsheet for an Option B measurement and verification of a variable volume fan conversion. In this example, the baseline conditions have been established by short-term monitoring of the fan motor and a load profile developed as well through short-term monitoring and extrapolation to a year-long load profile by means of linear regression of the short-term load monitoring data and applying the linear regression equation ($Y = mX + b$).

RATE APPLICATION

This method has Option C in mind and assumes that either the utility meter is being employed to measure and record both baseline and postretrofit energy use, or that a meter of similar character has been applied to the facility, and that the baseline energy use has been recorded in such a way that the present rate schedule can be applied to it. That is, the peak demand and energy use in each TOU period is available.

In this instance, the current rate schedule is applied to the recorded energy use and the total cost calculated for both the baseline and postretrofit situations. The cost avoided is simply the difference between the two.

A wealth of proprietary software is already commercially available to implement this methodology, such as Faser, Metrix, and Utility Manager, to name three.

CALIBRATED SIMULATION

This method is not for the faint of heart, and is oriented towards Option D. This method, perhaps due to the extremely wide variation in simulation skill and acumen among its practitioners, has a reputation for being completely hypothetical, extremely effective, or anywhere in between.

Simply put, calibrated simulation requires significant rigor and clear demonstration of its faithful emulation of reality if it is to possess veracity. To achieve this goal, this approach would encompass, e.g., the creation of a computer simulation model of a building or sub-system (say a chiller plant) in its baseline state, and the calibration (and demonstration thereof) of the model to reality. In addition, the retrofitted facility would also be modeled and calibrated as well. In the case of a chiller plant, the reality to which the models are calibrated might be a dedicated utility-style electric meter through which all power consumed by the plant is measured, and other specific measurements, perhaps instantaneous pump and cooling tower electrical demand, total cooling provided by the plant (ton hours output), etc.

Because both the baseline and retrofit conditions are simulated and calibrated, there can be considerable faith, then, in the veracity of the units of energy and the time-related patterns of energy use in the model.

Assuming that the simulation tool used for the modeling has the ability to incorporate and apply the rate schedules in use, both models may be run with whatever current rate schedule is in effect, and very accurately calculate the operation cost of the baseline and the retrofit facilities. Avoided cost, then, is simply the difference between the two.

CONCLUSION

The bottom line of all these efforts, again, is to translate the "technical" determination of units of energy saved into a financial result which management may make use of. Without doing so, energy engineers run the risk of being dismissed as being irrelevant by upper management, so this step in the M&V process is, perhaps amazingly, the one that may be the most important of all!

Investment Analysis Techniques

James W. Dean
Office of Strategic Analysis and Governmental Affairs, Florida Public Service Commission, Tallahassee, Florida, U.S.A.

Abstract
This entry explores various investment evaluation techniques with special attention to their application in energy investments. Key components of the techniques are described, including the concept of the time-value of money, discount rates, and the role of risk and its consideration in performing a financial assessment of a project. Financial evaluations from simple payback periods to internal rate of return (IRR) analysis are discussed with the entry concluding that net present-value analysis is, in almost all cases, the preferred evaluation technique.

INTRODUCTION

You have just been informed that your six-digit lottery ticket hit the $50 million *Big Payout Mega Lottery*. You now are entitled to $5 million per year for ten years or you can take a one-time payment of $30 million. What is the best decision? For the lucky winner, this decision hinges on what economists call the time preference of consumption. An individual could take all the money in a single payout and have the opportunity to immediately acquire goods and services or the individual could defer the opportunity to spend the money and receive larger, future annual payouts. With little knowledge of finance, the newly created millionaire could use a more formal analysis and identify which of the two payout options afford the largest financial return.

While few of us will face such a joyful exercise in our personal finances, everyone who makes financial decisions in their personal or business environment will either implicitly or explicitly have to make a decision like our lottery winner. Individuals who consider the rated miles per gallon expectations in purchasing a car or who consider the energy-efficiency rankings in purchasing a new appliance are in some fashion doing a financial analysis. Likewise, a corporation or business has a fiduciary responsibility to make investments that maximize the overall return to the firm. Many financial decisions involve multiple time periods and uneven cash flows, and without some analytical tools to simplify and compare options, individuals and companies would be stymied in their efforts to estimate the total net worth of investments or to select from competing opportunities that would maximize their overall monetary gain.

In the first part of this entry, two fundamental concepts used in performing financial analyses will be introduced: the time-value of money and the discount rate. The latter portion of the entry explores a variety of financial techniques that are commonly used in evaluating and ranking the value of investment opportunities when cash flows occur over time. These kinds of applications are commonplace in energy investments. Examples include investments in oil and gas drilling projects, power plants, transmission lines, natural gas pipelines, and energy-efficiency investments. In the energy industry in particular, many projects require substantial upfront capital and the associated revenue stream generally occurs over long time periods. However, the investment evaluation techniques discussed here are generic and are routinely used in most applications. Finally, the two most commonly used analytical techniques—present-value analysis and IRRs—are discussed and their relative advantages and disadvantages are examined.

FUNDAMENTALS OF INVESTMENT EVALUATION

It is critical to appreciate that the value of money is time dependent. Money received now has more value than money received in the future as long as there is a positive interest rate that an investor can earn. The proof of this statement is intuitive. If given some amount less than a dollar today, one could, with a positive interest rate, have a dollar in the future. Thus, a dollar today cannot be equal to a dollar in the future given a positive interest rate environment. Developing a comparable value for time disparate dollars is done using a variety of present-value techniques.

One of the most commonly employed investment metrics is the simple payback period. Its strength is in its

Keywords: Present-value analysis; Internal rate of return; Discount rate; Simple payback; Variable discount rates; Net present value analysis.

computational simplicity. The payback period is the number of years (or months) until the revenue stream equals or exceeds the initial project outlay. This technique is frequently used in advertisement to convince potential customers how shrewd a purchase might be. For example, assume a consumer were to spend $500 for the installation of attic insulation to make his house more energy efficient. If this investment saves $100 a year in energy costs, then the simple payback period would be five years. Payback analysis does permit a relative ranking of project worthiness when multiple projects are being evaluated. In other words, projects with shorter paybacks would tend to be superior to longer-dated projects.

However, the simplicity of the technique is offset by two important omissions. The simple payback does not account for the time-value of money nor does it assign any value to the positive cash generated after the breakeven period is reached. In addition, if projects have cash flows that switch from negative to positive and back, even relative rankings are obscured when comparing projects.

Payback analyses can be improved upon by calculating a current value for the future cash flows up to the payback period. Doing this typically results in a longer payback than the simple payback. This approach more accurately reflects the value of the capital investment that has been "tied up" in the project. However, properly valuing the time dependency of the cash flows against the initial investment outlay does not remedy the other problem of correctly accounting for cash flows beyond the breakeven point.

The correct solution to this problem entails using present-value analysis for the life of the entire project. Present-value analysis offers a powerful analytical tool to compare cash flow streams of both inflows (revenue) and outflows (expenditures) and standardizes the magnitude and timing of the flows such that the values are represented in today's currency values. The term "current dollars" refers to values that have been standardized to reflect values in today's dollars and "nominal dollars" refers to the value in the future periods under consideration. When present-value analyses incorporate the value of any initial capital expenditure, and year-by-year inflows and outflows are netted out, the final valuation constitutes a "net present value" (NPV) of the overall project's worth.

In the simple case, a one-year present-value term can be represented by:

$$PV = CF_1/(1 + r_1)$$

where CF_1 is the cash flow in time period 1 and r represents the rate of return that the investor is willing to accept for an alternative investment with comparable risks.

By extension, the present value of multiple years of cash flows can be represented by:

$$PV = \frac{CF_1}{(1 + r_1)^1} + \frac{CF_2}{(1 + r_2)^2} + \frac{CF_3}{(1 + r_3)^3} + \cdots + \frac{CF_t}{(1 + r_t)^t}$$

This equation can be collapsed into:

$$PV = \sum_{t=1}^{N} \frac{CF_t}{(1 + r)^t}$$

This basic formula can be extended to include capital outlays. With the addition of any initial capital outlay CF_0, this present-value analysis becomes a NPV of the form:

$$NPV = CF_0 + \sum_{t=1}^{N} \frac{CF_t}{(1 + t)^t}$$

The CF_0 term is only the initial outlay divided by $(1+r)^0$, which equals the outlay divided by one. However, multiyear outlays are likely to occur, especially on large construction projects. In this case, the outlays are likewise discounted and summed along with future cash inflows. Thus, the NPV formula can be further reduced to account for the initial and subsequent time periods, resulting in:

$$NPV = \sum_{t=0}^{N} \frac{CF_t}{(1 + t)^t}$$

Each CF_t represents the balance of cash flow for each time period. Positive flows are offset by any outflows such as maintenance, labor, accrued interest, or any other cost. Negative flows should be offset by projected revenues, impact of taxes, depreciation, and any terminal salvage value.

For most capital budgeting analyses, an annual end-of-year convention is used to simplify the timing of receipts or expenditures. However, projects involving large capital expenditures or large cash inflows frequently incorporate more discrete time periods for booking cash flows. This is especially true for multiyear, capital-intensive projects that incur substantial interest and construction costs prior to generating revenue. Examples in the utility industry include power plant and refinery construction schedules. Because hundreds of millions of dollars can be spent over the course of a year, accrued interest during construction can be substantial. Thus, when comparing multiple projects that have large intrayear cash flow differences, more fractional time periods provide greater accuracy of total project costs.

If one uses an end-of-year accounting convention, then the cost of funds during construction is assumed to be zero and interest begins to accrue at the beginning of the subsequent year. Conversely, if all cash flows are assumed to occur at the beginning of the year, then accrued interest is overstated. The analyst may elect to do mid-year expenditures to average these out. For projects that require greater scrutiny or for managing actual construction budgets, more discrete time periods such as months or quarters can be used as the unit of analysis. Of course, the discount rate should be adjusted to reflect the compounding impacts of the more discrete time periods.

Another complexity involved with cash inflows and outflows is ensuring that inflation is appropriately accounted for in the analysis. In performing net present-value analysis, there are two strategies that can be used to adjust the cash flow streams. As previously mentioned, dollars are accounted for in either nominal or real terms. Nominal dollars measure cash flow including the impact of inflation whereas real dollars adjust for inflationary expectations. One can convert the nominal inflows and outflows into real cash flows by dividing by an anticipated inflation factor. In this case, a real rate of return would be used as the discount factor in the NPV formula. Alternatively, the cash flows could be stated in nominal dollars, but the value of r would be adjusted higher to account for inflation-related risk.

Finally, it is important to note that any initial cash outlay represents incremental project costs. For example, if special equipment has been purchased or if buildings have been constructed to undertake a project but the project is later abandoned, then such costs are called “sunk costs” in economic jargon. If a subsequent project is undertaken, the initial capital outlays should not include any unrecoverable, sunk costs. However, any additional first-year outlays and all future cash flows should be included in the analysis. If these previously incurred costs have residual value and could be sold or leased to generate cash inflows, then these values would be reflected in the initial year’s outlay. If these costs have no recoverable value, regardless of what the initial costs were, then for purposes of evaluating project investments, their outlay value is zero when used in subsequent project evaluations.

DETERMINING THE APPROPRIATE DISCOUNT RATE

In business applications, the r term is referred to as the discount rate or cost of capital and is a rather complex concept. At its most basic, the discount rate embodies all known sources of risk and therefore reflects what investors must anticipate earning to assume those risks. Thus, as project risk increases, the discount rate used in evaluating any specific project must also go higher.

Examples of project risk abound. In inflationary investment periods, the investor must be compensated for the loss of purchasing power between time periods. Second, the discount rate must capture the relative risks associated with a particular investment decision. Examples include uncertainty of cash inflows, uncertainty related to completing the project, and uncertainty surrounding the political and legal climate in which the project will operate. Opposition to the construction of large infrastructure projects such as liquefied natural gas terminals or power plants is common. Prudent investors will require a greater return to lend capital to finance such projects if the possibility exists that the project will not be completed and thus incur uncompensated development costs, or on the other extreme, if the project is completed but a change in political regimes leads to the nationalization of the project by a foreign government. These types of risks are typically referred to as project-specific risks.

Moreover, the appropriate discount rate is almost unique in that it will vary depending on if the investor is an individual, a business, or a government agency. Within these subgroups, individual circumstances will further define the preferences to defer consumption and the willingness to assume other risks. For many individuals, the need or preference for immediate consumption results in very high discount rates. In the case of individual consumers investing in conservation and energy-efficiency technologies, discount rates vary inversely with income and for individuals with limited capital personal discount rates can be extraordinarily high.

Businesses include a number of components in assessing project risk. Projects are examined for intrinsic or project-specific risks, as discussed above. In addition, the project will be examined in the context of all the firm’s projects and in the context of other market opportunities. Thus, determining what is the appropriate discount rate to use is conceptually difficult, even if the arithmetic computation of the net present-value formula is straightforward.

One factor that goes into the development of the appropriate discount rate is a firm’s cost of capital. For businesses that use a combination of equity and debt to finance projects, the weighted average cost of these component sources of capital typically reflect the individual company’s discount rate. This assumes, however, that any individual business has a risk profile identical to that of the industry as a whole. In other words, if your “riskiness” is exactly the mean riskiness of comparable businesses in your industry sector, then a starting point for assessing individual projects would be the firm’s cost of capital. Any specific project would need additional scrutiny to account for any unique project risks and the appropriate discount rate that should be used in the analysis could be higher or lower than the firm’s cost of capital.

Finally, because debt is frequently a tax-deductible expense, the debt component should be adjusted for tax savings. The following formula would result in an approximate after-tax cost of capital:

$$\text{Weighted after tax cost of capital} = \frac{r_D(1 - T)D + r_E E}{D + E}$$

where r_D is the required interest on debt, T is the appropriate marginal tax rate, D is the amount of debt that is financed, r_E is the expected return on equity, and E is the equity value. It is important to note that the marginal cost or last-source cost of capital is the correct factor to use as the discount rate for new investments. This discount rate would be the appropriate rate to use in any present-value analysis as long as the various projects under consideration possessed similar risk characteristics. As a convention throughout this entry, discount rate and cost of capital are used synonymously.

ALTERNATIVE INVESTMENT METRICS

Net present-value analysis provides a final value on a project-specific basis. Generally, a positive NPV should be undertaken and a negative project should not. However, given that capital is limited and not all investment opportunities afford the same return, alternative investment criteria can be useful in comparing projects. The discussion below should lead to caution when these alternative techniques are used without consideration of the net present-value results. Decision makers can end up with confused if not outright misleading results if these alternative techniques are used in isolation.

Many finance professionals, especially those in the public sector, rely on benefit-to-cost analyses as analytical tools. Most investment opportunities involve both cash outflows and inflows. When present-value analysis is applied and the annual outflows and inflows are not netted out but are instead simply discounted back as current dollars, then the ratio of the present-value benefits (inflows) divided by the present value of costs (outflows) gives a relative ranking against which multiple projects can be judged. In corporate finance, such rankings are referred to as profitability indexes.

Alternatively, the IRR is another commonly used investment metric. Most corporate finance texts define the IRR as that discount rate which equates the present value of a project's expected cash inflows to the present value of the project's cash outflows. The resultant percentage, when applied to the NPV equation, would result in a zero present value for the project.

In terms of the actual formula for IRR, the fundamental net present-value equation is set to zero and IRR notation replaces r for the discount rate.

$$0 = \sum_{t=0}^{N} \frac{CF_t}{(1 + IRR)^t}$$

Thus, IRR answers the question of what is the internally generated return on investment when assuming a project's cash flows result in a breakeven project. In one sense, IRR is a measure of profitability based only on the timing and magnitude of internally generated cash flows of the project. It is not the same as the discount rate the company has determined is needed to initiate the project. Only when a project results in a zero NPV will those two terms be equal.

Frequently, corporate finance professionals prefer the IRR metric because the concept is familiar to shareholders, directors, senior managers, and external investors. However, the use of internal rates of return as investment criterion warrants some caution. Prior to the proliferation of handheld business calculators and spreadsheets, the value of IRR was largely calculated by iterative estimation techniques. Depending on the scope and duration of the cash flow streams, this exercise could be rather burdensome. Spreadsheets and handheld calculators have eliminated these practical difficulties. Interpreting and acting upon IRR results is still problematic, however. Internal rates of returns when considered in isolation can lead to some erroneous decisions on the profitability ranking of different investment opportunities.

It is important to understand how IRR analyses relate to present-value analyses. Present-value analysis specifies the discount rate or cost of capital a priori. This rate is based on external factors such as prevailing interest rates and the expected return on invested equity for projects with similar risk attributes. Thus, any positive present value would imply a positive return on invested capital and indicates the project should be undertaken. The calculation of an IRR asks a different question. Given the expected positive and negative cash flows resulting in a zero present value, what would be the implied return on invested capital?

There are two basic scenarios to consider. Investment capital is frequently, but not always, limited. With adequate funds, such that any two or more projects can be undertaken, an IRR greater than the cost of capital and a positive present-value analysis lead to the same conclusion—undertake the projects. Most firms and individuals do not have unlimited funds. In these cases, selecting one project eliminates the opportunity to undertake the second one. These are referred to as mutually exclusive projects. With mutually exclusive cases like these, the two metrics can result in, at best, ambiguous decision criteria and, at worst, conflicting investment-decision rules.

A NPV AND IRR COMPARISON

Let us explore how the NPV and IRR results can lead to potentially conflicting investment signals. Assume that two project opportunities are available. They have the following cash flows:

Year	Project A ($)	Project B ($)
0	−5000	−5000
1	2500	500
2	1500	1000
3	1000	1250
4	800	1800
5	500	2500

As the analyst assigned to evaluate the two projects, you are told that the company's cost of capital is 5%. You are directed to prepare an NPV and IRR analysis and to make a recommendation to the board of directors. The handy spreadsheet functions indicate that at 5% cost of capital, the NPVs for Project A and B are $624.06 and $859.71, respectively. The IRR function on the spreadsheet produces an IRR of 11% for Project A and 10% for Project B. Because both projects have positive NPVs and the IRR is greater than the cost of capital, the recommendation should be to undertake both projects. In this example, project feasibility is independent. In other words, capital is available to complete both opportunities.

The ambiguity occurs if these are mutually exclusive projects. Typically, this implies capital is not available to do both. While Project B has the higher NPV, its IRR is lower than Project A's. Which recommendation should be made to the board, and more importantly, how do you explain this anomaly as part of the PowerPoint presentation?

A graphic presentation of the relationship between discount rates and NPVs can help explain the apparent conflict. The table below calculates the NPV for these two projects from a zero discount rate to 15% using increments of 5%.

Cost of capital (%)	Project A NPV ($)	Project B NPV ($)
0	1300.00	2050.00
5	624.06	859.71
10	109.62	1.69
15	−285.53	−621.81

Next, the NPVs are plotted against the cost of capital and presented in Fig. 1 below.

A number of characteristics about the two investment projects can be gleaned from this chart. First, notice that at the lower range for the cost of capital, Project B has higher NPVs—simply because of the higher cash inflows and these inflows losing little time value due to the lower discount rates being applied. The two project NPV streams intersect and cross over when the discount rate is approximately 8.2%. At this rate, the NPVs for both projects are approximately $279. For any discount rate above this level, Project A has a higher NPV and would be the preferred project until it turns negative around 11.3%. Project B turns negative around 10% while Project A still has a positive $109 NPV.

The internal rates of return for Project A and Project B are 11 and 10%, respectively. Recall that the NPV calculation specifies the firm's actual cost of capital for the project. If the NPVs are positive and the IRR is greater

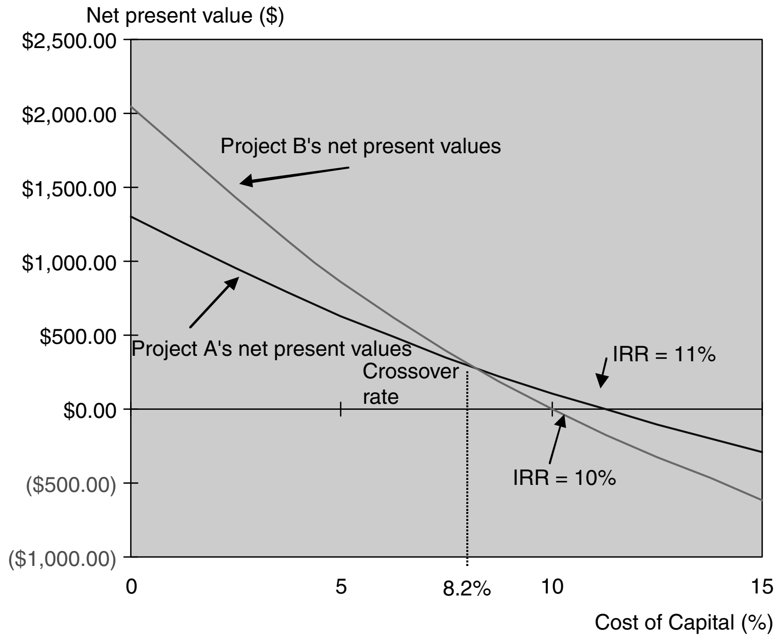

Fig. 1 The net present values of two projects.

Inv–Light

than the underlying cost of capital, then both projects yield positive returns and should be undertaken. If the actual cost of capital is 10%, then as previously noted, Project B is only marginally cost effective. If the actual cost of capital was 10.1%, Project B's NPV turns to a -$12. At this point, the 10% IRR is lower than the cost of capital and Project B should not be undertaken. Again, Project A's IRR of 11% exceeds the required cost of capital and remains a viable investment.

Let's return to the limited capital or mutually exclusive case. If only one of the projects can be undertaken, which one is the superior selection? If both IRRs exceed the required cost of capital, then the decisions should default to the project with the highest NPV. This option maximizes the return to the firm. The ambiguity occurs when the actual cost of capital is less than the crossover or intersection rate. The graph indicates that in all such cases, the NPVs for Project B are higher than for Project A. Yet, the IRR is higher for Project A. If one were explaining the selection before the board of directors, would Project A with the higher IRR not be the more defensible investment?

The answer is no. These mixed investment signals are being generated by the forced computation of the IRR and the assumed reinvestment rate of cash proceeds from the two projects. Because IRR analyses force a discount rate to result in a zero NPV, the formula results in a high rate that is necessary to discount the large, front-loaded cash flows from Project A back to zero to offset the initial capital outlay. Implicit in this process is the assumption that the earlier cash proceeds are reinvested at the IRR. The net present-value method assumes that the proceeds are reinvested at the firm's cost of capital. Therefore, the back-end-loaded cash stream generated by Project B is being discounted at a lower and more realistic cost of capital rate that results in a higher NPV. As mentioned earlier in this exposition, the discounting of the magnitude and timing of the cash flows is causing these divergent results between IRR and NPV analyses.

Table 1 presents two cash flow patterns that dramatically indicate how the IRR can lead to the selection of an inferior project when exclusivity exists.

The NPV of Project A is $1715 when a 10% cost of capital figure is used. At 10%, Project B has an NPV of $1872. With no other information, Project B would be the preferred option. However, the IRRs lead to a different and erroneous conclusion. Project A has an IRR of 23% and Project B yields only a 15% IRR. Here again, the timing and magnitude of cash flows are distorting the two criteria because the mathematical solution of deriving the IRR forces a higher rate to be used to discount the early positive cash flows in Project A back to zero.

VARIABLE DISCOUNT RATES

Another confounding problem when calculating IRR is when the discount rates vary over the project horizon. This can occur when the cost of capital varies because of differences in the yield curve, or term structure, of debt. Because the IRR is derived as a single point value using iterative techniques, the calculated value must be the same for each year of the analysis. However, companies may have a different cost of debt for financing the early years of a project vs. the cost of capital for the later year financing requirements. For example, low cost, short-term commercial paper may be used for the early year's financing on a project and higher cost bonds for the remainder of the project's life. Internal rate of return techniques cannot easily handle this complexity. Other factors that might change the discount rate are phased in changes to the tax rates or depreciation schedules.

Another odd result can occur when projects have cash flows that switch between positive and negative values. Sometimes referred to as nonnormal cash flows, applying IRR techniques can result in more than one IRR being generated. This is likely to occur when a project generates a positive NPV for some portion of the project life and then the cash outflows generate a negative NPV value for several years and then reverse back to positive. The analyst can end up with two return rates and little confidence in which rate accurately captures the true IRR. Net present-value analyses can address issues like these by permitting time varying discount rates.

CONCLUSIONS

It should be evident from the discussion above that net present-value metrics have a variety of features that make them preferable to IRR analysis. They are computationally more reliable while providing a clearer indication of the value that a specific project generates for the bottom line.

Table 1 NPV and IRR comparison-example cash flows

Project	CF_0	CF_1	CF_2	CF_3	CF_4	CF_5	CF_6	CF_7	CF_8	CF_9	CF_{10}
A	−9000	6000	1000	3000	150	150	150	150	150	150	150
B	−9000	1800	1800	1800	1800	1800	1800	1800	1800	1800	1800

The conventional decision rule states that a firm should undertake all projects with positive NPVs and IRRs that are greater than the discount rate. However, in situations where projects are mutually exclusive, IRR should be carefully evaluated before using it as the primary indication of a project's profitability. Despite the widespread use of IRR, practitioners of investment analyses should employ this technique only as a secondary evaluation tool to net present-value strategies.

This entry has provided an overview of the mechanics of net present-value analyses and discussed several of the conceptual issues involved using these techniques. However, such a brief treatise does a disservice to novices using these evaluation techniques. The description and examples all have yielded a single NPV that belies major simplifications of assumptions and ignores the single most difficult factor to quantify—the project's risk. For example, we assumed that the cash flows for any project were known with certainty; we assumed the cost of capital was constant over the project's life; and we assumed any two projects had identical risk profiles. Such certainty allows a calculated, single-point NPV estimate to be confidently taken to lenders to seek financing for the project.

In real applications, such certainty rarely exists. As a consequence, a toolbox of additional analytical techniques can be incorporated into NPV analysis to give investors a more complete assessment of project parameters. Most of these tools are designed to better quantify and thus illuminate the risk associated with investments. For example, recent work in option theory allows option value to be incorporated into the project's pro forma. This may be particularly important when early development work is being undertaken with uncertain cost factors such as volatile interest rates or wide ranging estimates in construction costs. The ability to proceed, terminate, or transfer a project prior to a substantial commitment of capital can increase project flexibility and thus can impart real value to the project's overall worth.

Along these same lines, practitioners frequently will use sensitivity analyses to change the value of critical variables to assess the impact on the NPVs. Such efforts result in a series of NPVs under varying conditions such as high and low interest rate environments. Even more sophisticated Monte Carlo techniques run literally thousands of combinations of factors to develop a statistical distribution of NPVs for any given project. With Monte Carlo distributions, profitability is described in terms of probable payouts instead of single-point estimates. We mention these tools to remind readers that while NPV is the linchpin for investment analysis, it is only the starting point.

LEED-CI and LEED-CS: Leadership in Energy and Environmental Design for Commercial Interiors and Core and Shell

Nick Stecky
NJS Associates, Denville, New Jersey, U.S.A.

Abstract
The U.S. Green Building Council (USGBC) has followed up on its very successful Leadership in Energy and Environmental Design for New Construction (LEED-NC) rating system with two new systems—one for Commercial Interiors (CI) and the other for Core and Shell (C&S). (U.S. Green Building Council (www.USGBC.ORG) LEED green building rating systems for Commercial Interiors and Core and Shell).[1] These two companion programs, LEED for C&S and CI, were developed in response to marketplace demand for a LEED rating system that would enable tenant organizations to have a green workplace while enabling developers the opportunity to provide green buildings for tenants to move into. In the commercial building developer marketplace as currently exists, developers can build a basic building consisting of a C&S with few to no interior fitouts. As tenants are secured, interior fitouts are constructed in accordance with tenant requirements. The result of this process is that the developer can control the greenness of the C&S, and the tenant can control the greenness of the fitout spaces, but neither of them controls the whole building design. Leadership in Energy and Environmental Design for New Construction was unable to accommodate effectively the need to "unbundle" the various elements of a green building—hence, the development of C&S and CI. This entry concludes with a short discussion of some of the obstacles that the USGBC and the LEED programs have met and overcome, and with a forecast of LEED activities.

SUMMARY INTRODUCTION OF TWO NEW LEED RATING SYSTEMS—LEED-CS AND LEED-CI

LEED-CI for Commercial Interiors and LEED-CS for Core and Shell

Leadership in Energy and Environmental Design for Core and Shell (C&S) and Commercial Interiors (CI) were developed in response to marketplace demand for a LEED rating system that would enable tenant organizations to have a green workplace while enabling developers the opportunity to provide green buildings for tenants to move into. In the developer marketplace as currently exists, developers can build a basic building consisting of a C&S with few to no interior fitouts. As tenants are secured, interior fitouts are constructed in accordance with tenant requirements. The result of this process is that the developer can control the greenness of the C&S, and the tenant can control the greenness of the fitout spaces, but neither of them controls the whole building design. Thus, it becomes difficult to apply Leadership in Energy and Environmental Design for New Construction (LEED-NC)—which is based upon whole-building design, interiors as well as C&S—to the commercial developer's building process. The USGBC recognized this dilemma and developed the LEED-CI and C&S rating systems based upon LEED-NC. Consider CI and C&S to be an unbundling of the NC rating system that assigns responsibilities for LEED credits to the entity that has control over those sections. For example, the developer will be responsible for site location, site work, building envelope, central Heating Ventilation and Air Conditioning (HVAC), energy-consuming systems, etc. The tenant will be responsible for the interior spaces, products, office lighting, furniture, paints, office HVAC, etc.

One may ask: how is it known which system to apply, NC or the combination of CI and C&S? The USGBC response is to use NC when the owner is the occupant and has control over the C&S as well as the interior spaces. Note that the two systems, CI and C&S, were developed for circumstances wherein the owner/developer is a different entity from the tenants or occupants. The USGBC goes further in its discussion of this question to include a clarifying statement that C&S and CI are not an option for owners who wish to achieve exemplary performance in the C&S while failing to meet LEED standards in the buildings' fitout. Applicability will become clearer after reading the actual LEED credits per system later in this entry. Note also that throughout this entry, the term LEED credits will be used interchangeably with LEED points.

Keywords: Leadership in Energy and Environmental Design (LEED); Sustainability; Energy efficiency; Indoor air quality; LEED-CI; LEED C&S; LEED Commercial Interiors; LEED Core and Shell.

LEED-CI

Leadership in Energy and Environmental for Commercial Interiors addresses the specifics of tenant spaces primarily in office, retail, and industrial buildings. It was formally adopted in the fall of 2004. The companion rating, Leadership in Energy and Environmental Design for C&S, is currently being balloted, and adoption is expected in the fall of 2006. Together, LEED-CI and LEED-CS will establish green building criteria for commercial office real estate for use by both developers and tenants.

Leadership in Energy and Environmental Design for Commercial Interiors serves building owners and occupants, as well as the interior designers and architects who design building interiors and the teams of professionals who install them. It addresses performance areas including water efficiency, energy efficiency, HVAC systems and equipment, resource utilization, furnishings, and indoor environmental quality.

Benefits of LEED-CI

A number of potential benefits arise out of LEED-CI, many of which are results of the CI focus on providing ideal indoor environments. Included are elements such as daylighting, temperature control, improved ventilation, and adherence to American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) Standard 62.1-2004, Ventilation for Acceptable Indoor Air Quality[2] and Standard 55, Thermal Environmental Conditions for Human Occupancy.[3] Thus, CI provides for occupant well being and productivity. It can also aid in retaining employees and reducing absenteeism. Liability due to poor indoor air quality is reduced. Marketability is increased; churn costs are reduced; and maintenance and operations costs are reduced. The result is an optimum workplace environment that can generate large savings for management.

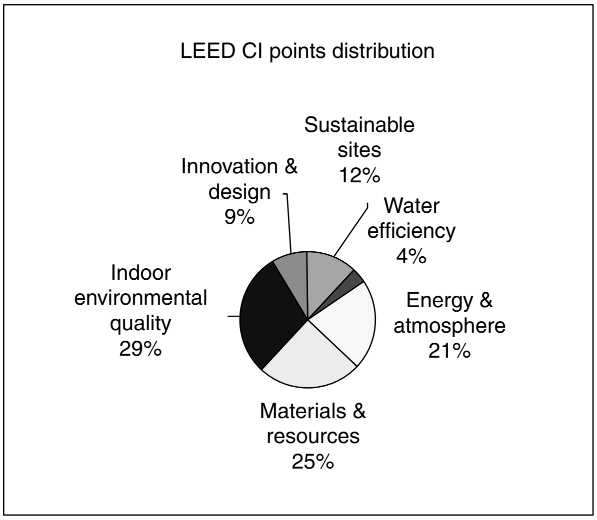
LEED for Commercial Interiors (CI)

- Addresses the design and construction of interiors in existing buildings and tenant fitouts in new C&S buildings
- Pilot: 2002–2004
- Achievements: more than 45 projects in pilot
- LEED-CI adopted in fall 2004.

LEED-CI Point Distribution

Note the same five basic categories as the LEED-NC rating system, but with different weighting from NC. Energy and Atmosphere is the largest point category in NC, but it ranks only third in CI points contributions. This is as expected because CI's influence is primarily on interior spaces, and the interior professionals (such as interior designers and architects) have the major influence.

LEED-CI maximum possible points per category	
Sustainable sites	7
Water efficiency	2
Energy and atmosphere	12
Materials and resources	14
Indoor environmental quality	17
Innovation and design process	4
LEED accredited professional	1
Total points available	57



As in LEED-NC, there are four levels of LEED-CI certification:

Certified	21–26
Silver	27–31
Gold	32–41
Platinum	42–57

LEED-CI—A Technical Review

The LEED formats for rating a green building consist of:

- Prerequisites. These are mandatory requirements, and all must be satisfied before a building can be certified.
- Credits. Each credit is optional, with each contributing to the overall total of credits. This total is used to

determine the level of rating that a building will earn, ranging from Green at the lower level to Silver, Gold, and Platinum.

Sustainable Sites. The maximum number of possible credits is 7. The following credits are very similar to what was described in the LEED-NC section.

Prerequisites. None in this category.

Credits

- Site Selection. Up to 3 credits available; requires the selection to be a LEED Certified Building or to locate the tenant in a building that has in place two or more of the following: Brownfield Development, Stormwater Management Rate and Flow, Stormwater Management Treatment, Heat Island Reduction for roof or nonroof, Light Pollution Reduction, Water Efficient Irrigation, Innovative Wastewater Technologies, Water-Use Reduction, Onsite Renewable Energy, and other quantifiable environmental performances. The obvious choice for the tenant entity that wants to be in a LEED-CI facility is to locate in a LEED-NC or C&S building. Otherwise, the multiple requirements for the alternative path to these credits can become difficult to satisfy without a great deal of participation on the part of the owner.
- Development Density and Community Connectivity. 1 credit available. The intent is to channel development to urban areas with existing infrastructure, protect greenfields, and preserve habitat and natural resources.
- Alternative Transportation. Total of 3 credits available through three categories:
  - Proximity to commuter, light-rail, subway station, or bus transportation
  - Provide for bicycle commuting by requiring secure bicycle storage and convenient shower/locker facilities for 5% or more of the tenants
  - Limit the number of parking spaces for single-occupancy vehicles and provide priority for vans and carpooling

Water Use Efficiency. Only 2 credits available.

Prerequisites. None in this category.

Credits

- Water-Use Reduction. 1 point. Requires tenant to use 20% less water in aggregate than the water-use baseline calculated for the tenant space after meeting the Energy Policy Act of 1992 fixture performance requirements.
- Water-Use Reduction. 1 additional point if the water-use reduction is 30% instead of the 20% listed in the first credit.

Energy and Atmosphere. Up to 12 credits available.

Prerequisites. Three required.

- Fundamental Commissioning. Focus on HVAC and R, lighting, daylighting and associated controls, renewable energy systems, and domestic hot water systems.
- Minimum Energy Performance. Comply with American Society of Heating, Refrigerating and Air Conditioning Engineers/Illuminating Engineers Society of North America (ASHRAE/IESNA) Standard 90.1-2004[4] or the local energy code, whichever is more stringent.
- Chloro Flouro Carbon (CFC) Reduction in Heating Ventilation and Air Conditioning and Refrigeration (HVAC&R) Equipment. To reduce ozone depletion, require zero use of CFC-based refrigerants in tenant HVAC&R systems.

Credits

- Optimize Energy Performance Lighting Power. Up to 3 credits. The first credit requires the lighting power allowance to be 15% less than the ASHRAE/IESNA baseline standard. The second credit is for 25% better than the standard, and the third credit is for 35% or better than the standard.
- Optimize Energy Performance Lighting Controls. 1 credit available; requires use of daylight sensors to control lighting levels within 15 ft of windows or skylights.
- Optimize Energy Performance HVAC. Up to 2 credits. There are two options for compliance. The first relates to equipment efficiency, as described in the New Buildings Institute, Inc. publication "Advanced Buildings: Energy Benchmark for High Performance Buildings." In addition, provide appropriate zone controls for temperature control. The second way to compliance is to demonstrate that HVAC system-component performance criteria for tenant spaces are 15% better than the ASHRAE/IESNA standard for 1 credit. An additional credit is given if the performance is 30% better than the ASHRAE/IESNA standard.
- Optimize Energy Performance Equipment and Appliances. Up to 2 points. This applies to all Energy Star-eligible equipment installed in the project, including appliances but excluding HVAC and lighting and building envelope products (these were covered in sections above), and earns 1 point if 70% of applicable equipment is Energy Star rated. The second point is earned if 90% of applicable equipment is Energy Star rated.
- Enhanced Commissioning. Earns 1 point. In addition to the Fundamental Commissioning prerequisite, this credit requires additional commissioning to do design review before construction, to review the energy-related systems, to develop a manual for recommissioning, and to verify that training requirements for operations personnel are completed.
- Energy Use. Up to 2 points; provides two case paths to compliance. Case A requires submetering for energy

use in the tenant spaces and negotiating a lease wherein the tenant pays the energy bills, which are not included in the rent. The purpose of this is to highlight to the tenant the actual costs of energy and thereby encourage conservation. In the alternative Case B, install continuous metering for energy end uses such as lighting systems and controls, constant and variable motor loads, Variable Frequency Drive (VFD) applications, chiller efficiencies at variable loads, cooling loads, boiler efficiencies, and more.

- Green Power. 1 point; requires that at least 50% of the tenant's electricity come from renewable sources by engaging in at least a 2-year energy contract.

Materials and Resources. Up to 14 possible credits in this category.

Prerequisites. One required in this section.

- Storage and Collection of Recyclables. Provide a tenant-accessible area for the collection and storage of materials including glass, paper, metals, cardboard, and plastic.

Credits

- Long-Term Commitment. 1 point; requires that the tenant remain in the same location for no fewer than 10 years to encourage choices that will conserve resources.
- Building Reuse, Maintain 40 or 60% of Interior Nonstructural Components. 2 possible credits. For 1 credit, maintain at least 40% by area of the existing nonshell, nonstructure components, such as walls, floors, and ceilings. Make it 2 credits if it is 60% reuse.
- Construction Waste Management. Up to 2 credits available. Divert from landfills construction-related materials through the use of a waste management plan. Divert 50% for 1 credit or 75% for 2 credits.
- Resource Reuse. 2 possible credits; requires the use of at least 5% of building construction materials, excluding furniture and furnishings for 1 credit. If 10% is reused, it is 2 credits.
- Resource Reuse—30% Furniture and Furnishings. 1 point; requires the use of salvaged, refurbished, or used furniture and furnishings for 30% of the total budget for these items.
- Recycled Content. 2 points possible. The intent is to increase demand for recycled content and materials. These include post- and preconsumer materials used in furniture and furnishings. If 10%, it is 1 credit; if 20%, it is 2 credits.
- Regional Materials 20% Manufactured Regionally. 1 point available. Use a minimum of 20% combined value of furniture, materials, and products that are manufactured regionally within a radius of 500 mi.
- Regional Materials 10% Extracted and Manufactured Regionally. 1 point. In addition to the regional materials above, use a minimum of 10% of the combined value of construction materials and products extracted, harvested, or recovered as well as manufactured within 500 mi.
- Rapidly Renewable Materials. 1 point. Use rapidly renewable materials for 5% of the total value of all materials and products used.
- Certified Wood. 1 point. When using wood products, use a minimum of 50% certified by the Forest Stewardship Council.

Indoor Environmental Quality (IEQ). Up to 17 possible credits in this category. Note the use of the phrase IEQ instead of the more common phrase indoor air quality. IAQ is a fundamental part of IEQ, but IEQ encompasses much more than air quality, as outlined below.

Prerequisites

- Minimum IAQ Performance. Satisfy the requirements for ventilation based upon ASHRAE Standard 62.1-2004, Ventilation for Acceptable Indoor Air Quality.
- Environmental Tobacco Smoke (ETS) Control. The most common path to compliance is simply to prohibit smoking in the building. This has become common practice and is frequently required by codes. Alternative paths to compliance include the construction of dedicated smoking rooms with dedicated HVAC and exhaust systems.

Credits

- Outdoor Air Delivery Monitoring. 1 point; provide permanent monitoring and alarm systems that provide feedback on ventilation system performance.
- Increased Ventilation. 1 point; increase the outdoor air ventilation by 30%, above required by ASHRAE Standard 62.1-2004. However, this can significantly increase the building's energy consumption. Reference the ASHRAE Green Guide for ways to ameliorate the negative energy impacts of this measure.
- Construction IAQ Management Plan. 2 points available. The first point is earned during construction by developing and implementing an IAQ Construction Management Plan. It includes protection from moisture for building materials, special air filters for HVAC during construction, and replacing all filter media prior to occupancy. The second point is for Before Occupancy. It includes optional requirements for building flushout or an IAQ test procedure to ensure suitability of the space before occupancy.
- Low Emitting Materials. Up to 5 points available for five categories of products. The intent is to specify low Volatile Organic Compound (VOC)-emitting products.

Inv–Light

These product categories are adhesives and sealants, paints and coatings, carpet systems, composite wood and laminate adhesives, and systems furniture and seating.

- Indoor Chemical and Pollutant Control. 1 point; minimize the exposure of occupants to potential contaminates and chemical pollutants that can adversely affect IAQ. Methods to achieve this include entryway systems such as grates to trap dirt. Where hazardous products may be used, such as janitorial closets, provide dedicated exhausts and spill containment.
- Controllability of Systems, Lighting. 1 credit; provide lighting controls for at least 90% of the occupants.
- Controllability of Systems, Temperature, and Ventilation. 1 point; provide at least 50% of the occupants the ability to adjust thermal and ventilation conditions to suit individual needs and preferences. This may be an energy-waster, depending upon the HVAC systems in place. Reference the ASHRAE Green Guide for ways to deal with this issue.
- Thermal Comfort Compliance. 1 credit; comply with ASHRAE Standard 55-2004, Thermal Conditions for Human Occupancy. Note that Standard 55 is based upon providing conditions that will satisfy 80% of the population, which implies that 20% may not be comfortable. This may become an energy-efficiency and a comfort dilemma for operations personnel.
- Thermal Comfort, Monitoring. 1 point; provide a permanent monitoring system and process to ensure compliance with the ASHRAE 55 credit listed above.
- Daylight and Views, Daylight for 75 and 90%. Up to 2 credits available; provide occupants a connection between indoor and outdoor spaces through the use of daylight. If a minimum daylight factor of 2% is achieved for 75% of the occupants, it is 1 point. If that factor is for 90% or more of the occupants, it is 2 points.
- Daylight and Views, Views for 90% of the Seated Spaces. 1 point. Achieve direct line of sight to the outdoor environment for at least 90% of those spaces normally occupied.

Innovation and Design Process. Up to 4 points available. This is a way to encourage the innovation and evolution of LEED through the recognition of exceptional performance above the requirements set by LEED. It includes identification of the intent of the credit, the proposed requirements, the proposed submittals, and the design approach.

Leadership in Energy and Environmental Design for Accredited Professional. 1 credit. This is the use of a LEED Accredited Professional (AP) as one of the principal participants in the project team.

LEED Core and Shell, C&S

Based upon the LEED-NC rating system for NC and major renovation, LEED-CS was developed in recognition of the unique nature of C&S developments. In particular, there is the lack of developer control over key aspects such as interior finishes, lighting, and HVAC distribution. Thus, the scope of CS is limited to those elements of the project under the direct control of the developer.

When CS is combined with its companion rating system, LEED-CI for commercial interiors, the USGBC addresses the entire building, core, shell, and interiors, but with responsibility assigned to those parties having direct control of their particular sections. Currently in the ballot phase, CS is expected to be adopted in the fall of 2006.

Precertification

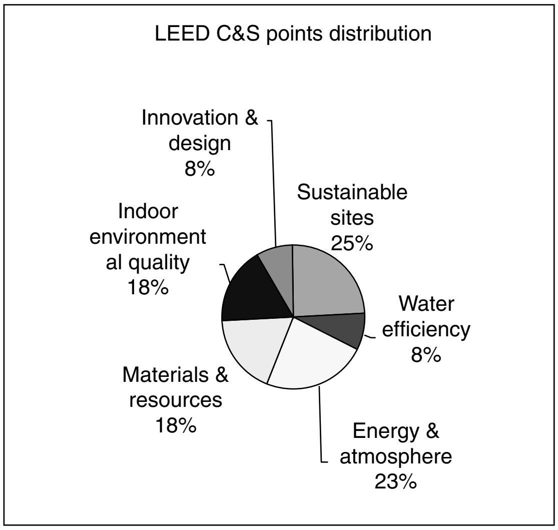
Many times, an LEED-CS building will be built speculatively, without tenants or an interior fitout design. Therefore, the USGBC recognized the need for LEED-CS projects to be precertified prior to the building's construction. This way, the developer can promote his building as a LEED-compliant design and position his building in the competitive marketplace. This is different from other LEED products, wherein certification is awarded after construction is complete. But in fact, what is precertified is only the building's design. Precertification does not guarantee future certification. All it provides is a conditional promise in writing from the USGBC that if in fact the C&S are constructed in accordance with the precertification documents, and if the USGBC full-documentation process is followed, the building will be certified.

LEED-CS Credit Categories

Below is a summary of where the points will be for LEED-CS. Note the similarities to LEED-NC and that Energy and Atmosphere is the largest point category. This particular version of C&S is the ballot version for adoption. Earlier versions varied slightly during the public comment stages, and this ballot represents the final version, pending some last-minute changes.

Possible points	
Sustainable sites	15
Water efficiency	5
Energy and atmosphere	14
Materials and resources	11
Indoor environmental quality	11
Innovation and LEED AP	5
Total points available	61

Inv–Light



Four levels of certification	
Certified	23–27 points
Silver	28–33 points
Gold	34–44 points
Platinum	45–61 points

LEED Core and Shell, C&S, Technical Review

The format of LEED C&S is similar to LEED-NC and CI. There are prerequisites and credits. There are the five basic categories of credits: Sustainable Sites, Water Efficiency, Energy and Atmosphere, Materials and Resources, and Indoor Environmental Quality. There are also credits for Innovation and Design Process.

Sustainable Sites. Maximum available points is 15.

Prerequisites. There is one prerequisite.

- Construction Activity Pollution Prevention. Create and implement an erosion and sedimentation control plan for all construction activities of the project.

Credits

- Site Selection. 1 credit available. The intent is to discourage inappropriate development and to reduce the environmental impacts of the building's location. A list of prohibited development is provided, which includes wetlands, prime farmlands, land especially identified as habitat for threatened or endangered species, and public parkland.
- Development Density and Community Connectivity. 1 point available; encourage development in areas with existing infrastructure. There are two options: Development Density, which is to build on a previously used site and in a community with a minimum density of 60,000 ft^2 per acre, and Community Connectivity, which is to construct on a previously developed site within one-half mile of a residential zone with an average density of 10 units per acre and within one-half mile of basic services with pedestrian access.
- Brownfield Redevelopment. 1 point available; develop on a site documented as contaminated by means of American Society for Testing and Materials (ASTM) E1903-97 Phase II Environmental Site Assessment.
- Alternative Transportation. Up to 4 credits available; 1 credit each for access to public transportation, provision of bicycle storage and changing rooms, low-emitting and fuel-efficient vehicles, parking capacity, and a plan to promote vans and carpooling and discourage single vehicle occupancy.
- Site Development. 2 credits available. The first credit is for protecting or restoring habitat for greenfield sites and limiting site disturbance to 40 ft beyond the building perimeter or, for previously developed sites, restoring or protecting 50% of the site area. The second credit is for maximizing open space. Three options are available. The first option is to reduce the development footprint. The second option, for areas with no local zoning requirements, is to provide vegetated open spaces adjacent to the building. The third option, where a zoning ordinance exists but has no requirement for open space, is to provide vegetated open space equal to 20% of the project site area.
- Stormwater Design. 2 credits available. The first credit is for quantity control of stormwater peak discharges and a management plan to protect stream channels. The second credit refers to quality control of discharges. It refers to an implementation plan to promote infiltration and to capture and treat stormwater runoff from 90% of the annual rainfall.
- Heat Island. 2 credits available. The first credit is for nonroof applications and includes strategies to provide vegetation for shade, high-reflectance paving materials, or open grid pavement, or placing a minimum of 50% of parking spaces under cover. The second credit for roof applications includes strategies that can be roofs with a high Solar Reflectance Index, a green vegetation-covered roof, or a combination of the two.
- Light Pollution Reduction. 1 credit available; reduce light trespass from the building, including outdoor lighting as well as overflow from interior lighting.
- Tenant Design and Construction Guidelines. Provide tenants design and construction information that includes a description of sustainable design features incorporated into the C & S part of the project. This serves to educate and encourage tenants to complete the sustainability promise of the project. It also includes LEED CI guidance.

Inv–Light

Water Efficiency. No prerequisites are required in this section. A total of 5 credits is available in this section.

Credits

- Water Efficient Landscaping. Up to 2 credits available. The first credit is for a reduction of 50% or more in the use of potable water for landscaping, calculated from the midsummer baseline consumption. The second credit is for the use of nonpotable water for irrigation or the use of no irrigation through the careful selection of landscaping vegetation.
- Innovative Wastewater Technologies. 1 credit. Two options are available. The first option is to reduce potable-water use for sewage conveyance by the use of water-conserving plumbing or the use of nonpotable water for flushing. The second option is to treat 50% or more of wastewater on site to tertiary standards and reuse it on site.
- Water-Use Reduction. Up to 2 credits; employ strategies that in aggregate use less than the baseline consumption, as calculated to meet the Energy Policy Act of 1992 performance. A 20% reduction gets 1 credit; a 30% reduction gets 2 credits.

Energy and Atmosphere. Up to 14 credits available in this category. There are three prerequisites required.

Prerequisites

- Fundamental Commissioning of the Building Energy Systems. This refers to a commissioning of the basic energy-consuming systems in the C&S. They include HVAC and R, the building automation system, lighting, lighting controls, domestic hot water systems, renewable energy systems, and daylighting.
- Minimum Energy Performance. The project is to be designed to comply with ASHRAE/IESNA Standard 90.1-2004. This includes the mandatory provisions and either of the following two: the prescriptive requirements, which follow the prescriptive information provided in the standard, or the performance requirements, which are based upon energy-consumption computer modeling of the building's energy systems. The modeling method allows the design team greater flexibility in overall design.
- Fundamental Refrigerant Management. Requires zero use of CFC refrigerants to reduce ozone depletion. In reusing an existing building that contains CFCs, a phaseout plan must be implemented before project completion, although application for special consideration to extend the phaseout will be considered on its merits.

Credits

- Optimize Energy Efficiency. Up to 8 credits available. This is the single largest category for LEED credits. There are three optional paths. Option 1 is to perform a building energy-consumption simulation and compare this with the baseline established as part of the prerequisite for minimum energy performance. Credits are awarded for the percentage that is better than the baseline. For example, 1 credit is given for NC if it is 10.5% better or for an existing building renovation if it is 3.5% better. This goes up to 8 credits for NC when it is 35% better or existing buildings when they are 28% better. Option 2 is a prescriptive path for 3 credits by following the ASHRAE Advanced Energy Design Guide for Small Office Buildings. An additional 3 credits are available in Option 2. One credit is given by improving the building envelope beyond the ASHRAE Design Guide[5] baseline design. Another credit is given for lighting systems that comply with all the ASHRAE Design Guide recommendations, and the third credit is given for HVAC and service water heating systems that comply with all recommendations of the ASHRAE Design Guide. Option 3 can earn only 1 credit, to comply with the Basic Criteria and Prescriptive Measures of the NBI Advanced Buildings Benchmark version 1.1, with the exception of several sections, including Design, Construction, and Operations Certification, Energy Code Compliance, Indoor Air Quality, Refrigeration Equipment Efficiency, Monitoring and Trend Logging, Networked Computer Monitor Control, and Cool Roofs.
- On-Site Renewable Energy. 1 credit; requires that at least 1% of the building's baseline annual energy cost be renewable energy generated on site.
- Enhanced Commissioning. 1 credit. This refers to commissioning more comprehensive than the Fundamental Buildings Commissioning Prerequisite. It includes a design review prior to construction, the review of all submittals for energy-consuming systems, the development of a systems manual for future operations staff, verification that operating personnel have been properly trained, and continued project involvement for at least 10 months after completion by reviewing building operations and developing a plan of resolution for outstanding commissioning-related activities.
- Enhanced Refrigerant Management. 1 credit. There are two optional ways to comply. Option 1 is to not use refrigerants. This may be satisfied by having no mechanical cooling. Option 2 is to select refrigerants for HVAC and R that minimize or eliminate the emission of compounds that contribute to ozone depletion and global warming.
- Measure and Verification (M&V). There are two credits available. The first credit is for the base building, which includes a Measurement & Verification, M & V, Plan that will provide the necessary

infrastructure, usually part of the Building Automation System, BAS. This is to measure base building energy consumption for electricity and other services for least one year of postconstruction occupancy. The second credit is available for tenant submetering to provide ongoing tenant responsibility for energy bills. Again, this can be done through sensors that are part of the BAS.

- Green Power. 1 credit; requires that at least 35% of C&S base-building electricity comes from renewable energy sources by engaging in a green power purchase contract for at least a 2-year duration.

Materials and Resources. Up to 11 credits available, with one prerequisite.

Prerequisite

- Storage and Collection of Recyclables. Provide an easily accessible area that serves the entire building and that is dedicated to the collection and storage of recyclable materials.

Credits

- Building Reuse: Maintain a Percentage of Existing Walls, Floors, and Roof. Up to 3 credits available; extend the life cycle of existing buildings by maintaining a percentage of the existing structures, including walls, floors, and roof. The first credit is for 25% reuse; 50% reuse earns a second credit; and at 75% reuse, a third credit is earned.
- Construction Waste Management. Up to 2 credits available; divert construction and demolition materials from disposal by recycling and reusing a percentage of nonhazardous construction and demolition debris. Develop and implement a plan to identify, sort, and set aside materials for reuse. The first credit is earned for 50% diversion from disposal. An additional credit is earned if 75% is diverted.
- Materials Reuse. Earns 1 credit; use salvaged, refurbished, or reused materials, the sum of which is 1%, based upon the cost of the total value of materials for the project.
- Recycled Content. Up to 2 credits available; requires the use of recycled content such that the sum of postconsumer recycled content plus one-half of the preconsumer constitutes a percentage of the total cost of materials on the project. If that percentage is 10%, 1 credit is earned. For 20% or more, 2 credits are earned.
- Regional Materials: Extracted, Processed and Manufactured Locally. Up to 2 credits available. The intent is to use materials or products that have been extracted, harvested, recovered, or manufactured locally within 500 mi of the job site. If the total is 10% by cost of total materials used, this earns 1 credit. If the total is 20% or more, 2 credits are earned.
- Certified Wood. 1 credit. For all wood products used, ensure that a minimum of 50% of wood-based products is certified in accordance with the Forrest Stewardship Council. This can include furniture as well as building structural components.

Indoor Environmental Quality. There are two prerequisites and a total of 11 credits available in this category.

Prerequisites

- Minimum IAQ Performance. Comply with Sections 4–7 of ASHRAE 62.1-2004, Ventilation for Acceptable Indoor Air Quality.
- Environmental Tobacco Smoke (ETS) Control. Three optional paths for compliance. The first option is to prohibit smoking in the building and locate any designated outdoor smoking areas at least 25 ft away from the building and all air intakes. Prohibition is the simplest option to use. Option 2 consists of several parts: (1) Prohibit smoking except in designated areas; (2) designated smoking areas must have isolated HVAC and exhaust systems, separate from the house systems; (3) use of differential air pressures is required to ensure that smoke does not infiltrate into nonsmoking space; and (4) outdoor designated spaces are to be at least 25 ft away from the building and all building air intakes. The third option is for residential applications. This requires prohibition of smoking in all common areas and locates outdoor smoking areas at least 25 ft away.

Credits

- Outdoor Air Delivery Monitoring. Earns 1 credit; requires permanent monitoring systems to provide feedback on ventilation system performance to ensure that it is working up to design performance. For mechanically ventilated spaces, refer to ASHRAE 62.1-2004. For naturally ventilated spaces, use CO2 monitoring to ensure that ventilation is adequate.
- Increased Ventilation. Earns 1 credit. For mechanically ventilated spaces, increase breathing zone ventilation rates at least 30% more than the minimum required by ASHRAE 62.1-2004. Note that this can come at the cost of large energy losses unless energy-conserving measures such as heat recovery are used. For naturally ventilated spaces, follow the guidelines outlined in the Carbon Trust Good Practice Guide 237 and the Chartered Institution of Building Services Engineers Applications Manual 10:2005.
- Construction IAQ Management Plan: During Construction. 1 credit. Implement an IAQ management plan for the construction preoccupancy phases of the building. This includes meeting the control measures of the Sheet Metal and Air Conditioning National Contractors Association (SMACNA) IAQ Guidelines for Occupied Buildings under Construction, 1995, Chapter 3.[6] This credit also requires protection of construction materials from moisture damage and mold growth.

- Low-Emitting Materials. Up to 3 points available. Four categories of low-emitting materials are listed here. The intent is to reduce the indoor air contaminants that may be odorous, irritating, or harmful—essentially striving to have an indoor environment with a minimum of VOCs and other irritating substances. Categories are adhesives and sealants, paints and coatings, carpet systems, composite wood, and agrifiber products. Compliance with two of these categories earns 1 credit. Compliance with three categories earns 2 credits, and compliance with all four categproes earns 3 credits.
- Indoor Chemical and Pollutant Source Control. Earns 1 credit. Design to control and minimize pollutant entry into buildings. This is accomplished by using entryway systems to prevent dirt and particulates from entering the building. Where hazardous materials may be stored, such as in janitorial closets, provide exhaust systems. And for mechanically ventilated spaces, provide air filtration that has a Minimum Efficiency Ratings Value (MERV) of 13 or better.
- Controllability of Systems. 1 credit. Provide individual comfort controls for a minimum of 50% of the building occupants to enable adjustments to suit individuals' needs. Operable windows can be used in lieu of comfort controls in certain settings. Obviously, this may have a very negative impact on overall building energy consumption unless it is well designed and managed.
- Thermal Comfort: Design.1 credit. Design the HVAC systems and building envelope to comply with ASHRAE Standard 55-2004 for Thermal Comfort. This applies only to C&S projects that are providing the base-building HVAC system. If the tenant is to provide the HVAC, this credit is not available to the C&S applicant. However, it would be available for the tenant under CI. Note that this standard recognizes that 80% of building occupants will find this condition fully acceptable, which implies that possibly 20% will be uncomfortable to some degree.
- Daylighting and Views. Up to 2 points available, depending upon the percentage of occupants who have daylighting as defined in the credit requirements. Daylighting compliance requires a calculation that includes glazing factors, window areas, floor space geometry, and other factors. Details are supplied in the USGBC LEED documents. The intent of these credits is to provide occupants a connection to outdoor spaces through the introduction of daylight and outdoor views. For 75% compliance, the project earns 1 credit. For 90% compliance, it earns 2 credits.
- Innovation and Design Process. Earns up to 4 credits, in similar fashion as described in LEED-CI previously.
- LEED Accredited Professional. Earns 1 credit to have an LEED AP as a principal member of the project team.

You can download all four of the LEED rating systems. The rating-systems downloads are free. However, other tools and workbooks, such as the reference guides, do have a fee associated with them, with discounts given to members:

1. Visit the U.S. Green Building Council Web site at www.usgbc.org/leed.
2. Choose a rating system.
3. Click the rating system you would like to download.

DISCUSSION OF LEED

The USGBC was formed to transform the built environment and the processes that constitute the design, construction, and operation of buildings. However, there are critics who say the USGBC has not lived up to its promise and has not made a difference in the marketplace. Leadership in Energy and Environmental Design and the USGBC have experienced their share of criticism because of this. Typically, these criticisms focus on the complexity of the LEED certification process. It is detail oriented, very demanding, and time consuming, and there is no guarantee that a building will pass certification even after all the work is done. In addition to process concerns, green buildings have been criticized as being too expensive to build. Many in the buildings industry believe that building green might be analogous to "gold plating." Green seems to add much cost with insufficient value added.

Another question has been about the ability of the design community and product suppliers to deliver green products. Are there enough trained professionals? Also, are there enough green products available at comparable costs to standard materials? In addition, some may say that the USGBC is too internally focused and not inclined "to play well with others," such as with other organizations and trade associations.

The USGBC has recognized these problems and concerns, and has acted vigorously to resolve these issues. First, regarding market penetration, although there are still not many certified green buildings, the marketplace is abuzz with arguments—pro and con—about sustainability and green buildings. So although actual penetration is slight when compared with all buildings, almost none of those new buildings is built without a discussion of green. The USGBC has in fact already transformed the marketplace; it has made sustainable green buildings a major topic of discussion and argument. As for interest in, if not outright acceptance of, LEED, it is evident everywhere. It ranges from major corporations to all levels of government and to educational and health-care industries, etc. At this point, the U.S. Army, Air Force, and Navy, and other Department of Defense agencies require LEED.[7]

Rick Fedrizzi, current head of the USGBC and one of its founders, likens LEED to an adolescent. Leadership in Energy and Environmental Design is still growing, maturing, and finding better ways to do its job.[8] Fedrizzi has compared the adaptability of LEED with the U.S. Constitution. Although the authors of the original LEED

NC 2.0 made the best possible document at the time, they recognized that changing forces in the global effort for sustainability would require the evolution of LEED. Thus, LEED has incorporated the innovation credits, which encourage and reward creativity, risk-taking, and innovation. Leadership in Energy and Environmental Design can be amended in a fashion similar to a constitutional amendment. All stakeholders, essentially all USGBC members, have not only the opportunity, but also the responsibility to vote on changes. The current results of this evolution have been the development of new LEED products such as C&S, CI, and Existing Buildings. In the wings are LEED for Homes and Neighbourhood Development. Besides new LEED products, there are variations in the existing programs being developed. There are versions of LEED-NC for schools, labs, health-care facilities, etc. being considered. Another modification to LEED being considered is the regionalization of LEED. Currently, regional advisory teams are being recruited from the membership, through the USGBC local chapters. These teams will consider creating regionalized LEED criteria based upon local factors affecting sustainability. For example, for the arid Southwest, water is a critical resource, and its conservation should have a greater emphasis than it does in the current LEED programs. So maybe additional water-related credit categories will be developed for the Southwest. Similarly, in the mid-Atlantic states, water is less an issue than it is in the Southwest, but open spaces, landfills, and uncontrolled development are greater concerns.

The USGBC has also streamlined the certification process and provided online document templates to facilitate the certification process. Additional efforts to facilitate the process continue.

As for professional development, the USGBC recognized very early that sustainable buildings will need not only a roadmap for sustainable buildings (for example, LEED), but also the professionals to deliver this product. Professional training, seminars, and accreditation have been cornerstones of the USGBC effort, and these educational programs are expanding. The USGBC is determined to ensure that there are enough trained professionals. With these trained professionals comes the development of experienced LEED design teams. In the beginning of sustainable design and construction, green buildings were difficult and more expensive to build than conventional buildings. But now, with experienced teams, newer green projects are coming in at very comparable prices to conventional buildings. The perceived cost premium for green has faded away.

Last, the USGBC has welcomed the membership of trade associations, which were previously prohibited. In addition, other organizations have actively joined with the USGBC. In 2002, ASHRAE signed a memorandum of understanding (MOU) with the USGBC to develop joint programs. Among the results of this teaming have been the development of the ASHRAE Green Guide, the Small Buildings Design Guide and USGBC, ASHRAE/IESNA, and ANSI Standard 189, which will provide code language for the design and construction of green buildings.[9]

CONCLUSION

Where is LEED going? What is the future? We can see there are new products being developed for different markets. We see the regionalization of LEED credits. There is teaming with other interested and related organizations. But the current focus of efforts has been primarily on the design and construction of new and renovated buildings. The focus has been on the architects to lead the sustainable design team, consisting of engineers, interior designers, suppliers, and contractors. But when the new building is constructed, the ribbon at the entranceway has been cut, and the LEED certification plaque is mounted on the wall, everyone shakes hands, and compliments go all around for a job well done! But is it? Is this the end? Or is it the end of the beginning? I would call this a transition from beginning to operations.

Leadership in Energy and Environmental Design certification is similar to the educational process. We send students to the best schools, and they receive the best grades and earn their diplomas. But does it all stop there? No. The graduates now must deliver on their promise of excellence. Over their working life of 30 or 40 years, they must deliver on their promise. It is the same with a building. It will have to be operated in a superior fashion over many years for it also to deliver on that high-performance promise made so many years ago when that ribbon was cut. But then, we do have LEED for Existing Buildings, and that's for another entry.

LEED-NC: Leadership in Energy and Environmental Design for New Construction

Stephen A. Roosa
Energy Systems Group, Inc., Louisville, Kentucky, U.S.A.

Abstract

The Leadership in Energy and Environmental Design (LEED™) Green Building Rating System is a set of rating systems for various types of construction projects. Developed by the U.S. Green Building Council (USGBC), the rating systems evolved with the intent of helping to "fulfill the building industry's vision for its own transformation to green building." [U.S. Green Building Council. *LEED green building rating system*. 2004.] The rating systems developed by the USGBC are for new construction, existing buildings, core and shell construction, commercial interiors, homes, and residences. This article considers one of these systems, LEED-NC. It discuses the influences that shaped development of LEED-NC for new construction and major renovations, details how the process works, and considers how new projects are scored. The article concludes by providing a brief assessment of the program's strengths and weaknesses.

INTRODUCTION

Land development practices have yielded adverse environmental consequences, urban dislocation, and changes in urban infrastructure. Urban development in particular has long been associated with reduced environmental quality and environmental degradation.[2] The rate at which undeveloped land is being consumed for new structures—and the growing appetite of those structures for energy and environmental resources—has contributed to ecosystem disruption and has fostered impetus to rethink how buildings are sited and constructed. While urban developmental patterns have been associated with environmental disruptions at the local and regional scales, the scientific assessments of global impacts have yielded mixed results. In part as a reaction to U.S. development patterns that have traditionally fostered suburbanization and subsidized automobile-biased transportation infrastructure, design alternatives for structures with environmentally friendly and energy efficient attributes have become available.

According to the United Nations Commission on Sustainable Development, "air and water pollution in urban areas are associated with excess morbidity and mortality … Environmental pollution as a result of energy production, transportation, industry or lifestyle choices adversely affects health. This would include such factors as ambient and indoor air pollution, water pollution, inadequate waste management, noise, pesticides and radiation."[3] It has been demonstrated that a relationship exists between the rates at which certain types of energy policies are adopted at the local level and select indicators of local sustainability.[4] As more urban policies focus on the built environment, buildings continue to be the primary building blocks of urban infrastructure. If buildings can be constructed in a manner that is less environmentally damaging and more energy efficient, then there is greater justification to label them as "green" buildings.

The concept of sustainability has evolved from considerations of land development, population growth, fossil fuel usage, pollution, global warming, availability of water supplies, and the rates of resource use.[5] Thankfully, a vocabulary of technologies and methodologies began to develop in the 1970s and 1980s that responded to such concerns. Driven by ever increasing energy costs, energy engineers began to apply innovative solutions, such as use of alternative energy, more efficient lighting systems and improved electrical motors. Controls engineers developed highly sophisticated digital control systems for heating, ventilating and air conditioning systems. With growing concerns about product safety and liability issues regarding the chemical composition of materials, manufacturers began to mitigate the potential adverse impacts of these materials upon their consumers. Resource availability and waste reduction became issues that began to influence product design. In the span of only 25 years, local governments made curbside recycling programs in larger U.S. cities nearly ubiquitous. Terms and phrases such as "mixed use planning," "brownfield redevelopment," "alternative energy," "micro-climate," "systems approach," "urban heat island effect," "energy assessments," "measurement and verification," and "carrying capacity" created the basis for a new vocabulary

Keywords: Leadership in energy and environmental design (LEED); Sustainability; Sustainable development; Planning; Indoor air quality (IAQ); LEED for new construction.

which identifies potential solutions. All of these concerns evolved prior to the 1992 U.N. Conference on the Environment and Development, which resulted in the Rio Agenda 21 and clarified the concept sustainability.

In regard to the built environment, architectural designers renewed their emphasis on fundamental design issues, including site orientation, day lighting, shading, landscaping, and more thermally cohesive building shells. Notions of "sick building syndrome" and illnesses like Legionnaires' disease, asthma and asbestosis, jolted architects and engineers into re-establishing the importance of the indoor environmental conditions in general and indoor air quality (IAQ) in particular when designing their buildings.

The decisions as to what sort of buildings to construct and what construction standards to apply are typically made locally. Those in the position to influence decisions in regard to the physical form of a proposed structure include the builder, developer, contractors, architects, engineers, planners, and local zoning agencies. In addition, all involved must abide by regulations that apply to the site and structure being planned. The rule structure may vary from one locale to another. What is alarming is that past professional practice within the U.S. building industry has only rarely gauged the environmental or energy impact of a structure prior to its construction. Prior to the efforts of organizations like the U.S. Green Building Council (USGBC) (established in 1995), the concept of what constituted a "green building" in the United States lacked a credible set of standards.

THE CONCEPT OF GREEN BUILDINGS

Accepting the notion that sustainable, environmentally appropriate, and energy efficient buildings can be labeled "green," the degree of "greenness" is subject to multiple interpretations. The process of determining which attributes of a structure can be considered "green" or "not green" is inconclusive and subjective. Complicating the process, there are no clearly labeled "red" edifices with diametrically opposing attributes. While it is implied that a green building may be an improvement over current construction practice, the basis of attribute comparison is often unclear, subjective, and confusing. It is often unclear as to what sort of changes in construction practice, if imposed, would lead the way to greener, more sustainable buildings. If determinable, the marketplace must adjust and provide the technologies and means by which materials, components, and products can be provided to construction sites where greener buildings can arise. Since standards are often formative and evolving, gauging the degree of greenness risks the need to quantify subjective concepts.

There are qualities of structures, such as reduced environmental impact and comparatively lower energy usage, which are widely accepted as qualities of green construction practices. For example, use of recycled materials with post-consumer content that originates from a previous use in the consumer market and post-industrial content that would otherwise be diverted to landfills is widely considered an issue addressable by green construction practices. However, evaluation of green building attributes or standards by organizations implies the requirement that decisions be based on stakeholder consensus. This process involves input to the decision-making processes by an array of representative stakeholders in often widely diverse geographic locations. For these and other reasons, developing a rating system for green buildings is both difficult and challenging.

RATING SYSTEMS FOR BUILDINGS

Rating systems for buildings with sustainable features began to emerge in embryonic form in the 1990s. The most publicized appeared in the United Kingdom, Canada, and the United States. In the United Kingdom, the Building Research Establishment Environmental Assessment Method (BREEAM) was initiated in 1990. BREEAM™ certificates are awarded to developers based on an assessment of performance in regard to climate change, use of resources, impacts on human beings, ecological impact, and management of construction. Credits are assigned based on these and other factors. Overall ratings are assessed according to grades that range from pass to excellent.[6]

The International Initiative for a Sustainable Built Environment, based in Ottawa, Canada, has its Green Building Challenge program with more than 15 countries participating. The collaborative venture is geared toward the creation of an information exchange for sustainable building initiatives and the development of "environmental performance assessment systems for buildings."[7] In the United States, agencies of the central government co-sponsored the development of the Energy Star™ program, which provides "technical information and tools that organizations and consumers need to choose energy-efficient solutions and best management practices."[8] Expanding on their success, Energy Star™ developed a building energy performance rating system which has been used for over 10,000 buildings.

Entering the field at the turn of the new century, the USGBC grew from an organization with just over 200 members in 1999 to 3500 members by 2003.[9] The LEED™ rating system is a consensus-developed and reviewed standard, allowing voluntary participation by diverse groups of stakeholders with interest in the application and use of the standard. According to Boucher, "the value of a sustainable rating system is to condition the marketplace to balance environmental guiding principles and issues, provide a common basis to communicate performance, and to ask the right questions at the start of a project."[10] The first dozen pilot projects using the rating system were certified in 2000.

THE LEED-NC RATING SYSTEM

The USGBC's Green Building Rating System is a voluntary, consensus-developed set of criteria and standards. This rating system evolved with a goal of applying standards and definition to the idea of high-performance buildings. The use of sustainable technologies is firmly established within the LEED project development process. LEED loosely defines green structures as those that are "healthier, more environmentally responsible and more profitable."[1]

LEED-NC 2.1 is the USGBC's current standard for new construction and major renovations. It is used primarily for commercial projects such as office buildings, hotels, schools, and institutions. The rating system is based on an assessment of attributes and an evaluation of the use of applied standards. Projects earn points as attributes are achieved and the requirements of the standards are proven. Depending on the total number of points a building achieves upon review, the building is rated as Certified (26–32 points), Silver (33–38 points), Gold (39–51 points) or Platinum (52 or more points).[11] Theoretically, there are a maximum of 69 achievable points. However, in real world applications, gaining certain credits often hinders the potential of successfully meeting the criteria of others. While achieving the rating of Certified is relatively easily accomplished, obtaining a Gold or Platinum rating is rare and requires both creativity and adherence to a broad range of prescriptive and conformance-based criteria.

The LEED process involves project registration, provision of documentation, interpretations of credits, application for certification, technical review, rating designation, award, and appeal. Depending on variables such as project square footage and USGBC membership status, registration fees can range up to $7500 for the process.[12]

LEED PREREQUISITIES CATEGORIES AND CRITERIA

To apply for the LEED labeling process, there are prerequisite project requirements which earn no points. For example, in the Sustainable Sites category, certain procedures must be followed to reduce erosion and sedimentation. In the category of Energy and Atmosphere, minimal procedures are required for building systems commissioning. Minimal energy performance standards must be achieved (e.g., adherence to ANSI/ASHRAE/IESNA Standard 90.1-1999, Energy Standard for Buildings Except Low-Rise Residential Buildings, or the local energy code if more stringent), and there must be verification that CFC refrigerants will not be used or will be phased out. In addition, there are prerequisite requirements outlining mandates for storage and collection of recyclable material, minimum IAQ performance (the requirements of ASHRAE Standard 62-1999, Ventilation for Acceptable Indoor Air Quality must be adhered to), and the requirement that non-tobacco smokers not be exposed to smoke.

In addition to the prerequisite requirements, the LEED process assigns points upon achieving certain project criteria or complying with certain standards. The total points are summed to achieve the determined rating. Projects can achieve points from initiatives within the following sets of categories: Sustainable Sites (14 points), Water Efficiency (5 points), Energy and Atmosphere (17 points), Materials and Resources (13 points), and Indoor Environmental Quality (15 points). Use of a LEED Accredited Professional (1 point) to assist with the project[13] earns a single point. Additional points are available for Innovation and Design Process (maximum of 4 points).

Within each category, the specific standards and criteria are designed to meet identified goals. In the category of Sustainable Sites, 20.2% of the total possible points are available. This category focuses on various aspects of site selection, site management, transportation and site planning. The goals of this category involve reducing the environmental impacts of construction, protecting certain types of undeveloped lands and habitats, reducing pollution from development, conserving natural areas and resources, reducing the heat island impacts, and minimizing light pollution. Site selection criteria are designed to direct development away from prime farmland, flood plains, habitat for endangered species and public parkland. A development density point is awarded for projects that are essentially multi-story. If the site has documented environmental contamination or is designated by a governmental body as a brownfield, another point is available. In regard to transportation, four points are available for locating sites near publicly available transportation (e.g., bus lines or light rail), providing bicycle storage and changing rooms, provisions for alternatively fueled vehicles and carefully managing on-site parking. Two points in this category are obtained by limiting site disturbances and by exceeding "the local open space zoning requirement for the site by 25%."[14] In addition, points are available by following certain storm water management procedures, increasing soil permeability, and attempting to eliminate storm water contamination. Potential urban heat island effects are addressed by crediting design attributes such as shading, underground parking, reduced impervious surfaces, high albedo materials, reflective roofing materials, or vegetated roofing. Finally, a point is available for eliminating light trespass.

Water efficiency credits comprise 7.2% of the total possible points. With the goal of maximizing the efficiency of water use and reducing the burden on water municipal systems, points are credited for reducing or eliminating potable water use for site irrigation, capturing and using rainwater for irrigation, and using drought tolerant or indigenous landscaping. This section of the LEED standard also addresses a building's internal water consumption. Points are available for lowering aggregate water consumption and reducing potable water use. Reducing the wastewater quantities or providing on-site tertiary wastewater treatment also earns points.

Energy and Atmosphere is the category that offers the greatest number of points, 24.6% of the total possible. The intents of this category include improving the calibration of equipment, reducing energy costs, supporting alternative energy, reducing the use of substances that cause atmospheric damage, and offering measurement and verification criteria. Optimizing the design energy cost of the regulated energy systems can achieve a maximum of ten points. To assess the result, project designs are modeled against a base case solution which lacks certain energy-saving technologies. Interestingly, the unit of measure for evaluating energy performance to achieve credits is not kilocalories or million Btus, but dollars. Points are awarded in whole units as the percentage of calculated dollar savings increases incrementally. In addition to the ten points for energy cost optimization, a maximum of three additional points is available for buildings that use energy from on-site renewable energy generation. Purchased green power is allocated a single point if 50% of the electrical energy (in kWh) comes from a two year green power purchasing arrangement. This category provides points for additional commissioning and elimination of the use of HCFCs and halon gases. Measurement and Verification (M&V) is allowed a point, but only if M&V options B, C, and D, as outlined in the 2001 edition of the International Measurement and Verification Protocol (IPMVP), are used.

The Materials and Resources category represents 18.8% of the total possible points. This category provides credit for material management; adaptive reuse of structures; construction waste management; resource reuse; use of material with recycled content; plus the use of regionally manufactured materials, certain renewable materials and certified wood products. A point is earned for providing a space in the building for storage and collection of recyclable materials such as paper, cardboard, glass, plastics and metals. A maximum of three points is available for the adaptive reuse of existing on-site structures and building stock. The tally increases with the extent to which the existing walls, floor, roof structure, and external shell components are incorporated into the reconstruction. LEED-NC 2.1 addresses concerns about construction waste by offering a point if 50% of construction wastes (by weight or volume) are diverted from landfills and another point if the total diversion of wastes is increased to 75%. A project that is composed of 10% recycled or refurbished building products, materials, and furnishings gains an additional two points. Another two points are available in increments (one point for 5%, two points for 10%) if post-consumer or post-industrial recycled content (by dollar value) is used in the new construction. To reduce environmental impacts from transportation systems, a point is available if 20% of the materials are manufactured regionally (defined as being within 500 miles or roughly 800 km of the site), and an added point is scored if 50% of the materials are extracted regionally. A point is available if rapidly renewable materials (e.g., plants with a ten year harvest cycle) are incorporated into the project, and yet another point is earned if 50% of the wood products are certified by the Forest Stewardship Council.

The category of Indoor Environmental Quality allows 21.7% of the possible total points available. The goals include improving IAQ, improving occupant comfort, and providing views to the outside. With ASHRAE Standard 62-1999 as a prerequisite, an additional point is available for installing CO_2 monitoring devices in accordance with occupancies referenced in ASHRAE Standard 62-2001, Appendix C. A point is also available for implementing technologies that improve upon industry standards for air change effectiveness or that meet certain requirements for natural ventilation. Systems that provide airflow using both underfloor and ceiling plenums are suggested by LEED documentation as a potential ventilation solution. Points are available for developing and implementing IAQ management plans during construction and prior to occupancy. The requirements include using a Minimum Efficiency Reporting Value (MERV) 13 filter media with 100% outside air flush-out prior to occupancy. There are points available for use of materials that reduce the quantity of indoor air pollutants in construction caused by hazardous chemicals and by volatile organic compounds in adhesives, sealants, paints, coatings, composite wood products, and carpeting. A point is offered for provision of perimeter windows and another for individual control of airflow, temperature, and lighting for half of the non-perimeter spaces. Points are available for complying with ASHRAE Standard 55-1992 (Thermal Environmental Conditions for Human Occupancy), Addenda 1995, and installing permanent temperature and humidity control systems. Finally, points are gained for providing 75% of the spaces in the building with some form of daylighting and for providing direct line of-sight vision for 90% of the regularly occupied spaces.

In the category of Innovation and Design Process, 7.2% of the total possible points are available. The innovation credits offer the opportunity for projects to score points as a result of unusually creative design innovations, such as substantially exceeding goals of a given criteria or standard.

ASSESSING LEED-NC

The LEED-NC process has numerous strengths. Perhaps the greatest is its ability to focus the owner and design team on addressing select energy and environmental considerations early in the design process. The LEED design process brings architects, planners, energy engineers, environmental engineers, and IAQ professionals into the program at the early stages of design development. The team adopts a targeted LEED rating as a goal for the project. A strategy evolves based on selected criteria. The team members become focused on fundamental green design practices that have often been overlooked when traditional design development processes were employed.

Furthermore, the LEED program identifies the intents of the environmental initiatives. Program requirements are stated and acceptable strategies are suggested. Scoring categories attempt to directly address certain critical environmental concerns. When appropriate, the LEED-NC program defers to engineering and environmental standards developed outside of the USGBC. The components of the program provide accommodation for local regulations. Case study examples, when available and pertinent, are provided and described in the LEED literature. To expedite the process of documenting requirements, letter templates and calculation procedures are available to program users. The educational aspects of the program, which succinctly describe select environmental concerns, cannot be understated. A Web site provides updated information on the program with clarifications of LEED procedures and practice. The training workshops sponsored by the USGBC are instrumental in engaging professionals with a wide range of capabilities.

These considerations bring a high degree of credibility to the LEED process. Advocates of the LEED rating system have hopes of it becoming the pre-eminent U.S. standard for rating new construction that aspires to achieve a "green" label. To its credit, it is becoming a highly regarded standard and continues to gain prestige. Nick Stecky, a LEED Accredited Professional, firmly believes that the system offers a "measurable, quantifiable way of determining how green a building is."[15]

Despite its strengths, the LEED-NC has observable weaknesses. The LEED-NC registration process can appear to be burdensome, and has been perceived as slowing down the design process and creating added construction cost. Isolated cases support these concerns. Kentucky's first LEED-NC school, seeking a Silver rating, was initially estimated to cost over $200/ft^2 ($2152/m^2) compared to the local standard costs of roughly $120/ft^2 ($1290/m^2) for non-LEED construction. However, there are few comparative studies available to substantially validate claims of statistically significant cost impact. Alternatively, many case studies suggest that there is no cost impact as a result of the LEED certification process. It is also possible that the savings resulting from the use of certain LEED standards (e.g. reduced energy use) can be validated using life-cycle costing procedures. Regardless, LEED-NC fails as a one-size-fits-all rating system. For new construction, Kindergarten to 12th-grade (K-12), school systems in New Jersey, California, and elsewhere have adopted their own sustainable building standards.

There are other valid concerns in regard to the use of LEED-NC. In an era when many standards are under constant review, standards referenced by LEED are at times out of date. The ASHRAE Standard 90.1-1999 (without amendments) is referenced throughout the March 2003 revision of LEED-NC. However, ASHRAE 90.1 was revised, republished in 2001, and the newer version is not used as the referenced standard. Since design energy costs are used to score Energy and Atmosphere points, and energy use comparisons are baselined against similar fuels, cost savings from fuel switching is marginalized. In such cases, the environmental impact of the differential energy use remains unmeasured, since energy units are not the baseline criteria. There is no energy modeling software commercially available that has been specifically designed for assessing LEED buildings. LEED allows most any energy modeling software to be used, and each has its own set of strengths and weaknesses when used for LEED energy modeling purposes. It is possible for projects to comply with only one energy usage prerequisite, applying a standard already widely adopted, and still become LEED certified. In fact, it is not required that engineers have specialized training or certification to perform the energy models. Finally, LEED documentation lacks System International (SI) unit conversions, reducing its applicability and exportability.

A number of the points offered by the rating system are questionable. While indoor environmental quality is touted as a major LEED concern, indoor mold and fungal mitigation practices, among the most pervasive indoor environmental issues, are not addressed and are not necessarily resolvable using the methodologies prescribed. It would seem that having a LEED-accredited professional on the team would be a prerequisite rather than a optional credit. Projects in locations with abundant rainfall or where site irrigation is unnecessary can earn a point by simply documenting a decision not to install irrigation systems. The ability of the point system to apply equally to projects across varied climate classifications and zones is also questionable and unproven.

While an M&V credit is available, there is no requirement that a credentialed measurement and verification professional be part of the M&V plan development or the review process. Without the rigor of M&V, it is not possible to determine whether or not the predictive preconstruction energy modeling was accurate. The lack of mandates to determine whether or not the building actually behaves and performs as intended from an energy cost standpoint is a fundamental weakness. This risks illusionary energy cost savings. Finally, the M&V procedures in the 2001 IPMVP have undergone revision and were not state-of- the-art at the time that LEED-NC was updated in May 2003. For example, there is no longer a need to exclude Option A as an acceptable M&V alternative.

The LEED process is not warranted and does not necessarily guarantee that in the end, the owner will have a "sustainable" building. While LEED standards are more regionalized in locations where local zoning and building laws apply, local regulations can also preempt certain types of green construction criteria. Of greater concern is that it is possible for a LEED certified building to devolve into a building that would lack the qualities of a certifiable building. For example, the owners of a building may choose to remove bicycle racks, refrain from the purchase of green energy after a couple of years, disengage control systems, abandon their M&V program, and remove recycling centers—yet retain the claim of owning a LEED certified building.

CONCLUSION

The ideal of developing sustainable buildings is a response to the environmental impacts of buildings and structures. Developing rating systems for structures is problematic due to the often subjective nature of the concepts involved, the ambiguity or lack of certain standards, and the local aspects of construction. While there are a number of assessment systems for sustainable buildings used throughout the developed world, LEED-NC is becoming a widely adopted program for labeling and rating newly constructed "green" buildings in the United States. Using a point-based rating system, whereby projects are credited for their design attributes, use of energy, environmental criteria, and the application of select standards, projects are rated as Certified, Silver, Gold, or Platinum.

The LEED-NC program has broad applicability in the United States and has been proven successful in rating roughly 150 buildings to date. Its popularity is gaining momentum. Perhaps its greatest strength is its ability to focus the owner and design team on energy and environmental considerations early in the design process. Today, there are over 1700 projects that have applied for LEED certification. Due to the program's success in highlighting the importance of energy and environmental concerns in the design of new structures, it is likely that the program will be further refined and updated in the future to more fully adopt regional design solutions, provide means of incorporating updated standards, and offer programs for maintaining certification criteria. It is likely that the LEED program will further expand, perhaps offering a separate rating program for K-12 educational facilities. Future research will hopefully respond to concerns about potential increased construction costs and actual energy and environmental impacts.

Life Cycle Costing: Electric Power Projects

Ujjwal Bhattacharjee
Energy Engineering Program, University of Massachusetts—Lowell, Lowell, Massachusetts, U.S.A.

Abstract
Life-cycle cost (LCC) assessment involves the estimation of major expected costs within the useful life of a power system. Life-cycle cost estimation facilitates investment decisions before acquiring or developing assets associated with a power project. Life-cycle cost analysis allows comparison of different investment alternatives and thus enables determination of the most cost-effective system. A framework has been developed to conduct LCC analysis of energy projects, with the focus on two phases of a project's life: (i) the development, construction, and commissioning phase and (ii) the operation phase. The energy projects considered are: (i) a 520 MW coal power plant; (ii) a 50 MW wind power project; and (iii) a 3-kWp grid-tied residential PV system. The LCC assessment considers costs associated with the debt servicing, variable costs, interest on working capital, depreciation, annual operation and maintenance costs, etc. The results indicate that the installed cost of wind and coal power projects is comparable. However, the LCC of electricity from the wind power project is around twice that of the coal power plant. The cost of electricity from the PV system is around ten times higher than that from the coal power source.

In this study, a framework has been developed to quantify the financial and fiscal incentives (FIs) offered by federal and state agencies to promote renewable energy technologies. This enables studying the effect of FIs on the LCC of electricity generated from the PV and wind power systems. The state-offered FIs considered are sales tax exemption on the purchase of system components, property tax exemption, income tax rebate, and capital subsidy on the system cost. The FIs offered by the federal agencies are the accelerated depreciation for capital recovery, the production tax incentive, and the income tax rebate. For the residential PV system, the state offered upfront capital subsidy on the system cost and avoided cost of electricity due to onsite power generation contribute in reducing electricity cost (LCC) by 65%. Similarly, the LCC of electricity from the 50 MW wind power project is significantly reduced when the FIs are considered. The accelerated depreciation for capital cost recovery and the production tax credit contribute in reducing the cost of electricity by 65%. The LCC of electricity generated from the PV and wind-based energy systems could be significantly less than that generated from coal power projects when the effects of financial incentives are considered.

INTRODUCTION

Life-cycle cost (LCC) assessment involves the estimation of major expected costs within the useful life of an asset. Life-cycle cost estimation facilitates investment decisions for acquiring or developing an asset. According to Woodward (Ref. 13, p. 336), "LCC of a physical asset begins when its acquisition is first considered and ends when it is finally taken out of service for disposal or redeployment (when a new LCC begins)." LCC analysis allows comparison of different investment alternatives and, thus, the determination of the most cost-effective system. For example, decisions based on a low initial cost do not guarantee low LCC. To conduct LCC, the major costs associated with the development of a project needs to be evaluated. The major costs associated with a project can broadly be categorized into the following:

- Initial cost consisting of
  - — Acquisition and financing costs,
  - — Procurement cost, and
  - — Installation and commissioning costs
- Operation and maintenance costs
- Cost of asset disposal after its useful life

To illustrate the LCC for energy projects, we will consider three case studies. These are: (i) a 520 MW coal power project; (ii) a 50 MW utility scale wind project; and (iii) a 3-kW grid-tied residential solar power unit. The rationale for choosing coal, wind, and solar-based power projects is twofold. First, the relevance of the energy source used for electricity generation is considered and, second, the complexity involved in calculating LCC associated with the scale of a project is reviewed.

The relevance of the three energy sources is as follows: coal has been and is expected to remain a major source of electricity generation. For example, in 1971, coal contributed 40% to the total global electricity supply,

Keywords: Life-cycle cost; Coal; Wind; PV; Financial incentives.

while the corresponding value in 2002 was 39%.[8] Wind has made substantial inroads into the utility scale commercial electricity supply during the last 10–15 years. In recent years, distributed grid-tied residential solar photovoltaic (PV) power systems have been demonstrating viability due to state-(and utility-) offered financial (and fiscal) incentives, especially in Japan, Germany, and several states in the United States.

In terms of the complexities involved in the LCC calculations, those for a small PV power system would be simple in comparison to calculations for a large coal power project. For example, a typical 3-kWp (DC) residential solar system could be procured and installed quickly. On the other hand, a large coal power project (as well as nuclear and large hydro power projects) could take several years to construct and commission.

In this article, major cost components associated with the different power systems are briefly described in "Coal, Wind, and Solar Power Systems." In "Methodology for Calculation of the Life-Cycle Cost," a simple framework for the LCC calculation has been developed. The results of the LCC calculations for the three different power systems are discussed in "Results and Discussion," with concluding remarks in "Conclusions."

COAL, WIND, AND SOLAR POWER SYSTEMS

The three power systems, i.e., coal, wind, and PV power systems, operate in significantly different manners. Therefore, the costs associated with each differ. For example, the initial cost for installing a PV system is high as compared to that for coal and wind power projects. However, the resource needed for electricity generation for the PV is free and the same holds true for a wind power system.

Inv–Light

Coal Power Plant

A coal power plant consists of the steam and turbine generator sections. Major mechanical systems of the plant are: water system, heat cycle make-up system, coal handling plant, ash handling plant, fuel oil system, compressed air system, ventilation and air-conditioning system, fire protection systems, and miscellaneous auxiliaries. The electrical systems are: generator, transformer, switchyard, control and instrumentation systems. Coal power plants are usually constructed either near coal mines (in order to reduce the transportation cost of coal) or near load centers to reduce the electricity transmission losses. Coal power plants are generally operated through onsite "operational and maintenance" personnel. Once the plant has outlived its designed life (around 25–30 years), it is usually retrofitted and made operational.

Wind Power Project

A wind power plant consists of turbines and towers, foundations, access roads, switch gear, instrumentation and control systems, etc. Small wind power projects are generally remotely operated. In general, for every 10–20 turbines, one operator is needed.[11] Wind power projects offer potential socioeconomic benefits to local communities. Typically, for a 50 MW power project, 50 jobs are created during the construction phase. During the operation phase one job is created for every 5–8 MW of the installed capacity.[12] The turbines are repowered, replacing the old and typically smaller wind turbines with new equipment when the design life of the equipment diminishes.[11]

Photovoltaic Power System

A small rooftop (3-kWp) PV system consists of around 20–30 PV modules tied on to panel mountings with the roof. Direct grid-tied inverters convert the DC power produced by the PV to AC power. The safety equipment includes a DC combiner box for wiring, a DC disconnect to facilitate servicing, and an AC disconnect to isolate the PV system from the grid.

Cost Components of Energy Projects

The costs associated with the useful life of a project are categorized (in Introduction) as initial cost, operation and maintenance cost, and disposal cost. Wind and coal power projects usually undergo retrofit after useful design life. Therefore, disposal or decommissioning of these plants is not considered in this study. Similarly, PV modules disposed from the rooftop may not be associated with high costs. Additionally, the recycling of PV modules is unlikely to produce high value products.[6]

The initial costs associated with a power project before commencement of construction activities are typically the project site survey, land lease agreements, power purchase agreements, etc. (see Table 1) for coal and wind power projects. For the PV system, an assessment of energy produced from solar irradiance is completed at the location where the system is to be installed.

During the construction period, the costs are divided into two categories: (i) capital cost and (ii) noncapital cost. Capital costs are associated with the procurement of physical assets, such as boiler, wind turbine, and PV panels, respectively, for coal, wind, and PV power projects. The noncapital costs are associated with services needed for the deployment of physical assets, e.g., costs associated with legal services, erection, testing, and commissioning. In Table 2, the capital and noncapital costs associated with coal, wind, and PV power systems are provided. During the operation phase of the plant, the costs usually considered are variable costs (cost of fuel

and consumables), operation and maintenance costs, debt servicing costs, etc. (the environmental costs associated with emissions and solid wastes during the operation of the coal power plant have not been considered in this study).

These are explained in detail in "Methodology for Calculation of the Life-Cycle Cost."

METHODOLOGY FOR CALCULATION OF THE LIFE-CYCLE COST

In this section, a framework for the calculation of LCC has been developed. The LCC considers costs associated with two phases of a power system, i.e., the construction and commissioning phase and the operation phase. Therefore, the costs associated during the former are due to interest during construction (IDC), financing charges, and taxes and duties (Fig. 1). Those associated with the operation phase are due to depreciation, interest on working capital, loan repayment, and variable costs (Fig. 1).

Annual Electricity Generation

The annual electricity generated from the ith power project, E_i (in kWh), is calculated considering the number of hours a plant operates in a year. While annual energy generated is strongly related to the wind speed for a wind power plant, the calorific value of the coal used is important for a coal power plant.

$$E_i = 8760 \times 1000 \times P_{\mathrm{cap}} \times f_{\mathrm{e},i} \tag{1a}$$

where P_{cap} (in MW) is the rated capacity of the plant. $f_{\mathrm{e},i}$ is the effective capacity factor of the ith power plant (i.e., coal or wind power plants). The effective capacity factor considers the plant's overall efficiency of energy conversion and the auxiliary power consumed to operate several electrical and mechanical systems associated with the plant. For example, around 10% of the total electricity produced in a coal power plant is utilized as auxiliary power.[3]

Annual electricity generated from a PV system, E_{PV} (in kWh), is related to annual average daily equivalent sunshine hours [ESH; the ESH is equal to the average monthly daily solar irradiation in kWh/m^2/day. PV modules are rated at 1 kWh/m^2 incident irradiation (or one sun). In other words, ESH represents the capacity factor for a PV system. It indicates the number of hours per day that the system is expected to operate] of the place the PV system is installed.

Table 2 Capital and noncapital costs of energy projects

Capital cost category	Noncapital cost category
520-MW coal power project	
Steam generator	Erection testing and commissioning
Turbine generator	Construction insurance
Balance of plant	Engineering and overheads
Mechanical Systems	Preliminary expenses
Coal handling plant	Land and site development
Ash handling plant	Owner's engineers expenses
Cooling towers and circulating water system	Operators training
Other mechanical systems	Start-up fuel
Electrical Systems	Legal fees, taxes, and duties
Generator and transformer	Establishment expenses
Switchyard	
Balance of electrical systems	
Instrumentation and control systems	
Initial spares

Miscellaneous fixed assets	
50-MW wind power project	
Turbine and tower	Erection testing and commissioning
Foundations	Construction insurance
Electrical infrastructure	Engineering and overhead
Substation	Assembly and checkout
Transmission upgrade	Preliminary expenses
Roads and grading	Legal fees, taxes, and duties
Control systems	
Control buildings	
Central building	
3-kW Grid-tied photovoltaic system	
Photovoltaic modules	Assembly and installation
Inverter	
DC and AC disconnects	
Wire and cables	
Panel mounts	

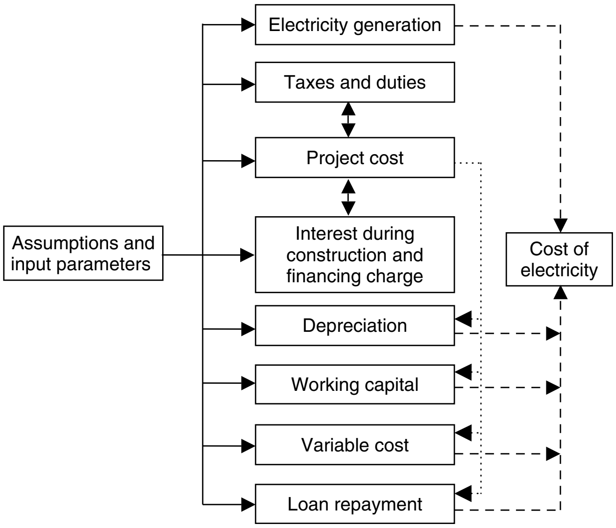

Fig. 1 Components contributing to LCC of electricity for coal and wind power projects.

$$E_{PV} = 356 \times ESH \times PV_{cap} \times \eta_{inv} \times (1 - f_{T,d}) \times (1 - f_w) \quad (1b)$$

PV_{cap} is the capacity of the PV system in kW, η_{inv} is inverter efficiency, and $f_{T,d}$ and f_w are the fraction of the rated module output adjusted for temperature dust load, and wire loss, respectively. The values of these parameters are given in Appendix B. The ESH varies with the system tilt angle. It is usually least at 90° system tilt, the maximum being at the latitude angle tilt. However, ESH available at the latitude +15° angle has been used in the study as, for this panel tilt, the solar energy available across each month in a year is (generally) uniform.[2]

Depreciation

Depreciation of a physical asset relates to the loss in its value over time. For energy projects, depreciation is usually assessed based on the accounting concept that the depreciated value of the asset is allocated over years and treated as an operating expense. Thus, the annual depreciated cost of an asset is used for allocation rather than valuation.[9] The method for depreciation calculation could be either: (i) straight-line depreciation; (ii) declining balance depreciation; (iii) sum-of-the-year digit depreciation; or (iv) modified accelerated capital recovery system (MACRS). In this study, the MACRS method has been used to calculate asset depreciation. The depreciation rate is likely to vary for different assets of the plant. For example, electrical components usually attract higher depreciation rates as compared to mechanical systems. The annual depreciation of the assets, DEP, can be expressed as:

$$DEP = \sum (PC_{P\&M} + PC_{CW} + PC_{MFA}) \times r_{dep} \leq PC \times f_{dep} \quad (2)$$

$PC_{P\&M}$, PC_{CW}, and PC_{MFA} (in \$) represent the asset components of the project cost (PC) for plant and machinery, civil works, and miscellaneous fixed assets, respectively. The depreciation rate is represented by r_{dep}. As mentioned above, different depreciation rates are likely to be applicable for the three categories of the depreciable assets. However, in this study, all assets are depreciated with the same annual depreciation rate. f_{dep} is the depreciable fraction of the project cost.

Financing Charge

During the project construction and commissioning period, a part of the project cost is funded through equity and the balance through a loan. The amount of the loan drawdown depends on the equipment and services that have been supplied during the construction of the project. And the corresponding interest on the loan is compounded on a monthly basis. Financing charges are usually associated with the loan amounts and categorized as[4,10]:

1. Management agreement fee
2. Commitment fee
3. Bank guarantee commission
4. Bank guarantee fee
5. Financial advisory fee

The financing charges, as a fraction of the loan, may be a one-time upfront charge or a recurring charge based on periodic drawdown of loan amounts. For example, the management agreement fee, bank guarantee fee, financial advisory fee are one-time upfront charges.[10] Charges accrued on bank guarantee commission and commitment fee are progressive in nature. Mathematically, the financing charge (FC) can be expressed as:

$$FC = \sum_k FC_k = \left[\underbrace{(CC_{i,j} + NCC_{i,g}) \times f_l \times f_m}_{\text{Upfront finance charge}} + \underbrace{\left[\sum_{k=1}^{n} (CC_{i,j} \times f_{i,j,k,n}) + \sum_{k=1}^{n} (NCC_{i,g} \times f_{i,g,k,n}) \right] \times f_l \times f_o}_{\text{Progressive finance charge}} \right] \quad (3)$$

where $CC_{i,j}$ is the capital cost corresponding to ith project for its jth component—for example, the wind turbine (the jth component) for the wind power project (the ith project). $NCC_{i,g}$ represents the noncapital cost of the ith project for

Inv–Light

its gth component (e.g., legal expenses). f_l is the fraction of $CC_{i,j}$ and $NCC_{i,g}$ funded through the loan. A fraction of f_l is f_m, representing the mth upfront financing charge. $f_{i,j,k,n}$ is the fraction of $C_{i,j}$ supplied in the kth month and n is the maximum number of months required for its construction and commissioning. $f_{i,g,k,n}$ is the fraction of $NCC_{i,g}$ phased in the kth month and f_o represents a fraction of f_l associated with the oth progressive financing charge.

Equity finance is the provision of money or goods and services that gives partial ownership of assets and liabilities of a project to an investor(s). Large corporations normally raise equity by selling shares and bonds in the capital market and also through allotment of preferential shares to investors. The structure of equity ownership, its concentration, and composition are crucial for equity investors. The composition of the equity investor can be an individual, a family or family group, a holding company, a bank or an institutional investor like an investment company, a pension fund, an insurance company, or a mutual fund.[1] Equity investors require a minimum return on investment for their capital and they claim residual surpluses from project cash inflows.

Debt is the amount of money loaned by a party to another party at a mutually agreed repayment terms. Debt is characterized by several attributes, such as repayment period (or maturity), repayment provisions, seniority, security, and interest rates. Debt maturity can be characterized in terms of short-term (up to 1 year), medium-term (up to 5 years), and long-term (more than 5–7 years) loan repayment periods.

Interest During Construction

Interest during construction is the accumulated monthly interest on the loan used to finance construction and commissioning activities of a project. For example, a large coal power project takes around three or more years for its construction and to become operational. The IDC will depend on the phasing of equipment and services required during construction of the project and the corresponding loan drawdown to finance the same. Therefore, the IDC can be expressed as:

$$\mathrm{IDC} = \sum \left\{ \left[\sum_{k=1}^{n} (CC_{i,j} \times f_{i,j,k,n}) + \sum_{k=1}^{n} (\mathrm{NCC}_{i,g} \times f_{i,g,k,n}) \right] \times f_l + \mathrm{FC}_k \right\} \times \left(\frac{I_J}{12} \right) \quad (4)$$

where I_J is the annual interest rate on J sources of the loan. It is normal for large power projects to secure loans from more than one source.

Project Cost

The total cost of a power project considers three important components and these are: (i) the project's capital and noncapital costs; (ii) the IDC; and (iii) the financing cost. The project cost can be calculated as:

$$\mathrm{PC} = \left(\sum \mathrm{CC}_i + \sum \mathrm{NCC}_i \right) + \mathrm{IDC} + \mathrm{FC} \quad (5)$$

Variable Cost

The variable costs associated with a plant are typically the cost of consumables and the "operation and maintenance" costs. For a coal power plant, the consumables are coal, oil, and water, whereas these costs' components are not applicable in the case of wind and solar power projects. The variable cost can be expressed as:

$$\mathrm{VC} = \sum [\{(S_{\mathrm{coal}} \times C_{\mathrm{coal}}) + (S_{\mathrm{oil}} \times \rho_{\mathrm{oil}} \times C_{\mathrm{oil}})\} \times E_i + (8760 \times \mathrm{plf} \times S_{\mathrm{water}} \times C_{\mathrm{water}}) + (\mathrm{CC}_i \times f_{\mathrm{O\&M}} \times f_{\mathrm{vc}})] \times (1 + e)^t \quad (6)$$

where S_{coal}, S_{oil}, and S_{water} are specific coal, oil, and water consumptions, respectively. The cost of coal, secondary oil, and water are represented as C_{coal} (in \$/t), C_{oil} (in \$/t), and C_{water} (in \$/1000 m^3/h). The density of oil is ρ_{oil}. It is worth mentioning that even in a coal power plant, oil (or, as it's usually termed, secondary oil) is used as a fuel during the boiler startup. In calculating the variable cost, a fraction of the capital cost is assumed to meet the operation and maintenance of the plant ($f_{\mathrm{O\&M}}$). Further, this fraction is subdivided into components contributing to the variable cost (f_{vc}) and fixed cost. The annual average plant load factor for the coal power plant is given as plf. The annual inflation rate is represented as e in the tth year.

Interest on Working Capital

In order to maintain uninterrupted operation of a large power plant, some working capital is required to meet the costs arising out of unanticipated circumstances. For example, in a coal power plant, a few months of consumables (coal and oil) would always be stocked in case of temporary disruption in fuel supply. In addition, costs associated with debt servicing (or the loan repayment) and operation and maintenance for a few months are also considered in the working capital. The working capital is generally funded through very short-term loans (i.e., loans for a few months). The interest rate applicable to the working capital is likely to be higher than

Inv–Light

that for long-term loans. The total interest on working capital (I_{WC}) can be calculated as:

$$I_{WC} = i_{wc} \times \left[\sum \left(VC_i \times \frac{\beta_i}{12}\right) + LR \times \frac{\gamma}{12}\right] \quad (7)$$

where i_{wc} is the annual interest on working capital and VC_i is the ith component of the variable cost (e.g., costs of coal and oil and the "operation and maintenance" cost) for which the provision of working capital is required. β_i is the number of months of working capital needed, corresponding to VC_i. Loan repayment is the value of annual loan repayment and γ the number of months for which the working capital for LR is required.

Taxes and Duties

The taxes and duties are applicable to different components of the project's capital and noncapital costs. Import duty is levied on part of the goods and services procured from overseas. Local, state, and federal taxes and duties, such as sales tax, apply to the equipment and services required for the project. Mathematically, the costs of taxes and duties can be expressed as:

$$TD = \sum (CC_i + NCC_i) \times R_{TD,i} \quad (8)$$

where $R_{TD,i}$ is the rate of tax or duty for the ith component of capital or noncapital costs.

Loan Repayment

As mentioned before, a certain fraction (f_d) of the total project cost is funded by debt (D) and the rest by equity. However, it is likely that large projects raise debt from more than one source (J sources) such that:

$$D = f_d \times PC = \sum D_J \quad (9a)$$

$$LR = \sum LR_J = \sum_q \left\{ \underbrace{\left[\frac{D_J}{T_{L,J} \times q_J}\right]}_{\text{Principal amount}} + \underbrace{\frac{D_J \times I_J}{q_J}}_{\text{Interest amount}} \right\} \quad (9b)$$

LR is the annual loan repayment amount. $T_{L,J}$ is the period of the loan repayment (in years) and I_J is the interest on Jth loan. q_J is the number of loan repayments in a year. In Eq. 9b, the principal payment remains constant throughout the term of the loan period. However, the interest is paid on the declining balance of the loan amount (D_J). Therefore, in the loan repayment proceeds, the interest amount is high during the initial years of the loan term. Toward the final years of the loan term, the principal amount is the major component of the loan repayment.

Life-Cycle Cost of Electricity

The LCC of the electricity (in \$/kWh) of a project is obtained by taking all of the associated costs within the life of the project (N) into account and adjusting with a discount rate (d). The selection of a suitable discount rate is important for LCC analysis since a high discount rate will tend to favor options with low capital costs, short life spans, and high recurring costs, while a low discount rate will have the opposite effect (Ref. 13, p. 338). The LCC of electricity can be expressed as:

$$E_{LCC} = \sum_{t=1}^{N} \left\{ \frac{1}{E_i} \frac{1}{[1 + (d - e)]^{t-1}} \times [ROE + DEP + VC + I_{WC} + LR + TD] \right\} \quad (10a)$$

$$E_{LCC,PV} = \sum_{t=1}^{N} \frac{1}{E_{PV}} \frac{1}{[1 + (d - e)]^{(t-1)}} \times (C_{sys,PV} + C_{Rpl} + f_{O\&M-PV} C_{sys,PV}) \quad (10b)$$

where E_{LCC} is the LCC of electricity from the wind or the coal based power projects. $E_{LCC,PV}$ is the LCC of electricity from the PV system. ROE is the return on equity invested into the project. An investor is likely to expect minimum return on investment (as equity) into the power project. In the present study, the equity return is assumed at 16%. $C_{sys,PV}$ and C_{Rpl}, respectively, are the capital cost of the PV system and the replacement cost of equipment within the system life (i.e., inverter replacement every 10 years). $f_{O\&M-PV}$ is the fraction of the system's capital cost assumed to meet the annual operation and maintenance costs associated with the system (see Appendix B).

Financial and Fiscal Incentives Offered on Renewable Energy Systems

Eq. 10 shows all of the costs associated with the energy project/plant added and discounted (with an inflation adjusted real discount rate) to obtain the present value of the LCC. However, any financial or fiscal incentive offered to an energy system also needs to be adjusted in its LCC. In recent years, several renewable energy (RE) technologies were aided with financial and fiscal incentives (FIs) offered by the federal and respective state governments in order to mainstream RE as a viable option (see Ref. 5 for an in-depth analysis of the effects of FIs on the users of solar energy technologies). In the United States, about 22 states have adopted the "Renewable Energy Portfolio Standard" (RPS) or a similar framework, (see www.dsireusa.org for an overview of federal and

Table 3 Financial incentive on PV and wind energy systems

Technology	Sector	Federal incentives and the incentive level	State incentives and the incentive level
PV	Residential	Income tax credit for maximum of \$2000 or 30% of the system cost	Property tax exemption: for 20 years assumed at 1.5% of the system cost per year Capital subsidy: offered by the MTC at \$2/kW$_{dc}$ Capital subsidy: offered by MTC for state (Massachusetts) manufactured components at \$0.5/kW$_{dc}$ 100% sales tax exemption Income tax credit at maximum of \$1000 Production credit: sale of renewable energy certificates at 6 cents/kWh offered by mass Energy
Wind	Commercial / Industrial	Modified accelerated cost recovery system—100% of the total asset depreciation in five years, using MACRS rates Production tax credit: renewable energy certificate (REC) at 1.9 cents/kWh for first 10 years from 2005 (with inflation adjusted in the subsequent years). Also, the REC sale is assumed for rest of the plant life	Property tax exemption: for 20 years assumed at 1.5% of the project cost per year 100% sales tax exemption

The values of the incentives have been used from www.dsireusa.org (accessed on 09/05/2006). However, note that the incentive levels change from time to time.

state financial incentives on RE technologies) which has been emerging as an effective mechanism to increase the share of RE in a state's energy mix. Typically, the financial incentives offered by the federal agencies on RE technologies are: the accelerated depreciation for cost recovery, renewable electricity production tax credit, etc. The state-offered FIs are: sales tax rebate, income tax credit, property tax exemption, system cost buy-down rebate, etc. In addition, the applicability of FIs vary considerably among the RE technologies, as well as among the sectors (i.e. residential, commercial, and industrial sectors) and the states in which the RE systems (or projects) are implemented.[2] Therefore, to illustrate the effects of FIs on LCC, we consider the incentives applicable in the state of Massachusetts on PV and wind-based RE technologies. In addition, the federal incentives applicable to the PV and wind-based energy systems have also been considered (Table 3). The present value of the various FIs can be calculated as:

$$ST = CC_i \times r_{ST} \tag{11a}$$

where ST (in \$) is the present value of the state sales tax exemption on purchase of RE equipment and systems. This is assumed to apply on the capital cost of the respective energy system or project (i.e., PV system and wind power project). r_{ST} is the sales tax rate applicable in a state. For MA, its value is 5% of the capital cost.

$$PT = \sum_{t=1}^{N_{PT}} \frac{1}{[1 + (d - e)]^{t-1}} \times PC \times \left[1 - \frac{t}{N_{PT}}\right] \times r_{PT} \tag{11b}$$

where PT (in \$) is the present value of annual property tax assessed on the installed RE project/system. Note that the property tax is assessed annually on a diminishing value of the project cost (PC) by a factor $[1-t/N_{PT}]$. N_{PT} is the maximum number of years the project is exempted from the property tax payment (which is 20 years in Massachusetts, as shown in Table 3) and r_{PT} is the property tax rate.

$$CS_{PV} = PV_{cap} \times (r_{CS-sys} + r_{CS-comp}) \tag{11c}$$

CS_{PV} (in \$) is the capital subsidy (or, as commonly referred to, the system buy-down rebate) offered on a PV system. Capital subsidy is usually offered as an upfront rebate on the rated capacity of the PV system. r_{CS-sys} and $r_{CS-comp}$ (in \$/kW$_{DC}$ or \$/kW$_{AC}$) are the subsidy rates on system and components manufactured respectively in the state (Table 3).

$$IR = (IR_{state} + IR_{fed}) \tag{11d}$$

where IR (in \$) is the income tax rebate offered to a buyer of a PV system. The IR_{state} and IR_{fed} are the dollar amounts of the income tax rebate offered by state and federal agencies, respectively (Table 3). In this study, the income tax rebate is assumed to be availed by the buyer of the system in the very first year it is purchased. However, the income tax rebate is generally offered with the provision to carry it forward for more than one year (usually for 3–5 years).

$$\text{DEP}_{\text{ACCL}} = \sum_{t=1}^{N_{\text{ACCL-DEP}}} \frac{1}{[1 + (d - e)]^{t-1}} \times \text{PC} \times r_{\text{ACCL-DEP},t} \tag{11e}$$

Accelerated depreciation of the project assets has been a useful mechanism that allows a commercial (and/or an industrial) entity an early recovery of the project costs. For example, the current provisions allow 100% project cost recovery within 5 years of project operation by applying accelerated depreciation rates. In Eq. 11e, DEP_{ACCL} (\$) is the present worth of the depreciated value of the project cost within a period of $N_{\text{ACCL-DEP}}$ (years) with a depreciation rate of $r_{\text{ACCL-DEP},t}$, applicable in the tth year.

$$\begin{aligned} \text{REC}_{\text{Wind}} = & \sum_{t_1=1}^{N_{\text{REC}}} \left\{ \frac{1}{[1 + (d - e)]^{t_1-1}} \times \left(E_i \times \frac{P_{\text{REC},1}}{100} \right) \times (1 + e)^{t_1} \right\} \\ & + \sum_{t_2=N_{\text{REC}}+1}^{N} \left\{ \frac{1}{[1 + (d - e)]^{t_2-1}} \times \left[E_i \times \frac{P_{\text{REC},2}}{100} \right] \times (1 + e)^{t_2} \right\} \end{aligned} \tag{11f}$$

where REC (\$) is the present value of renewable energy certificates (RECs) generated from the wind power project. The capped price of an REC unit is 1.9 cents/kWh, starting from 2005, and it is adjusted with the annual inflation rate in the subsequent years. $P_{\text{REC},1}$ is the unit REC price (cents/kWh) for period (t_1) of the first 10 years of the plant's operation (Table 3) and is a tax exempt revenue source. It is assumed that the RECs generated beyond the first 10 years to the end of the plant life (period t_2) could also be sold at the unit price of $P_{\text{REC},2}$; however, revenue generated from REC sale is taxable. In this study, the unit price for REC for both periods is assumed to be the same. The RECs generated from the PV system can also be sold, however, at a unit rate different from that of a wind power plant and can be expressed as:

$$\text{REC}_{\text{PV}} = \sum_{t=1}^{N} \left\{ \frac{1}{[1 + (d - e)]^{t-1}} \times \left(E_s \times \frac{P_{\text{REC,PV}}}{100} \right) \times (1 + e)^{t} \right\} \tag{11g}$$

where $P_{\text{REC,PV}}$ (in cents/kWh) is the price of a REC unit generated from the PV system.

The financial advantage of installing a PV system to generate electricity on a residential site is that it partially offsets the cost of electricity purchased from grid. Therefore, the energy costs saved due to the PV system can be obtained as:

$$\text{ES} = \sum_{t=1}^{N} \frac{1}{[1 + (d - e)]^{t-1}} \times E_{\text{PV}} \times T_{\text{R}} \tag{11h}$$

where ES is the cost of the grid electricity avoided due to on-site electricity generation and T_{R} is the electricity tariff applicable in the residential sector. Therefore, the effect of financial incentives on the life cycle of electricity from wind and PV power systems can be expressed as:

$$E_{\text{LCC,Incetives}} = E_{\text{LCC}} - \left(\text{ST} + \text{PT} + \frac{\text{REC}_{\text{Wind}}}{E_i} + (\text{DEP}_{\text{ACCL}} - \text{DEP}) \right) \tag{11i}$$

$$E_{\text{LCC-PV,Incetives}} = E_{\text{LCC-PV}} - \left(\text{ST} + \text{PT} + \frac{\text{REC}_{\text{PV}}}{E_{\text{PV}}} + \text{IR} + \text{CS}_{\text{PV}} + \text{ES} \right) \tag{11j}$$

RESULTS AND DISCUSSIONS

The cost profile of coal, wind, and PV power systems are different since each system operates in a different manner. For instance, the installed cost of coal and wind-based projects are comparable while that for a PV system is high. As shown in Table 4, the installed cost of the coal and wind power project are \$1210/kW and \$1353/kW. For the PV system, it is \$7840/kW. The costs, input parameters, and associated assumptions are given in Appendices A–D.

It can also be noticed from Table 3 that for the coal power project, the IDC and financing charge comprise around 16% of the total project, while the corresponding value for the wind power project is less than 10%. This is due to the fact that coal power projects take a longer time to implement than wind power projects. This also indicates the importance of commissioning a project on time and within the budget. To reduce the IDC, a project developer would ideally prefer to invest the equity funds before the loan. This provides banks additional security for loans offered to project developers. In fact, for large green-field power projects, banks normally allow loan drawdown after a substantial part of the project equity funds have been invested. This is because after investing a large part of the equity, a project developer's commitment to complete the project on time and budget is likely to increase.

On the other hand, a project developer would prefer to schedule payments to the project's construction and commissioning contractors as close to the project completion schedule as possible to reduce the IDC. However, this would increase financial risks for the contractors. Usually, the project contracts are designed such that a

Table 4 Cost components of coal, wind, and PV power systems

Cost Category	Coal (million $)	Wind (million $)	PV ($)
Capital cost	445.5	49.9	23,520
Non-capital cost	86.0	11.8	—
Interest during construction	61.5	2.1	—
Financing charge	36.2	3.8	—
Total project cost	629.2	67.7	23,520
Project capacity	520 MW	50 MW	3 kW
Unit cost	1210 $/kW	1353 $/kW	7840 $/kW

certain percentage (10%–15%) of the contractual amount is paid to the contractor as mobilization advances to commence activities. The balance payments are made progressively, based on achieving predetermined project construction and commissioning milestones.

The annual electricity tariff for coal and wind power plants follow a similar trajectory, except that the electricity tariff for a wind power plant is higher than that for the coal power plant, as shown in Fig. 2a and b.

For both coal and wind power projects, the sharp decline of the electricity tariff in the 11th year is due to the full amortization of loan repayments. In the 15th year, the deprecation costs are also fully adjusted. Thereafter, the funds required to meet the fixed charges reduce substantially. From the 15th year onward, the components of the variable charge contribute largely to the electricity tariff. Because wind power projects do not require fuel during operation, the electricity tariff is predominantly dictated by the fixed cost components of the project. On the other hand, for coal power plants, the components of variable charge contribute largely after the loan repayment and depreciation costs are fully adjusted.

The levelized cost or the LCC of electricity is shown in Fig. 3 for the three power projects considered in this study. The costs, input parameters, and assumptions are given in Appendices A–D. As expected, the LCC of electricity from a coal power plant is the least expensive, followed by wind, while it is highest for the PV system. It is interesting to note that the installed cost (in $/kW) of a solar system is about six times higher than that for the coal power project (Table 3). However, the levelized cost of electricity from these two sources differs by around ten times. This effect is due to the different capacity factors utilized by these systems. A coal power plant usually operates around 80% of the time in a year, while a PV system operates only

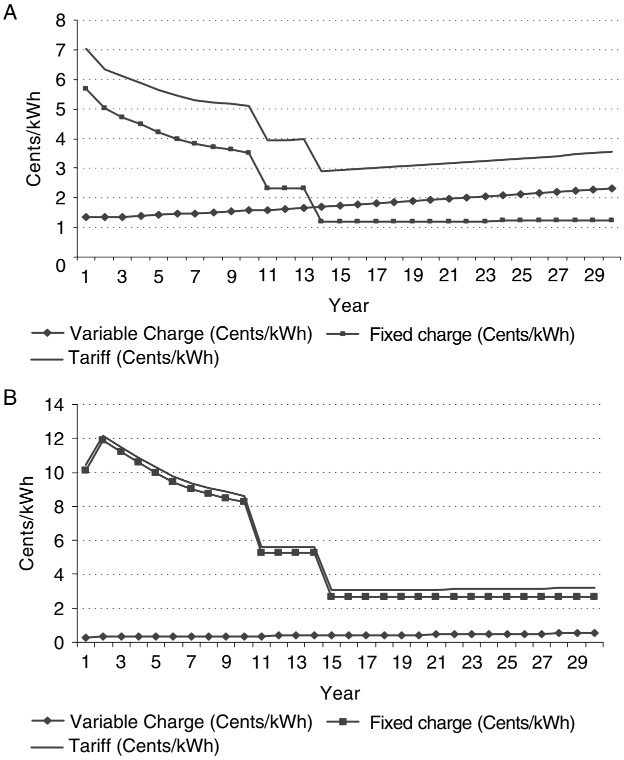

Fig. 2 (A) Annual electricity cost for the 520-MW coal plant. (B) Annual electricity cost for the 50-MW wind plant.

around 15% in a year. The levelized cost of electricity from the wind power plant is around twice that of the coal power project and the corresponding values are 4.4 and 7.6 cents/kWh, respectively.

From the above discussion, it can be inferred that the cost of electricity associated with wind and PV-based power systems can possibly impede investors or individuals from installing such systems for electricity generation. In order to promote the use of electricity from RE sources, several state and federal agencies in the United States (and several other countries) have been offering FIs for RE technologies. Typically, the state-offered FIs consist of sales tax exemption on the purchase of system components, property tax exemption, income tax rebate, capital subsidy on the system cost, etc. The FIs offered by federal agencies are typically the accelerated depreciation on the project cost for faster recovery of the capital, the production tax incentive, income tax rebate, etc.

To illustrate the effects of FIs on the LCC of electricity from the PV system and the wind power project considered in this study, the federal and Massachusetts state financial (and fiscal) incentives offered on residential PV system and utility scale wind power projects have been used.

The FIs have a significant effect on the LCC of electricity generated from the PV system. The capital subsidy on the system, along with the electricity costs saved due to onsite power generation, contributes to a

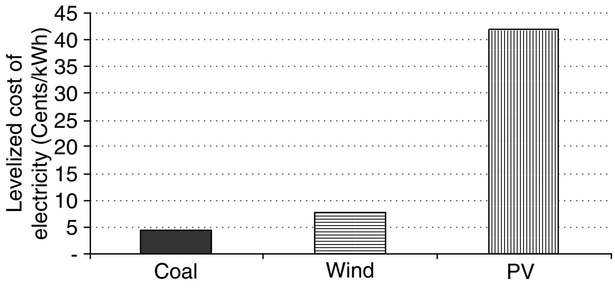

Fig. 3 Levelized cost of electricity from coal, wind, and PV-based power systems.

reduction of as much as 65% of the LCC of electricity from the system (Fig. 4). When several other FIs, such as federal and state income tax rebates, state sales and property tax exemptions, and the sale of RE credits generated from the electricity produced by the system are considered, the LCC of electricity from the PV system is negative (Fig. 4).

Similarly, the LCC of electricity from the 50 MW wind power project is significantly reduced when the effect of FIs is considered. The accelerated depreciation for capital cost recovery and the production tax credit contribute to reducing the cost of electricity by 65% (Fig. 5). The LCC of electricity from the wind power project without the FIs is 7.6 cents/kWh and when the effect of FIs is considered, the corresponding value is 2.1 cents/kWh (Fig. 5).

The cost of electricity from coal, wind, and PV-based power systems after considering the effects of FIs are compared in Fig. 6. The cost of electricity generated from the PV-and wind-based energy systems could be significantly less than that generated from coal power projects (contrary to the conventional belief; however, the financial incentives on PV and wind-based RE systems vary considerably from state to state. Therefore, the results of this study are only illustrative in nature). This is (possibly) one of the reason for large-scale deployment of residential PV systems and utility scale wind power projects in several parts of the United States (and elsewhere) in the recent years.

CONCLUSIONS

Life-cycle cost assessment provides an estimate of the major expected costs that can be incurred within the useful life of an asset. Life-cycle cost estimation is a tool that influences investment decisions for acquiring or developing an asset. It allows for the comparison of different investment alternatives and thus enables determination of the most cost-effective system. This study has attempted to develop a framework for conducting LCC analysis of energy projects by focusing on two phases of a project's life-cycle costs, these are

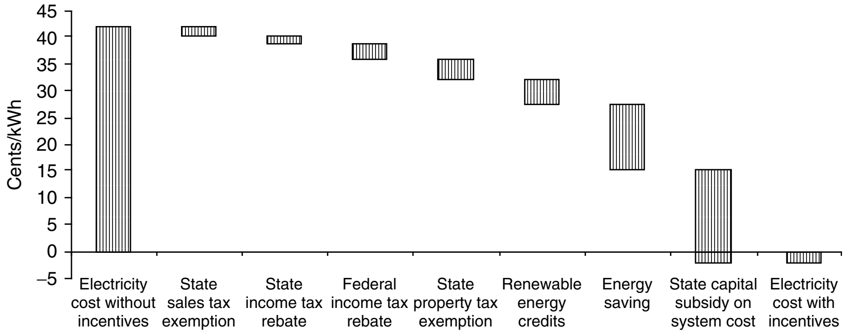

Fig. 4 Effect of financial incentives on the levelized cost of electricity from the 3-kW PV system.

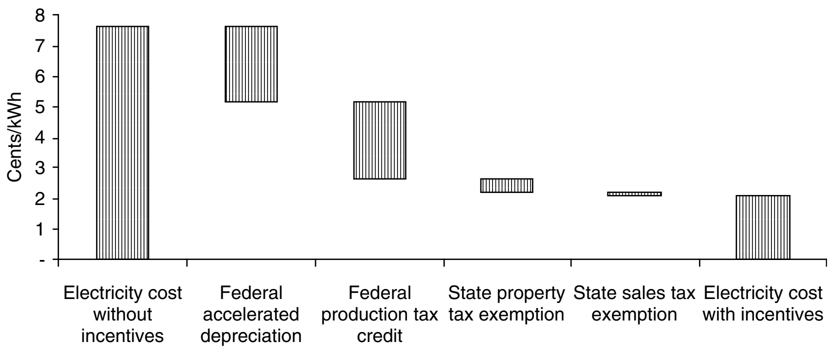

Fig. 5 Effect of financial incentives on the levelized cost of electricity from the 50-MW wind power project.

Inv–Light

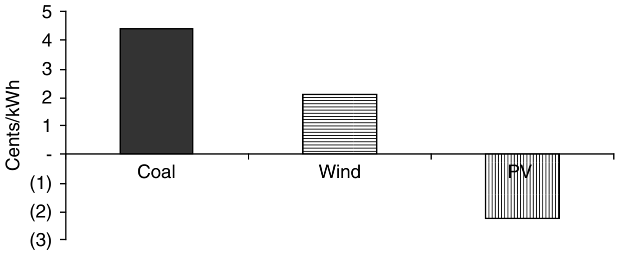

Fig. 6 Levelized cost of electricity with financial incentives from coal, wind, and PV-based power systems.

(i) the development, construction, and commissioning phase and (ii) the operation phase. The energy projects considered were: (i) a 520-MW coal power plant; (ii) a 50-MW wind power project; and (iii) a 3-kWp grid-tied residential PV system. The LCC assessment considers costs associated with the debt servicing, variable costs, interest on working capital, depreciation, annual operation and maintenance cost, etc. Most of these costs are applicable for large (or utility scale) power projects and the effect of these costs on the electricity produced from a grid-tied residential PV system is negligible. The LCC of electricity from the PV system is around ten times higher than that from the coal power source when the effects of financial incentives are not considered. Similarly, the LCC of electricity from the wind power project is around twice that from the coal power plant without considering the FIs. The annual cost of electricity generated from a coal power plant is balanced between fixed and variable costs, while that for the wind power project is largely contributed by fixed cost.

In addition, a framework has been developed to quantify the financial and fiscal incentives offered by federal and state agencies to RE technologies. This enables studying the effect of FIs on the LCC of electricity generated from the PV and wind power systems. For the residential PV system, the state offered upfront capital subsidy on the system cost and the cost of electricity that was avoided due to the contribution of onsite power generation in reducing electricity cost (LCC) by 65%. Similarly, the LCC of electricity from the 50-MW wind power project is significantly reduced when the effect of FIs is considered. The accelerated depreciation for capital cost recovery and the production tax credit contribute to reducing the cost of electricity by 65%. The cost of electricity generated from the PV and wind-based energy systems could be significantly less than that generated from coal power projects when the effects of financial incentives are considered in the calculation of the LCC of electric power projects.

Life Cycle Costing: Energy Projects

Sandra B. McCardell
Current-C Energy Systems, Inc., Mills, Wyoming, U.S.A.

Abstract
Life cycle costing for energy projects is described as a decision-making tool for energy projects, with several examples and a spreadsheet that can be used as a template for calculations. The focus of the chapter is on the principles of life cycle costing to provide managers and professionals a methodology to compare a variety of complicated projects having different costs and benefits.

INTRODUCTION

Life cycle cost analysis (LCCA) is a useful technique for comparing the relative economic benefits of several energy efficiency opportunities among which one must choose. It can also be used to assess the viability of particular investment opportunities.

The technique is one borrowed and adapted from financial analysis. As applied to energy efficiency project analysis, it has developed a particular set of procedures and approaches, and is often used for compliance enforcement as well as for its original purpose in economic decision-making.

LCCA can be simple, with few variables necessary or used, or it can be so complex that a computer model is required to examine the integrated costs and benefits of several energy efficiency systems.

This chapter is designed as a resource for those who assess energy efficiency (and other) investments. It focuses on the ways in which LCCA can be used to inform and support energy project decision-making, with an emphasis on the general approach and example spreadsheets that can be used for a simple analysis.

Computer models employ the same techniques but use the power of the computer to provide an analysis based on iterative simulations that are value-timed for periods of 20 or 30 years. A brief list of some of the more commonly used computer-modeled LCCA systems is included for those who may be interested; computer models are outside the scope of this chapter, however.

DEFINITIONS

Blended utility rate: The utility rate is the basis on which the utility charges for its products (electricity or natural gas) and its services (for example, transmission costs in the case of natural gas, power factor penalties and demand charges in the case of electricity). For general economic analysis including life cycle costing for energy projects, a "blended" utility rate should be used. A blended rate summarizes all charges for the month and then divides that number by the amount consumed. (For more detailed engineering and economic analyses, time-of-use parameters and differential quantity charges may require that the utility rate components be adjusted individually, but the blended rate gives a reasonable approximation for most purposes.)

Btu/sf: Energy use for a building is often summarized and compared on the basis of Btu/sf, or British thermal units/square foot of facility area. This useful measure converts electrical, natural gas, propane, and other energy sources to Btu and then divides the total by the number of square feet in the facility. Most "benchmark" energy comparisons use this number for total utility usage.

Energy efficiency measure (EEM): Any energy project may be composed of one or more EEMs (such as replacing single-pane windows with double-paned and appropriately glazed windows) that are individual measures designed to reduce utility costs by themselves and in concert with other EEMs.

Internal rate of return (IRR): This popular traditional financial investment comparison method evaluates projects based on all associated projected cash flows. Potential investments are normally compared either to one another or to an organization's stated target or "hurdle rate."

Life cycle analysis (LCA): LCA is a concept that is outside the scope of this chapter. It is an emerging technique designed to capture the full economic effect of the environmental costs associated with a product, project, or service, including production, transportation, end of life, and other costs.

Life cycle cost analysis (LCCA): LCCA (also known as life cycle costing) is an economic evaluation tool that is extremely useful in both evaluating and comparing energy projects. It takes into account the timing of those costs and

Keywords: Life cycle costing; Life cycle cost analysis; Economic analysis; Total owning costs; Payback period; Energy cost modeling; Building analysis.

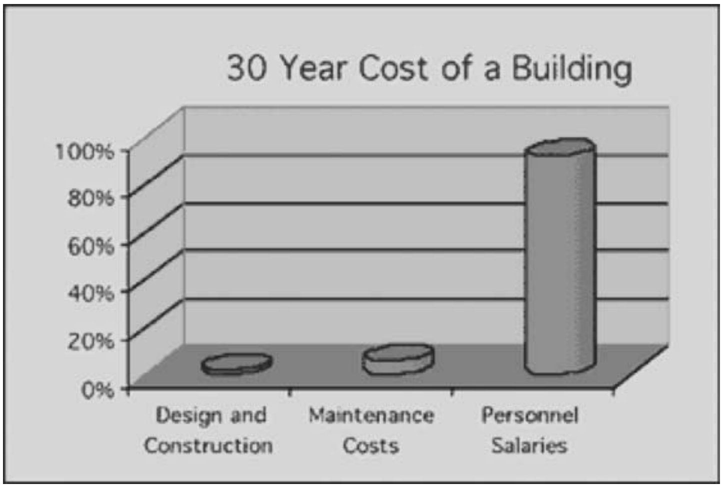

Fig. 1 Thirty-year cost of a building.
Source: From Whole Building Design Guide, Sieglinde Fuller (see Ref. 1).

benefits, as well as the associated time value of money, returning a single value for the total life cycle cost of the energy project.

Net present value (NPV): The NPV is a traditional financial analysis tool that takes all cash flows expected from a project and discounts them back to the present; positive numbers are generally seen as worthwhile investments.

Payback period: The simple payback period (PB period or simple payback) is a traditional measure used in evaluating energy projects. The calculation divides the total installation cost by the savings projected to determine the number of months it will take to pay back the investment.

Time value of money: This phrase encompasses the idea that a dollar received or spent today is worth more than a dollar received or spent in the future. Inflation is part of the reason for this; the other is that one can use the dollar today in other ways, whereas one must wait to receive and use the dollar tomorrow.

Total owning costs: This term is synonymous with life cycle cost but is used more frequently in the residential context.

THE ANTECEDENTS OF LIFE CYCLE COSTING FOR ENERGY PROJECTS

LCCA is similar to most economic decision-making tools in that it takes a variety of monetary flows and converts them to a single number, making comparisons among alternatives or an organization-designated benchmark relatively simple. As is true of all such tools, it is essentially a way to compare such divergent items as apples, oranges, and kumquats with a shared metric.

The challenge of comparing unlike items on an economic basis is one humans have faced since the beginning of time. Imagine the difficulties of the early traders who had to hold in their heads the comparative values of silks, olives, and pottery throughout their trading regions, in every season.

Money was, of course, the original method used to give similar values to disparate items, and with its introduction traders had a common way to assess the value of very different commodities (as well, of course, as providing a commonly recognized and portable medium of exchange).

As money became one of the foundations on which our civilization and commercial systems were built, other improvements were made as well: the time value of money (sometimes expressed in the phrase "A dollar today is worth more than a dollar tomorrow") was recognized; with the increasing complexity of the industrial age, project costs and benefits for a variety of complicated projects were analyzed economically; and disparate activities and items were reduced to numbers for comparison. Both of these characteristics are included in LCCA.

In the 1970s, when energy savings investments were first undertaken as stand-alone projects to reduce costs, the economic approach first used was the simple payback period (SPB period). This simple and easily understood measure simply divides the project price by the savings projected, showing that the investment would be recouped in 9 months, or 2.5, or 10 years. Although SPB periods are easy to calculate and explain, they ignore the time value of money, utility rate changes, and any operational or maintenance cost increases or decreases. In fact, they present only part of the story, and it is the author's contention that LCCA should be the preferred method. In fact for organizations interested in an economic evaluation method that also integrates itself better into their other business decisions, LCCA has come to be the norm.

Note: LCCA should be distinguished from life cycle analysis, LCA, which is the emerging trend toward accounting for each aspect of a product's life from its inception through to its disposal or recycling, including the embedded cost of the energy used to manufacture and

Table 1 Gas station example, current situation

Building type	Gas station
Date of construction	1970
Square feet	7000
Description	Concrete block construction on slab, 1–2 floors, flat roof, single-paned windows, T12 fluorescent lights with magnetic ballasts inside; HID outside; 4 leaded/unleaded vehicle pumps; 6 for truck diesel
Electricity use and yearly cost	$23,000 and 102,000 Btu/sf/yr
Natural gas use and yearly cost	$21,000 and 223,000 Btu/sf/yr
Total Btu/sf/year	325,000
Energy cost/sf/year	$7.71
Maintenance costs	$5000
Operating schedule	24 h
Major energy using systems	Heating, cooling, lights

transport the product. Although LCA draws from the legacy of LCCA, it is a different tool that focuses on the global environmental costs and benefits of a particular product.

THE FRAMEWORK OF LIFE CYCLE COSTING

The concept of life cycle costing is one that is in fact familiar to us all. When we purchase a car, for example, we do basic research on fundamentals: fuel efficiency, maintenance records, and resale value. We consider our driving patterns and the length of time we plan to have the vehicle. That is essentially an economic assessment. We overlay that information on a strategic and technical assessment. First, what do we really want the car for? Is it for work, for hauling livestock, for soft summer nights on an open highway, for transporting teams of youngsters? Then we examine how the various possibilities fit that need. What is the vehicle's performance, its reliability, its safety record? Finally (when we are being reasonable), we make our decision based on these strategic, technical, and economic grounds.

When the task is the design of an energy efficient building, the approach is a similar one. To make a reasonable decision, it is important to consider strategic, technical, and economic aspects of the purchase/construction or retrofit question. The only difference is that with the lifetime of a building being 30–50 years, these decisions are even more critical.

In fact, as shown in Fig. 1, construction costs represent only about 2% of the total cost of a building, with operations and maintenance costs (including utilities) representing 6%, and associated personnel costs representing 92%. (This last statistic also highlights the reason that energy projects usually are also designed to increase occupancy comfort; in any facilities other than heavy-industrial buildings, those occupants are the single greatest cost.)

Life cycle costing is a method not only for analyzing the reasonableness of one particular decision or group of decisions, but also for examining the advantages of one investment vis-à-vis another. To a greater or lesser extent, depending on the complications inherent in the decision, it models reality—which means that the calculation mechanism can be a scrap of paper, a simple spreadsheet, or a complicated and multifaceted computer model. The same principles apply in all cases, but each is appropriate in different circumstances.

For large projects, life cycle costing standards have been developed by ASTM International (www.astm.org) and the National Institute of Standards and Technology (NIST) (www.nist.gov), and the principles inherent in those standards are extremely useful even when the calculations are less complicated than whole-building analyses.

Stage 1: Describe the Current Situation

First, LCCA incorporates the characteristics of the current situation, to give one a picture of "what is" against which to compare. This can take many forms, as shown in Tables 1 and 2.

The level of complexity in these two analyses is very different, but the principle is the same: it is important first to know what the current situation is and then to benchmark that against similar buildings (either out of one's own experience or by using a benchmarking tool such as EnergyStar; www.energystar.gov).

In these cases, for example, it becomes evident that the gas station has an immense opportunity for energy savings, as the normal energy usage in this particular climate would be approximately 2,00,000 Btu/sf/yr. (Expressed in this way, it is a measure of utility usage across various types of energy sources.) It is also clear that although the electricity and natural gas costs are almost identical, the gas usage in Btu/sf/yr is that upon which the greatest emphasis should

Table 2 HVAC system example, current situation

System type	HVAC system
Date of installation	1980
Manufacturer and model number	Trane packaged rooftop air conditioner with natural gas heating package
Description	25 ton, 350 MBH input heater
Nameplate efficiency	Estimated EER of 6
Thermal zones	2
Utility rate schedule	Local REA, average blended electricity cost $0.87
Operating schedule	24 h
Heating & cooling season	8 months heating, 4 months cooling
Maintenance costs	$860/yr

be placed. Also, maintenance costs are quite high in relation to comparable facilities, and that information too will be useful in defining the energy projects to be recommended for the facility.

For the HVAC system, any unit with an energy efficiency rating (EER) of six is about half as efficient as it should be—which provides a great deal of scope for reduced utility costs in both heating and cooling seasons. This is particularly true because the unit runs 24 h a day, all year long, so the increased efficiency should have a significant impact.

These "current" situation descriptions (and the possible energy efficiency measures associated with them) become the first step in the LCCA—the base against which other alternatives will be compared. When the analyst thoroughly understands the current picture, the next step is to examine the facility for upgrade and efficiency possibilities.

Table 3 shows a brief example comparing the life cycle cost (or total owning cost) of an incandescent light bulb vs. a compact fluorescent (CFL) bulb. The light in each case is assumed to operate 4 h per day or 1400 h per year. The CFL lasts about 7 year, whereas the incandescent bulb lasts less than 1 year; with 9 replacements, the LCCA analysis shows the CFL, at $14.94, to be a better choice than the incandescent bulb at $44.54. (As a side note, actual electrical costs have increased, and a recent recalculation for the Denver, Colorado market produced an LCCA for the CFL of $18.76 and an LCCA for the incandescent bulb of $62.04.)

Table 3 Total owning cost of an incandescent vs a CFL light bulb

	Incandescent bulb (60 W)	15 W compact fluorescent bulb
Initial cost ($)	0.25	7.00
Annual operation ($)	7.03	1.26
7-year life cost ($)	44.29	7.94
Life cycle cost ($)	44.54	14.94

Source: From www.focusonenergy.com savings analysis worksheet (see Ref. 2).

Stage 2: Definition of the Energy Project

The next step is to define the proposed project. As with the purchase of a car, this requires the definition of strategic, technical, and economic factors. In addition, for each alternative, both immediate and long-term costs and benefits should be described and understood.

This definition is necessary for both simple stand-alone projects and for energy efficiency measures that impact strongly on multiple elements and systems in a building. In almost every case, however, there will be long-term implications for each improvement. An EEM (energy efficiency measure) of "replacing incandescent exit signs with new fixtures illuminated by LEDs," for example, does not impact the operation of the building significantly. On the other hand, there will be significant differences in maintenance and operation costs, because LED exit lights and batteries can last at least 10 years, whereas incandescent bulbs are supposed to be replaced annually.

It is precisely this type of decision that LCCA is designed to facilitate. LED exit lights are more expensive than their incandescent versions and have no effect on building operation but do significantly reduce long-term maintenance expenses. More importantly, their longer battery life makes them safer. LCCA can aggregate these costs and benefits, and provide consistent and complete information for a decision on the appropriate emergency lighting choice.

One brief note is that in most LCCA analyses, intangible costs and benefits (increased safety, lower risk, increased occupancy comfort, increased employee health, and so on) are not accounted for unless they can be quantified in some way (reduced employee sick days from better air quality and less mold, for example). It is possible and increasingly common, however, for the value of such intangible factors to be included in LCCA by weighting the variables in a statistically appropriate way, by rating the importance of several intangible factors and then grading each alternative for its performance against those factors.

When the proposed project or alternative projects have been defined (which is predominantly the responsibility of the consultants, engineers, and operations personnel), the impact of the energy efficiency improvements—both short term and long term—can be quantified. This step is the essence of LCCA, and although the details can be quite complicated, the premise is simple: Projected economic impacts for each period should be calculated, most easily by completing a table with costs and assumptions over the project life (as shown below).

In the single-technology exit light replacement example cited above, it would be important to quantify the following variables:

- Wattage difference between old lights and new LED lights
- Cost (including labor) for old lights and new LED lights
- Number of fixtures to be replaced
- Frequency of changeouts at present and cost to change lights (including labor)
- Projected frequency of changeouts and cost to change lights
- Residual value or disposal costs of both old lights and new LED lights
- Current utility rates and any projected changes over the life of the project
- Time value of money, or discount rate that should be used to convert future dollars to current ones
- Projected project cost

Even in a simple example such as the LED exit lights, other variables might usefully be included in a very large building and probably would be included in a computer model. Among them would be:

- Anticipated changes in material and/or labor costs
- Possible vandalism costs
- Inventory carrying cost for replacements

In most projects, however, these additional parameters would not provide materially different answers and, thus, are not likely to be worth the effort of research and calculation.

If exit light replacement can decrease electricity usage by approximately 70% per fixture and has long-term effects on maintenance and operations, it is easy to imagine that the picture becomes exceedingly complicated when one is looking at a whole building with integrated systems and interlocking issues.

For the architects and design engineers planning to build a new recreation center with an indoor swimming pool, for example, the technical considerations involved in defining the project are many, complicated, and interrelated, and all have financial implications. It is for cases such as this that the computer LCCA models integrating energy use and economic considerations are designed, because energy use is a key component of long-term cost; the more involved models run hourly simulations of buildingwide energy use to understand the entire economic picture.

Whether the analysis is simple or complex, however, the steps are the same. With the recreation center, the first step remains a description of the current situation (or, as here with new construction, a benchmark building). Second, the project must be defined strategically, technically, and financially.

With planned construction that is as complicated as a new recreation center, a computer model including LCCA should then be used to simulate results. For building developers who are planning to apply for U.S. Green Building Council LEED (Leadership in Energy and Environmental Design) certification, such modeling is critical, but it can be extremely useful for any facility for which construction and operating costs are constrained. With the help of computer models, the technical, energy use, and financial information provided by the model can often reduce both initial construction and long-term operating costs—although, of course, the main benefit comes from reducing the larger, long-term operating costs. For this purpose, the model should be run several times, with different assumptions or using alternative equipment, to achieve optimal whole-building results before comparing the project with other possibilities. (LCCA is a tool designed to be used as a decision-making tool for managers and operational personnel. Energy modeling, on the other hand, is best accomplished by professionals trained both in the use of the specific modeling program and in analyzing the output produced by the model.)

Stage 3: Determine and Quantify Costs and Benefits

In any analysis as potentially complicated as LCCA, it is important to include all appropriate costs and benefits. On the other hand, it is easy to go overboard in collecting information, unnecessarily increasing the complexity of the variables to be considered and, thus, delaying the decision which should be made. This is an important point because with energy projects (in contrast to most potential projects evaluated by organizations for consideration), delays do not conserve cash by reducing expenditures, but instead reduce the cash available by maintaining operating expenses at an unnecessarily high level.

The costs to be considered for an energy-project LCCA analysis generally can be described as follows:

- First costs. Depending on the project, this could be construction cost, purchase or other acquisition cost, installation costs, etc.
- Operations costs. These include the following:
  - Maintenance costs
  - Repair costs
  - Subunit replacement costs (as in the replacement of a bulb in a light fixture)
  - Utility costs
- Replacement costs
- End-of-life value or cost, which might include disposal, demolition, or residual value, depending on the project or product
- Finance charges
- Benefits and/or costs that are nonmonetary but that (if quantifiable through weighting or by some other method) are important to the decision The LCCA approach, like most other financial calculators, takes each cost or benefit into account in the year in which it occurs and then discounts or adjusts the value of those flows to the present.

For the third step, again, the appropriate variables (in addition to the design and technical data that is collected for Stage 2) will need to be defined, and they address essentially the same issues as those in the LED exit-lights example. They might include the following (using the indoor-pool example):

1. How often will the pool be occupied, and by how many people?
2. How often will there be spectators, and how many?
3. What lighting levels will be required—during the day and at night?
4. What are the normal outside weather conditions?
5. How easy is it to change lights, and what will each change cost per light?
6. What are the utility rates, including demand charges?
7. What is the projected change in utility rates over the period when the building will be occupied?
8. What is the anticipated life of the facility and its major components?
9. What is the disposal cost or residual value of short-lived building systems or components?
10. What is the projected yearly maintenance cost?

It is a very complicated picture.

When looking at a retrofit option, however—for example, a recreation center with a swimming pool already in place—the complications increases dramatically. "What is" can be known, of course, along with what is working and what is not, what is proving to operate in the way it was designed to operate, and what is causing difficulties for one reason or another. Therefore, a description of the current situation is possible, but an analysis of the issues raised by the project—even when confined to those that have energy usage implications—is quite difficult.

Naturally, most complications come from the interactions of various systems. The humidity in the pool-room air must be controlled, for example, and in a dry climate, that damp heated air might be exhausted through the locker room; heat might also be recovered from the exhaust system and used in other parts of the building. The advisability of this approach would depend on and impact the design of the air handling system, the size of the pool, the numbers of spectators, the hours of use, the pool lighting, and a number of other factors. Each important system interaction can be accounted for with a variety of the building modeling tools available on the market, and the implications for the operation of the building accounted for and understood.

LCCA allows one to take the next step, which is to assess the cost implications of the actions that might be taken to improve the situation in the future. Thus, it looks at both future costs and benefits of any energy efficiency system improvements. With whole buildings or more involved systems, the complications can mushroom because of the complexity of the building and the interactions among systems, and computer models can take such implications into account. The principle for comparison remains the same, and for most projects, a simple spreadsheet LCCA assessment is more than sufficient.

LIFE CYCLE COSTING AND ITS USES

Life cycle costing is in fact an outgrowth of several standard methods for calculating the economic impacts of various decisions over time. It is similar in many ways to the standard business measure of net present value (NPV), which takes future cash flows from any proposed investment (both in and out) and calculates their value in current dollars; when the outcome is positive, the project makes economic sense. A similar measure is the internal rate of return (IRR), which provides a percentage return on the investment after calculating costs and benefits from today forward; usually, companies have a hurdle rate, and an IRR must exceed that number for the project to be considered.

LCCA is in the same mould. It reduces energy project complexity down to one number that can then be easily compared with the same calculations performed on other projects. Because life cycle costing includes both current and future benefits and costs, and discounts for the time value of money, it gives a far more realistic picture than the payback period discussed earlier.

Table 4 Lighting retrofit example, Stage 1 (Current situation) and Stage 2 (Proposed situation)

	Stage 1 (current situation)	**Stage 2 (proposed situation)**
Description	100 fixtures; 2 bulb 4 ft long 34-Watt T12 FL fixtures with magnetic ballasts, ½ lenses broken, fixtures need cleaning but otherwise OK, fixture wattage 84, personnel unhappy with light provided; fixtures 2 years old	T8 lamps and electronic ballasts, to be installed in the same fixture; all fixtures to be cleaned. Total wattage 59, increased light levels 10%. Group replacement anticipated every 3 years
First costs		
Design cost		$1000
Lenses for fixtures	50 lenses at $8 each	50 lenses at $8 each
Ballasts		$10.50 each, group replacement
Bulbs		$3.00 each
Installation and cleaning cost (incl. labor)	$20.00 per fixture on "ad hoc" basis	$10.00
Fixture cost	$44.52	$44.52
Numbers of fixtures	100 (100 ballasts, 200 bulbs)	100 (100 ballasts, 200 bulbs)
Operating and maintenance costs		
Bulb replacement (incl. cleaning and labor)	$28 each, replaced as needed, average ¼/year	
Ballast replacement (incl. cleaning and labor)	$21.50 each, replaced as needed, average ¼/year	
Repairs	$200/year	
Electricity	$0.08 blended rate/kWh	
Replacement/retirement cost		
Expected life	4 years	4 years
End of life disposal costs—lamp	$1	$1
End of life disposal costs—ballast	$1.75	
Salvage value at end of life	0	0
General assumptions and costs		
Finance charges	0	0
Expected fixture life	10 years	10 years
Discount rate (nominal rate for 10 years)	6.1%	6.1%
Utility rate changes expected	Increase 2% yearly	Increase 2% yearly
Usage changes expected	None	None
Non-monetary costs	Complaints regarding lighting levels and color, "look" of the facility	
Non-monetary benefits		Increased light levels and better attractiveness of facility
Cost escalation projection	None	None
Hours of operation	24 h	24 h

Inv–Light

Life cycle costing can be used in different ways, depending on the situation and the circumstances:

- With new buildings (and principally through computer models incorporating life cycle costing), design, systems, site placement, materials, equipment choice, and other options can be modeled and evaluated so that the best possible choices are made, both in construction and in operating cost.
- With existing buildings, LCCA can be used to:
  - — Compare the current situation with that proposed under several design scenarios.
  - — Choose the optimum balance between retrofit cost and operating expenses.
  - — Choose one or several possible energy efficiency options among a number of possibilities.
- For states and other governmental agencies, as well as large corporations, LCCA models can be required for both projects and systems as prerequisites to approval, and often, the particular variables to be used and the specific computer model that is acceptable will be specified.

Many of the computerized technical and economic modeling programs are excellent, accounting for the interactions among various systems and possibilities, and giving a true picture of a complicated set of interrelationships. They are not fundamentally different, however, from a spreadsheet-based LCCA, which any manager can use with relative ease. Where a full economic analysis and computerized modeling for various design alternatives are required, they should be done by engineers or designers experienced in the particular modeling program to be used; their analyses of the competing alternatives and recommendations regarding options to install will very likely be worth far more than the cost of their services.

EXAMPLE

Let's take an example: a small lighting retrofit. First, Table 4 describes both the current situation and the proposed retrofit throughout the anticipated life of the project.

For the third stage of quantifying costs and benefits, additional variables are defined, and the LCCA spreadsheet is constructed for the life of the project—in this case, 8 years, which is the remaining projected life of the fixtures. The retrofit option also includes group relamping of bulbs and ballasts every 3 years, with a guarantee from the manufacturer to cover any materials and maintenance costs between those times (Tables 5 and 6).

Table 5 Lighting retrofit example, Stage 3 (Determine and quantify costs and benefits) – Current situation

	Year 1	Year 2	Year 3	Year 4	Year 5	Year 6	Year 7	Year 8
First cost								
Design cost								
Lenses	$8×50							
Ballasts								
Bulbs								
Installation & cleaning incl. labor								
Fixture cost								
No. of fixtures								
O&M costs								
Total bulb replacement	$21.50 per bulb, 25% of 200 per year							
Total ballast replacement	$28.00×25%×100							
Repairs	$200	$200	$200	$200	$200	$200	$200	$200
Electricity	Fixture watts×number of fixtures×hours used in a year/1000, increasing 2%/year compounded							
Replacement/retirement cost								
Expected life	10 years total for fixtures; 8 years remaining							
Lamp disposal	$1 per lamp, 25% of 200 per year							
Ballast disposal	$1.75 per ballast, 25% of 100 ballasts per year							
Salvage value	$0

When the data has been input into the spreadsheet, Microsoft Excel or a similar program is used to calculate the life cycle cost of the proposed project based on that information.

Based on the assumptions shown above and with the cost and benefit calculations assigned to their particular years, cash flows for each year are first summed for each year and then discounted back to the present. In Excel, this can be done by using the NPV formula, which allows both discount rates and differential cash flow by period. If an organization does not have a generally accepted internal discount rate, appropriate rates for the United States, drawn from the President's annual budget submission, can be found in the ASTM International standard.[3]

Then the life cycle cost for the proposed project is compared with the life cycle cost for the current situation, and a decision can be made to proceed or not, based on a good economic assessment.

LIFE CYCLE COSTING CALCULATORS AND MODELS

The same approach and components could be used for widely different types of projects, and in fact, many LCCA calculators for an incredible variety of products are available on the Web sites of many organizations that are interested in fostering energy efficiency. Following are two examples:

- For an electric griddle, www.fishnick.com/tools/calculators/egridcalc.php is a calculator from the Food Service Technology Center, which also offers other food service-related calculators.[4]
- For transformers, the Copper Development Institute has an excellent set of formulas that can be used to evaluate alternative transformer possibilities. These formulas are available at www.copper.org/applications/electrical/energy/trans_life_cycle.html.[5]

As noted, a multitude of computer models include energy project LCCA in addition to their core focus areas (which may be energy costs, integrated building design, or other specialties). These are well summarized by the National Institute of Building Sciences[6] and are listed here for reference:

- Screening tools: FRESA, FEDS
- Architectural design tools: ENERGY-10, Building Design Advisor, Energy Scheming

- Load calculation and HVAC sizing tools: Hap, TRACE, DOE-2, BLAST, VisualDOE, EnergyPlus
- Economic assessment tools: BLCC, Quick BLCC.

CONCLUSION

Life cycle costing analysis is a tool that combines financial, technical, and other information considered over time to facilitate decision-making. The variables in use, the cost of whole projects or systems, and regulatory requirements can make the use of complex computer modeling vital. The principles of LCCA, however, are relatively simple and straightforward. The techniques can be used for small as well as large decisions, and provide managers and decision-makers a way to compare possibilities that are not on the surface comparable.

Mastering the techniques of simple LCCA calculation is possible for any well-informed professional. Such mastery in turn facilitates communication among those professionals and technically trained experts needed for more complex modeling. Thus, LCCA can be a useful tool both for making decisions and for talking about those decisions.

ACKNOWLEDGMENTS

Lighting Controls

Craig DiLouie
Lighting Controls Association, National Electrical Manufacturers Association, Rosslyn, Virginia, U.S.A.

Abstract
Automatic lighting controls have become a standard feature in new construction due to prevailing energy codes. Advancements in technology now enable a broad range of globalized and local, automatic and manual control strategies to generate energy savings and support visual needs.

INTRODUCTION

Lighting controls are an essential part of every lighting system. The most basic example of a lighting control is the common switch. When the switch is flipped on, the circuit is closed, enabling the flow of current to operate the connected lighting system.

A wide variety of devices and systems are used to control lighting systems in commercial and industrial buildings. Of particular interest is lighting automation, which presently represents a major frontier in building and energy management. Automated lighting controls automatically switch or dim lighting systems based on a given input. The automation of this functionality can provide significant benefits.

In some industries, lighting accounts for more than 60% of a facility's electrical bill and 40% of the total energy bill. Automated lighting controls can contribute significantly to operating cost savings by switching or dimming the lights according to time of day, whether the space is occupied, amount of available daylight, current level of light output from the lamp, and other factors. According to the New Buildings Institute, which developed the *2001 Advanced Lighting Guidelines*, automatic lighting controls can reduce lighting energy consumption by 50% in existing buildings and at least 35% in new construction. Related to a reduction in energy consumption are load shedding and peak demand reduction, which can reduce demand charges imposed by the utility (Fig. 1).

In addition, lighting automation can provide mood setting, via the ability to alter a space through dimming or color changing; flexibility, by allowing users to instantly adapt a space to different uses; the ability to establish a responsive lighting system that can be globally and locally controlled with automatic operation; the ability to adapt electric lighting systems to daylighting strategies; enhanced security; decreased "light pollution" (skyglow, light trespass, and glare), by dimming or switching outdoor lights based on time of night or occupancy; enhancement of workspaces with a technology that has visible effects; and potential increased worker satisfaction, by enabling users to control their own light levels. The list goes on.

Lighting automation can be completely automated or can contain elements of manual operation; it can be localized, global or both; it can be hardwired or wireless; and it can be used for switching or dimming. A wide variety of proven and developing technologies is now available to achieve a wide variety of building and energy management goals (Table 1).

COMMON STRATEGIES

Lighting controls can perform one or more of seven basic functions: on/off, occupancy recognition, scheduling, task tuning, daylight harvesting, lumen depreciation compensation, and demand control.

On/Off is the basic control function, achieved through switching.

Occupancy recognition is used in intermittently occupied areas, typically to turn lights on automatically when the area becomes occupied and off when it becomes unoccupied. Some occupancy recognition devices are manual-on, automatic-off. The occupancy sensor technology is typically ultrasonic (sensing changes in transmitted sound waves returning to the device), passive infrared (sensing changes in heat in the area), or a combination of the two.

Scheduling is used for areas of predictable occupancy, in which a control system dims, activates or shuts off a lighting system on a predetermined schedule. Local manual overrides are usually provided. A typical weekday lighting schedule is shown in Fig. 3.

Tuning entails adjusting the light output of a lighting system to a desired level needed for a task or other purpose, such as aesthetics or mood setting. This can be achieved through either dimming or switching layers of lighting (such as bi-level switching, in which half of a lighting system is shut off in a space while the other half continues operating).

Keywords: Lighting; Controls; Switching; Dimming; Lamps; Ballasts; Occupancy sensors; Scheduling; Daylight harvesting.

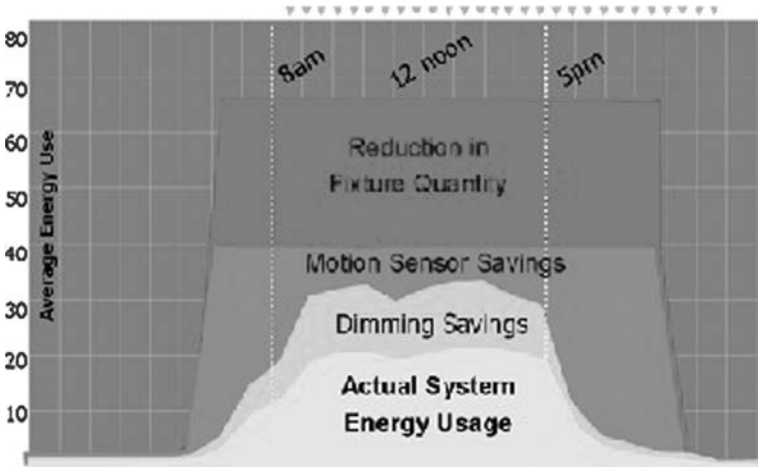

Fig. 1 A complete lighting upgrade can save energy on multiple levels, including fixed load reduction through reduced fixtures or lower-wattage lamp ballast systems, and variable load reduction through strategies such as occupancy recognition, scheduling and personal dimming.
Source: From Light Right Consortium.

Daylight harvesting is used to enable lighting systems to respond to ample available daylight by dimming or some level of switching.

Lumen depreciation compensation takes advantage of the fact that most lighting systems are overdesigned to account for a gradual reduction of light output of lamps as they advance in operating age. Similar to daylight harvesting, this strategy entails measuring available light in the space and dimming the light output to maintain a constant level.

Demand control involves switching or dimming lighting systems during utility peak demand periods, which results in energy cost savings and also potentially significantly lowers demand charges (Tables 2 and 3).

TYPICAL CONTROLS

Lighting controls generally can be categorized as manual or automatic, although some may have features of both

Fig. 2 A growing number of light fixtures are now available with integrated automatic lighting controls, such as this recessed basket, which includes an integrated sensor.
Source: From Lightolier.

Table 1 Benefits of automatic lighting controls in various space types

Space type	Benefit
Discount retail store	In an open retail space with daylighting, dimming can reduce electric lighting use but allow the lights to be on, making the store seem "open for business"
Conference room, classroom, auditorium, etc.	Dimming lighting can facilitate a variety of visual presentations
Health care facility	Daylight-driven dimming can provide a smooth and unnoticeable transition to electric lighting as daylight levels decrease, while maintaining the desired light level
Restaurant	Preset scene dimming controls can make changing the ambiance as the day goes on consistent and as easy as pressing a button
Office area	Even in an open office area, occupants can be given the option of dimming the light fixture over their workstation to suit their personal preferences

Source: From Lighting Controls Association (see Ref. 1).

types of operation. Manual controls require immediate human intent to turn the lighting on or off or adjust its output. Automatic controls initiate actions for lighting systems based on registered events or programming.

Control options can be grouped as switching controls, dimming controls, and integrated lighting control systems.

Switching controls turn lights on and off, and many perform other functions as well. At a minimum, every space should be equipped with manual switching to permit occupants or facility operators to control lighting usage.

Lighting contactors: lighting contactors permit manual or automatic control of large blocks of lighting loads.

Local wall switches: local wall switches (a.c. snap switches) are the most commonly used control devices for local lighting control. For best results, switches should be located to be convenient to users and to encourage deactivation of lighting whenever appropriate. Wall switches also can be applied to develop a flexible lighting control scheme by layering the lighting in the space, with different layers controlled by different switches.

Key-activated switches: key-activated switches are wall switches that turn lighting on and off by a key. They are installed to prevent unauthorized or accidental use of certain lighting circuits. They are particularly useful for HID light sources that must cool down before they can be activated.

Intelligent on/off local devices: intelligent on/off local devices consist of at least two elements: (1) a logic or intelligence module, and (2) a power switching device. The logic or intelligence elements vary depending on the needs of the specific applications. The intelligent input in its simplest form can be a time control or an occupancy sensor. Each typically is used to control a single load and is wired directly to it.

Time controls, also known as time clocks or time switches, activate and deactivate their loads at user-determined times, and are therefore most suitable for areas where occupancy is predictable (with local overrides often being desirable). Some are microprocessor based, allowing operators to program more on/off actuations per day, as well as create special schedules for holidays or certain functions. Outdoor lighting time controls often use an astronomical feature that automatically compensates the control schedule for sunrise and sunset time shift during the year.

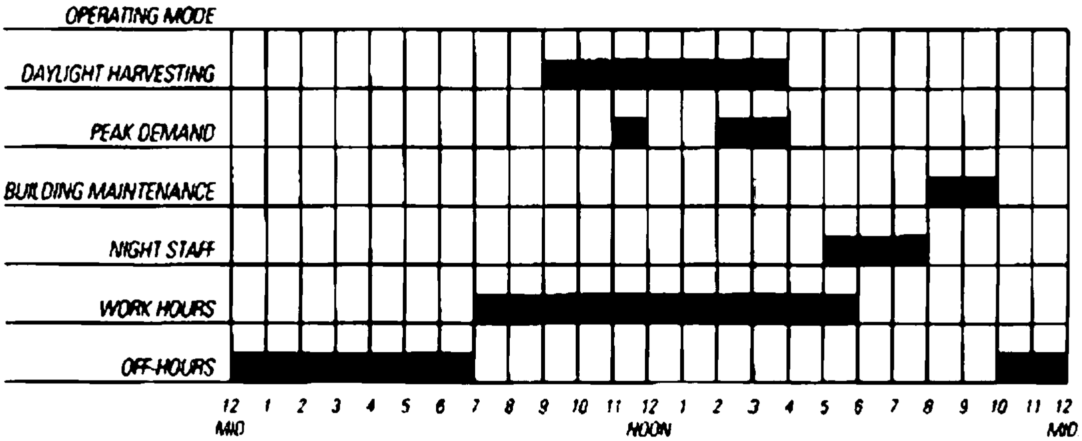

Fig. 3 Typical weekday lighting schedule.

Table 2 Typical lighting control applications

Typical lighting control applications			
Type of control	**Private office**	**Open office—daylit**	**Open office—interior**
Occupancy sensors	++	++	++
Time scheduling	+	++	++
Daylight dimming	++	++	0
Bi-level switching	++	+	+
Demand lighting	+	++	++

++, good savings potential; +, some savings potential; 0, not applicable.
Source: From Federal Energy Management Program, U.S. Department of Energy (see Ref. 3).

Occupancy sensors are automatic switches that control lighting based on the presence or absence of people (see Figs. 5 and 6). Their primary function is to switch electric illumination off automatically in an unoccupied space after the last person leaves that space, saving energy (see Table 4). A timing control provides light for a period of time after the area is vacated.

Table 4 Typical energy savings with occupancy sensors

Occupancy area	Energy savings (%)
Private office	13–50
Classroom	40–46
Conference room	22–65
Restrooms	30–90
Corridors	30–80
Storage areas	45–80

Source: From U.S. Environmental Protection Agency.

Photocell controls respond to changes in ambient light. When the ambient light level falls to a user-determined level, lighting is switched on. When the ambient light increases to a user-determined level, lighting is switched off.

Low-voltage controls: low-voltage switching systems provide a more flexible switching platform than standard line-voltage switches. The simplest system consists of a transformer that produces 24 V or less, relays that are wired to the loads, and on/off switches that are connected by low-voltage wiring to the relays. Each relay can control up to one full branch circuit (20 A).

Table 3 Operating cost comparisons for private office and open office spaces, using various types of controls

Operating cost comparison private office, 128 ft^2

Performance	Base case	Occupancy sensors	Daylighting	Occupancy sensor + daylighting
Annual energy use[a]	450 kWh	340 kWh	330 kWh	250 kWh
Annual energy cost	$33	$24	$24	$18
Annual energy cost savings	—	$9	$9	$15

Operating cost comparison open office area, 1000 ft^2

Performance	Base case	Time scheduling	Occupancy sensors	Daylighting	Time scheduling + daylighting
Annual energy use[b]	5700 kWh	5100 kWh	5000 kWh	4200 kWh	3700 kWh
Annual energy cost	$340	$305	$300	$250	$220
Annual energy cost savings	—	$35	$40	$90	$120

[a] Average daily "on" hours for wall switch is 14.7. Average daily occupied hours for the office is 12.9.
[b] Average daily "on" hours for wall switch is 9.1. Average daily occupied hours for the office is 6.8., Cost-effectiveness assumptions: Each of the two operating cost comparisons assumes that the workspace has approximately 1.5 W/ft.^{2} of ceiling lighting, with parabolic troffer luminaires containing T-8 lamps and electronic ballasts. Daylighting examples assume a design light level of 55 footcandles at work surfaces. Assumed electricity price: $0.06/kWh, the Federal average electricity price (including demand charges) in the U.S.

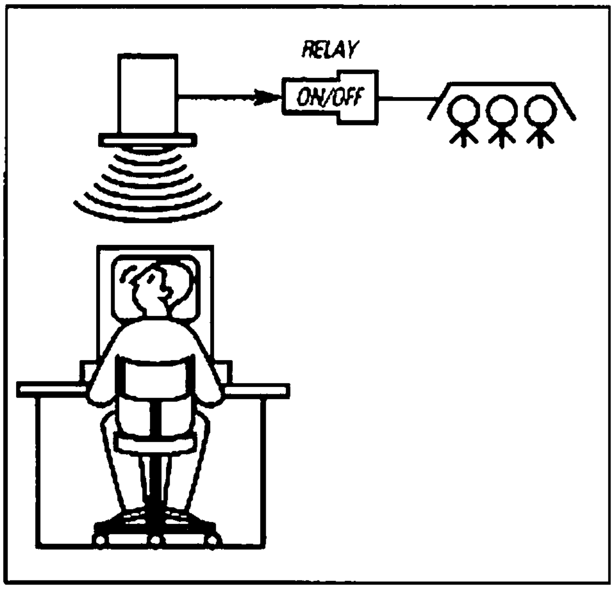

Fig. 6 Occupancy sensor system.
Source: From Lighting Controls Association (see Ref. 2).

Low-voltage wiring provides inherent wiring flexibility while also providing the foundation for simple lighting automation (Fig. 7).

Step-level HID controls: step-level HID lighting controls are relay systems that operate mercury vapor, metal halide, and high-pressure sodium lighting at either full light output or less (e.g., 50%) (Fig. 8).

Dimming controls are available for most types of lighting. They can be integrated into automatic lighting control systems and can be used manually as well. Some dimming controls require use of dimming ballasts, while others employ an electronics package installed in the panelboard or elsewhere within the system.

Wallbox dimmers: wallbox dimmers are manual controls that give occupants more control over their visual environment. Various control configurations are available, including linear slides, rotary knobs, raise/lower buttons, preset panels, and wireless remotes.

Integrated dimmers: integrated dimmers integrate a variety of features into a wallbox configuration. Commonly included features are multiple channel control, with which all or selected fixtures on a circuit are controlled by a single dimmer; multiple presets; and universal circuitry that allows each dimming channel to control incandescent, low-voltage incandescent, fluorescent, cold-cathode, or neon light sources (Fig. 9).

System dimmers: system dimmers offer lighting control for larger applications in which wallbox and integrated products are impractical or higher performance is required. These systems consist of dimmer cabinets and control stations, typically connected with low-voltage control wires (Fig. 10).

Dimming ballasts: variable output ballasts integrate dimming capability into fluorescent (see Fig. 11) and HID (see Fig. 12) ballasts so that they can dim the lamps according to manual, scheduled, or event-based input. An example of manual input is giving each occupant personal dimming control of his or her lighting system. An example of scheduled input is dimming the lamps across areas of a facility at preset times of day for demand control. An example of event-based input is daylight harvesting, in which a photocell is used to measure light levels, and the ballast dims the lamps to maintain a preset light level based on whether ample daylight is available.

Programmed-start ballasts: most available dimming ballasts for fluorescent lamps are rapid-start electronic ballasts or programmed-start electronic ballasts. Programmed-start ballasts are of interest with or without dimming capability. They are rapid-start ballasts that

Source: From Lighting Controls Association (see Ref. 2).

preheat the electrodes more accurately to minimize damage to the electrodes during the startup process (according to a program), and therefore can optimize lamp life. While supplying the preheat voltage, the ballast minimizes the lamp voltage, thereby reducing glow current during this phase with its associated degrading effect on lamp life. As a result, programmed-start ballasts can provide up to 100,000 starts, ideal for applications where the lamps are frequently switched, such as spaces with occupancy sensors.

Integrated lighting control systems consist of manual or automatic components designed to control compatible

dimming ballasts. They can be interfaced with other microprocessor-based centralized lighting control systems or building automation systems. These systems can perform all of the functions that are important to energy optimization. They can sense conditions in each area or zone and control lighting to yield maximum energy efficiency without affecting visual comfort or other conditions (Fig. 13).

Microprocessor-based centralized programmable lighting control: a microprocessor-based centralized programmable lighting control system is basically a microprocessor-based centralized controller. Although it

Fig. 12 HID dimming ballast. HID dimming ballasts are relatively new and are growing in popularity.
Source: From Advance.

is designed principally for lighting, it is capable of handling other loads. Photocells and other controls can be integrated into the system.

Microprocessor-based programmable controllers can be integrated into networked lighting control systems that allow schedules and other programmable functions to be entered and then changed from a central operator console. Networked systems also allow input from devices such as master switches, photocells, occupancy sensors, telephones, or load-shed contacts to control relays or dimmers. In addition, the network allows the central collection of operating data and status information.

The typical networked control system shown in Fig. 14 provides automated lighting control for applications ranging from a small office building to a mall to an industrial complex. Each of the distributed control panels has standalone automation capability. The network links these controllers to a central operator terminal (PC). Besides supporting such features as telephone control and distributed master switching, these systems can provide energy management data. Providing networked lighting controls also ensures that the lighting can be effectively integrated with other building controls (controlling security, etc.) to provide full intelligent lighting operation.

Building automation systems: building automation controls generally are microcomputer- or minicomputer-based systems that are capable of controlling lighting systems as well as HVAC, security, and fire safety systems.

EVALUATING LIGHTING CONTROL OPTIONS

Once the general type of control system has been decided upon, the next step is specifying the specific control devices. In order to do so, it is essential to establish criteria for evaluating options. Some of the key criteria to consider are given below.

Cost-effectiveness: lighting controls that reduce energy consumption and/or reduce demand are an investment in profitability. Control options should be evaluated based on initial installed cost vs operating cost savings to determine return on investment and the payback period. Options that generate the highest return on investment and meet other selection criteria are more desirable.

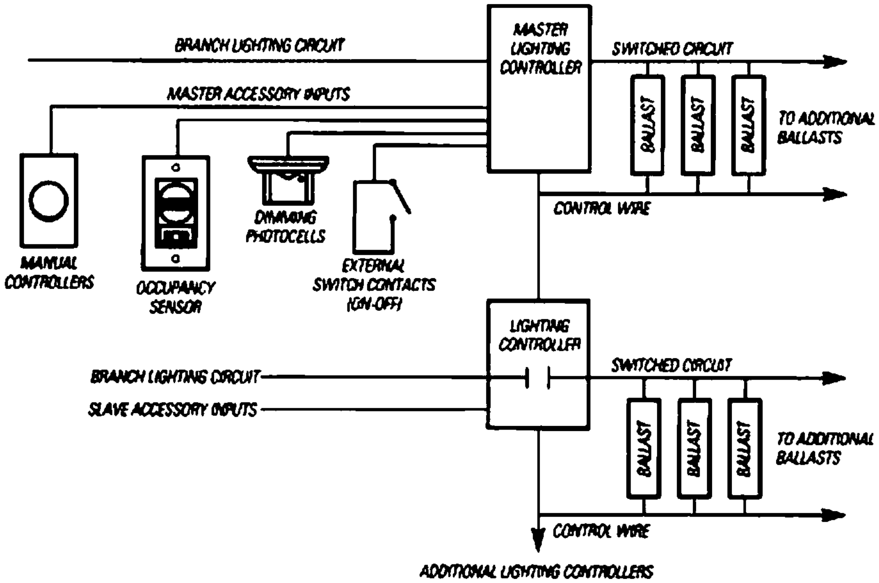

Fig. 13 Integrated lighting control system.
Source: From Lighting Controls Association (see Ref. 2).

Inv–Light

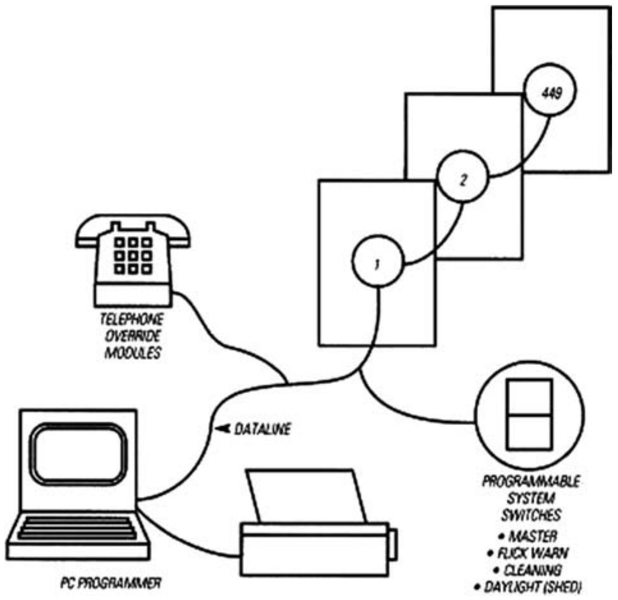

Fig. 14 Networked intelligent panels.
Source: From Lighting Controls Association (see Ref. 2).

Adaptability: for projects in existing facilities, lighting controls should be evaluated based on how well they can be adapted to the facility, and how advantageous they will be. For example, can the new control system be interfaced existing local controls, or will the controls have to be replaced? If daylight harvesting is of interest, is there sufficient daylight to warrant it? Adaptability applies not only to applying controls to existing spaces; but also to ensuring, in both existing spaces and new construction, that the control system is scalable to future space use and potential advances in technology.

Flexibility: controls can be evaluated based on the degree of flexibility required from the lighting system, which in turn is based on how the space is used. In a gymnasium, for example, a variety of activities can occur, from sporting events to assemblies and plays. A flexible lighting system enabled by appropriate controls can respond to all of these uses.

Maintainability: maintainability refers to the ease with which a system is maintained, something determined through evaluation of two principal factors: (1) in-house maintenance support through training programs and manuals, and (2) the availability of professionally trained maintenance persons employed, licensed, or authorized by the manufacturer.

Wiring diagrams of the system also are essential during maintenance procedures; someone who understands the diagrams must be available. Do not assume that a given manufacturer can always provide effective maintenance on a timely basis. Check references to determine how satisfied other users of the proposed system are with the maintenance services provided. Key concerns in this regard are completeness of preventive maintenance, responsiveness and capability of outside maintenance, and the availability of a service maintenance agreement.

Reliability: reliability relates to how well the system performs and the way in which it performs. System performance can be determined primarily by talking with other users of the system. They can relate how often breakdowns occur and the time required to restore equipment to its pre-failure condition. Most modern controls are highly reliable.
