KNM-BC 1 Site Chemeron. Locality EAGRU site J.M. 85/BPRP#2. Surface/in situ Surface. Date of discovery 1965. Finder John Kimengich. Unit “The fossil was found weathered out on the surface of an exposure of the Upper Fish Beds” (Martyn and Tobias 1967, p. 478). Horizon Approximately 2.4 m above the Lower Tuffs (Deino and Hill 2002, p. 143 and Fig. 2). Bed/member Upper Fish Beds. Formation **Chemeron Formation**. Group N/A. Nearest overlying dated horizon KAP-3 lapilli. Nearest underlying dated horizon ALD86-1B “near the top of the Lower Tuffs” (Deino and Hill, 2002, Table 1a, p. 145). Geological age Between 2.456 ± 0.006 and 2.393 ± 0.013 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved partial right temporal bone. Announcement Martyn and Tobias 1967. Initial description Martyn and Tobias 1967. Photographs/line drawings and metrical data Martyn and Tobias 1967, Hill et al. 1992, Sherwood et al. 2002, Lockwood et al. 2011. Detailed anatomical description N/A. Initial taxonomic allocation Hominidae *gen. et sp. indet.* Taxonomic revisions *Australopithecus boisei* (Tobias 1991b), *Homo sp. indet.* (Hill et al. 1992), *Homo rudolfensis* (Wood 1999), *Homi-*

nini gen. et sp. indet. (Lockwood et al. 2011). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Transitional hominin. Significance This securely dated isolated temporal includes several morphological traits said to align it with *Homo* (Sherwood et al. 2002). However, Lockwood et al.’s (2011) morphometric and phylogenetic study of the specimen found ambiguous phenetic affinities and little evidence for a cladistic relationship with *Homo*, echoing the original finding of Martyn and Tobias (1967). Location of original **National Museums of Kenya**, Nairobi, Kenya.

KNM-BK Prefix for fossils accessioned at the Kenya National Museum (now **National Museums of Kenya**) that derive from sites in the Baringo region, Kenya, that are in the Kaphthurin Formation (e.g., **KNM-BK 8518**). *See also* **Kaphthurin Formation**; **National Museums of Kenya**.

KNM-CH Prefix for fossils accessioned at the Kenya National Museum (now **National Museums of Kenya**) that derive from sites in the Baringo region, Kenya (e.g., Chesowanja), that are in the Chemoigut Formation (e.g., **KNM-CH 1**). *See also* **Chemoigut Formation**; **National Museums of Kenya**.

KNM-CH 1 Site Chesowanja. Locality Area 2. Surface/in situ Surface. Date of discovery 1970. Finders N/A. Unit It was described as coming from “yellow marls” that “overly the green silts in the west” in Carney et al. (1971), but Bishop et al. (1971, p. 205) suggest it was recovered from a “grey tuffaceous grit.” Horizon N/A. Bed/member N/A. Formation **Chemoigut Formation**. Group N/A. Nearest overlying dated horizon Chesowanja basalt. Nearest underlying dated horizon Unknown. Geological age $>1.42 \pm 0.07$ Ma. Developmental age Sub-adult. Presumed sex Female. Brief anatomical description The specimen consists of a partial face, part of the frontal bone, and the anterior part of the base of a hominin cranium. The preserved teeth in the facial fragment include the right C-M¹. Announcement Carney et al. 1971. Initial description Carney et al. 1971. Photographs/line drawings and metrical data Carney et al. 1971. Detailed anatomical description N/A. Initial taxonomic allocation “Late robust australopithecine.” Taxonomic revision *Australopithecus boisei* (Szalay 1971). Current conventional taxonomic allocation *Paranthropus*

boisei. Informal taxonomic category Megadont archaic hominin. Significance The generally massive build of the face, the absolute and relative size of the dentition and details of facial morphology were all judged to be characteristic of *P. boisei* (Carney et al. 1971). However, when they compared KNM-CH 1 with OH 5 Carney et al. (1971) interpreted the greater postorbital breadth and the apparent absence of temporal ridges in KNM-CH 1 as evidence that it sampled "...a population of evolved robust australopithecines, most likely descended from *A. boisei*" (*ibid*, p. 513). Szalay (1971) and others were not persuaded that the cranial capacity of KNM-CH 1 was large, nor were they convinced that its morphology departed from that of *P. boisei*. The KNM-CH 1 cranium is now more usually interpreted (e.g., Howell 1978b, Wood 1991) as a small-bodied probably female member of *P. boisei*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-CH 304 Site Chesowanja. Locality Area 2. Surface/in situ Surface. Date of discovery 1978. Finders Bernard Ngeneo and Wambua Mangao. Unit The five cranial vault fragments were found in two separate scatters, 15 m apart. The fragments most likely came from the same "silting-up channel" in "clayey silts" that yielded the fauna and artifacts at the GnJi 1/6 "burnt clay" site. Horizon N/A. Bed/member N/A. Formation Chemoigut Formation. Group N/A. Nearest overlying dated horizon Chesowanja basalt. Nearest underlying dated horizon Unknown. Geological age $>1.42 \pm 0.07$ Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description The specimen consists of five cranial vault fragments (A–E). They include parts of the occipital (A), the parietals (B and D), and the temporal (C) bone(s). Announcement Gowlett et al. 1981. Initial description Gowlett et al. 1981. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions None. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Although KNM-CH 304 consists of just a few fragments of a calotte the nature and location of the ectocranial cresting on the occipital bone, the presence of *striae parietalis*, and the evidence for an **occipito-marginal system** of cranial venous sinuses and the geological age of the

specimen all point to it belonging to *P. boisei*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER Prefix for fossils accessioned at the Kenya National Museum (now **National Museums of Kenya**) that derive from a series of sites that used to be known as East Rudolf, and which are now referred to informally as **Koobi Fora** (e.g., KNM-ER 3733). *See also* **Koobi Fora**; **National Museums of Kenya**.

KNM-ER 406 (NB: Referred to as FS-158 when announced and later given a "KNM-ER" number) Site Koobi Fora (Ileret). Locality Area 10. Surface/in situ Surface. Date of discovery 1969. Finder Richard Leakey. Unit N/A. Horizon N/A. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age $c.1.7$ Ma. Developmental age Adult (but some cranial vault sutures are unfused). Presumed sex Male. Brief anatomical description Nearly complete but edentulous cranium. Most of the surface bone is missing from the alveolar processes and surface bone has also been lost from the malar region and the underside of the sphenoid. Endocranial volume 510 ± 10 cm³ (Holloway 1983c). Announcement Leakey 1970. Initial description Leakey et al. 1971. Photographs/line drawings and metrical data Leakey et al. 1971, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions *Paranthropus boisei*. Current conventional taxonomic allocation *P. boisei*. Informal taxonomic category Megadont archaic hominin. Significance Two mandibular fragments (KNM-ER 403 and 404) and a poorly preserved palate (KNM-ER 405) had suggested the presence of *P. boisei* at Koobi Fora, but the discovery of KNM-ER 406 confirmed it. It conforms to the same basic **bauplan** as OH 5 (a modest-sized neurocranium associated with a large, wide, orthognathic face) but it also showed morphological differences in facial and ectocranial morphology. These differences, and the ones between it and **KNM-ER 407** and **732**, helped researchers establish the types of intraspecific variation to be expected within a sexually dimorphic megadont archaic early hominin taxon. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 407 (NB: Referred to as FS-210 when announced and later given a “KNM-ER” number) Site Koobi Fora (Ileret). Locality Area 10. Surface/in situ Surface. Date of discovery 1969. Finder Mwongela Muoka. Unit N/A. Horizon N/A. Bed/member KBS Member. Formation **Koobi Fora Formation**. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon **KBS Tuff**. Geological age *c.*1.85 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Well-preserved presumed small-bodied female adult calvaria in three pieces that preserve most of both parietals and the posterior two-thirds of the frontal, the base, and sides of the cranial vault and the left petrous temporal. Endocranial volume 506 cm³ (Falk and Kasinga 1983), 510 cm³ (Holloway 1983c). Announcement Leakey 1970. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Australopithecus boisei* (Leakey 1976a). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The cranial base is smaller than that of KNM-ER 406 but otherwise it conforms to the same basic **bauplan**. Unlike **KNM-ER 406** the vault has no ectocranial crests. The overall resemblance to KNM-ER 406 along with the differences between it and KNM-ER 406 suggested an attribution to *P. boisei*, but as a small-bodied presumed female. The difference in ectocranial morphology between it and KNM-ER 406 helped researchers establish the type of sex-related intraspecific variation to be expected within a sexually dimorphic megadont archaic early hominin taxon. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 732.

KNM-ER 732 Site Koobi Fora (Ileret). Locality Area 10. Surface/in situ Surface. Date of discovery 1970. Finder Harrison Mutua. Unit N/A. Horizon N/A. Bed/member KBS Member. Formation **Koobi Fora Formation**. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon **KBS Tuff**. Geological age *c.*1.7 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Well-preserved cranium of a presumed small-bodied adult female, preserving facial morphology and dental evidence. Preserved portions include the right side of the face, including the alveolar

process from the right canine alveolus to the maxillary tuberosity, part of the right side of the basicranium, the frontal, and parts of both parietals. Most of the surface bone is missing from the alveolar process and the only tooth crown preserved is the lingual half of the P⁴. Surface bone has also been lost from the vault and mastoid region. Endocranial volume 500 cm³ (Holloway 1983c). Announcement Leakey 1971. Initial description Leakey et al. 1972. Photographs/line drawings and metrical data Leakey et al. 1972, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Australopithecus sp. indet.* Taxonomic revisions *Australopithecus boisei* (Leakey 1973b), *Australopithecus africanus* (Wolpoff 1978a), *Paranthropus boisei* (Robinson 1960). Current conventional taxonomic allocation *P. boisei*. Informal taxonomic category Megadont archaic hominin. Significance Conforms to the same frontal and facial **bauplan** as **OH 5** (modest-sized neurocranium with prominent glabella associated with an orthognathic face widest in its middle part) but it shows morphological differences in facial and ectocranial morphology that helped researchers establish the types of sex-related intraspecific variation to be expected within a sexually dimorphic megadont archaic early hominin taxon. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 407.

KNM-ER 736 Site Koobi Fora. Locality Area 103. Surface/in situ Surface. Date of discovery 1970. Finder Meave Leakey. Unit N/A. Horizon A6+7m. Bed/member KBS Member. Formation **Koobi Fora Formation**. Group Omo Group. Nearest overlying dated horizon Lower Koobi Fora Tuff (1.48 Ma). Nearest underlying dated horizon **KBS Tuff**. Geological age *c.*1.6 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description The shaft of a left femur, broken proximally just distal to the lesser trochanter and distally proximal to the divergence of the supracondylar lines. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Leakey et al. 1972, Day 1976, Leakey et al. 1978. Detailed anatomical description Leakey et al. 1972. Initial taxonomic allocation *Homo sp.* Taxonomic revisions of *Australopithecus* (Leakey et al. 1972), *Homo* (Day 1976), *Homo erectus* (Walker 1993). Current conventional taxonomic allocation *Homo erectus* or *Homo ergaster*. Informal

taxonomic category Pre-modern *Homo*. Significance This massive platymeric femoral shaft has a clearly developed *linea aspera* and for these reasons it is now generally attributed to *Homo* as *H. erectus*. However, if *Homo rudolfensis* proves to be valid taxon, then it is conceivable it could belong to that taxon. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 737 Site Koobi Fora. Locality Area 103. Surface/in situ Surface. Date of discovery 1970. Finder Richard Leakey. Unit N/A. Horizon LKF-1m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Lower Koobi Fora Tuff (1.48 Ma). Nearest underlying dated horizon KBS Tuff. Geological age *c.*1.5 Ma. Developmental age Late adolescent or adult. Presumed sex Unknown. Brief anatomical description A left femur, lacking the greater and lesser trochanter, head, most of the neck, and the condyles. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Day and Leakey 1973, Leakey et al. 1978. Detailed anatomical description Day and Leakey 1973. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Homo erectus* (Day and Leakey 1973). Current conventional taxonomic allocation *H. erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance The shaft of the KNM-ER 737 femur is platymeric and it bears a clearly defined *linea aspera* and for these reasons it is now generally attributed to *Homo* as *H. erectus*. However, if *Homo rudolfensis* proves to be valid taxon, then it is conceivable that it could belong to that taxon. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 738A Site Koobi Fora. Locality Area 105. Surface/in situ Surface. Date of discovery 1970. Finder Bernard Ngeneo. Unit N/A. Horizon KBS CC. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age *c.*1.87 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Two fragments of a proximal left femur. The proximal fragment preserves the head, neck, and lesser trochanter; the distal fragment preserves a portion of the medial half of the diaphysis. The shaft bears a trace of a fracture callus. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Leakey

1971, Leakey et al. 1972. Detailed anatomical description Leakey et al. 1972, Walker 1973. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei* or *Homo habilis*. Informal taxonomic category Megadont archaic or transitional hominin. Significance One of the first femora to be recovered from Koobi Fora that differed from the femoral morphology associated with later *Homo* and resembled the femora of *Paranthropus robustus* in that the femoral neck shows the same marked anteroposterior flattening as that seen in the two proximal femora from Swartkrans, SK 82 and SK 97. This is one of several proximal femoral fragments that fuelled the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence from OH 62 suggests that much the same morphology is also seen in *H. habilis* in which case this and other similar femora could belong to *H. habilis*. It is one of the earliest examples of a healed fracture in a hominin long bone. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 739 Site Koobi Fora. Locality Area 1. Surface/in situ Surface. Date of discovery 1970. Finder Harrison Mutua. Unit N/A. Horizon CHA-18m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon Lower Ileret Tuff. Geological age *c.*1.45 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A right humerus lacking its head and the greater and lesser tubercles. The shaft is thick and the muscular attachments are highly developed. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Leakey 1971, Leakey et al. 1978. Detailed anatomical description Leakey et al. 1972, McHenry 1973. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions *Homo rudolfensis* (Lague and Jungers 1996). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance KNM-ER 739 is one of the best-preserved humeri from Koobi Fora and differs strikingly from humeri of *Homo sapiens* in having a pronounced brachioradialis flange and a deltopectoral crest. Visual inspection (Senut and Tardieu 1985) and the results of a broad comparative analysis (Lague and Jungers 1996) of distal humerus shape variation linked this specimen with KNM-ER 1504, which

shares morphological similarities with KNM-ER 3735 (Leakey et al. 1989), the fragmentary partial skeleton attributed to *H. habilis*. Based on its similarity with humeri of early *Homo* and its large size, Lague and Jungers (1996) suggest that KNM-ER 739 be tentatively attributed to *H. rudolfensis* whereas most authors have considered it to be most likely attributable to *P. boisei* (Leakey 1971, McHenry 1973, Day 1976, Howell 1978b). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 741 Site Koobi Fora. Locality Area 1. Surface/in situ Surface. Date of discovery 1970 Finder Mary Leakey. Unit Collection unit 5. Horizon ILN+10m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon Lower Ileret Tuff. Geological age c.1.45 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Proximal end and adjacent shaft of a left tibia. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Leakey et al. 1972, 1978. Detailed anatomical description Leakey et al. 1972. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions *Homo erectus* (Walker 1993, Brown et al. 2001). Current conventional taxonomic allocation *H. erectus* or *Hominini gen. et sp. indet.* Informal taxonomic category N/A. Significance One of several well-preserved tibiae from Koobi Fora, KNM-ER 741 has been attributed to *H. erectus* based on a comparison (Walker 1993) with KNM-WT 15000 (a juvenile associated skeleton attributed to early *H. erectus* or *H. ergaster*) but because so little is known about the tibial morphology of early hominins other than *Australopithecus afarensis* it may be premature to rule out the possibility that it belongs to *Homo habilis* or to *Paranthropus boisei*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 803 Site Koobi Fora. Locality Area 8. Surface/in situ Surface. Date of discovery 1971. Finder Meave Leakey. Unit N/A. Horizon BPT+1m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon N/A. Geological age c.1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A partial

associated skeleton of an adult comprising the lower left C, right I¹, a fragment of the shaft of the left ulna, a fragment of a radius shaft, an abraded base of a metacarpal, a fragment of a phalangeal shaft, a fragment of a proximal phalanx (possibly II or III), a partial shaft of the left femur, a partial shaft of the left tibia, a fragment of the medial condyle of the left tibia, fragments of the left and right fibula, a fragmentary left talus, left metatarsal III except its head, the base of left metatarsal V, a fragment of the shaft of proximal pedal phalanx I, two intermediate pedal phalanges (possibly II and III), and a terminal toe phalanx. Announcement Leakey 1971. Initial description Leakey 1971. Photographs/line drawings and metrical data Day and Leakey 1973, Leakey et al. 1978. Detailed anatomical description Day and Leakey 1973. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Homo erectus* (Wood 1976, 1991, Walker 1993, Ruff and Walker 1993). Current conventional taxonomic allocation *H. erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance KNM-ER 803 is one of the few associated skeletons that has been attributed to *H. erectus* or *H. ergaster*. However, whereas the C and I¹ are large enough to suggest that KNM-ER 803 does not represent *Paranthropus boisei*, there is not sufficient taxonomically diagnostic evidence (e.g., there is no proximal femur) to rule out its attribution to *Homo habilis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 813 Site Koobi Fora. Locality Area 104. Surface/in situ Surface. Date of discovery 1971. Finder Bernard Ngeneo. Unit N/A. Horizon A2-4m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age c.1.78 Ma. Developmental age Unknown. Presumed sex Unknown. Brief anatomical description The right talus and a fragment of the distal shaft of the right tibia apparently from a single individual. Announcement Leakey 1972. Initial description Leakey and Wood 1973. Photographs/line drawings and metrical data Wood 1974, Leakey et al. 1978. Detailed anatomical description Leakey and Wood 1973, Gebo and Schwartz 2006. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo erectus* or *Homo ergaster* (Tobias 1991b), *Homo rudolfensis* (Wood 1992). Current

conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The morphological differences between OH 8 and KNM-ER 813 suggest these two fossil tali do not belong to the same species (Wood 1974, Gebo and Schwartz 2006). If OH 8 belongs to *Homo habilis*, then KNM-ER 813 (together with Omo 323-76-898) may belong to either *H. rudolfensis* or to *H. erectus*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 815 Site Koobi Fora. Locality Area 10. Surface/in situ Surface. Date of discovery 1971. Finder Andrew Hill. Unit Collection unit 4. Horizon N/A. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age 1.77 ± 0.10 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A weathered proximal femur retaining its neck, base of the lesser trochanter, and the subtrochanteric diaphysis. Announcement Leakey 1972. Initial description Leakey and Walker 1973. Photographs/line drawings and metrical data Leakey and Walker 1973, Leakey et al. 1978. Detailed anatomical description Leakey and Walker 1973, Walker 1973. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The femoral neck shows the same marked anteroposterior flattening seen in the two proximal femora from Swartkrans, SK 82 and SK 97, attributed to *Paranthropus robustus*. This is one of the proximal femur fragments that fuelled the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence from OH 62 suggests that much the same morphology is also seen in *Homo habilis*, in which case this and other similar femora could belong to *H. habilis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 820 Site Koobi Fora (Ileret). Locality Area 1. Surface/in situ *In situ*. Date of discovery 1971. Finder Harrison Mtua. Unit N/A. Horizon N/A. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon N/A. Geological

age *c.*1.6 Ma. Developmental age Juvenile (both dm_1 and dm_2 are heavily worn). Presumed sex Unknown. Brief anatomical description Well-preserved juvenile mandible. The right and left sides of the corpus, the base of the left ramus, the crowns and roots of the deciduous canines and molars, the crowns and roots of the permanent incisors and M_1 , the germs of the M_2 , and the crypts for the M_3 s. Announcement Leakey 1972. Initial description Leakey and Wood 1973. Photographs/line drawings and metrical data Leakey and Wood 1973, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo ergaster* (Groves and Mazák 1975). Current conventional taxonomic allocation *Homo erectus* or *H. ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance Along with KNM-ER 992, KNM-ER 820 provided the first evidence of a *H. erectus*-like mandibular morphology that was in several ways more primitive than that seen in the *H. erectus* hypodigm from Java and Zhoukoudian. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 992.

KNM-ER 992 Site Koobi Fora (Ileret). Locality Area 3. Surface/in situ Surface. Date of discovery 1971. Finder Bernard Ngeneo. Unit N/A. Horizon ILN+10m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.52 Ma. Developmental age Subadult (both M_3 s show occlusal wear, but the roots of both the M_3 s are incomplete with wide-open apices). Presumed sex Unknown. Brief anatomical description Mandible broken close to the midline but otherwise well preserved. It includes both sides of the corpus, part of the right and much of the left ramus, and the crowns and roots of the canines to the M_3 s on both sides. Announcement Leakey 1972. Initial description Leakey and Wood 1973. Photographs/line drawings and metrical data Leakey and Wood 1973, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo ergaster* (Groves and Mazák 1975). Current conventional taxonomic allocation *Homo erectus* or *H. ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance This mandible was made the holotype of *H. ergaster*. Along with KNM-ER 820, KNM-

ER 992 provided the first evidence of a *H. erectus*-like mandibular morphology that was in several ways more primitive than that of *H. erectus* from Java and Zhoukoudian. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 820.

KNM-ER 993 Site Koobi Fora. Locality Area 1. Surface/in situ Surface. Date of discovery 1971. Finder Kamoya Kimeu. Unit Collection unit 5. Horizon ILN+10m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon Lower Ileret Tuff. Geological age *c.*1.45 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right femur lacking its proximal end. Announcement Leakey 1972. Initial description Leakey 1972. Photographs/line drawings and metrical data Leakey 1972, Leakey and Walker 1973, Leakey et al. 1978. Detailed anatomical description Leakey and Walker 1973, Walker 1973. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The femoral shaft is moderately robust, platymeric in the proximal portion but more circular in cross-section distally owing to the development of a pilaster. Although the femoral condyles are abraded, the knee is highly valgus with a bicondylar angle of about 15° (from vertical) compared with mean modern human values of between 8.5° and 10.7° (Tardieu and Trinkaus 1994). This suggests a substantial inter-acetabular distance and thus wide hips for this individual. While it has been attributed to *P. boisei*, the lack of associated craniodental fossils leaves its attribution open to question. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 999 Site Koobi Fora (Ileret). Locality Area 6A. Surface/in situ Surface. Date of discovery 1971. Finder Kamoya Kimeu. Unit G. Horizon Collection unit 6, approximately 9–11 m above the bottom of the Guomde Formation (Leakey et al. 1978). Bed/member The specimen likely derives from undifferentiated Middle–Late Pleistocene sediments above the Chari Member. Formation Likely unassigned strata between the Koobi Fora Formation and the Galana Boi Formation *sensu stricto*. Group N/A. Nearest overlying

dated horizon Galana Boi Formation. Nearest underlying dated horizon Chari tuff. Geological age Bräuer et al. (1997) reported direct uranium-series dating ages for the specimen of 301 ka (+infinity/–96 ka) by uranium–thorium and >180 ka by uranium–protactinium. Developmental age Adult. Presumed sex Male, based on its large size. Brief anatomical description A massive left femur lacking most of the distal epiphysis and with substantial damage to the greater trochanter and head. The femur has a high neck–shaft angle, a pronounced *linea aspera*, but a moderate **pilastric index**. The estimated bicondylar length of the complete bone is between 470 and 500 mm. Announcement Day and Leakey 1974. Initial description Day and Leakey 1974. Photographs/line drawings and metrical data Leakey et al. 1978, Trinkaus 1993. Detailed anatomical description Day and Leakey 1974, Trinkaus 1993. Initial taxonomic allocation *Homo*. Taxonomic revisions Late archaic *Homo sapiens*, anatomically modern *Homo sapiens*, *Homo helmei*. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern *Homo*. Significance Despite its geological antiquity, the femur is essentially modern human-like in its anatomy, supporting speculation that a modern human-like lower-limb morphology had emerged in Africa by *c.*300 ka. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1463 Site Koobi Fora. Locality Area 1A. Surface/in situ Surface. Date of discovery 1972. Finder Kamoya Kimeu. Unit Collection unit 5. Horizon MFB+1m. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon Lower Ileret Tuff. Geological age *c.*1.4 Ma. Developmental age Adult. Presumed sex Unknown, possibly male based on size. Brief anatomical description The neck and intact shaft of a right femur; the head, the greater and lesser trochanters, and the condyles are missing. Announcement Leakey 1973. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Leakey et al. 1978. Detailed anatomical description Day et al. 1976. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The femoral neck shows the same

marked anteroposterior flattening as that seen in the two proximal femora from Swartkrans, SK 82 and SK 97, attributed to *Paranthropus robustus*, so this is one of the proximal femur fragments that fuelled the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence from OH 62 suggests that the same morphology is also seen in *Homo habilis*, in which case this and other similar femora could belong to *H. habilis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1464 Site Koobi Fora. Locality Area 6A. Surface/in situ Surface from the same locality as KNM-ER 801, 802, 1171, 1816, 1823, 1824, 1825, and 3737. Date of discovery 1972. Finder Peter Nzube Mutiwa. Unit N/A. Horizon LIL-8m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Lower Ileret Tuff. Nearest underlying dated horizon KBS Tuff. Geological age *c.*1.7 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved right talus. Announcement Leakey 1973. Initial description Leakey 1973. Photographs/line drawings and metrical data Day et al. 1976, Leakey et al. 1978, Gebo and Schwartz 2006. Detailed anatomical description Day et al. 1976, Gebo and Schwartz 2006. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions *Incertae sedis* (Day et al. 1976, Gebo and Schwartz 2006), *Australopithecus boisei* (Grausz et al. 1988). Current conventional taxonomic allocation *Hominini gen. et sp. indet.* Informal taxonomic category N/A. Significance This enigmatic talus shows pronounced trochlear wedging, a short neck, and a strong lateral flange suggesting a tibiofibular articulation different from that of modern humans. It does not clearly align with either specimens attributed, rightly or wrongly, to *Paranthropus* or to *Homo aff. erectus*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1465 Site Koobi Fora. Locality Area 11. Surface/in situ Surface. Date of discovery 1972. Finder Kamoya Kimeu. Unit Collection unit 5. Horizon Approximately MFB. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.42 Ma. Developmental age Unknown. Presumed sex Unknown. Brief anatomical description Two frag-

ments of a proximal femur, a fragment of the shaft and neck missing both trochanters, and a small portion of the head. Announcement Leakey 1973. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976. Detailed anatomical description Day et al. 1976. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The femoral neck shows the same marked anteroposterior flattening as that seen in the two proximal femora from Swartkrans, SK 82 and SK 97, attributed to *Paranthropus robustus*, so this is one of the proximal femur fragments that fuelled the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence from OH 62 suggests that the same morphology is also seen in *Homo habilis*, in which case this and other similar femora could belong to *H. habilis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1470 Site Koobi Fora (Karari Ridge). Locality Area 131. Surface/in situ Surface. Date of discovery 1972. Finder Bernard Ngeneo. Unit N/A. Horizon KBS-36m. Bed/member upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.88–1.95 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Cranium lacking most of the base; the base was finely fragmented when discovered. The reassembled cranium comprises separate calvarial and facial components; there is a join at nasion but it is not possible to determine the facial angle with any reliability. Bromage et al. (2008) used Enlow's 90° "PM-NHA rule" (Enlow and Azuma 1975) to suggest the face was most likely more prognathic than in the original reconstruction. Most of the surface bone of the specimen is missing and the specimen has suffered from plastic deformation which according to Walker (1981, p. 203) has depressed the parietotemporal suture on the right side so that "the right temporal and porion have been carried downwards and forwards." Endocranial volume 752 cm³ (Holloway 1983c). Bromage et al. (2008) suggest their more prognathic reconstruction of KNM-ER 1470 is not compatible with this estimate, but Holloway's methodology is

well tried and it is difficult to see how the endocranial volume could be as low as the value (625 cm³) predicted by the regression used in Bromage et al. (2008) and in fact the latter authors suggest a more reasonable endocranial volume estimate of 700 cm³. Announcement Leakey 1973c. Initial description Day et al. 1975. Photographs/line drawings and metrical data Day et al. 1975, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo habilis* (Leakey 1976a), *Pithecantropus rudolfensis* (Alexeev 1986), *Homo rudolfensis* (Groves 1989, Wood 1992). Current conventional taxonomic allocation *H. habilis* or *H. rudolfensis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The cranial vault is similar in shape to that of *H. habilis*, but larger. The face is more orthognathic than that of *H. habilis* and it is widest in the midface, not in the upper face as in the case in *H. habilis*. Holloway (1983c) suggested the endocranial morphology of KNM-ER 1470 is more *Homo*-like than the endocasts of australopiths. It is either a large-bodied presumed male of an inclusively interpreted *H. habilis* (in which case *H. rudolfensis* is a junior synonym of *H. habilis*) or it is the **lectotype** of *H. rudolfensis*, a second species of early *Homo*. Walker (1976) was one of the first to point out the relatively primitive nature of the shape of the calvaria (e.g., widest part of the vault is low down). Similar cranial vault morphology is seen in KNM-ER 1590 and similar upper facial and endocast morphology is seen in the KNM-ER 3732 calotte. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1471 Site Koobi Fora. Locality Area 131. Surface/in situ Surface. Date of discovery 1972. Finder Bernard Ngeneo. Unit Collection unit 3. Horizon KBS-27m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age c.1.88–1.95 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Proximal portion of a right tibia with abrasion of the cortex below the condyles and above the tibial tuberosity. Announcement Leakey 1973. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Leakey et al. 1978. Detailed anatomical description Day et al. 1976. Initial taxonomic allocation *Australopithecus*.

Taxonomic revisions N/A. Current conventional taxonomic allocation Hominini *gen. et sp. indet.* Informal taxonomic category Archaic hominin. Significance The initial attribution to *Australopithecus* (Leakey 1973) implies that its morphology departs sufficiently from the morphology seen in modern humans to suggest it may belong to *Paranthropus boisei*. However, more detailed study is warranted before attributions to other contemporaneous hominin taxa can be ruled out. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1472 Site Koobi Fora. Locality Area 131. Surface/in situ Surface. Date of discovery 1972. Finder John Harris. Unit N/A. Horizon KBS-30m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age c.1.88–1.95 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A nearly complete right femur. Announcement Leakey 1973b. Initial description Leakey 1973a. Photographs/line drawings and metrical data Day et al. 1975, Leakey et al. 1978. Detailed anatomical description Day et al. 1975. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo erectus* or *Homo ergaster* (Tobias 1991b), *Homo rudolfensis* (Wood 1992). Current conventional taxonomic allocation *Homo sp.* Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The most notable feature of KNM-ER 1472 (and KNM-ER 1481) is its overall length, which resembles the femora of later members of the genus *Homo* and contrasts with the relatively short femora of *Australopithecus* taxa (e.g., A.L. 288-1). KNM-ER 1472 (along with KNM-ER 1481) was found geographically close to the cranium KNM-ER 1470 and is more or less the same geological age. Compared with the evidently archaic morphology (i.e., small head, and long, anteroposteriorly flattened neck) of the hominin femora previously recovered at Koobi Fora (e.g., KNM-ER 738A, 815, and 993), KNM-ER 1472 was clearly more modern human-like. Some have suggested that it shares diagnostic morphology with *H. erectus* (Kennedy 1983a), and others have suggested, for no particularly compelling reason other than its **sympatry** and approximate synchronicity with KNM-ER 1470, it should be attributed to

H. rudolfensis (Wood 1992). Ruff's (1995) biomechanical analysis showed that the distinctively mediolaterally broad, platymeric femoral shaft with an inferiorly positioned minimum breadth seen in KNM-ER 1472, KNM-ER 1481, and KNM-WT 15000 can be explained by elevated bending moments resulting from a long femoral neck (especially when combined with a wide inter-acetabular distance). McHenry and Corruccini (1978) used traditional linear data to compare the morphology of early hominin femora, including KNM-ER 1472. Their results showed that among early hominin femora from East and southern Africa, the relatively large femoral head and rounded femoral neck of KNM-ER 1472 (and 1481) were more like those of modern humans and distinct from the smaller femoral heads and anteroposteriorly narrow necks of australopith femora such as KNM-ER 1503, SK 82, and SK 97 (see also Day 1969a, Walker 1973, Wood 1976). Richmond and Jungers (2008) showed that KNM-ER 1472 and 1481 bear a stronger resemblance to femora securely attributed to *Homo* (e.g., KNM-WT 15000, the Berg Aukas I femur) than they do to australopith femora, including A.L. 288-1. Using three-dimensional landmark data in addition to traditional measurements, Harmon (2009) confirmed that KNM-ER 1472 (and 1481) shared these anatomical features, as well as a short greater trochanter, with femora securely attributed to *Homo* (e.g., the Berg Aukas I femur) compared with femora such as KNM-ER 738A, 815, 993, 1503, and 1505. It is for these reasons that most knowledgeable researchers now consider KNM-ER 1472 likely belongs to early African *H. erectus*, or to *H. rudolfensis* (if there is some convincing independent evidence that this taxon has a less archaic femoral morphology than *Homo habilis*). Whatever its ultimate taxonomic allocation, the morphometric evidence from KNM-ER 1472 (and 1481) suggests a pattern of bipedalism virtually identical to that inferred for *H. erectus* had emerged by 1.9 Ma. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1476 Site Koobi Fora. Locality Area 105. Surface/in situ Surface. Date of discovery 1972. Finder Kamoya Kimeu. Unit Collection unit 4. Horizon KBS CC. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.1.87 Ma. Developmental age Adult. Presumed

sex Unknown. Brief anatomical description Three geologically associated hominin lower limb fragments that are presumed to come from the same individual, a left talus (1476A), proximal end of a left tibia (1476B), and fragment of the diaphysis of a right tibia (1476C). Announcement Leakey 1973. Initial description Leakey 1973. Photographs/line drawings and metrical data Day et al. 1976, Leakey et al. 1978. Detailed anatomical description Day et al. 1976, Gebo and Schwartz 2006. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance One of the better-preserved hominin tali from Koobi Fora and one of the few associated with other skeletal elements. Gebo and Schwartz (2006) concluded that KNM-ER 1476 shares distinctive morphology with tali from Kromdraai (TM 1517) and Olduvai Gorge (OH 8) and suggested that they all belong to megadont archaic hominins. However, secure attributions of isolated postcranial remains must be tentative until relevant taxonomically unambiguous associated skeletons are recovered. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1481 Site Koobi Fora. Locality Area 131. Surface/in situ Surface. Date of discovery 1972. Finder John Harris. Unit N/A. Horizon KBS-12m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age c.1.89 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Associated elements of the left lower limb, including a nearly complete femur, proximal tibia, distal tibia, and the distal end of the fibula. Announcement Leakey 1973b. Initial description: Leakey (1973a). Photographs/line drawings and metrical data Day et al. 1975, Leakey et al. 1978, Kennedy 1983a. Detailed anatomical description Day et al. 1975, Kennedy 1983a, Trinkaus 1984. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo erectus* or *Homo ergaster* (Kennedy 1983b, Tobias 1991b), *Homo habilis* (Trinkaus 1984), *Homo rudolfensis* (Wood 1992). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo* or transitional hominin.

Significance The most notable feature of the KNM-ER 1481 femur (KNM-ER 1481A) and the KNM-ER 1472 femur is their overall length, which resembles the femora of later members of the genus *Homo* and contrasts with the relatively short femoral length in *Australopithecus* (e.g., A.L. 288-1). KNM-ER 1481 was found geographically close to the cranium KNM-ER 1470, and is more or less the same geological age. Compared with the evidently archaic morphology (i.e., small head, and long, anteroposteriorly flattened neck) of the hominin femora previously recovered at Koobi Fora (e.g., KNM-ER 738A, 815 and 993), KNM-ER 1481A was clearly more modern-human-like. Some have suggested that it shares diagnostic morphology with *H. erectus* (Kennedy 1983a) and others have suggested, for no particularly compelling reason other than its **sympatry** and approximate synchronicity with KNM-ER 1470, it should be attributed to *H. rudolfensis* (Wood 1992). Ruff's (1995) biomechanical analysis showed that the distinctively mediolaterally broad, platymeric femoral shaft with an inferiorly positioned minimum breadth seen in KNM-ER 1472, KNM-ER 1481, and KNM-ER-WT 15000 can be explained by elevated bending moments resulting from a long femoral neck (especially when combined with a wide inter-acetabular distance). McHenry and Corruccini (1978) used traditional linear data to compare the morphology of early hominin femora, including KNM-ER 1472. Their results showed that among early hominin femora from East and southern Africa, the relatively large femoral head and rounded femoral neck of KNM-ER 1472 (and 1481A) were more like those of modern humans and distinct from the smaller femoral heads and anteroposteriorly narrow necks of australopith femora such as KNM-ER 1503, SK 82, and SK 97 (see also Day 1969a, Walker 1973, Wood 1976). Richmond and Jungers (2008) recently showed that KNM-ER 1472 and 1481A bear a stronger resemblance to femora securely attributed to *Homo* (e.g., KNM-WT 15000, the Berg Aukas I femur) than they do to australopith femora, including A.L. 288-1. Using three-dimensional landmark data in addition to traditional measurements, Harmon (2009) used three-dimensional landmark data to confirm that KNM-ER 1481A and 1472 shared these anatomical features, as well as a short greater trochanter, with femora such as KNM-ER 738A, 815, 993, 1503, and 1505. It is for these reasons

that most knowledgeable researchers now consider KNM-ER 1481 most likely belongs to early African *H. erectus* or to *Homo rudolfensis* (if there is some convincing independent evidence that this taxon has a less archaic femoral morphology than *H. habilis*). Whatever its ultimate taxonomic allocation, the morphometric evidence from KNM-ER 1481 (and 1472) suggests a pattern of bipedalism virtually identical to that of *H. erectus* had emerged by 1.9 Ma. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1482 Site Koobi Fora (Karari Ridge). Locality Area 131. Surface/in situ Surface. Date of discovery 1972. Finder H. Muluilu. Unit N/A. Horizon KBS-33m. Bed/member upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age c.1.88–1.95 Ma. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Mandibular body preserved from the distal root of the M₁ on the right side to an oblique break through the ramus on the left side, plus three dental fragments. Announcement Leakey 1973. Initial description Leakey and Wood 1974. Photographs/line drawings and metrical data Leakey and Wood 1974, Wood 1991. Detailed anatomical description Leakey and Wood 1974, Wood 1991. Initial taxonomic allocation Hominidae *gen. et sp. indet.* Taxonomic revisions aff. *Paraustralopithecus* (Leakey 1974), *Australopithecus boisei* (Howell 1978a, White 1977b), *Australopithecus robustus* (Suwa 1988), *Homo* sp. (Wolpoff 1988), *Homo aethiopicus* (Groves 1989), *Homo sp. indet.* (Wood 1991). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo* or transitional hominin. **Significance** As can be seen from the range of taxa it has been assigned to, KNM-ER 1482 cannot be easily accommodated in any of the existing recognized taxa. However, Wood (1991) suggested that the form of the corpus and the size and shape of the tooth crowns and roots and especially the thickness of the enamel (Beynon and Wood 1986) effectively ruled out its allocation to *Paranthropus boisei*. It most likely belongs to the nexus of specimens that some link with the origins of *Homo*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1500 Site Koobi Fora. Locality Area 130. Surface/in situ Surface. Date of discovery 1972. Finder John Kimengich. Unit N/A. Horizon N/A. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.9 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description An associated skeleton including a clavicle fragment, the glenoid of the left scapula, fragment of left distal humerus shaft, proximal end and shaft fragment of the right radius, proximal end and shaft fragment of the right ulna, left radius shaft fragment, left proximal femur fragment, distal left femur, nearly complete left tibia (proximal half and distal third), distal end and shaft fragment of right tibia, proximal right metatarsal III, and a small fragment of the base of the mandibular corpus. Announcement Leakey 1973b. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Leakey et al. 1978, Wood 1991. Detailed anatomical description Wood 1991, Grausz et al. 1988. Initial taxonomic allocation *Australopithecus sp. indet.* Taxonomic revisions *Australopithecus boisei* (Grausz et al. 1988). Current conventional taxonomic allocation *Paranthropus boisei* or Hominini *gen. et sp. indet.* Informal taxonomic category Megadont archaic or transitional hominin. Significance KNM-ER 1500 is one of the few hominin associated skeletons from Koobi Fora and many interpret it to be a small *P. boisei* individual. This species diagnosis is based on the morphology of the fragment of the base of the mandibular corpus (Grausz et al. 1988), which is robust and has a rounded inferior border. However, while this morphology is consistent with it being a small *P. boisei* individual, it is also consistent with it belonging to whatever taxon the KNM-ER 1802 mandible belongs to (i.e., *Homo rudolfensis* or *Homo habilis*). Whatever species it represents, KNM-ER 1500 does not have enlarged lower limb joints like those of modern humans; instead, it resembles A.L. 288-1 and *Pan troglodytes* in having small lower limb joints relative to the joints of its upper limbs. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1503, 1504, 1505 Site Koobi Fora. Locality Area 123. Surface/in situ Surface. Date of discovery 1972. Finders Maundu Muluila (KNM-ER 1503), M. Mbithi (KNM-ER 1504), and Bernard Ngeneo (KNM-ER 1505). Unit Collection

Unit 4. Horizon C4-5m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.87 Ma (Feibel et al. 2009). Developmental age Adult. Presumed sex Female, based on small size. Brief anatomical description These fossils comprise five well-preserved specimens that may derive from a single individual. KNM-ER 1503 is a proximal femur, KNM-ER 1504 is a small distal humerus, and KNM-ER 1505 comprises a left femoral head and a fragment of the distal shaft of a left femur. Announcement Leakey 1973a. Initial description Leakey 1973a. Photographs/line drawings and metrical data Leakey 1973a, Day et al. 1976, Leakey et al. 1978. Detailed anatomical description Day et al. 1976. Initial taxonomic allocation *Australopithecus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The KNM-ER 1503 proximal femur has a small head and a long, anteroposteriorly compressed neck, the KNM-ER 1504 distal humerus is small, but it has a broad distal shaft and strongly developed medial and lateral epicondyles, and the femoral head of KNM-ER 1505 is small. If these specimens do belong to a single individual, that individual is absolutely small and its proximal femoral morphology resembles that of the two proximal femora from Swartkrans, SK 82 and SK 97, attributed to *Paranthropus robustus*. Thus, KNM-ER 1503 and 1505 are among the proximal femoral fragments that fuelled the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence, albeit less complete, from OH 62 suggests that the same morphology is also seen in *Homo habilis*, in which case this and other similar femora could belong to *H. habilis*. The distal humeral morphology (KNM-ER 1504) resembles that of the large KNM-ER 739 humerus (Leakey 1973a) and differs from other extant hominoid and fossil hominin humeri in having a shape characterized by a more projecting medial epicondyle (associated with a greater biepicondylar width), shallower olecranon fossa, narrower zona conoidea width, smaller minimum anteroposterior trochlear width, wider lateral pillar, and wider medial pillar (Lague and Jungers 1996). No matter what taxon it is eventually assigned to, if the fossils in this group do belong to one individual their size suggests that individual is most likely a female. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1590 Site Koobi Fora (Ileret). Locality Area 12. Surface/in situ Surface. Date of discovery 1972. Finder Bernard Ngeneo. Unit N/A. Horizon Approximately C4+. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Okote Tuff. Nearest underlying dated horizon KBS Tuff. Geological age *c.*1.85 Ma (Feibel et al. 1989), but an alternative, younger, age of 1.8 Ma has been suggested (Brown et al. 2006). Developmental age Immature. Presumed sex Male. Brief anatomical description Cranial vault fragments with associated permanent and deciduous maxillary teeth. The cranial fragments include most of the left and right parietal bones and part of the frontal bone. The associated dentition provides an estimated age at death of 4.0–8.2 years based on a modern human standard and 5.5–6.0 years based on a non-human great ape standard (Smith 1986). Endocranial volume >800 cm³. Announcement Leakey 1973b. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo habilis* (Howell 1978b), *Homo rudolfensis* (Groves 1989, Wood 1992). Current conventional taxonomic allocation *H. habilis* or *H. rudolfensis*. Informal taxonomic category Transitional hominin. Significance The calotte is similar in shape and a little larger in size than that of KNM-ER 1470, but whereas KNM-ER 1470 has no tooth crowns preserved, KNM-ER 1590 provides good evidence about the size and morphology of the maxillary dentition of a KNM-ER 1470-like hominin. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 1470.

KNM-ER 1802 Site Koobi Fora (Karari Ridge). Locality Area 131. Surface/in situ Surface. Date of discovery 1973. Finder John Harris. Unit N/A. Horizon below GPC. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.88–1.95 Ma. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Well-preserved mandible, including both sides of the corpus but lacking any evidence of the ramus. The crowns of three premolar and four permanent molar

teeth are well preserved. Announcement Leakey 1974. Initial description Day et al. 1976. Photographs/line drawings and metrical data Day et al. 1976, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions *Homo rudolfensis* (Groves 1989, Wood 1992). Current conventional taxonomic allocation *H. habilis* or *H. rudolfensis*. Informal taxonomic category Transitional hominin. Significance A mandible with a relatively robust mandibular corpus and with premolar and molar crowns and roots that differ from the morphology of the Olduvai hypodigm of *Homo habilis* (e.g., more complex premolar roots and M₁ crowns with C6s). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1805 Site Koobi Fora (Karari Ridge). Locality Area 130. Surface/in situ *In situ*. Date of discovery 1973. Finder Paul Abell. Unit N/A. Horizon KBS+11m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Geological age *c.*1.85 Ma (Feibel et al. 1989). Suwa et al. (2007) suggest that the age may be “ill-constrained” and maybe be between 1.8 and 1.6 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Incomplete skull comprising the calvaria, the lower part of the face and the mandibular corpus. The calvaria includes the posterior of the frontal, both parietals and most of the temporal bones. Although the maxillary dentition is nearly complete (only the left I¹ and the right P³ are missing) the combination of occlusal wear, chemical erosion, and other post-mortem damage has removed most of the occlusal morphology. The crowns and roots of the mandibular molars are preserved, but only the roots of the mandibular premolars remain. Endocranial volume 582 cm³ (Holloway 1983c). Announcement Leakey 1974. Initial description Day et al. 1976. Photographs/line drawings and metrical data Wood 1991, Day et al. 1976. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Australopithecus sp. indet.* Taxonomic revisions *Homo africanus* (Olson 1978), *Homo ergaster* (Groves and Mazák 1975), *Homo erectus* (Wolpoff 1978b), *Australopithecus boisei* (Tobias 1980a), *Homo habilis sensu lato* (White et al. 1981), *Australopithecus africanus* (Falk 1986b), *Homo habilis sensu stricto* (Wood 1991). Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Transitional hominin. Significance Although KNM-ER 1805

has a compound nuchal crest that is the only morphology linking it with *Paranthropus boisei* and almost all of its morphology is inconsistent with it being assigned to *Au. africanus*. It is most similar to *H. habilis* specimens from Olduvai and along with KNM-ER 1813 it is the best evidence for that taxon at Koobi Fora. However, Thompson (1993) cautioned researchers about the “peculiar basicranial proportions” and the “unusual features of the frontal, occipital, and dentition of KNM-ER 1805” (p. 261) and Prat (2002) referred to a “number of unique features that differentiate it from other hominids” (p. 32). Falk (1983b) suggested that “the frontal lobe of KNM-ER 1805 is clearly pongid-like and similar to frontal lobes of earlier dated South African australopithecines” (p. 1073). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1808 Site Koobi Fora (Koobi Fora Ridge). Locality Area 103. Surface/in situ Surface. Date of discovery 1973. Finder Kamoya Kimeu. Unit N/A. Horizon A6-2m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Lower Koobi Fora Tuff. Nearest underlying dated horizon KBS Tuff. Geological age c.1.6 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description An associated skeleton including the right mandibular condyle, fragments of the mandibular body and associated dentition, maxilla, right temporal, right supraorbital torus, left side of the occipital, atlas vertebra, much of the right clavicle, two fragments of the left scapula, distal portion of the left humerus, most of the shaft of the right humerus, two fragments of the ilium, parts of both femora, left fibula shaft fragment, and assorted long-bone fragments. Sections through the long bones show evidence of new bone growth beneath the periosteum. Announcement Leakey 1974. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985, Leakey et al. 1978, Wood 1991. Detailed anatomical description Wood 1991, Walker et al. 1982. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo erectus* (Walker et al. 1982). Current conventional taxonomic allocation *H. erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance After KNM-WT 15000, KNM-ER 1808 is the most complete skeleton of East African *Homo erectus*, but the bones are affected by an exuberant deposit

of subperiosteal woven bone. The etiology of this pathology is uncertain. It may be a case of hypervitaminosis-A, possibly from eating an excess amount of uncooked carnivore liver (Walker et al. 1982), or it may be the result of a treponemal disease such as yaws (Rothschild et al. 1995). Whatever its cause, it is an early example of paleopathology in a hominin. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 1813 Site Koobi Fora (Bura Hasuma subregion). Locality Area 123. Surface/in situ In situ. Date of discovery 1973. Finder Kamoya Kimeu. Unit N/A. Horizon N/A. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.1.88–1.90 Ma (Feibel et al. 1989). An alternative, younger, age of 1.65 Ma has been suggested (Gathogo and Brown 2006), but others dispute the grounds for the revised age. Suwa et al. (2007) suggest that its age is ill-constrained and that it may be anywhere from >1.8 Ma to 1.55 Ma, but Feibel et al. (2009) present a cogent argument that KNM-ER 1813 must be older than 1.87 Ma and may be older than 1.89 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Nearly complete cranium missing the roof of the right mandibular fossa, part of the border of the foramen magnum, much of the sphenoid, the right zygomatic arch, the left malar region, and most of the body of the ethmoid. Aside from the I¹, there is at least one well preserved crown of each tooth. Endocranial volume 510 cm³ (Holloway 1983c). Announcement Leakey 1974. Initial description Day et al. 1976. Photographs/line drawings and metrical data Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Australopithecus sp. indet.* Taxonomic revisions *Homo africanus* (Olson 1978), *Homo habilis* (Howell 1978b), *Australopithecus cf. africanus* (Walker 1981), *Homo antequus* (Ferguson 1987), *Homo ergaster* (Groves 1989), *Homo habilis* (Wood 1991), holotype of *Homo microcranous* (Ferguson 1995). Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Transitional hominin. Significance The small endocranial volume of KNM-ER 1813 prompted some researchers to allocate this specimen to *Au. africanus*, but its overall

morphology and especially the morphology of the cranial base is unlike that of *Au. africanus*. Its affinities are with early *Homo* and if that taxon is to be divided into *H. habilis* and *Homo rudolfensis* the cranial vault and facial and dental morphology of KNM-ER 1813 are closer to the former than to the latter. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 2598 Site Koobi Fora. Locality Area 15. Surface/in situ Surface. Date of discovery 1974. Finder Peter Nzube. Unit N/A. Horizon KBS-4m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.87 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description An occipital fragment that preserves lambda and the medial portions of the lambdoid sutures. Announcement Leakey 1976b. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation cf. *Homo* aff. *H. erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo ergaster* or *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Although this is only a cranial fragment, the thickness of the cranial vault, the rugosity of the occipital torus, and the acuteness of the angle between the external surface of the squamous and nuchal parts of the occipital are all strong indicators that this specimen represents a pre-modern *Homo* taxon and if so it would be among the earliest evidence, if not the earliest evidence, for such a taxon in East Africa. However, Suwa et al. (2007) do *not* accept the *c.*1.88–1.9 Ma age. Instead, they cite White (1996; but it should be 1995) as the basis for their suggestion that KNM-ER 2598 “was found on a desert-pavement lag surface that potentially samples overlying deposits now eroded away” (p. 135). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 2602 Site Koobi Fora. Locality Area 117. Surface/in situ Surface. Date of discovery 1974. Finder Wambua Mangao. Unit N/A. Horizon Just above the Tulu Bor Tuff. Bed/member Tulu Bor Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Toroto Tuff. Nearest underlying dated

horizon Tulu Bor Tuff. Geological age *c.*3.2–3.3 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Several broken and weathered portions of a cranium including substantial portions of the occipital, the parasagittal parts of both parietals, a piece of right frontal, left zygomatic, several fragments of the deciduous dentition, and a fragment of a molar germ. Announcement Leakey 1976b. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Kimbel 1988, Wood 1991. Detailed anatomical description Kimbel 1988, Wood 1991. Initial taxonomic allocation *Hominini sp. indet.* Taxonomic revisions *Australopithecus afarensis* (Boaz 1988, Kimbel 1988), *Australopithecus sp. indet.* Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance If KNM-ER 2602 does belong to *Au. afarensis* then it would be the first evidence of that taxon recovered from a Kenyan fossil site and, with the possible exception of the hominins from Kubi Algi, it would be the only evidence of that taxon from Koobi Fora. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 3228 Site Koobi Fora (Koobi Fora Ridge). Locality Area 102. Surface/in situ Surface. Date of discovery 1974–5. Finder Bernard Ngeneo. Unit N/A. Horizon Level C1-10m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age 1.89 ± 0.05 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A right pelvic bone missing the pubic and ischial rami. Announcement Leakey 1976b. Initial description Leakey 1976b. Photographs/line drawings and metrical data Rose 1984. Detailed anatomical description Rose 1984. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Homo erectus* (Rose 1984). Current conventional taxonomic allocation *H. erectus* or *Homo habilis*. Informal taxonomic category Pre-modern *Homo*. Significance KNM-ER 3228 is presently the earliest pelvic bone that suggests a form of bipedalism similar to that of *Homo sapiens*. The KNM-ER 3228 pelvic bone is similar to the modern human morphology in many ways including functionally significant features such as the relative lengths of the ischial body and tuberosity, sagittally expanded iliac blade, large acetabulum, and the positions of the

sacroiliac articular area and the acetabulosacral buttress (Rose 1984). However, KNM-ER 3228 resembles archaic hominin pelvic bones in some features including an iliac blade that (a) diverges somewhat laterally (relative to lower parts of the hip) and (b) is oriented at a relatively wide angle relative to the sagittal plane and a somewhat protuberant anterior superior iliac spine region. The KNM-ER 3228 specimen also shares some morphology with the OH 28, Arago XLIV, Jinniushan, and the Gona BSN49/P27 pelvic bones (e.g., broad, laterally flaring ilia, pronounced acetabulocrystal buttress, and a deep fossa for the origin of gluteus medius). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 3728 Site Koobi Fora (Koobi Fora Ridge). Locality Area 100. Surface/in situ Surface. Date of discovery 1975. Finders N/A. Unit N/A. Horizon C2+5m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age 1.89 ± 0.05 Ma. Developmental age Adult. Presumed sex Probably male based on size. Brief anatomical description Shaft and neck of a left femur. Announcement Leakey and Walker 1985. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985. Detailed anatomical description N/A. Initial taxonomic allocation N/A. Taxonomic revisions N/A. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance It is one of the better preserved and oldest members of a group of femora from Koobi Fora that share a long and anteroposteriorly compressed neck (others include KNM-ER 738A, 815, 993, and 1503). A similar morphology is seen in two proximal femora from Swartkrans, SK 82 and SK 97, attributed to *Paranthropus robustus*, so this is one of the proximal femur fragments that continues to fuel the suggestion that similar femora from Koobi Fora belonged to *P. boisei*. But evidence from OH 62 suggests that the same morphology is also seen in *Homo habilis*, in which case this and other similar femora could belong to *H. habilis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 3732 Site Koobi Fora. Locality Area 115. Surface/in situ Surface. Date of discovery 1975. Finder M. Muluila. Unit N/A. Horizon GPC+1m.

Bed/member upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age $c.1.88-1.95$ Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A single fragment comprising most of the calotte, which is better preserved on the left than on the right side, plus the left zygoma; there is a separate natural endocast. Announcement Leakey 1976. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985, Wood 1991. Detailed anatomical description Leakey and Walker 1985, Wood 1991. Initial taxonomic allocation Hominidae *gen. et sp. indet.* Taxonomic revisions aff. *Homo sp. indet.* (Wood 1991), *Homo rudolfensis* Wood (1992). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The lack of the distinctive frontal morphology of *Paranthropus boisei* rules out allocation to that taxon, and the robust upper face make allocation to *Homo ergaster* unlikely. The fragment looks to be a smaller version of KNM-ER 1470 and Wood (1992) included it in the hypodigm of *H. rudolfensis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 3733 Site Koobi Fora (Koobi Fora Ridge). Locality Area 104. Surface/in situ Surface. Date of discovery 1975. Finder Bernard Ngeneo. Unit N/A. Horizon A2+6m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age $c.1.78$ Ma (Feibel et al. 1989). An alternative, younger, age of 1.65 Ma has also been suggested (Brown et al. 2006). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Well-preserved cranium missing only portions of the face and nasal cavity. Some of the anatomy of the cranial base is obscured by matrix and there is some plastic deformation of the cranial base and face, but overall the preservation allows for useful morphological detail. The maxillary dentition is represented by the crown and roots of the right M² and the damaged crowns of the right P³, P⁴, and M¹ and left P⁴, M¹, and M². Endocranial volume 848 cm³ (Holloway 1983a). Announcement Leakey and Walker 1976. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and

Walker 1985, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo erectus* Taxonomic revisions *Homo ergaster* (Groves 1989). Current conventional taxonomic allocation *H. erectus* or *H. ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance There is widespread consensus that KNM-ER 3733 resembles *H. erectus* crania from Java and China. What is at issue is whether the generally less-derived morphology displayed by KNM-ER 3733 (and also KNM-ER 3883) is just a manifestation of intraspecific geographical variation within *H. erectus*, or whether it indicates that KNM-ER 3733 and KNM-ER 3883 belong to a separate species, *H. ergaster*, that would be the sister taxon of *H. erectus*. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 3883.

KNM-ER 3735 Site Koobi Fora. Locality Area 116. Surface/in situ Surface, then from sieving. Date of discovery 1975. Finder Kamoya Kimeu. Unit N/A. Horizon F1-4m. Bed/member Upper Burgi Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.88–1.9 Ma. Developmental age Adult. Presumed sex If it belongs to *Homo habilis* (see below) possibly a male based on how its size compares with that of OH 62. Brief anatomical description An associated skeleton consisting of 14 cranial fragments plus postcranial fragments belonging to the upper limb girdle (clavicle and scapula), upper limb (radius, ulna, and two hand phalanges), axial skeleton (sacrum), and lower limb (femur and tibia). Announcement Leakey and Walker 1985. Initial description Leakey et al. 1989. Photographs/line drawings and metrical data Leakey et al. 1989, Wood 1991. Detailed anatomical description Wood 1991, Haeusler and McHenry 2004, 2007. Initial taxonomic allocation *H. habilis*. Taxonomic revisions *Homo sp. indet.* (Wood 1991). Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo*. Significance The cranial morphology precludes allocation to *Paranthropus boisei*, some of it is consistent with an allocation to *Homo erectus*, but it is most like the morphology of *H. habilis*. The postcranial evidence has been compared preliminarily with A.L. 288-1 and OH 62, and was found to be more like the latter than the former (Leakey et al. 1989). Haeusler and McHenry (2004) concluded that

the proportions of upper- to lower-limb shaft diameters in KNM-ER 3735 could be encountered among modern humans, but not chimpanzees. In a later paper (Haeusler and McHenry 2007) the same authors suggested that KNM-ER 3735 and A.L. 288-1 had relatively small sacra compared to modern humans, but that KNM-ER 3735 had a proportionately longer radial neck and, by inference, a longer forearm than *Australopithecus afarensis* [e.g., “the robusticity of the scapular spine and relative radial neck length” show “a more ape-like pattern in KNM-ER 3735 than in A.L. 288-1” (*ibid*, p. 18)]. These authors also claim that KNM-ER 3735 is consistent with the “the possible evolution of *A. africanus* into *H. habilis*” (*ibid*, p. 22). If KNM-ER 3735 does belong to *H. habilis* then it is consistent with an assessment that the relative limb strengths of OH 62 and *H. erectus* are very different (Ruff 2009). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 3883 Site Koobi Fora. Locality Area 1. Surface/in situ Surface. Date of discovery 1976. Finders Richard Leakey and Maundu Muluila. Unit N/A. Horizon N/A. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon N/A. Geological age *c.*1.50–1.65 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Well-preserved calvaria, but with considerable cracking of the surface bones, insinuation of the matrix, and plastic deformation. Endocranial volume 804 cm³ (Holloway 1983c). Announcement Leakey and Walker 1985. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985, Wood 1991. Detailed anatomical description Wood 1991. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Homo ergaster* (Groves 1989). Current conventional taxonomic allocation *H. erectus* or *H. ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance There are many general similarities between KNM-ER 3883 and KNM-ER 3733 and most researchers who have studied them in detail (e.g., Picq 1983, Rightmire 1984, Wood 1991) assign these two crania to the same taxon. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 3733.

KNM-ER 3884 Site Koobi Fora. Locality Western edge of Area 5 on the Ileret Ridge.

Surface/in situ Some fragments found on the surface, others were excavated and thus were *in situ*. Date of discovery 1976. Finder Wambua Mangao. Unit N/A. Horizon N/A. Bed/member Galana Boi (Feibel et al. 1989), initially attributed to the Guomde Formation, most of which is now subsumed into the Chari Member. The specimen likely derives from undifferentiated sediments above the Chari Formation. Formation Likely unassigned strata between the **Koobi Fora Formation** and the **Galana Boi Formation sensu stricto**. Group N/A. Nearest overlying dated horizon Galana Boi Formation. Nearest underlying dated horizon Chari Tuff. Geological age Bräuer et al. (1997) reported direct **uranium-series** ages for the specimen of 272 ka (+infinity/−113 ka) by uranium-thorium and >180 ka by uranium-protactinium. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A fragmentary **cranium** of which the posterior half of the cranial vault, frontal, maxillae, and the dentition are well preserved. Announcement Day 1986. Initial description Bräuer et al. 1992b, Bräuer 2001. Photographs/line drawings and metrical data Bräuer et al. 1992b, Bräuer 2001. Detailed anatomical description N/A. Initial taxonomic allocation Late archaic *Homo sapiens*. Taxonomic revisions None. Current conventional taxonomic allocation Late archaic *H. sapiens* or *Homo helmei*. Informal taxonomic category Pre-modern *Homo*. Significance The posterior of the cranial vault is anatomically modern in configuration, but the frontal bone is more receding and broader, and bears a larger supraorbital torus than most modern human crania. Its mix of primitive and modern features, in association with its likely antiquity, is consistent with the hypothesis that modern humans evolved in Africa. Location of original National Museums of Kenya, Nairobi.

KNM-ER 5428 Site Koobi Fora. Locality Area 119. Surface/in situ Surface. Date of discovery 1978. Finders Not reported. Unit N/A. Horizon BPT-1m. Bed/member KBS/Okote Member (Feibel et al. 1989). Formation **Koobi Fora Formation**. Group Omo Group. Nearest overlying dated horizon Lower Ileret Tuff. Nearest underlying dated horizon KBS Tuff. Geological age *c.*1.54 Ma (Feibel et al. 1989). Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved right talus. Announcement Leakey and Walker 1985. Initial description Leakey

and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985. Detailed anatomical description N/A. Initial taxonomic allocation N/A. Taxonomic revisions *Homo erectus* (Walker 1993). Current conventional taxonomic allocation *H. erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance KNM-ER 5428 is the most modern human-like of all the hominin tali (including **KNM-ER 813**) from the Koobi Fora Formation. If it does belong to *H. erectus*, this hints at subtle yet perhaps important differences in gait between transitional hominins and *H. erectus*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-ER 6020 Site Koobi Fora. Locality Area 8A. Surface/in situ Surface. Date of discovery 1980. Finders Not reported. Unit N/A. Horizon N/A. Bed/member KBS Member. Formation **Koobi Fora Formation**. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age 1.77 ± 0.10 Ma. Developmental age Adult. Presumed sex Male, based on large size. Brief anatomical description A massive but heavily weathered distal end of a right humerus. Announcement Leakey and Walker 1985. Initial description Leakey and Walker 1985. Photographs/line drawings and metrical data Leakey and Walker 1985. Detailed anatomical description N/A. Initial taxonomic allocation N/A. Taxonomic revisions None. Current conventional taxonomic allocation *Hominini gen. et sp. indet.* Informal taxonomic category N/A. Significance KNM-ER 6020 is similar in size to **KNM-ER 739**, but it differs from the latter in having only a weakly developed brachioradialis flange. A detailed comparative analysis of KNM-ER 6020 has yet to be undertaken. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* **KNM-ER 739**.

KNM-ER 13750 Site Koobi Fora. Locality Area 105. Surface/in situ Surface. Date of discovery 1985/6. Finder Aila Derekitich. Unit N/A. Horizon KBS CC. Bed/member KBS Member. Formation **Koobi Fora Formation**. Group Omo group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age $c.$ 1.87 ± 0.05 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A calotte, plus much of the right zygomatic process and zygomatic bone. Much of the surface bone has

been removed by erosion. Endocranial volume Approximately 480–530 cm³ (Holloway 1988, Leakey and Walker 1988, Brown et al. 1993). Announcement N/A. Initial description Leakey and Walker 1988. Photographs/line drawings and metrical data Leakey and Walker 1988. Detailed anatomical description Leakey and Walker 1988. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions None. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Apart from some of the details of the sagittal crest, KNM-ER 13750 resembles KNM-ER 406, which is some 100 ka younger. Thus, KNM-ER 13750 and KNM-ER 406 are examples of the temporal stability of the cranial morphology of the presumed males of *P. boisei*. It supports the hypothesis that *P. boisei* provides an example of evolutionary stasis. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 406.

KNM-ER 23000 Site Koobi Fora. Locality Area 104. Surface/in situ “Mostly *in situ*.” Date of discovery 1990. Finder Benson Kyongo then excavated by Meave and Richard Leakey. Unit N/A. Horizon A2–9m. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.85 Ma. Developmental age Young adult. Presumed sex Male. Brief anatomical description A calvaria comprising the frontal, the temporal, and parietals of both sides, most of the squamous part of the occipital, the most lateral parts of the greater wings of the sphenoid, and a mesial fragment of the crown and root of a mandibular molar. The bone is permeated by cracks but there is little, or no, matrix-infilling. Brown et al. (1993) commented on the calvaria that there was “very mild distortion which precluded a perfect fitting together of the bones” (*ibid.*, p. 149). Endocranial volume 491 cm³ (Brown et al. 1993). Announcement N/A. Initial description Brown et al. 1993. Photographs/line drawings and metrical data Brown et al. 1993. Detailed anatomical description Brown et al. 1993. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions None. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance KNM-ER 23000 is a well-preserved calvaria similar in geological age to OH 5 and

the differences between the two approximately synchronic specimens [e.g., greatest height of the sagittal crest posterior in OH 5 whereas it is anterior in KNM-ER 23000, with a consequent lack of a compound temporonuchal crest in the latter; thin cranial vault bones that overlap at asterion in the former and thicker cranial bones and no temporo-parietal and parieto-occipito/temporal overlap at asterion in the latter (Kimbel and Rak 1985); bilateral occipito-marginal cranial venous drainage in the former and unilateral occipito-marginal cranial venous drainage in the latter] provide a good illustration of the range of phenotypes, especially of ectocranial and facial morphology, that can be expressed within a single early hominin taxon. Otherwise KNM-ER 23000 is a good example of the temporal persistence and geographical distribution of the distinctive cranial morphology of the presumed males of *P. boisei* and it supports the general hypothesis that *P. boisei* provides an example of evolutionary stasis. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* OH 5.

KNM-ER 42700 Site Koobi Fora. Locality “Area 1.” Surface/in situ *In situ*. Date of discovery 2000. Finder Frederick Manthi. Unit N/A. Horizon Between the IL02–043 tuff above and the Main Ileret Caliche below. Bed/member KBS Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Lower Ileret Tuff (1.527±0.014 Ma). Nearest underlying dated horizon KBS Tuff. Estimated geological age *c.*1.55 Ma. Developmental age Young adult/late subadult. Presumed sex Unknown. Brief anatomical description Well-preserved calvaria missing only portions of the right side of the anterior cranial base and part of the right side of the cranial vault. The spheno-occipital synchondrosis is two-thirds fused. There is some plastic deformation of the anterior part of the cranial vault. Endocranial volume 691 cm³ (Spoor et al. 2007). Announcement Spoor et al. 2007. Initial description Spoor et al. 2007. Photographs/line drawings and metrical data Spoor et al. 2007. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Homo* sp. (Baab 2008). Current conventional taxonomic allocation *H. erectus* Informal taxonomic category Pre-modern *Homo*. Significance Despite the small overall size of this calvaria, the researchers involved in the recovery of KNM-ER 42700 cite its overall shape (after correction for deformation), details of the cranial base

(specifically the angle between the tympanic and the petrous elements of the temporal bone), and the keeling of the frontal and parietal bones to support their recommendation that the calvaria be assigned to *H. erectus*. If this allocation survives refutation then it would be evidence of a substantial period of sympatry between *H. erectus* and *Homo habilis* and Spoor et al. (2007) suggest that this would be evidence that “an anagenetic relationship between the two taxa is implausible” (*ibid*, p. 690). Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 42703.

KNM-ER 42703 Site Koobi Fora. Locality Area 8. Surface/in situ Surface. Date of discovery 2000. Finder John Kaatho. Unit N/A. Horizon N/A. Bed/member Okote Member. Formation Koobi Fora Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff (1.383±0.028 Ma). Nearest underlying dated horizon Lower Ileret Tuff (1.527±0.014 Ma). Estimated geological age c.1.44 Ma. Developmental age Young adult/late subadult. Presumed sex Unknown. Brief anatomical description Right maxilla that preserves up to the midline and the zygomatic and palatine processes, as well as the heavily worn crowns and roots of the right canine back to the M³. Announcement Spoor et al. 2007. Initial description Spoor et al. (2007). Photographs/line drawings and metrical data Spoor et al. 2007. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The molars are smaller than those of *Homo habilis* and they are within the size range of *H. erectus*. On this basis its discoverers allocated it to *H. erectus*, and unless its taxonomic allocation is refuted, it and KNM-ER 42700 suggest that *H. erectus* and *H. habilis* were most likely sympatric in East Africa. Location of original National Museums of Kenya, Nairobi, Kenya. *See also* KNM-ER 42700.

KNM-ES Prefix for fossils accessioned at the Kenya National Museum (now the **National Museums of Kenya**) that derive from Eliye Springs, Kenya (e.g., KNM-ES 11693). *See also* National Museums of Kenya; Eliye Springs.

KNM-ES 11693 Site West Turkana. Locality Eliye Springs. Surface/in situ Surface find on a

beach on the western shore of Lake Turkana at Eliye Springs. Date of discovery 1986. Finders Dr and Mrs Till Darnhofer. Unit N/A. Horizon N/A. Bed/member Probably Pleistocene sediments beneath the Galana Boi Formation. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Uncertain, but possibly Middle to Late Pleistocene, but based only on comparisons with other hominin crania purported to be of Middle Pleistocene age. The cranium and several other fossils appear to be in a secondary context after having eroded from nearby sedimentary exposures and moved by wave action to the find spot. The other fossils recovered belong to extant taxa, hippo, crocodile, and Cape buffalo. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A heavily mineralized, darkly stained, well-preserved cranium that lacks the supraorbital region, parts of the nasal bones, most of both maxillae and zygomatic bones, and all of the dentition. The endocranium is filled with matrix, but data from CT scans shows a strongly flexed endocranial base. The cranial vault bone is strikingly thick and the outer table porous; this may be due chronic anemia in childhood. Endocranial volume 1243 cm³. Announcement Bräuer and Leakey 1986a. Initial description Bräuer and Leakey 1986a. Photographs/line drawings and metrical data Bräuer and Leakey 1986a, 1986b, Bräuer et al. 2004. Detailed anatomical description Bräuer and Leakey 1986b, Bräuer et al. 2003, 2004. Initial taxonomic allocation *Homo sapiens* “late archaic grade.” Taxonomic revisions Possibly *Homo helmei* (Foley and Lahr 1997, Howell 1994). Current conventional taxonomic allocation *H. sapiens* or *H. helmei*. Informal taxonomic category Pre-modern *Homo*. Significance The cranium is long, low, and broad, but the occipital is more rounded and the frontal bone much closer to vertical than in specimens such as Kabwe and Saldanha; overall it resembles the cranium from Florisbad. KNM-ES 11693 is one of the best-preserved African fossils of a population that may have been transitional to, or closely related to, anatomically modern *Homo sapiens*. Location of original National Museums of Kenya, Nairobi.

KNM-KP Prefix for fossils accessioned at the Kenya National Museum (now the **National Museums of Kenya**) that derive from localities

at Kanapoi, Kenya (e.g., KNM-KP 31724). *See also National Museums of Kenya; Kanapoi.*

KNM-KP 271 Site Kanapoi. Locality “On the surface of exposures at the base of the west side of Naringangoro Hill” (Patterson and Howells 1967, p. 64). Surface/in situ Surface. Date of discovery 1965. Finder Bryan Patterson. Unit N/A. Horizon “Upper fossiliferous zone”...“distributary channel associated with the Kanapoi tuff” (Leakey et al. 1995, p. 571). Bed/member N/A. Formation Kanapoi Formation. Group N/A. Nearest overlying dated horizon Kanapoi Tuff. Nearest underlying dated horizon Upper pumiceous tuff. Geological age c.4.1 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Distal left humerus. Announcement Patterson and Howells 1967. Initial description Patterson and Howells 1967. Photographs/line drawings and metrical data Patterson and Howells 1967. Detailed anatomical description Hill and Ward 1988. Initial taxonomic allocation Hominidae cf. *Australopithecus* sp. Taxonomic revisions *Homo* (Senut 1981), *Australopithecus afarensis* (Hill and Ward 1988), *Australopithecus anamensis* (Leakey et al. 1995). Current conventional taxonomic allocation *Australopithecus anamensis*. Informal taxonomic category Archaic hominin. Significance This distal humerus, the first hominin to be recovered from Kanapoi, was a puzzle because, notwithstanding its antiquity, it was closer morphologically to modern humans than is a temporally much younger distal humerus from Kromdraai that belongs to TM 1517, the holotype of *Paranthropus robustus*. If KNM-KP 271 does belong to *Au. anamensis* then this taxon has a remarkably modern human-like distal humeral morphology. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-KP 29281 Site Kanapoi. Locality N/A. Surface/in situ Surface. Date of discovery 1994. Finder Peter Nzube. Unit N/A. Horizon N/A. Bed/member N/A. Formation Kanapoi Formation. Group N/A. Nearest overlying dated horizon Upper pumiceous tuff. Nearest underlying dated horizon Lower pumiceous tuff. Geological age c.4.15 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description A mandible preserving the corpus with all the tooth crowns present and undamaged. Part of the left temporal bone most likely belongs to the same

individual. Announcement Leakey et al. 1995. Initial description Leakey et al. 1995. Photographs/line drawings and metrical data Leakey et al. 1995, Ward et al. 1999b. Detailed anatomical description Ward et al. 1999b. Initial taxonomic allocation *Australopithecus anamensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. anamensis*. Informal taxonomic category Archaic hominin. Significance The distinctive symphyseal morphology of this mandible was one of the reasons for creating a new species, *Au. anamensis*, for the Kanapoi hypodigm and KNM-KP 29281 is its holotype. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-KP 29285 Site Kanapoi. Locality N/A. Surface/in situ Surface. Date of discovery 1994. Finder Kamoya Kimeu. Unit N/A. Horizon N/A. Bed/member N/A. Formation Kanapoi Formation. Group N/A. Nearest overlying dated horizon Kanapoi Tuff. Nearest underlying dated horizon Upper pumiceous tuff. Geological age c.4.1 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The proximal and distal ends of a tibia, together with the adjacent shaft; the middle third of the shaft is missing. Announcement Leakey et al. 1995. Initial description Leakey et al. 1995. Photographs/line drawings and metrical data Leakey et al. 1995, Ward et al. 1999b. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus anamensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. anamensis*. Informal taxonomic category Archaic hominin. Significance The tibia displays several features consistent with bipedalism (e.g., rectangular proximal surface, straight and robust shaft, small fibular articulation, and a horizontally orientated distal articular surface). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-KP 29287 Site Kanapoi. Locality N/A. Surface/in situ Surface. Date of discovery 1994–5. Finder Samuel Ngui. Unit N/A. Horizon N/A. Bed/member N/A. Formation Kanapoi Formation. Group N/A. Nearest overlying dated horizon Kalokwanya Basalt. Nearest underlying dated horizon Kanapoi Tuff. Geological age c.4.0 Ma; “likely to be only marginally younger than the Kanapoi Tuff” (Leakey et al. 1998, p. 63).

Developmental age Adult. Presumed sex Unknown. Brief anatomical description Mandible with P₄–M₂ of both sides, plus the left I₁, both I₂s, the right P₃, and both M₃s. Announcement Leakey et al. 1998. Initial description Leakey et al. 1998. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus anamensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. anamensis*. Informal taxonomic category Archaic hominin. Significance This mandible is larger than that of the holotype and the size and morphology of the canine suggests it belonged to a male individual. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-KP 31724 Site Kanapoi. Locality N/A. Surface/in situ Surface. Date of discovery 1996. Finder Peter Nzube. Unit N/A. Horizon N/A. Bed/member N/A. Formation Kanapoi Formation. Group N/A. Nearest overlying dated horizon Upper pumiceous tuff. Nearest underlying dated horizon Lower pumiceous tuff. Geological age c.4.15 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved left capitate. Announcement Leakey et al. 1998. Initial description Leakey et al. 1998. Photographs/line drawings and metrical data Leakey et al. 1998. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus anamensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. anamensis*. Informal taxonomic category Archaic hominin. Significance This left capitate shares at least one feature (a laterally facing facet for the second metacarpal) with the extant apes that is not seen in later hominins such as *Australopithecus afarensis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-LT Prefix for fossils accessioned at the Kenya National Museum (now National Museums of Kenya) that derive from localities at Lothagam, Kenya (e.g., KNM-LT 329). See also National Museums of Kenya; Lothagam.

KNM-LT 329 Site Lothagam. Locality Locality 1. Surface/in situ Surface. Date of discovery 1967. Finder “A.D. Lewis, assistant to B. Patterson” (Oakley et al. 1977). Unit N/A. Horizon “The lowermost part of the Apak Member, less

than 3 m above the Purple Marker” (Leakey and Walker in Leakey and Harris 2003, p. 249). Bed/member Apak Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon “Pumiceous bed that lies 17 m below the Lothagam Basalt and 35 m above the Purple Marker” (McDougall and Feibel 1999, p. 249) c.4.2 Ma. Nearest underlying dated horizon Purple Marker c.5.23 Ma. Geological age c.4.5–5.0 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A piece of the right side of the body of the mandible. The oblique anterior fracture surface runs from mesial to the M¹ at the alveolar process to between M₁ and the M₂ at the base; the posterior fracture surface is also oblique and runs from just distal to the roots of the M₃ at the alveolar process to just anterior to the mandibular angle. The crown of the M₁ is preserved, but all that remains of the M₂ and M₃ is their root systems. Dentine is exposed on the main buccal cusps of the M₁. Announcement Patterson et al. 1970. Initial description Kramer 1986, White 1986b. Photographs/line drawings and metrical data Kramer 1986, White 1986b, Hill and Ward 1988, Hill et al. 1992, Leakey and Walker 2003. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus* sp. cf. *Australopithecus africanus*. Taxonomic revisions *Australopithecus* sp. cf. *Australopithecus afarensis* (Kramer 1986, and by inference McHenry and Corruccini 1980 and White 1986b), *Australopithecus afarensis* (Hill and Ward 1988), *Australopithecus* cf. *afarensis* (Hill et al. 1992), *Australopithecus* sp. cf. *Australopithecus anamensis* (by inference Leakey and Walker 2003). Current conventional taxonomic allocation *Australopithecus* sp. or *Ardipithecus* sp. Informal taxonomic category Archaic or possible primitive hominin. Significance For a long time the KNM-LT 329 mandible was among the few tantalizing pieces of evidence (e.g., other evidence included the Kanapoi humerus, KNM-KP 271, the Lukeino molar, KNM-LU 335, and the Tabarin mandible KNM-TH 13150) of one, or more, African hominin, perhaps even hominid, taxa that predated *Au. afarensis*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-LU Prefix for fossils accessioned at the Kenya National Museum (now National Museums of Kenya) that derive from sites in the Lukeino Formation in the Baringo region,

Kenya (e.g., KNM-LU 335). *See also* National Museums of Kenya; Lukeino Formation.

KNM-LU 335 Site Cheboit. Locality N/A. Surface/in situ Surface. Date of discovery 1973. Finder Martin Pickford. Unit N/A. Horizon N/A. Bed/member Kapgoywa Member. Formation Lukeino Formation. Group N/A. Nearest overlying dated horizon Kaparaina Basalts. Nearest underlying dated horizon Kabarnet Trachytes. Geological age *c.*6 Ma. Developmental age Adult. Presumed sex N/A. Brief anatomical description A left lower molar, either M₁ or M₂, but probably an M₁. Announcement Pickford 1975. Initial published description Pickford 1975. Photographs/line drawings and metrical data N/A. Detailed anatomical description There is no detailed anatomical description, but McHenry and Corruccini (1980) undertook an analysis of the diameters (not the areas) of the main cusps and concluded that their results did not support the “separation of the Lukeino molar from the genus *Pan*” (*ibid.*, p. 397). Ungar et al. (1994) undertook a multivariate analysis of the crown morphology of KNM-LU 335 based on the relative locations of the cusp tips and the peripheral termini of the main fissures. Their conclusions were somewhat different from those of McHenry and Corruccini, for the latter authors found that the flaring of the buccal surface of the crown had no modern analogues in modern humans and chimpanzees, and they further concluded that their results “do not exclude KNM-LU 335 as a potential ancestral morphotype for *Pan* and *Homo*” (*ibid.*, p. 165). Initial taxonomic allocation Hominidae *gen. et sp. indet.* Taxonomic revisions *Orrorin tugenensis* (Senut et al. 2001). Current conventional taxonomic allocation *O. tugenensis*. Informal taxonomic category Possible primitive hominin. Significance The first specimen of the hypodigm of *O. tugenensis* to be discovered. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-OG Prefix for fossils accessioned at the Kenya National Museum (now National Museums of Kenya) that derive from localities at Olorgesailie (e.g., KNM-OG 45500). *See also* National Museums of Kenya; Olorgesailie.

KNM-OG 45500 Site Olorgesailie. Locality OL 45500. Surface/in situ Frontal fragment was found *in situ* in June 2003 within a sediment block that had been removed from the site in 1999; the

remaining fragments were found in July and August, 2003 on the surface of the slope below where the block was extracted. Date of discovery June, July, and August, 2003. Finders Messrs Kanunga, Kilonzi, Kinyua, Kioko, Mumo, Nume, and Potts. Unit Sandy silts containing reworked diatomite and volcanic cobbles just above the Member 5 paleosol. Horizon See above. Bed/member Member 7. Formation Olorgesailie Formation. Group N/A. Nearest overlying dated horizon Air-fall ash at the top of Member 8. Nearest underlying dated horizon Pumice clasts from Member 5. Geological age 970–900 ka. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Frontal and left temporal bones and nine cranial vault fragments. No endocast has been reconstructed, but Potts et al. (2004) suggest that the endocranial volume is likely to be less than 800 cm³. Announcement Potts et al. 2004. Initial description Potts et al. 2004. Photographs/line drawings and metrical data Potts et al. 2004. Detailed anatomical description N/A. Initial taxonomic allocation Compared to, but not formally assigned to *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation cf. *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Although the KNM-OG 45500 calvaria is incomplete, it comes from a time interval in which hominin fossil evidence is frustratingly scarce. Enough is preserved for it to be confidently allocated to *H. erectus*. It is one of a growing number of fossil specimens from this species that appear to be characterized by small body size (as inferred from the size of the cranium). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-OL This was cited as the prefix for fossils accessioned at the Kenya National Museum (now National Museums of Kenya) that derive from localities at Olorgesailie (e.g., KNM-OL 45500) (Potts et al. 2004), but the correct prefix is KNM-OG. *See also* National Museums of Kenya; Olorgesailie.

KNM-OL 45500 This was cited as the accession number for the hominin frontal fragment from Olorgesailie (Potts et al. 2004) but the correct accession number is KNM-OG 45500.

KNM-TH Prefix for fossils accessioned at the Kenya National Museum (now National

Museums of Kenya) that derive from sites in the Tugen Hills in the Baringo region, Kenya (e.g., KNM-TH 13150). *See also* National Museums of Kenya; Tugen Hills.

KNM-TH 13150 Site Tabarin. Locality BPRP#77. Surface/*in situ* Surface. Date of discovery 1984. Finder Kiptalam Cheboi. Unit N/A. Horizon N/A. Bed/member N/A. Formation Chemeron Formation. Group N/A. Nearest overlying dated horizon 4.3 Ma. Nearest underlying dated horizon 4.428 ± 0.005 Ma. Geological age 4.42 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragment of the right side of the mandibular corpus with M₁, M₂, part of the alveolus of M₃, and part of the root and alveolus of P₄. Announcement Hill 1985. Initial description Hill 1985. Photographs/line drawings and metrical data Hill 1985. Detailed anatomical description Hill 1985, Ward and Hill 1987. Initial taxonomic allocation cf. *Australopithecus afarensis*. Taxonomic revisions *Homo antequus praegens* Ferguson, 1989. Current conventional taxonomic allocation *Ardipithecus ramidus*. Informal taxonomic category Possible primitive hominin. Significance With hindsight the KNM-TH 13150 mandible may be the first evidence of *Ar. ramidus* to be recovered and if it belongs to this taxon it would extend its known geographical range. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-TH 45519–45522, KNM-TH 46437–46440 Site Kapthurin. Locality Loc.99. Surface/*in situ* Surface. Date of discovery KNM-TH 45519–45522 (2004), KNM-TH 46437–46440 (2006 and thereafter). Finders B. Kimeu, N. Kanyenze, and M. Macharwas. Unit N/A. Horizon N/A. Bed/member K3'. Formation Kapthurin Formation. Group N/A. Nearest overlying dated horizon K2 (545 ± 3 ka). Nearest underlying dated horizon K4 (284 ± 12 ka). Geological age c.545 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description KNM-TH 45519 and 45520 are, respectively, well-preserved right and left upper central permanent incisors with broad, spatulate, crowns, KNM-TH 45521 the crown of a left upper molar, probably the M¹, KNM-TH 45522 is an upper or lower supernumary molar, KNM-TH 46437–46438 are upper lateral incisors, KNM-TH 46439 is a lower lateral incisor, and KNM-TH 46440

is a P⁴. Announcement McBrearty and Jablonski 2005 (NB: KNM-TH 45522 was not reported in this paper). Initial description McBrearty and Jablonski 2005. Photographs/line drawings and metrical data McBrearty and Jablonski 2005. Detailed anatomical description N/A. Initial taxonomic allocation *Pan sp. indet.* Taxonomic revisions None. Current conventional taxonomic allocation *Pan.* Informal taxonomic category Panin. Significance These teeth, probably from the same individual, represent the first fossil evidence of the panin clade; thus they are the first fossils to be attributed to the extant sister clade of hominins. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT Prefix for fossils accessioned at the Kenya National Museum (now National Museums of Kenya) that derive from localities within the West Turkana site complex (e.g., KNM-WT 8556). *See also* National Museums of Kenya; West Turkana.

KNM-WT 8556 Site West Turkana. Locality Lomekwi (LO5). Surface/*in situ* Surface. Date of discovery 1982. Finder Peter Nzube. Unit N/A. Horizon N/A. Bed/member Lomekwi Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon Lokalalei Tuff. Nearest underlying dated horizon Tulu Bor Tuff. Geological age 3.26 ± 0.10 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Mandibular corpus that extends from just distal to the left P₃ to midway along the right M₂. The crowns or partial crowns of the left and right P₃, and the right P₃ and M₃ are preserved. Announcement Brown et al. 2001. Initial description Brown et al. 2001. Photographs/line drawings and metrical data Brown et al. 2001. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions aff. *Kenyanthropus platyops* (Leakey et al. 2001). Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance Significance Leakey et al. (2001) point out how it differs from *Au. afarensis* and Kimbel and Deleuzene (2009) in their review of *Au. afarensis* agree, writing “Although Leakey et al. (2001) discussed these specimens in the context of their description of the species *Kenyanthropus platyops*, they did not attribute them to this

taxon; they did enumerate ways in which they departed from *A. afarensis* morphology, especially in the dentition—which we can affirm from examination of the original fossils” (*ibid.*, p. 13). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 15000 Site West Turkana. Locality Nariokotome III (NK-III). Surface/in situ Surface, then *in situ*. Date of discovery August 1984, then four seasons of excavation. Finders Kamoya Kimeu, then excavated by a team led by Alan Walker. Unit N/A. Horizon “Siltstone that immediately overlies a tuff identified as a component ash of the Okote Tuff complex” (Brown et al. 1985, p. 788). Bed/member Natioo. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon Chari Tuff. Nearest underlying dated horizon Immediately above the Okote Tuff complex. Geological age “Very close to 1.6 Myr” (*ibid.*, p. 788) [NB: according to Brown et al. 2006, NK-III is above the tuff that was correlated to a tuff in the Kaitio drainage, which places it stratigraphically above the Ebei Tuff, dated to 1.47 Ma (McDougall and Brown 2006). The implication is that KNM-WT 15000 should be closer to 1.44 Ma in age]. Developmental age Adolescent, on the basis that the second permanent molars are just in occlusion and the M³ germs are probably only just crown complete. The most precise and accurate chronological age estimate based on tooth microstructure (Dean and Smith 2009) suggests an age of *c.*8 years of age (range 7.5–8.9 years); the modern human equivalent would be *c.*12 years old. Presumed sex Male. Brief anatomical description At the time of its recovery KNM-WT 15000 was the most complete early hominin skeleton, as well as being remarkably free from plastic deformation. It is so complete it is easier to list what major elements are *missing* rather than what is preserved. The KNM-WT 15000 cranium is complete apart from the supraorbital tori, and the axial skeleton lacks most of the cervical and some of the thoracic vertebrae, parts of the sacrum and pelvic bone and some ribs. The upper limbs lack the left scapula and humerus, both radii, and most of the hand bones. The lower limbs lack the proximal end of the right femur, most of the epiphyses of the bones of the leg, and most of the bones of the foot. Endocranial volume 909 cm³ (Walker and Leakey 1993). Estimated stature At the time of death 160 cm; 185 cm is

the projected stature estimate for an equivalent adult (Walker and Leakey 1993), but see Graves et al. (2010) for a more more modest (about 163 cm) stature estimate. Estimated body mass At the time of death 48 kg; 68 kg is the projected body mass for an equivalent adult (Walker and Leakey 1993). Ruff (2007) provides an estimate of 50–53 kg at the time of death based on the size of the femoral head, and a similar estimate was provided by Aiello and Wood (1994) based on orbit size. Announcement Brown et al. 1985. Initial description Brown et al. 1985. Photographs/line drawings and metrical data Brown et al. 1985, Walker and Leakey 1993. Detailed anatomical description Walker and Leakey 1993. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Homo ergaster* (Wood 1991, p. 270). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance It is difficult to exaggerate the importance of the KNM-WT 15000 skeleton for before its discovery relatively little was known about the postcranial skeleton, ontogeny, and life history of *H. erectus*. It provided conclusive proof of the limb proportions and limb morphology of one of the earliest taxa within the genus *Homo* and in doing so helped researchers make more sense of the isolated limb bones recovered from sites such as Koobi Fora. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 16002 Site West Turkana. Locality Lomekwi (LO3). Surface/in situ Surface. Date of discovery 1985. Finder John Harris. Unit N/A. Horizon N/A. Bed/member Lokalalei. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon Kalocho Tuff. Nearest underlying dated horizon Tulu Bor Tuff. Geological age 2.7±0.03 Ma (Brown et al. 2001). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right femur preserving the neck and shaft, but missing the head, both trochanters, and the distal end. Announcement Brown et al. 2001. Initial description Brown et al. 2001. Photographs/line drawings and metrical data Brown et al. 2001. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus sp. indet.* Taxonomic revisions None. Current conventional taxonomic allocation *Australopithecus sp. indet.* Informal taxonomic category Archaic hominin. Significance There

are very few relatively well-preserved femora from this important time range and there is a possibility that this femur may belong to *Paranthropus aethiopicus*. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 16005 Site West Turkana. Locality Given as Kangatukuseo II (KU2) in Feibel et al. (1989) but listed as Kangatukuseo III (i.e., KU3) in Walker et al. 1986. Surface/in situ Surface. Date of discovery 1985. Finders Not known. Unit 3.8 m below the Lokalalei Tuff or 19 m above the Lokalalei Tuff. Horizon N/A. Bed/member Lomekwi – Upper. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon Lokalalei Tuff. Nearest underlying dated horizon Tulu Bor Tuff. Geological age *c.*2.55 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The upper part of the corpus of an adult mandible that extends from just distal to the M₁ on the right, to the mid-point of the M₃ alveolus on the left. The roots of the anterior teeth are preserved except for the left I₁, as are most of the worn crowns of the left P₃ to M₂ and the right P₃ to M₂. Announcement Walker et al. 1986. Initial description Leakey and Walker 1988. Photographs/line drawings and metrical data Walker et al. 1986, Leakey and Walker 1988. Detailed anatomical description Leakey and Walker 1988. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions None. Current conventional taxonomic allocation *Paranthropus aethiopicus*. Informal taxonomic category Megadont archaic hominin. Significance This mandible was found in sediments that are effectively synchronic (Harris et al. 1988) with those that contained KNM-WT 17000 and it is possible, if not probable, that this was the type of mandible that would have belonged to an individual in the same taxon as KNM-WT 17000. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 17000 Site West Turkana. Locality Lomekwi (LO1). Surface/in situ Surface. Date of discovery 1985. Finder Alan Walker. Unit N/A. Horizon Lokalalei Tuff. Bed/member Lomekwi – Upper (Harris et al. 1988), but Feibel et al. (1989) list it as coming from the Lokalalei Member; it is the Lokalalei Member. Formation Nachukui Formation [but some publications e.g., Feibel et al. (1989) refer to the Koobi Fora Formation]. Group Omo Group. Nearest overlying dated horizon

“Within the Lokalalei Tuff” (Feibel et al. 1989, p. 610). Nearest underlying dated horizon See above. Geological age 2.53±0.02 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Cranium missing the posterior part of the frontal, the anterior parts of the parietals, the lateral orbital margins, the zygomatic arches, parts of the sphenoid and the maxillae, and the occipital squame. Parts of the alveoli of the anterior teeth are preserved as are many of the roots of the postcanine teeth, but the only well-preserved tooth crown is that of the left P⁴. Endocranial volume Approximately 410 cm³ (Walker and Leakey 1988). Announcement Walker et al. 1986. Initial description Leakey and Walker 1988. Photographs/line drawings and metrical data Walker et al. 1986, Leakey and Walker 1988. Detailed anatomical description Leakey and Walker 1988. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions *Australopithecus aethiopicus* (Kimbel et al. 1988). Current conventional taxonomic allocation *Paranthropus aethiopicus*. Informal taxonomic category Megadont archaic hominin. Significance There are very few well-preserved crania in this time period, and the discovery of KNM-WT 17000 prompted a re-evaluation of the relationships among the more primitive hominin taxa such as *Australopithecus africanus* and *Australopithecus afarensis*, and the later, and presumed to be more derived, megadont archaic hominin taxa such *Paranthropus robustus* and *Paranthropus boisei*. Walker et al. (1986) and Leakey and Walker (1988, pp. 21–3) set out the reasons why they chose to interpret KNM-WT 17000 as belonging to “an early *A. boisei* population” (*ibid*, p. 22), rather than assign it to the available species *Paraustralopithecus aethiopicus*. By that time one of the authors of the paper that proposed the recognition of *P. aethiopicus* had already cast doubt on the wisdom of recognizing a new species (Coppens 1979), and Walker et al. (1986) suggested that if there was future need for a new taxon then that taxon should be subsumed into the genus *Australopithecus*, as *Au. aethiopicus*. Other researchers were more impressed with the differences between KNM-WT 17000 and the main hypodigm of *P. boisei*, and were not convinced the taxon to which KNM-WT 17000 belongs was part of a *P. boisei* lineage, but instead they suggested that the taxon might be a link between *Au. afarensis* and the common ancestor of *P. robustus* and *P. boisei* (e.g., Kimbel et al.

1988). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 17400 Site West Turkana. Locality Naiyena Engol (NY2). Surface/in situ Surface. Date of discovery Not known. Finders Not known. Unit Not known. Horizon Not known. Bed/member Kaitio Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon KBS Tuff. Geological age $c.1.77 \pm 0.10$ Ma. Developmental age Late juvenile. Presumed sex Probable female. Brief anatomical description A cranium that lacks the supraorbital region of the face, the zygomatic arches, some of the cranial base and cranial vault, and the occipital squame. The tooth crowns, with the exception of the medial incisors, are all present and well preserved; the M³ germs are exposed in their crypts. The paranasal sinuses are large and the temporal bone is extensively pneumatized. Endocranial volume 390–400 cm³ (Holloway 1988) and 500 cm³ (Brown et al. 1993). Announcement None. Initial description Leakey and Walker 1988. Photographs/line drawings and metrical data Leakey and Walker 1988. Detailed anatomical description Leakey and Walker 1988. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions None. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance This cranium is one of several late juvenile/young adult crania in the *P. boisei* hypodigm and it adds to our knowledge of the ontogeny of that taxon. It is the best-preserved face of *P. boisei* after OH 5. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 19700 Site West Turkana. Locality Nachukui (NC1). Surface/in situ Surface. Date of discovery 1988. Finder Kamoya Kimeu. Unit “8–8.5 m below stromatolite horizon S3” (Brown et al. 2001, p. 42). Horizon N/A. Bed/member Nariokotome Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon Lower Nariokotome Tuff. Geological age 1.0 ± 0.15 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The proximal end of an adult tibia. Announcement Brown et al. 2001. Initial description Brown et al. 2001. Photographs/line drawings and metrical data Brown et al. 2001. Detailed anatomical description Brown et al. 2001. Initial

taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance Other than KNM-WT 15000 few limb bones have been assigned to *H. erectus* or *H. ergaster*. Brown et al. (2001) assigned KNM-WT 19700 to *H. erectus* on the grounds that “this fragment compares closely...with KNM-WT 15000” (*ibid*, p. 43); “especially obvious is the way in which the epiphysis is set at a strong angle to the anteroposterior axis of the shaft” (*ibid*, p. 43). This compares with *Australopithecus* (i.e., *Paranthropus*) in which the “long axis of the epiphysis set at right angles to the anteroposterior axis of the shaft” (*ibid*, p. 43). Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 40000 Site West Turkana. Locality Lomekwi (LO-6N). Surface/in situ Surface. Date of discovery August 1999. Finder Justus Erus. Unit N/A. Horizon “Dark mudstone” (Leakey et al. 2001, p. 439). Bed/member Kataboi Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon 8 m below the β -Tulu Bor Tuff. Nearest underlying dated horizon 12 m above the Lokochot Tuff. Geological age $c.3.5$ Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A relatively complete but plastically deformed cranium in two parts, one preserving the neurocranium, the supraorbital region and part of the cranial base, the other preserving the rest of the face. Endocranial volume N/A. Announcement Leakey et al. 2001. Initial description Leakey et al. 2001. Photographs/line drawings and metrical data Leakey et al. 2001. Detailed anatomical description N/A. Initial taxonomic allocation *Kenyanthropus platyops*. Taxonomic revisions *Australopithecus afarensis* (White 2003). Current conventional taxonomic allocation *K. platyops*. Informal taxonomic category Archaic hominin. Significance The main reasons Leakey et al. (2001) did not assign this material to *Au. afarensis* are its reduced subnasal prognathism, anteriorly situated zygomatic root, flat and vertically orientated malar region, relatively small but thick-enameled molars, and the unusually small M¹ compared to the size of the P⁴ and M³. Some of the morphology of the new genus including the shape of the face is *Paranthropus*-like yet it lacks the postcanine megadontia that characterizes *Paranthropus* taxa.

The authors note the face of the new material resembles that of *Homo rudolfensis*, but they rightly point out that the postcanine teeth of the latter are substantially larger than those of KNM-WT 40000. *K. platyops* apparently displays a hitherto unique combination of facial and dental morphology. White (2003) has taken the view that the new taxon is not justified because the cranium could be a distorted *Au. afarensis* cranium, but these arguments have been challenged and/or refuted by Spoor et al. (2010). Although distortion could conceivably account for why the preserved cranial vault morphology differs from that of *Au. afarensis*, it cannot account for the much smaller postcanine teeth of KNM-WT 40000 compared to the *Au. afarensis* dentition. Location of original National Museums of Kenya, Nairobi, Kenya.

KNM-WT 42718 Site West Turkana. Locality Lokalalei (LA1α). Surface/in situ Surface. Date of discovery 2002. Finders Not reported. Unit “Yellow beige clayey siltstone” (Prat et al. 2005, p. 231). Horizon N/A. Bed/member Kalochoro Member. Formation Nachukui Formation. Group Omo Group. Nearest overlying dated horizon KBS Tuff. Nearest underlying dated horizon Kalochoro Tuff. Geological age 2.3–2.4 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description The unworn germ of a right M₁. Announcement Prat et al. 2005. Initial description Prat et al. 2005. Photographs/line drawings and metrical data Prat et al. 2005. Detailed anatomical description Prat et al. 2005. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions None. Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Transitional hominin. Significance The narrow crown, the absence of a C6, and mildly expressed protostylid suggest affinities with *Homo*. If this tooth does belong to *Homo*, it would be one of the earliest examples of this taxon. Location of original National Museums of Kenya, Nairobi, Kenya.

knock-in *See* knockout.

knock-out A genotype, usually of a model organism (e.g., mice), in which a particular gene has been rendered inoperative. Knockout mice are made through a targeted insertion of DNA into embryonic stem cells, and the subsequent introduction of these cells into blastocysts, which are then

implanted into a pregnant female mouse. To target a specific region of DNA, the inserted sequence has two regions that are complementary to DNA sequences that flank (i.e., they are upstream and downstream) of the targeted gene. There are two crucial selection steps in the process of making a knockout mouse. The first involves making sure the DNA is incorporated correctly into the genome of the embryonic stem cells. To accomplish this, two extra genes, one coding for neomycin resistance and the other coding for sensitivity to ganciclovir, are included with the DNA insertion. The gene for neomycin resistance is placed between the two complementary sequences and the gene coding for ganciclovir sensitivity is placed outside the two complementary sequences. If the sequence is not incorporated, the embryonic stem cells will be killed by neomycin. If the sequence is incorporated randomly into the genome, then it will also include the ganciclovir-sensitivity gene, which means that such cells will be killed by ganciclovir. However, if the sequence is inserted so as to replace the desired gene (which is the objective), it will include only the regions between (and including) the two complementary sequences. Such cells will be resistant to neomycin and will also survive being treated with ganciclovir. These are the cells selected for insertion into a blastocyst. Once the injected blastocyst is implanted, a second selection step is necessary to select for mice in which the inserted gene has been incorporated into the germ line. This is done by using stem cells from a mouse with a different coat colour than the mice from which the blastocyst is obtained. The first-generation mice are chimeras but breeding can establish lines of mice in which the inserted gene is segregating in such a way that “knockout” individuals can be compared to normal littermates. The ability to knockout specific genes has revolutionized developmental biology and genetics and in 2007 Mario Capecchi, Martin Evans, and Oliver Smithies were awarded the Nobel Prize for Physiology or Medicine for their pioneering work on this technology. A disadvantage of gene knockouts, however, is that they only tell researchers what happens to the organism when the targeted gene does not perform its function. Often the result is a non-viable embryo or there is no detectable phenotype, usually because other genes have overlapping functions with the one that was targeted. Interpreting such results can be like trying to figure out how a car works by taking components out one by one and seeing what each deletion does to the car’s

performance. To overcome these limitations, other related strategies have been developed. One is the use of multiple knockouts of related genes. Another is to replace the targeted gene with an allele that performs an altered function rather than one that is inactive; this is known as the knockin approach. A third is to make a knockout (or a knockin) that is conditional on the expression of some other gene. Such conditional knockouts only disrupt the function of the targeted gene in specific tissues or at specific times in development and thus can provide much more precise information about gene function. A somewhat different technology can be used to knockdown gene function through the use of morpholinos, which are small synthetic RNA molecules that block or reduce the translation of a specific protein. Transgenic technologies such as these have been used in human evolution and biological anthropology-related research. Mouse models, for instance, have been used to test the predicted relationship between brain size and cranial shape in hominins (Hallgrímsson and Lieberman 2008). An early use of transgenic mice in human evolutionary studies involved the role of growth hormone in producing allometric variation (Shea et al. 1990).

Kokiselei [etym. Named for an ephemeral river system (laga) in whose drainage the localities are located] (or KS) Refers to a complex of fossil localities in the Kaitio Member of the Nachukui Formation within the Kokiselei drainage in West Turkana, Kenya. *See also* West Turkana.

Kollé One of the “fossiliferous areas” within the Chad Basin; others include **Kossom Bougoudi**, **Koro Toro**, and **Toros-Menalla**. *See also* Chad Basin.

Kom Ombo (Location 24°28'N, 32°57'E, Egypt) History and general description Located on the east bank of the Nile in the southern area of Upper Egypt, Kom Ombo is an agricultural town known since antiquity for its 2ndC temple and its strategic location that facilitated control of trade routes from Nubia into the Nile Valley. The area's relevance to the Paleolithic was first recognized by Edmond Vignard who collected artifacts from multiple open-air sites on the approximately 500 km²/193 square mile Kom Ombo plain in 1919 and 1924. Temporal span and how dated? Primarily by correlation of technocomplexes. Sites on the edges of the plain and on the Nile and wadi terraces are **Lower and Middle Paleolithic** in age while those in the silt plain proper are primarily **Upper Paleolithic**. Published and unpublished **radiocarbon dates** determined during the 1960s suggest a span of 14,000 to around 9000 years BP for the local Upper Paleolithic Sebilian tool industry. The modern human

remains are well dated by radiocarbon to between 11,500 and 11,000 years BP. The rock art is estimated to date from *c.*15,000 BP. Hominins found at site Fragments of the vault of at least two crania assigned to *Homo sapiens* were recovered from a Sebilian II site, Gebel Silsila 2A, during excavations by the 1962–3 Yale University Prehistoric Expedition to Nubia. Archeological evidence found at site During his work in the early 20thC, Vignard defined a three-stage local tool industry that he termed the Sebilian after the nearby village of Sebil, and proposed, controversially, that it was a wholly indigenous outgrowth of the **Mousterian** tool industry of the Middle Paleolithic. Vignard's Sebilian I is characterized by short, broad Levallois flakes, retouched flake points, and, more rarely, scrapers and blades. The Sebilian II includes broad simple and retouched flake points with the addition of backed blades, large trapezoidal pieces triangular and crescent forms, grindstones, and a reduced frequency of Levallois flakes. The Sebilian III is characterized by many diverse geometric microliths, possibly linked to bow hunting, as well as end-of-blade scrapers, flake scrapers, stemmed points, perforators, and microburins. Also notable are the extensive examples of rock art found at Qurta I, II, and III on the Kom Ombo plain, which consist of roughly 160 mostly naturalistic depictions of animals and humans. Konso (Location 5°20'N, 37°25'E, Ethiopia; etym. Konso is the name of the region and its ethnic group) History and general description Previously known as Konso-Gardula, this site on the western flank of the **Ethiopian Rift System** was discovered in 1991 during the **Paleoanthropological Inventory of Ethiopia**. Temporal span and how dated? 1.9–0.8 Ma based on **argon-argon dating** of tuffs, tephrostratigraphy, and paleomagnetic correlation. All the hominins are from sediments dated to 1.5–1.3 Ma. Hominins found at site Field work conducted beginning in 1991 resulted in the discovery of 1.4–1.45 Ma hominin fossils that were assigned to *Homo erectus* and

subsequent discoveries (Suwa et al. 1997) include excellently preserved specimens of *Paranthropus boisei* dated to between 1.4 and 1.5 Ma, as well as other specimens attributed to *H. erectus*. Archeological evidence found at site Discoveries include <1.6 Ma **Acheulean** artifacts. Key references: Geology, dating, and paleoenvironment Asfaw et al. 1992, Katoh et al. 2000, Suwa et al. 2003, White and Suwa 2004, WoldeGabriel et al. 2005, McDougal and Brown 2006; Hominins Asfaw et al. 1992, Suwa et al. 1997, 2007; Archeology Asfaw et al. 1992, Beyene et al. 1997, Beyene 2003.

Konso-Gardula *See* Konso.

Koobi Fora [Location 3°35'–4°25'N and 36°10'–36°30'E, Kenya; etym. Koobi Fora is the local Das(s)enetch name for several low hills on the northeastern shore of Lake Turkana] History and general description Koobi Fora (formerly known as **East Rudolf** and also known as East Turkana) is a substantial area of outcrops and exposures on the northeastern shore of Lake Turkana. It is one of several fossil sites (the others include **Lothagam**, **Omo**, and **West Turkana**) within the Lower Omo and the Turkana Basin and its size and complexity make it equivalent to the larger study areas in Ethiopia (e.g., **Hadar**, Middle Awash). Richard **Leakey** recognized the paleontological potential of Koobi Fora region in 1967 when he was participating in the **International Omo Research Expedition**. The first **East Rudolf Expedition** to Koobi Fora in 1968 was based at **Allia Bay** and recovered three hominin fossils. Field seasons continued annually and when in 1975 the Kenya Government decreed that the name of the lake be changed from Lake Rudolf to Lake Turkana the **Koobi Fora Research Project** (or KFRP) superseded the East Rudolf Expedition and its members continued to explore, map, and undertake intensive paleoanthropological, paleontological, and archeological fieldwork in the Koobi Fora region until 1979 when the effort at Koobi Fora would down and the KFRP began to focus on other sites within the Turkana Basin. These many cumulative months of field seasons resulted in substantial collections held in the **National Museums of Kenya** in Nairobi. The strata from which fossil hominins have been recovered at Koobi Fora were originally assigned to the Kubi Algi, Koobi Fora, and the Guomde

Formations (Bowen and Vondra 1973), all overlain by the Galana Boi Beds. The three original formations have since been rationalized into a single unit called the **Koobi Fora Formation** within which eight members are recognized. The fossiliferous exposures were initially subdivided into three named subregions: **Ileret** in the north, **Koobi Fora** midway, and **Allia Bay** to the south. Within each of these subregions natural features such as sand rivers were used to divide the landscape into **collecting areas**. These are numbered 1–18 and 40–2 in Ileret, 101–10, 112, 114–21, 125, 127–31, and 133–9 in Koobi Fora, and 200–7, 210, 212, 250–4, and 260–1 at Allia Bay. Subsequently the scheme using three main subregions was superseded by one that recognizes seven subregions (Brown and Feibel 1991). Their names, together with the numbered collecting areas within each subregion, are given below in order from north to south: Il Dura (14, 15, 41, and 42), Ileret (1–12), Il Naibar Lowlands (116–17, 136–7), Karari Ridge (105, 118, 129, 131), Koobi Fora Ridge (102–15), Bura Hasuma (107, 110, 119–21, 123–4), and Sibilot (202–4, 207, 212, 250–2). All the vertebrate fossils recovered were recorded and numbered consecutively in a field book. Until 1970 hominin fossils from Koobi Fora had the prefix *FS* (acronym for field: surface) followed by a number (e.g., what are now **KNM-ER 406** and **407** were *FS-158* and *FS-210*, respectively). Since 1970 each hominin from Koobi Fora has the prefix **KNM** for the Kenya National Museum (now **National Museums of Kenya**) where they are curated, **ER** for East Rudolf, and then the field number (e.g., **KNM-ER 1813**). Temporal span and how dated? The Lonyumun Member, the oldest sediments in the Koobi Fora Formation, dates from 4.35 to 4.0 Ma, and the youngest, the Chari Member, dates from 1.39 to 0.7 Ma. The sediments have been dated using various radiogenic methods, **magnetostratigraphy**, and **biostratigraphy**. Hominins found at site Fossil hominins recovered from Koobi Fora have been assigned to *Paranthropus boisei* (e.g., **KNM-ER 406**, **407**, and **732**), *Homo erectus* or *Homo ergaster* (e.g., **KNM-ER 992**, **3733**, and **3883**), *Homo habilis* (e.g., **KNM-ER 1478**, **1501**, and **1813**), *Homo rudolfensis* (e.g., **KNM-ER 1470**, **1590**, and **1802**), and probably also *Australopithecus afarensis* (**KNM-ER 2602**). Several hominin footprint trails have also been uncovered. Archeological evidence found at site The Koobi Fora region is best known for its abun-

dant carefully excavated early Pleistocene **Oldowan** and **Developed Oldowan** archeological sites whose investigation was directed by Glynn **Isaac**. Extensive lateral sediment exposures combined with tephrostratigraphic correlations have permitted landscape-scale studies of early archeological and environmental variation. Other Pleistocene sites, particularly those characterized by **Acheulean** and **Middle Stone Age** artifacts, are sparse and their geological contexts are in many cases poorly understood. There is a robust mid-to-late regional **Holocene** archeological record, including sites characterized by fishing economies as well as early domesticates (primarily cattle) in the region. Key references: Geology, dating, and paleoenvironment Brown and Feibel 1991, Brown et al. 2006, McDougall and Brown 2006; Hominins Leakey and Leakey 1978, Wood 1991, Bennett et al. 2009; Archeology Bartheleme 1985, Rogers et al. 1994, Kelly 1996, Isaac 1997, Braun et al. 2009.

Koobi Fora Formation [Location 3°35'–4°25'N and 36°10'–36°30'E, Kenya; etym. Koobi Fora is the local Das(s)enetch name for several low hills on the northeastern shore of Lake Turkana] History and general description A substantial thickness of sediments on the northeastern shore of Lake Turkana. The strata from which fossil hominins have been recovered at Koobi Fora were originally assigned to the Kubi Algi, Koobi Fora, and the Guomde Formations (Bowen and Vondra 1973), all overlain by the Galana Boi Beds. These three formations have since been rationalized into a single unit called the Koobi Fora Formation within which eight members are recognized (Brown and Feibel 1986). Each member is defined as the sediments between the base of one designated tuff and the base of the designated tuff immediately overlying it. The members, starting at the base, are the Lonyumun, **Moiti**, **Lokochot**, **Tulu Bor**, **Burgi**, **KBS**, **Okote**, and the **Chari Members**. The name of the Lonyumun Member comes from a stream near its type section; the other names are taken from the name of designated tuff that forms the base of each member. The fossiliferous exposures are subdivided into seven subregions (Brown and Feibel 1991) and from north to south they are Il Dura, Ileret, Il Naibar Lowlands, Karari Ridge, Koobi Fora Ridge, Bura Hasuma, and Sibilot. Temporal span and how dated? The oldest member, the Lonyumun Member, dates from 4.35 to

4.0 Ma and the youngest, the Chari Member, dates from 1.39 to 0.7 Ma. The sediments have been dated using various radiogenic methods, **magnetostratigraphy**, and **biostratigraphy**. **Hominin evidence** Fossil hominins recovered from the Koobi Fora Formation have been assigned to or represent *Paranthropus boisei*, *Homo erectus* or *Homo ergaster*, *Homo habilis*, *Homo rudolfensis*, and probably also *Australopithecus afarensis*. There are also several footprint trails. **Archeological evidence** The Koobi Fora Formation includes evidence of **Oldowan**, **Developed Oldowan**, **Acheulean**, and **Middle Stone Age** sites and artifacts and there is a mid-to-late **Holocene** archeological record, including sites characterized by fishing economies as well as early domesticates (primarily cattle) in the region. Key references: **Geology, dating, and paleoenvironment** Brown and Feibel 1986, 1991, Brown et al. 2006, McDougall and Brown 2006; **Hominins** Leakey and Leakey 1978, Wood 1991, Bennett et al. 2009; **Archeology** Barthelme 1985, Rogers et al. 1994, Kelly 1996, Isaac 1997, Braun et al. 2009.

Koobi Fora hominin footprints Hominin footprints dating to *c.*1.4–1.53 Ma have been found at Koobi Fora, Kenya, on at least three footprint surfaces at two localities: FwJj14E located at Ileret and GaJi10 on the Koobi Fora Ridge. The three-dimensional shape of the hominin footprints on the three surfaces was captured using optical laser scanning, 13 landmarks were identified on each well-preserved print, and their shapes were compared using generalized **Procrustes analysis** (Bennett et al. 2009). The FwJj14E hominin footprints are better preserved than those at GaJi10 and those from the upper footprint surface at FwJj14E more numerous and include some that are better preserved than those from the lower footprint surface; thus data from the former provide most of the evidence used for morphometric analysis and functional interpretation. The hominin prints from both footprint surfaces at FwJj14E were described as having a “well-defined, deeply depressed and adducted hallux; visible lateral toe impressions that vary in depth of indentation; a well-defined ball beneath the first and second metatarsal heads; and a visible instep reflecting a medial longitudinal arch” (*ibid*, p. 1198). The average angle of hallucial abduction for the FwJj14E hominin footprints (14°) is significantly

greater than the mean for the modern human reference footprints (8°) and significantly smaller than the mean for the **Laetoli hominin footprints** (27°) (*ibid*, p. 1198). Compared to modern humans, the FwJj14E hominin footprints have a “narrower heel and ball area,” a “wider instep,” and “less pronounced arch elevation” (*ibid*, p. 1201), but when compared to the Laetoli hominin footprints the FwJj14E footprints have a “more contracted proximal mid-foot,” a “deeper instep,” and “the location of the narrowest point of the instep” is more proximal (*ibid*, p. 1201). Bennett et al. (2009) suggest that the morphology of the FwJj14E hominin footprints is consistent with modern human-style walking notably an “an adducted hallux, a medial longitudinal arch” and a “medial weight transfer before push-off” (*ibid*, p. 1201). Bennett et al. (2009) also suggest that although other taxa (*Homo habilis*, *Paranthropus boisei*) cannot be ruled out as the makers of the prints the morphology and size of the Ileret hominin footprints “are most consistent with the large size and tall stature evident in some *Homo ergaster/erectus* individuals” (*ibid*, p. 1201). *See also Homo erectus; Koobi Fora.*

Koobi Fora Research Project Paleoanthropological research along Lake Turkana (formerly Lake Rudolf) began in 1968 when Richard Leakey led a Kenya National Museum (now the **National Museums of Kenya**) expedition comprising Margaret Leakey, Paul Abell, Kamoya Kimeu, and two students, John Harris and Bernard Wood, to explore the deposits along the eastern shore of Lake Rudolf. During this initial survey the group identified extensive fossil deposits and recovered several fragmentary hominin fossils. As a result a base camp was established in the following year at a site along the lake shore called Koobi Fora. New scientists joining the project in 1969 included Kay Behrensmeyer, Meave Epps (now Meave Leakey), and Glynn Isaac. Behrensmeyer began the task of mapping the geology of the site, particularly the volcanic tuffs that facilitated radiometric dating of the deposits. Discoveries included Oldowan artifacts and two crania belonging to *Paranthropus boisei* (KNM-ER 406 and KNM-ER 407). In 1970 the **East Rudolf Research Project** was established under the leadership of Richard Leakey and Glynn Isaac and the number of participating scientists studying fossil mammals, including hominins, increased. A hominin mandible

discovered in 1971 (KNM-ER 992) later became the type specimen of *Homo ergaster* and in 1972 Bernard Ngeneo discovered a hominin cranium (KNM-ER 1470) that was to become the lectotype of *Homo rudolfensis*. Two crania discovered in 1973 (KNM-ER 1805 and KNM-ER 1813) were subsequently assigned to *Homo habilis*. Arguments over the dating of the KBS Tuff became a major issue since it had implications for the age of the KNM-ER 1470 cranium and of other hominins recovered from below the KBS Tuff and the controversy continued until its resolution in the early 1980s. In 1975 Lake Rudolf was renamed Lake Turkana by the Kenyan government and this prompted the East Rudolf Research Project to be renamed as the Koobi Fora Research Project and the first (KNM-ER 3733) of several hominin crania resembling *Homo erectus* was recovered. In 1981 the focus of research at Lake Turkana shifted from the east side to the west side of the lake and this led to the discovery in 1984 of a remarkably complete skeleton of an adolescent male at a locality called Nariokotome. The specimen (KNM-WT 15000) represents one of the most complete and earliest skeletons of *Homo erectus*. In 1985 researchers recovered the nearly complete cranium of a megadont archaic hominin (KNM-WT 17000) that was dated to *c.*2.5 Ma, making it substantially older than most other East African megadont archaic hominin fossils; it has been classified as either *P. boisei* or *Australopithecus aethiopicus*. The numerous geological, archeological, and paleoecological research projects undertaken during the 1980s (e.g., Kanapoi, Lomekwi, Lothagam) expanded the number of scientists working at Lake Turkana. Richard Leakey resigned from his position as director of the National Museums of Kenya in 1989 and Meave Leakey assumed leadership of research at Koobi Fora. The significance of the research carried out at Koobi Fora is exemplified by the publications in the *Koobi Fora Research Project* series. The six volumes in this series include *The Fossil Hominids and an Introduction to their Context, 1968–1974* (1978), *The Fossil Ungulates: Proboscidea, Perissodactyla, and Suidae* (1983), *The Fossil Ungulates: Geology, Fossil Artiodactyls, and Palaeoenvironments* (1991), *Hominid Cranial Remains* (1991), *Plio-Pleistocene Archaeology* (1997), and *The Fossil Monkeys* (2008).

Koobi Fora Ridge One of the designated subregions of the Koobi Fora region. *See Koobi Fora.*

Koobi Fora Tuff Complex *See Okote Tuff Complex.*

Kopwatu One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Koro Toro (Location 16°00'21"N, 18°52'34"E, Chad, Central Africa; etym. named after a local village) History and general description In a region called Bahr el Ghazal approximately 45 km/28 miles east of Koro Toro researchers identified more than 17 numbered localities where Pliocene fossiliferous sediments are exposed. Temporal span and how dated? 3.58±0.27 Ma based on biostratigraphy and cosmogenic nuclide dating. Hominins found at site There are four hominins from Koro Toro, three from locality KT 12 and one (a maxillary fragment) from KT 13. The three hominins from KT 12 are a mandibular fragment (KT 12/H1; the holotype of *Australopithecus bahrelghazali*), an upper premolar (KT 12/H2), and one (as yet unpublished) mandible fragment from the KT40 locality (Guy et al. 2008). Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Brunet et al. 1995, 1996, Lebatard et al. 2008; Hominins Brunet et al. 1995, 1996, Guy et al. 2008; Archeology N/A.

Kossom Bougoudi One of the “fossiliferous areas” within the Chad Basin; others include **Kollé**, **Koro Toro**, and **Toros-Menalla**. *See also Chad Basin.*

Kostenki (Location 51°23'N, 39°02'E, Russia; etym. named after the nearby town) History and general description The left bank of the Don River near Voronezh contains 28 open-air early Upper Paleolithic sites, known collectively as the Kostenki-Borshchevo localities. These sites have been excavated by various workers since the late 1800s. The age of these sites has been much studied, since they represent some of the oldest modern human occupations of Europe. Temporal span and how dated? Several methods including AMS radiocarbon dating and optically stimulated luminescence dating have been attempted, as well as magnetostratigraphic and geostratigraphic correlation. The sum of these methods suggests that the earliest deposits date to *c.*48 ka, and the latest to *c.*30 ka. The earliest Upper

Paleolithic deposits date to *c.*45 ka. Hominins found at site No fossils are found in the oldest layers. Two isolated teeth were found in the earliest Upper Paleolithic layer and these are tentatively assigned to *Homo sapiens*. More complete *H. sapiens* remains have been recovered from the later Upper Paleolithic/Aurignacian deposits. Archeological evidence found at site The lowest layers at the site contain a local "transitional" technocomplex, like the **Szletian**, that retains many Middle Paleolithic traits. The excavators suggest this was created by Neanderthals, but there are no fossils found in these layers. The earliest Upper Paleolithic layers contain a distinctive **Aurignacian** deposit, including bone and ivory artifacts, possible art, and shells. The later layers also contain Aurignacian assemblages, dwelling structures made of bones, and clay figurines. Key references: Geology, dating, and paleoenvironment Anikovich et al. 2007; Hominins Sinitsyn et al. 1997; Archeology Anikovich et al. 2007, Sinitsyn et al. 1997.

Kostenki-Borshchevo *See* **Kostenki**.

Kotzetang One of the three main areas within Zhoukoudian Locality 1. *See* **Zhoukoudian Locality 1**.

Kow Swamp (Location 35°55'S, 144°19'E, Australia; etym. named after the local swamp where the burials were discovered) History and general description Between 1968 and 1972 researchers recovered the primary burials of 17 robust anatomically modern human individuals from a silt and sand deposit 3.2 km/2 miles south of Leitchville, Victoria. Temporal span and how dated? Initially dated to the **Late Pleistocene** to **Early Holocene** by radiocarbon dating on associated charcoal (9590 years BP) and directly from the bone apatite of two specimens (KS 1, 10,070 years BP, and KS 9, 9300 years BP). More recent ages using optically stimulated luminescence dating on associated sediments place the Kow Swamp people during the **Last Glacial Maximum** (or LGM) (i.e., *c.*22–19 ka). Hominins found at site The 17 Kow Swamp individuals represent the largest single population of Late Pleistocene *Homo sapiens* known in the world. Their remarkable robusticity initially led researchers to link these modern humans directly to earlier *Homo erectus* specimens from Java. But another explanation for their osteological robusticity is that it represents long-term (*c.*20 ka) adaptation to a

deterioration in climatic conditions that culminated in the LGM. The Kow Swamp skeletal remains were re-interred in 1990. Archeological evidence found at site Quartz artifacts. Key references: Geology, dating, and paleoenvironment Thorne and Macumber 1972. Stone and Cupper 2003; Hominins Thorne and Macumber 1972, Kennedy 1984a, Habgood 1991, Brown 2010; Archeology Thorne and Macumber 1972.

KP Abbreviation of Kanapoi and the prefix used for fossils recovered from Kanapoi, Kenya. *See* **Kanapoi**.

Krapina (Location 46°10'N, 15°52'E, Croatia; etym. the name of a nearby town) History and general description The site is a sandstone rock-shelter in Hušnjakovo Brdo (Hill) where fossil mammal bones were discovered by local people when quarrying for building sand and stone. Dragutin **Gorjanović-Kramberger** found a fossil hominin molar when he visited Krapina in August 1899. Formal excavations, which began in September 1899 and lasted until 1905, yielded approximately 900 hominin fossils, more than 1191 lithic artifacts, and 3000 animal bones. Temporal span and how dated? Electron spin resonance spectroscopy dating on hominin dental enamel and uranium-series dating on the fauna suggest a short depositional event at the end of **Oxygen Isotope Stage** (or OIS) 6 or the beginning of OIS 5e (*c.*130 ka). Hominins found at site The roughly 900 hominin fossils represent a probable minimum of 70 individuals. They include Kr 1 (juvenile calotte) also known as the "A cranium," Kr 2 (juvenile occipital and parietals) also known as the "B cranium," Kr 3 (partial cranium) also known as the "C cranium," Kr 2/5 (parietals), Kr 6 (partial cranium) also known as the "E cranium," Kr 46 (juvenile maxilla with teeth) also known as the "B maxilla"), and Kr 59 (mandible) also known as the "J mandible." Several hundred specimens are cranial vault fragments, isolated teeth, and postcranial elements. Archeological evidence found at site **Mousterian**. The Krapina site is significant for a number of reasons. Some of these are historical in that Gorjanović-Kramberger's 1906 monograph is the earliest detailed monographic analysis of a sample of *Homo neanderthalensis* and his use of plain film radiography and fluorine dating were the first applications of these techniques to fossil hominins.

Early on the Krapina sample played an important role in debates about variation in Neanderthals. Because the sample includes many anatomical elements it has proved an important source of information about the pattern of intraspecific variation and the ontogeny of Neanderthals (Monge 2008). Krapina has also been influential in the debate over differences between early and “classic” Neanderthals in Europe (Smith 1976b), the accelerated pattern of Neanderthal growth and development (Wolpoff 1979, Mann et al. 1991), Neanderthal hunting (Miracle 2007), and the practice of cannibalism by Neanderthals (White 2001). Key references: Geology, dating, and paleoenvironment Rink et al. 1995, Simek and Smith 1997; Hominins Gorjanović-Kramberger 1906, Smith 1976b, Wolpoff 1979, Radović et al. 1988, Monge et al. 2008; Archeology Gorjanović-Kramberger 1913, Simek and Smith 1997, Karavanić 2007, Miracle 2007.

Kromdraai (Location 26°00′0″S, 27°45′0″E, South Africa; etym. Afrikaans for a “crooked turn,” referring to a bend in the road that runs along the Blaauwbank valley) History and general description Kromdraai is a complex of breccia-filled caves in Precambrian dolomite a mile or so east of Sterkfontein in the Blaauwbank valley in Gauteng Province, South Africa. In 1938 a local schoolboy, Gert Terblanche, found a hominin cranium at the site. He broke off all four of the teeth and gave one to the manager of the Sterkfontein mine (the same Mr Barlow who had managed the mine at Taungs), who showed it to Robert Broom. Broom recognized the tooth was unlike those he had collected at Sterkfontein so Broom visited Gert’s school and Gert took Broom to Kromdraai and showed him where he had hidden the cranium that became the type specimen (TM 1517) of *Paranthropus robustus*. There are two fossiliferous localities within 30 m of each other: Kromdraai A (the “faunal site” or “KA”) and Kromdraai B (the “hominid site” or “KB”). Three members, Members 1–3, are recognized in Kromdraai B. Temporal span and how dated? Biostratigraphy and magnetostratigraphy suggest that KB is c.2.0–1.5 Ma; Member 3 is likely between 1.78 and 1.65 Ma. Hominins found at site Thus far the majority of the hominin fossils have come from KB Member 3 and with only one exception they have been assigned to *P. robustus*. The exception, KB 5223, is a collection of decid-

uous and permanent isolated teeth presumed to come from a single individual. Braga and Thackeray (2003) claim that the size, shape, and morphology of the M₁ and dm₁ crowns of KB 5223 differ from the characteristic morphology of the equivalent teeth of *P. robustus* and resemble that of teeth belonging to early *Homo*. However, a study of the enamel microstructure of the right I₁ and M₁ of this specimen suggest that the teeth are not developing like those of *Homo* and in some critical ways (e.g., enamel extension and secretion rates) their development is more like that of *Paranthropus* (Lacruz 2007); Moggi-Cecchi et al. (2010) are also not convinced there is dental evidence of *Homo* at Kromdraai. A recently reported fragment of left humeral shaft (Thackeray et al. 2005) may well belong to the type specimen. Archeological evidence found at site Stone artifacts recovered from KA have been classified as **Developed Oldowan/Early Acheulean** and residue analysis suggests that the hominins were using them to process bone. Key references: Geology, dating, and paleoenvironment McKee et al. 1995, Thackeray et al. 2002b, Herries et al. 2009; Hominins Thackeray et al. 2001, 2005, Braga and Thackeray 2003, Lacruz 2007; Archeology Kuman et al. 1997, Thackeray et al. 2005.

Kruskal–Wallis test A nonparametric statistical test (i.e., it does not assume normally distributed variables) for difference in medians between two or more groups that is analogous to the **analysis of variance** (or ANOVA).

KS Abbreviation of Kow Swamp and the prefix for the hominin fossils recovered from Kow Swamp. Also an abbreviation of Kokiselei, one of several groups of localities within the site of West Turkana named after ephemeral river drainages. See **Kokiselei**; **Kow Swamp**; **West Turkana**.

Ksar 'Akil (Location 33°9′N, 35°6′E, Lebanon; etym. Palace of Akil) History and general description This cave site in eastern Lebanon was excavated in the 1920s, 1940s, and 1970s, and represents a type site for the Upper Paleolithic of the northern Levant. The early Upper Paleolithic deposits may be among the earliest in Eurasia, and include shell beads. Temporal span and how dated? Radiocarbon dating was attempted during the most recent excavations. The Mousterian

deposits were dated to $c.43$ ka, although this is probably an infinite date. Dates from the Upper Paleolithic layers average $c.32$ ka. The early Upper Paleolithic layers were not directly dated, but they may date to between 43 and 50 ka assuming constant rates of sediment accumulation. Hominins found at site None. Archeological evidence found at site Several layers that span from the late Middle Paleolithic through the Epipaleolithic were found in the 19 m-thick deposits. Key references: Geology, dating, and paleoenvironment Mellars and Tixier 1989; Hominins N/A; Archeology Azoury et al. 1988, Kuhn et al. 2001.

KSD-VP-1/1 Site Woranso-Mille. Locality KSD-VP-1. Surface/in situ Surface then *in situ*. Date of discovery February 10, 2005. Finder Alemayehu Asfaw, then excavation crew. Unit/horizon Mudstone. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Presumed C2An2/C2An3n boundary. Nearest underlying dated horizon Tuff dated by **argon-argon dating** to 3.6 ± 0.03 Ma. Geological age $c.3.6$ – 3.58 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Cervical vertebrae, four ribs, pelvic bone, scapula, shaft, and distal end of the humerus and shaft and proximal end of the ulna of the right side, clavicle, second rib, part of the adjacent shaft and the distal femur, and whole tibia of the left side. Announcement, initial description, photographs/line drawings, and metrical data Haile-Selassie et al. 2010a. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance This, the third adult associated skeleton of *Au. afarensis*, is substantially larger than A.L. 288-1 and thus enables researchers to get a sense of whether inferences based on the latter were influenced by any effects of scaling. Its describers interpret the preserved morphology as indicating that the “habitual bipedality” in *Au. afarensis* “was highly evolved.” Location of original **National Museum of Ethiopia**, Addis Ababa, Ethiopia.

KT Acronym for the Kilaytoli Tuff and prefix for fossils from the Koro Toro “fossiliferous area”, **Chad Basin**, Ethiopia. *See* **Koro Toro**.

KT 12/H1 Site **Koro Toro**. Locality KT 12. Surface/in situ Surface. Date of discovery January 23, 1995. Finders Not reported. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age $c.3.58 \pm 0.27$ Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A section of the left side of the mandibular corpus including the symphysis. It extends from the distal end of the left P₄ to the distal end of the right P₄ including the crowns of the left C–P₄ and the right I₂–P₄. Announcement Brunet et al. 1995. Initial description Brunet et al. 1996. Photographs/line drawings and metrical data Brunet et al. 1995, 1996. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus* aff. *Australopithecus afarensis*. Taxonomic revisions *Australopithecus bahrelghazali* Brunet et al. (1996). Current conventional taxonomic allocation *Au. bahrelghazali* or *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance Although KT 12/H1 is the holotype of *Au. bahrelghazali* its real significance is that the Koro Toro region is 2500 km/1550 miles west of the East African Rift Valley so it was the first sound evidence of an early hominin from a site outside of East and southern Africa. Location of original N'Djaména, Chad.

Kulkuletti (Location 8°03'N, 38°15'E, Ethiopia; etym. not known) History and general description Artifact-bearing area in the Gademotta Formation on the flanks of a collapsed caldera about 5 km/3 miles west of Lake Ziway in Ethiopia's **Main Ethiopian Rift System**. The tephra at Kulkuletti and **Gademotta** (approximately 2 km/1.2 miles away) have been correlated using **electron probe microanalysis** and the combination of the younger sediments at Kulkuletti with those found at Gademotta provides one of the oldest and richest samples of **Middle Stone Age** (or MSA) artifact assemblages. Temporal span and how dated? **Argon-argon dating** of sanidine crystals in tephra and correlation on the basis of field stratigraphic evidence and geochemical similarity suggest the Unit 10 tuff above the **Acheulean** and the oldest MSA strata are 280 ± 8 ka and the tuffaceous Unit D that overlies it has an age estimate of 180 ± 10 ka. Hominins found at site None. Archeological evidence found at site Among the more than 8000

recovered artifacts are **Levallois flakes**, **points**, and **cores** (many of them large), uniaxially and bifacially **retouched points**, as well as blades and blade cores. These are sufficient to attribute the artifacts from the two excavated strata at Kulku-letti to the MSA. **Obsidian** from the volcanics beneath the Gademotta Formation sediments was used as the primary stone raw material and the site was likely either a **quarry** or a near-quarry workshop. No faunal evidence has been recovered. Key references: Geology, dating, and paleoenvironment Laury and Albritton 1975, Morgan and Renne 2008; Archeology Schild and Wendorf 2005, Wendorf and Schild 1974.

Kŭlna (Location 49°25'N, 16°40'E, Czech Republic; etym. Czech for “shed”) History and general description The potential importance of this cave site near Sloup village 35 km/22 miles north of Brno was recognized in 1880. It was first excavated in the late 19thC and early 20thC, but it was not until 1961 that a formal program of excavation was begun. In 1965 hominin remains were recovered from layer 7a in association with stone artifacts described as **Mousterian** of the Micoquian tradition. Temporal span and how dated? Biostratigraphy, conventional **radiocarbon dating** (>45 ka BP uncalibrated), and **electron spin resonance spectroscopy dating** (layer 7a, c.50 ka BP) all suggest a Last Interglacial to Last Glacial date. Hominins found at site A partial maxilla (with I¹-M¹), a right parietal fragment, and isolated teeth have all been attributed to *Homo neanderthalensis*. Archeological evidence found at site Mousterian (Taubachian, Micoquian) and **Upper Paleolithic** (Magdalenian). Geology, dating, and paleoenvironment Valoch 1988, Rink et al. 1996; Hominins Jelinek 1966, Smith 1982; Archeology Valoch 1967, 1968.

Kumpari See Chongokni.

KUS Abbreviation of Kuseralee Dora. See Kuseralee Dora; Middle Awash study area.

KUS-VP-2/100 Site Kuseralee Dora. Locality Kuseralee Dora VP Locality 2. Surface/in situ Surface. Date of discovery November 7, 1995. Finder Unknown. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation **Sagantole Formation**. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff.

Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age c.4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Associated upper dentition comprising the right C, the right and left M¹, the left M², plus parts of the crowns of the right P³ and P⁴. Announcement White et al. 2009a. Initial description N/A. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance An associated dentition that includes both anterior and postcanine teeth. Location of original National Museum of Ethiopia, Addis Ababa.

Kuseralee Dora A concentration of fossil localities situated in the **Central Awash Complex** in the Afar Rift section of the East African Rift System in the **Middle Awash study area**, Ethiopia. Remains attributed to *Ardipithecus ramidus* have been found here.

k.y. (L. *kilo*=thousand) The abbreviation for a period of time expressed in thousands of years, as in “30 k.y. have elapsed since anatomically modern humans first reached Europe.” The result of an age determination, or **age estimate**, should be expressed differently, as in “the age of the anatomically modern human crania from the Omo is c.190 ka,” but many contemporary reports use the abbreviation “kyr.” See also **age estimate**.

kyphosis (Gk *kyphos*=bent forwards) The term kyphosis and its antonym **lordosis** refer to the angular relationship within or between sections of a compound structure (e.g., the vertebral column) or between two planes (e.g., the anterior and posterior components of the cranial base). Thus, the parts of the adult modern human vertebral column that are concave anteriorly (i.e., the thoracic and sacral) are referred to as being kyphotic, whereas the parts of the adult modern human vertebral column that are concave posteriorly (i.e., the cervical and lumbar regions) are referred to as being lordotic. With respect to the cranial base, organisms, or individuals with a smaller, more acute (i.e., more modern human-like) **cranial base angle** are said to have a more kyphotic **basicranium**, whereas organisms or individuals with a larger, more obtuse (i.e.,

more chimpanzee-like) cranial base angle have a more lordotic basicranium.

kyr (L. *kilo*=thousand) The way many contemporary reports abbreviate a period of time expressed in thousands of years, as in “30 kyr

have elapsed since anatomically modern humans first reached Europe”. The result of an age determination, or **age estimate**, should be expressed differently, as in “the age of the anatomically modern human crania from the Omo is *c.*190 ka.” *See also* **age estimate**.

L

L. Prefix used by the American contingent of the **International Omo Research Expedition** for localities in the **Shungura Formation** (e.g., L. 396). The prefix is also used for fossils found within one of the L. localities (e.g., L. 40-19).

L. 7a-125 Site Omo-Shungura. Locality 7-a. Surface/in situ Surface. Date of discovery 1968. Finder Not known. Unit N/A. Horizon Upper G 5. Bed/member Member G. Formation **Shungura Formation**. Group Omo Group. Nearest overlying dated horizon Tuff H. Nearest underlying dated horizon Tuff G. Geological age *c.*2.2 Ma. Developmental age Presumed adult. Presumed sex Unknown. Brief anatomical description A mandibular corpus that extends to just distal of the M₃ on both sides and includes the crowns of the right I₂-M₃ and the crowns of the left C-M₃ in different degrees of completeness. Announcement Howell 1969a. Initial description Howell 1969a. Photographs/line drawings and metrical data Howell 1969a. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus* cf. *boisei*. Taxonomic revisions *Australopithecus boisei* (Howell 1978, Coppens 1980). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Although the extensive matrix-filled cracking makes it difficult to be sure of what some of the pristine morphology would have been like, there is little doubt that this is one of the largest *P. boisei* mandibles in terms of the size of the corpus, yet it has one of the smallest canine crowns of known *P. boisei*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L. 40-19 Site Omo-Shungura. Locality L. 40. Surface/in situ "Found almost *in situ*, outcropping from E-5" (de Heinzelin 1983, p. 244). Date of discovery 1971. Finder Gerry Eck. Unit Sand. Horizon E-5. Bed/member Member E. Formation

Shungura Formation. Group Omo Group. Nearest overlying dated horizon Tuff F. Nearest underlying dated horizon Tuff E. Geological age *c.*2.35 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Nearly complete right ulna. The edges of the proximal articular surface are broken away and there are many linear cracks that limit the extent to which the size and shape of the shaft can be reconstructed, but any length measurements are liable to be accurate. Announcement Howell and Wood 1974. Initial description Howell and Wood 1974. Photographs/line drawings and metrical data Howell and Wood 1974. Detailed anatomical description Howell and Wood 1974. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions *Australopithecus* cf. *aethiopicus/boisei* (Howell et al. 1987), *Homo* (Aiello et al. 1999), *Paranthropus aethiopicus* (McHenry et al. 2007). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance The fact that researchers have difficulty assigning this relatively complete ulna to a taxon is a reflection of how little we know about the upper limb of 2-3 Ma-old hominins. McHenry et al. (2007) accepted Howell and Wood's (1974) assignment of L. 40-19 to *P. boisei*, but they also accept Aiello et al.'s (1999) assignment of OH 36 to *P. boisei* and thus conclude that the forelimb of *P. boisei* is highly variable. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L. 74a-21 Site Omo-Shungura. Locality 74-a (aka P 420). Surface/in situ Surface. Date of discovery 1968. Finder N/A. Unit N/A. Horizon G-3 to 5. Bed/member Member G. Formation **Shungura Formation**. Group Omo Group. Nearest overlying dated horizon Tuff H. Nearest underlying dated horizon Tuff G. Geological age *c.*2.2 Ma. Developmental age Presumed adult. Presumed sex Unknown. Brief anatomical description

The right side of the corpus of an adult mandible that extends from a fracture through the right I₂ alveolus to an oblique fracture that passes through the M₂ alveolus and the base of the ramus so that the inferior part of the anterior edge of the ramus is preserved but the angle is not. The crowns of the canine and P₄ are the only ones preserved but clean cross-sections through the roots of P₃ and M₁ are exposed. Announcement Howell 1969a. Initial description Howell 1969a. Photographs/line drawings and metrical data Howell 1969a. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus* cf. *boisei*. Taxonomic revisions *Au. boisei* (Howell 1978a, Coppens 1980). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance One of the earliest known mandibles of *P. boisei*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L. 338y-6 Site Omo-Shungura. Locality L. 338y* [*Omo-Shungura locality letter postfixes are listed in Howell and Coppens (1974) in capital letters, but Rak and Howell (1978) use lower case]. Surface/in situ *In situ*. Date of discovery Jean de Heinzelin recognized the occipital in a geological section and the two parietals were recovered from excavations conducted in 1969 by Gerry Eck, but subsequent excavations in the 1970–2 field seasons recovered no more of the hominin calvaria. Unit E-3. Horizon See above. Bed/member Member E. Formation Shungura Formation. Group Omo Group. Nearest overlying dated horizon Tuff F. Nearest underlying dated horizon Tuff D-3. Geological age c.2.4 Ma. Developmental age Juvenile (the spheno-occipital synchondrosis is unfused). Presumed sex Male on the basis of the precocious development of the ectocranial crests. Brief anatomical description All that remains of this incomplete juvenile calvaria is most of an occipital, both parietals, and a small fragment of the left side of the frontal, but these few elements are close to being perfectly preserved. Endocranial volume Approximately 420 cm³. Announcement Howell and Coppens 1974. Initial description Rak and Howell 1978. Photographs/line drawings and metrical data Rak and Howell 1978. Detailed anatomical description Rak and Howell 1978. Initial taxonomic allocation *Australopithecus boisei*. Taxonomic revisions Holloway (1981a) suggested that some features of the endocranial

morphology of the L. 338y-6 calvaria aligned it more with *Australopithecus africanus* or *Australopithecus afarensis* than with *Au. boisei*, but Leakey and Walker (1988) point out that many of these same features are seen in the KNM-WT 17000 cranium. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Despite being a juvenile the L. 338y-6 calvaria already manifests features seen in most adult *P. boisei* crania [e.g., the heart-shaped, or cardioid, foramen magnum, *striae parietalis*, temporal lines closest anteriorly, etc., but *contra* White and Falk (1999) it does *not* have an **occipito-marginal system** of endocranial venous drainage]. The calvaria provides important information about the ontogeny of *P. boisei* crania and these data were put to good use by Rak and Howell (1978). One of the two round holes in the anterior third of the right parietal is consistent with it being made by the canine of a large carnivore. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L. 894-76-898 Site Omo-Shungura. Locality L. 894. Surface/in situ Surface and then *in situ*. Date of discovery 1973 and then more recovered from excavations later that year and in 1974. Finders J. Mathias, J. Kithumbi, and Clark Howell. Unit “Silty sand”. Horizon G-28. Bed/member Member G. Formation Shungura Formation. Group Omo Group. Nearest overlying dated horizon Tuff H₂. Nearest underlying dated horizon Tuff G. Geological age c.2.0 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragments that make up approximately 30% of the cranium, including a fragment of the right maxilla, the right temporal that includes the mandibular fossa and the zygomatic arch, and a fragment of the vault around the left asterion. No anterior tooth crowns are preserved, but all but the left P⁴ of the postcanine tooth crowns are preserved. Announcement Boaz and Howell 1977. Initial description Boaz and Howell 1977. Photographs/line drawings and metrical data Boaz and Howell 1977. Detailed anatomical description Boaz and Howell 1977. Initial taxonomic allocation Boaz and Howell (1977) suggest that Omo L. 894-76-898 is an “an early species of *Homo*” (*ibid*, p. 105). The authors claim the partial cranium “most closely parallels Old. Hom. 24 and Old. Hom. 13” (*ibid*, p. 105) and thus by implication they

assign it to *Homo habilis*. Taxonomic revisions None. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Transitional hominin. Significance If this cranium does belong to *H. habilis* then it would be among the early evidence of that taxon and one of a small number of specimens from the Shungura Formation assigned to early *Homo*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L. 996-17 Site Omo-Shungura. Locality L 996 (this was originally a “P” locality, so some references refer to this fossil as “P. 996-17”). Surface/in situ Surface “on Upper Member K” (de Heinzelin 1983, p. 303). Date of discovery 1971. Finder N/A. Unit N/A. Horizon N/A. Bed/member Member K or older. Formation Shungura Formation. Group Omo Group. Nearest overlying dated horizon N/A. Nearest underlying dated horizon Tuff K. Geological age *c.*1.4 Ma. Developmental age Presumed adult. Presumed sex Unknown. Brief anatomical description Two cranial vault fragments, one “parietal,” and one near pterion that includes parts of the “frontal, sphenoid and parietal” (Coppens 1980, p. 219). Announcement Coppens 1980. Initial description Coppens 1980. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance These are fragments from a thick cranium (approximately 11.5 mm thick at lambda) and if it does belong to *H. erectus* it would be the best evidence of this taxon in the Shungura Formation. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

L’Homme de Tautavel *See* Caune de l’Arago.

LA Abbreviation of Lokalalei, one of several groups of localities within the site of West Turkana named after ephemeral river drainages. *See* Lokalalei.

La Chaise (Location 45°40’12”N, 0°26’48”E, France; etym. named after the nearby town) History and general description Discovered in 1850, the La Chaise cave complex is near Angoulême. There are three main galleries: Abri Suard, Abri

Bourgeois-Delaunay, and Grotte Duport (all named after the people who found them); the first two are the best-studied. Formal excavations were by P. David between 1930 and 1963 and he found several hominin remains in the Abri Suard. André Debénath excavated between 1967 and 1983 and found more hominin remains in both the Abri Suard and the Abri Bourgeois-Delaunay. Temporal span and how dated? Thermoluminescence dating and uranium-series dating suggest that Abri Suard dates to between 185 and 101 ka and Abri Bourgeois-Delaunay to between 146 and 106 ka. Hominins found at site Several cranial and postcranial fragments assigned to *Homo neanderthalensis* were recovered from the lower layers (Debénath’s layer 11) of Abri Bourgeois-Delaunay. The fossils from the Abri Suard are older and are described as being either Neanderthal or pre-Neanderthal. Many of the fossils in the Abri Suard come from juvenile individuals. Archeological evidence found at site The Abri Bourgeois-Delaunay contained Mousterian and Aurignacian deposits. Artifacts in the older deposits in Abri Suard have been assigned to the late Acheulean and the Mousterian. Key references: Geology, dating, and paleoenvironment Debénath 1974, Schvoerer et al. 1977, Schwarcz and Debénath 1979, Blackwell et al. 1983; Hominins Debénath 1974, 1977, Genet-Varcin 1974, 1975a, 1975b, 1976; Archeology Debénath 1977, Matilla 2004, 2005.

La Chaise-de-Vouthon *See* La Chaise.

La Chapelle-aux-Saints (Location 44°59’N, 1°43’E, France; etym. named after a nearby village) History and general description The cave of Bouffia Bonneval, near to the village of La Chapelle-aux-Saints, is located along the Sourdoire river, a tributary of the Dordogne, in the Corrèze, France. It is a small, shallow cave, no more than 4 m wide. Excavations at the site by A. Bouyssonie, J. Bouyssonie, and L. Bardon began in 1905 and they extended approximately 6 m into the cave. The site is best known for the nearly complete skeleton of *Homo neanderthalensis* recovered in 1908. Temporal span and how dated? Electron spin resonance spectroscopy dating of the hominin skeleton suggested an age of either *c.*47 ka or 56 ka depending on the radiation-uptake model used. Hominins found at site A single aged male hominin skeleton, **La Chapelle-aux-Saints 1**, was buried at the base of the infill that contained the archeological

assemblage. Archeological evidence found at site The excavators described only one archeological level in which they found a **Mousterian** assemblage. It was dominated by **scrapers**, but it also included **handaxes**, **discoids**, and **points**. The types and relative quantities of artifacts matched the **Quina Mousterian** assemblage (Bouyssonie et al. 1913). Although the excavators recovered many animal bones, none of them were worked. The fauna was dominated by *Rangifer tarandus*, but it also included *Bos/Bison*, *Equus*, *Capra ibex*, *Canis lupus*, *Canis vules*, *Rhinoceros*, *Hyena spelaea*, *Sus scrofa*, and *Arctomys*. Bouyssonie et al. (1913) suggested the cave sediments were laid down during a cold period. Key references: Geology, dating, and paleoenvironment Grün and Stringer 1991; Hominins Boule 1908, 1909, 1911, 1912, Trinkaus 1985, Heim 1989; Archeology Bouyssonie et al. 1908, 1913, Boule 1911.

La Chapelle-aux-Saints 1 Site La Chapelle-aux-Saints. Locality Mousterian layer. Surface/in situ *In situ*. Date of discovery 3 August 1908. Finders A. Bouyssonie, J. Bouyssonie, P. Bouyssonie, and L. Bardon. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Electron spin resonance spectroscopy dating** of the hominin skeleton suggested an age of either *c.*47 ka or 56 ka depending on the radiation-uptake model used. Developmental age *c.*40–45 years. Presumed sex Male. Brief anatomical description Nearly complete cranium and mandible with all of the postcanine teeth lost pre-mortem. There is significant resorption of the alveolar process of the mandible. Many postcranial elements are present, including 21 vertebrae, 20 ribs, a clavicle, both humeri, both radii (though fragmentary), both ulnae, some hand bones, pieces of the pelvic bone, both femora (though fragmentary), both patellae, both tibiae, an astragalus, a calcaneus, five right metatarsals, fragments of left metatarsals, and one pedal phalanx. Announcement Bouyssonie et al. 1908. Initial description Boule 1908, 1909. Photographs/line drawings and metric data Boule 1908, 1909, 1911, 1912, Trinkaus 1985, Heim 1989. Detailed anatomical description Boule 1908, 1909, 1911, 1912, Tappen 1985, Trinkaus 1985, Heim 1989. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic

allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance Marcellin Boule's original reconstruction of this fossil (1911, 1912) portrayed this individual as a stooped and hunched, which fostered the stereotype of Neanderthals as substantially less-evolved, both intellectually and physically, than modern humans. The reconstruction was corrected to a more upright posture in the 1950s (Straus Jr and Cave 1957). Other researchers, noting that this individual had lost all of its molar teeth and had widespread severe degenerative joint disease, and thus may not have been able to chew or hunt, argued that this was evidence that Neanderthals had a complex social system that involved care for less able individuals (Jolly and Plog 1982). Location of original Musée de l'Homme, Paris.

La Fate *See* Caverna delle Fate.

La Ferrassie (Location 44°57'N, 0°56'E, France; etym. named after a nearby village) History and general description The site of La Ferrassie, which is located in the Vézère valley between the towns of Bugue and Sauvignac-de-Miremont in the Dordogne, consists of a large and deep cave with a small rock-shelter to one side and a long rock-shelter to the other, all hollowed out from a south-facing cliff, overlooking a valley with a perennial spring. It was first explored by archeologists in 1896, when M. Tabanou excavated a small area of the site. In 1902, Denis Peyrony began systematic excavations that resulted in the removal of all the sediments in the shallow rock-shelter and the cave, and much of the talus slope below the longer rock-shelter was also excavated. Delporte and colleagues returned to the site in the late 1960s and early 1970s to focus on the **Aurignacian** and later levels. Temporal span and how dated? The dating of this site is problematic due to some mixing of the levels. Current dates rely on **radiocarbon dating** of fauna, **chronostratigraphic** correlations to other sites, and some **electron spin resonance spectroscopy dating** (or ESR). The oldest, **Mousterian**, levels have been correlated with the Ferrassie Mousterian at **Combe Grenal**, suggesting a date between 68 and 74 ka, which is equivalent to the transition between **Oxygen Isotope Stage** (or OIS) 5 and OIS 4. ESR ages on bovid teeth that may be from the Mousterian levels have been difficult to interpret, but they suggest a general age

of OIS 3. Radiocarbon dates from the later levels suggest the site was abandoned *c.*27 ka (i.e., during the Gravettian period). Hominins found at site The remains of eight hominin individuals were found at this site over the period from 1909 to 1921. There were two adults (**La Ferrassie 1** and **La Ferrassie 2**), three juveniles, one neonate, and two fetuses, at least one of which was probably intentionally buried with a possible grave good. One of the juveniles (**La Ferrassie 6**) was secondarily buried. Archeological evidence found at site The small rock-shelter and the cave contained archeological material from the Mousterian, Aurignacian, and Gravettian periods, and the talus slope below the longer rock-shelter contained Mousterian, **Châtelperronian**, Aurignacian, and Gravettian levels. Key references: Geology, dating, and paleoenvironment Capitan and Peyrony 1912a, 1912b, Mellars 1986, Texier 2001, Delpech and Rigaud 2001, Delpech 2007; Hominins Capitan and Peyrony 1912a, 1912b, Heim 1970, 1974a, 1974b, 1976, 1982a, 1982b; Archeology Capitan and Peyrony 1912a, 1912b, Peyrony 1934, Delporte 1969, 1978, Delporte and Tuffreau 1972/3, Delporte et al. 1977, 1983.

La Ferrassie 1 Site La Ferrassie. Locality **Mousterian** layer. Surface/in situ *In situ*. Date of discovery September 1909. Finders Peyrony and Capitan. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*68–74 ka. Developmental age *c.*45 years. Presumed sex Male. Brief anatomical description Well-preserved cranium with most of the face and nearly complete dentition, and many well-preserved postcranial elements, including 23 vertebrae, sacrum, 20 ribs, both clavicles, scapulae, humeri, radii, ulnae, pelvis, both femora, tibiae, fibulae, and some hand and foot bones. Announcement Capitan and Peyrony 1909. Initial description Boule 1921. Photographs/line drawings and metrical data Boule 1921, Heim 1970, 1974a, 1974b, 1976, 1982a. Detailed anatomical description Heim, 1970, 1974a, 1974b, 1976, 1982a. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance One of the more complete Neanderthal skeletons, and, together with **La Ferrassie 2** and **La Chapelle-aux-Saints 1**, it

was used by Marcellin **Boule** to reconstruct the morphology of Neanderthals. Although the anterior teeth of this individual were incorrectly placed in the reconstruction, there is evidence they may have played a non-masticatory role (Wallace 1975, Puech 1981). A piece of animal bone with incised marks on the surface was found in association with this individual, and Capitan and Peyrony (1909) suggested this was a grave good. Location of original **Musée de l'Homme**, Paris.

La Ferrassie 2 Site La Ferrassie. Locality **Mousterian** layer. Surface/in situ *In situ*. Date of discovery September 1910. Finders Peyrony and Capitan. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*68–74 ka. Developmental age *c.*25–30 years. Presumed sex Female. Brief anatomical description Fragmented cranium, though with most pieces represented, maxilla with six teeth, and three loose mandibular teeth. Well-preserved and complete postcranial skeleton, with 11 vertebrae, 19 ribs, both scapulae, humeri, one radius, one ulna, the pelvis, both femora, patellae, tibiae, fibulae, and parts of both hands and both feet. Announcement Capitan and Peyrony 1911. Initial description Boule 1921. Photographs/line drawings and metrical data Boule 1921, Heim 1970, 1974a, 1974b, 1976, 1982a. Detailed anatomical description Heim 1970, 1974a, 1974b, 1976, 1982a. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance This is one of the more complete Neanderthal skeletons, and, together with **La Ferrassie 1** and **La Chapelle-aux-Saints 1**, it was used by Marcellin **Boule** to make his reconstruction of Neanderthal morphology. Location of original **Musée de l'Homme**, Paris.

La Ferrassie 6 Site La Ferrassie. Locality **Mousterian** layer. Surface/in situ *In situ*. Date of discovery 1921. Finders Peyrony and Capitan. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*68–74 ka. Developmental age *c.*3–5 years. Presumed sex Unknown. Brief anatomical description Well-preserved, nearly complete skeleton of a juvenile, including 16–20

vertebrae, 11 ribs, both humeri, radii, ulnae, the pelvis, both femora, tibiae, one patellae, one fibula, and some hand and foot bones. The cranium is badly damaged and fragmentary, and was separated from the body. Announcement Capitan and Peyrony 1921. Initial description Capitan and Peyrony 1921. Photographs/line drawings and metrical data Capitan and Peyrony 1921, Peyrony 1934, Heim 1982b. Detailed anatomical description Heim 1982b. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The cranium of this individual appears to have been secondarily separated from the skeleton and reburied 1.25 m away. Peyrony and Capitan (1921) also found a large calcite stone with several cupules engraved on its surface overlying the grave of this individual, which they considered to be an intentional grave good. Location of original Musée de l'Homme, Paris.

La Madeleine (Location 44°58'05"N, 1°01'52"E, France; etym. named after a nearby village) History and general description La Madeleine is an extensive rock-shelter in a south-facing cliff along the floodplain of the Vézère river in the commune of Tursac in the Dordogne region. It was first explored by Lartet and Christy in 1863, and fully excavated by Peyrony and Capitan in 1921–2 (Capitan and Peyrony 1928). These investigations were followed up by Bouvier and others in attempt to better understand the stratigraphy of the site. The unique stone tool technology found at this site was named the **Magdalenian**, and examples of this technocomplex are found throughout western Europe. Temporal span and how dated? The Archeological layers have not been directly dated, but the Magdalenian burial of a child was dated by **radiocarbon dating** to c.10,190 years BP. This date is young when compared with other Magdalenian occupations, and it is unclear whether the burial is intrusive or if the dating was somehow compromised. Hominins found at site Several hominin remains were found at the site, but only two were more than small fragments. Near the middle of the deposit Lartet and Christy found the fragmentary remains of anatomically modern human, including parts of the skull, the mandible and a few long bones (Lartet and Christy 1864). They believed this was an intentional burial, even though it was not associated with any grave goods. The most famous fossil from La Madeleine is that of

a child (**LM4**) found in the uppermost layer, where several thousand pierced shells and other decorations were found with the burial (Capitan and Peyrony 1928, Peyrony 1928, Heim 1991, Vanhaeren and d'Errico 2001). Archeological evidence found at site Lartet and Christy's excavation took place over a brief period in 1863, and warranted only a two-page description of the site (Lartet and Christy 1864). They excavated a deposit that was 15 m by 5 m in area, and between 2.5 and 3 m deep, with what they described as a homogeneous fauna and tool typology. They found both bone and stone tools, including harpoons and carved pieces, and a large quantity of flint tools, including knives and scrapers. Capitan and Peyrony removed the backfill of the preceding excavations, and in the undisturbed areas they recognized three main sedimentary layers. Although later archeologists described further subdivisions within each of these layers, the overall pattern of these three layers and the archeological finds from each layer came to define the main stages within the classical Magdalenian period (Bouvier 1973). In sum, the Magdalenian is known for its bone harpoons, large quantities of stone burins, and bones and antlers decorated with engravings, mostly of animals. Key references: Geology, dating, and paleoenvironment Gambier et al. 2000, Bouvier 1973; Hominins Heim 1991; Archeology Lartet and Christy 1864, Capitan and Peyrony 1928, Bouvier 1973, Vanhaeren and d'Errico 2001.

La Naulette (Location 50°12'46"N, 4°55'53"E, Belgium) History and general description La Naulette is 1 km/0.6 miles southwest of Chaleux on the left bank of the River Lesse. Hominin remains were found in a series of campaigns by Dupont in 1866. Temporal span and how dated? The remains have not been dated, but were thought by Dupont to be older than "classic" *Homo neanderthalensis* because of their stratigraphic location. Hominins found at site An incomplete mandible with all teeth lost post-mortem, an ulna, and a third metatarsal of undiagnosed species. The mandible, thought to belong to a female, possesses primitive characteristics (e.g., the symphyseal region) but it does not show any *H. neanderthalensis* characters, such as a retromolar space. Metrically the mandible falls between the variation of Neanderthals and their predecessors. The ulna and third metatarsal, on the other hand, are said to be morphologically and metrically modern (although there is overlap with Neanderthals).

There is a possibility that the postcranial remains are intrusive but only direct dating will answer this question. Archeological evidence found at site No stone tools are associated with the human remains. Key references: Hominins Dupont 1866, 1867, 1872.

La Quina (Location 45°30'N, 0°17'E, France; etym. named after a nearby town) History and general description La Quina is located in the Charente region, southeast of the city of Angoulême. It is made up of a series of rock-shelters in and at the base of limestone cliffs lining a floodplain of the Voultron River. There were two main archeological accumulations. The main one, Station Amont, consisted of a roughly 7 m-deep deposit that extended more than 100 m along the base of the cliff. This deposit contained several **Mousterian** layers and yielded many faunal remains and stone tools, and more than 50 fragments from *Homo neanderthalensis* individuals. About 200 m to the southwest, the smaller accumulation, called Station Aval, contained Mousterian, **Châtelperronian**, and **Aurignacian** levels (Henri-Martin 1961). The upper area was first explored between 1881 and 1885 by Chauvet and Ramonet, then Henri Martin more thoroughly excavated both areas from 1905 to 1935; thereafter Martin's daughter, Germaine Henri-Martin, continued the excavations from 1953 to the late 1960s (Henri-Martin 1964), but she did not publish a comprehensive summary of her findings, nor was the stratigraphic context clear. After her death, the site was given to the Musée des Antiquités Nationales of France, and Arthur Jelinek and André Debénath have continued excavations at the site since 1985. Temporal span and how dated? Débenath and Jelinek dated two of their layers using **thermoluminescence dating** on burned flints to *c.*43 ka and *c.*48 ka, but these layers correspond to Martin's upper Mousterian levels, suggesting that the majority of the Station Amont is much older. Others have suggested dates corresponding to **Oxygen Isotope Stages 3–4**. Hominins found at site Fifty-three remains of Neanderthals were recovered in the Station Amont, but most of these are very fragmentary. One fairly complete Neanderthal skeleton, **La Quina H5**, was recovered and possibly represents an intentional burial. Archeological evidence found at site In the Station Amont Henri Martin described four Mousterian layers that graded into

each other. He interpreted these finds to indicate a local development and improvement in technology, that eventually included very rare bone tools and pierced teeth and bone pieces (Martin 1910). The stone tool technocomplex found in Martin's middle Mousterian layer became known as the Quina Mousterian, and is found at sites throughout Europe. Debénath and Jelinek (1998) excavated a small witness baulk and areas to the north and south of Martin and Henri-Martin's excavations in the Station Amont. While they also found only Mousterian deposits, their stratigraphy differs from that of Martin, making correlation between the new and old excavation difficult. The excavation of the Station Aval revealed a Mousterian level, a Châtelperronian level, and a "typical" Aurignacian level. Key references: Geology, dating, and paleoenvironment Debénath and Jelinek 1998; Hominins Martin 1911a, Martin 1911b, Martin 1912a, Martin 1912b, Martin 1913, Verna 2006, Verna et al. 2010; Archeology Henri-Martin 1961, Jelinek et al. 1989, Debénath and Jelinek 1998, Chase et al. 1994, Hardy 2004.

La Quina H5 Site La Quina. Locality N/A. Surface/in situ *In situ*. Date of discovery 18 Sept 1911. Finder Germaine Henri-Martin. Unit N/A. Horizon N/A. Bed/member Quina **Mousterian** Layer, or Martin's layer 3. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age >*c.*48 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Cranium, mandible, and fragments of cervical vertebrae, both scapulae, both clavicles, both humeri, one ulna, both femora. Announcement Martin 1911a. Initial description Martin 1911a. Photographs/line drawings and metrical data Martin 1912a. Detailed anatomical description Martin 1912a. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The two humeri assigned to this individual varied in circumference by about 11 mm, suggesting pathology of the right arm. Location of original Musée de l'Homme, Paris.

La Roche à Pierrot *See* Saint-Césaire.

Labeko Koba (Location 43°03'N, 2°29'W, Spain, etym. Basque for "baking caves") History

and general description This cave site is located in Guipúzcoa on the coast of the Basque Country of Spain. It was excavated between September 1987 and December 1988 primarily by Alvaro Arrizabalaga and Jesús Altuna as part of a salvage operation prior to the construction of a highway. Although the site was heavily affected by damage from water flow many of the discovered artifacts display signs of decoration and artistic behavior. Temporal span and how dated? Conventional **radiocarbon dating** of bone from the oldest and youngest layers have given dates of $29,750 \pm 740$ to $34,215 \pm 1265$ years BP. Hominins found at site None. Archeological evidence found at site Many bone and lithic artifacts were found in the five archeological layers. These layers record the start of the Upper Paleolithic in Cantabria, including the **Châtelperronian**, Proto-Aurignacian, and the **Aurignacian** technocomplexes. Key references: Geology, dating, and paleoenvironment Arrizabalaga and Altuna 2000, Arrizabalaga et al. 2003; Hominins N/A; Archeology Arrizabalaga and Altuna 2000, Arrizabalaga et al. 2003.

Laboratory for Human Evolutionary Studies Established in 1970 by Clark Howell within the Department of Integrative Biology at the University of California at Berkeley, and co-directed by Howell and Tim White. It is now directed by Tim White. It conducts fieldwork in Ethiopia, and has conducted fieldwork in Turkey. It is the home of the Researching Hominid Origins Initiative, which is a NSF-HOMINID program-funded initiative.

Laboratory of Vertebrate Paleontology Established in 1949 by the People's Republic of China, it was part of the Institute of Palaeontology within the **Chinese Academy of Sciences**. It was charged with continuing the study of early man in China by field and laboratory research. In 1953 it became an independent institute within the *Academia Sinica* and in 1957 changed its name again to the **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP).

labyrinth *See* bony labyrinth; membranous labyrinth.

lack-of-signal artifacts One of several technical problems involved in the data-acquisition stage of **computed tomography**. When fossils

are heavily mineralized and attenuation levels are high, the level of the X-rays reaching the detector may be quantitatively close to the level of the noise in the signal. A positive noise fluctuation is not disastrous, but a negative noise fluctuation reduces the signal to almost zero, and results in fine high-density streaks that can obscure the object of interest.

lack of spatial resolution One of several technical problems involved in the data-acquisition stage of **computed tomography**. In the scan plane resolution is limited by the beam geometry of the CT scanner (e.g., focal spot width, detector width, geometry) and it should not be limited by the pixel size if an appropriate reconstruction matrix size is chosen. Perpendicular to the scan plane, it is limited by the slice thickness and the slice-indexing geometry. The result of a limited spatial resolution in the resulting images is a blurring effect, so that an instantaneous transversal from, say, bone to air, is represented not by a sharp boundary, but by a gradual change in the density of the image. This means that when making linear measurements on CT images researchers have to make sure that the position of that transversal is halfway along the density slope that reflects the lack of spatial resolution. The researcher should not try and locate the termini of measurements by eye for this may lead to substantial errors, especially when the distances are relatively small.

lactase persistence The ability to digest lactose into adulthood. All mammals can digest milk as infants; however, this ability is typically lost after the infant is weaned. Specifically, the gene (called *LCT* in modern humans) that encodes the enzyme lactase is turned off. Lactase breaks down the sugar lactose into glucose and galactose, which can be absorbed into the bloodstream. In individuals who are lactose intolerant, this process does not take place and the lactose is metabolized by intestinal bacteria, which produce byproducts including hydrogen and methane (typically causing cramping, bloating, diarrhea, and nausea). In modern humans lactase persistence has evolved multiple times in populations with a history of herding and dairying (Bersaglieri et al. 2004, Itan et al. 2010, Tishkoff et al. 2007).

lactose intolerance *See* lactase persistence.

lacustrine (*L. lacus*=lake and *imus*=relating to) Anything that relates to lakes, so "lacustrine

sediments” are sediments formed in the bed of a lake.

LAD Acronym for **last appearance datum** (*which see*).

Laetoli (formerly Laetolil) [Location 3°13'27"S and 35°11'38"E, Tanzania; etym. Leakey et al. (1976) suggest that the name of the site derives from the Maasai name for a red lily plant (*Haemanthus*) that grows abundantly in the area. However, it is more likely that the name “Laetoli” is actually a corruption of the name of a local river called the Olaitole. Peter Kent, the geologist with Louis Leakey’s 1935 expedition to the area, recognized three stratigraphic subdivisions and named the lowermost the Laetolil Beds. However, in 1979 Mary Leakey reported that “the Tanzanian authorities have now asked that the term Laetolil should be dropped in favor of Laetoli” (Leakey and Hay 1979, p. 317). Hence the site is now called “Laetoli”, but for reasons to do with the rules of geological nomenclature the old name for the sediments, the “Laetolil Beds,” has to be retained] History and general description The site now called Laetoli is where fossiliferous sediments known variously as the Garusi River Series, the Vogel River Series, and the Laetolil Beds are exposed mainly along the headwaters of the Garusi River. The area was first explored by Louis Leakey and colleagues in 1935 and a hominin lower canine (M.42323, but published as “M.18773”) was recovered. In 1938–9 an expedition led by Ludwig Kohl-Larsen recovered three hominin fossils (Garusi I, II, and 4). Louis and Mary Leakey made a brief visit to the area in 1959 and Mary Leakey returned briefly to visit with Richard Hay in 1964. Attention was refocused on the area when George Dove reported finding fossil vertebrate teeth in the headwaters of the Gadjjengero River (that flows northwestward into Lake Masek) in 1974 and it was during that visit that Mary Leakey located hitherto unexplored exposures, from which her team recovered a hominin upper premolar and a juvenile mandible. The hominin-bearing Upper Laetolil Beds are exposed over an approximately 60 km²/23 square mile area and the discrete localities are numbered from 1 to 24. The hominin fossils referred to as Laetoli hominids (LH) 1–14 were collected in 1974–5 and the hominins numbered LH 15–19 and 21–30 (NB: LH 20 is a monkey) were collected by Mary

Leakey’s expedition between 1975 and 1979. An isolated upper molar (LH 31) was recovered by the **Institute of Human Origins’** expedition in 1987. Four more hominins (EP 1000/98, 162/00, 2400/00, and 1500/01) were collected between 1998 and 2001 by the **Eyasi Plateau Paleontological Project**. Fossil footprints of small and large animals, including the trails of three hominins (one individual is included in the footprints preserved at A in Locality 6 and at least two individuals at G in Locality 8) were first recognized in 1976. Temporal span and how dated? *Australopithecus afarensis* remains are restricted to the Upper Laetolil Beds dated to 3.85–3.63 Ma; *Paranthropus aethiopicus* is known only from the Upper Ndolanya Beds (2.66 Ma). The sediments have been dated using **potassium-argon dating** and **argon-argon dating**. Hominins found at site The 40 hominins recovered from Laetoli include a right maxillary fragment (Garusi I) the holotype of *Praeanthropus africanus*, a virtually complete mandibular corpus, the holotype of *Australopithecus afarensis* (LH 4), an associated skeleton (LH 21), a fragment of the right maxilla that has been assigned to *Paranthropus aethiopicus*, and a proximal tibia that may belong to the same taxon. A partial cranium of an archaic *Homo sapiens* (LH 18) is known from the **Late Pleistocene** Upper Ngaloba Beds. Archeological evidence found at site No tools are known from the Upper Laetolil Beds. A single stone artifact has been reported from the Upper Ndolanya Beds, but this is likely to be intrusive. **Middle Stone Age** and **Later Stone Age** artifacts are known from the Late Pleistocene Olpiro and Ngaloba Beds. Key references: Geology, dating, and paleoenvironment Drake and Curtis 1987, Hay 1987; Hominins Leakey et al. 1976, White 1977, 1980, Leakey 1987, Day et al. 1980; Archeology N/A. *See also* *Australopithecus afarensis*; *Laetoli hominin footprints*; *Paranthropus aethiopicus*.

Laetoli 18 *See* LH 18.

Laetoli Beds *See* Laetoli.

Laetoli hominin footprints In 1976, Andrew Hill, who was visiting Mary Leakey’s camp, discovered animal prints and raindrop impressions preserved on an exposed airfall tuff (White and Suwa 1987). In the following year,

Phillip Leakey and Peter Jones found a trail of five prints, potentially made by a hominin, at Footprint Site A and in 1978 Paul Abell discovered footprints of hominins and a variety of other animals at Footprint Site G; both sets of prints are in a series of footprint-bearing layers of petrified volcanic airfall ash (Leakey and Hay 1979) most likely emitted from the now quiescent Sadiman volcano, some 20 km/12.5 miles to the east. The age of the footprint-bearing stratum is estimated to be 3.66 Ma. Initially Ndibo Mbuika and later Tim White and Ron Clarke eventually uncovered a 41 m-long surface, of which 27.5 m exposed the surface of the footprint tuff. The excavations unearthed the trails of three hominin individuals at Site G. Two trails (G-1, G-2/3) occur side by side, suggesting that two individuals may have walked together; prints of the third individual (G3) were made in the prints of G2, obscuring some of the details of prints in both trails. A total of 38 footprints were uncovered in the G-1 trail, and 31 in the G-2/3 trail. Based on foot length estimated from the prints and limb lengths inferred from foot length and fossil anatomy, it is estimated that the hominins were moving at a leisurely 0.4–0.45 m/s walking pace (Tuttle et al. 1990). Researchers continue to debate interpretations of the prints. Virtually all researchers agree that the Laetoli hominin prints represent evidence of hominins well adapted for bipedal walking with derived foot anatomy, including relatively short toes and a hallux (big toe) more closely aligned with the other toes than is the case in the extant African apes. However, researchers disagree over interpretations regarding other aspects of foot anatomy and gait, with some arguing that the Laetoli prints were made by a hominin with a foot with a **longitudinal arch** and modern human-like hallux adduction and with a **gait** like that of modern humans (e.g., Leakey and Hay 1979, White and Suwa 1987, Tuttle et al. 1990, Raichlen et al. 2010) and others suggesting that the anatomy of the foot and/or the gait were not modern human-like (e.g., Stern and Susman 1983, Bennett et al. 2009). Prints of other animals found along with the hominin footprints include those of (in order of abundance) members of the Bovidae (especially *Madoqua*, dik-dik), Lagomorpha, Giraffidae (including large and small species), Rhinocerotidae, Equidae, Suidae, Proboscidea, Rodentia, Carnivora, and Cercopithecidae.

lag deposit What is left after high-energy flow (usually subaqueous) has preferentially removed the

finer-grained or lower-density components of the sediment. One effect of this is to concentrate particles that require a higher energy to transport them. The same process can result in the preferential concentration and accumulation of skeletal elements particularly within fluvial channels.

Lagar Velho (Location 39°45'20"N, 8°44'6"W, Portugal; etym. Portuguese for “old olive press”) History and general description The site is a rock-shelter located in the Lapedo gorge, about 7 km/4.3 miles east of the city of Leiria, in central Portugal. An early Upper Paleolithic burial was identified at the site in November 1998, and excavated as a salvage operation over 4 weeks (under the direction of João Zilhão), followed by more extensive area excavation of the Upper Paleolithic occupation levels in the subsequent decade (under the direction of Francisco Almdeida). The discovery occurred after the uppermost levels of the site had been bulldozed away, which brought about extensive breakage of the skull but only marginally affected the postcranial skeleton, which was buried a few centimeters deeper in a shallow pit. Temporal span and how dated? The burial was covered by approximately 3 m of sterile deposits, but about 20 m to the east the rock-shelter fill contained a rich Gravettian-to-Solutrean sequence that overlay a late **Oxygen Isotope Stage 3** non-archeological fluvial and colluvial succession. Lateral stratigraphic correlation and radiocarbon dating of associated finds place the burial event *c.*30 ka. Hominins found at site The burial contained the articulated postcranial skeleton of a 4–5-year-old child, with the mandible, dentition, and most of the fragments of the broken cranium having been recovered from surrounding disturbed sediments (**Lagar Velho 1**). Archeological evidence found at site The burial context provided detailed evidence of ritual (burning of a Scots pine branch prior to deposition of the body, body laid down with body ornaments and wrapped-up in a red-ochre-painted shroud, and deposition of grave gifts, namely parts of a deer at the head and feet, and a juvenile rabbit skeleton across the legs) and the Late Gravettian occupation surfaces were very well preserved, containing both evident features (e.g., hearths) and circumstantial evidence of activities *in situ* (e.g., about 100% by weight stone tool refitting). Key references: Duarte et al. 1999, Zilhão and Trinkaus 2002, Almeida et al. 2009, Bayle et al. 2010.

Lagar Velho 1 Site Lagar Velho. Locality Grid unit L20. Surface/in situ *In situ*. Date of

discovery November 28, 1998. Finders João Maurício and Pedro Souto. Unit/horizon gs complex. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Rabbit placed across lower legs radiocarbon dated to 23,920±220 years BP (OxA-8422). Nearest underlying dated horizon Scots pine charcoal under the body radiocarbon dated to 24,860±200 years BP (GrA-13310). Geological age c.24 ka. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Although clearly modern human by most anatomical criteria, the child also presented a series of traits (e.g., low crural index, receding symphysis, semispinalis capitis fossae, I₂ shoveling, dental maturational pattern) usually associated with *Homo neanderthalensis*. Announcement Duarte et al. 1999. Initial description Zilhão and Trinkaus 2002, Bayle et al. 2010. Photographs/line drawings and metrical data Zilhão and Trinkaus 2002, Bayle et al. 2010. Detailed anatomical description Zilhão and Trinkaus 2002, Bayle et al. 2010. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance The mosaic of anatomically modern human and archaic traits prompted the suggestion that Lagar Velho 1 provides evidence for admixture between Neanderthals and modern humans at the time of contact in Europe, but most assessments consider it to be within the range of variation of *H. sapiens*. Location of original Museu Nacional de Arqueologia, Lisbon, Portugal.

lagomorph See lagomorpha.

Lagomorpha (Gk *lagos* = hare, *morph* = form). The zoological order comprising rabbits, hares (Leporidae), and pikas (Ochotonidae). Lagomorpha resemble rodents superficially (e.g., they are small and appear to have only two upper incisors, which grow continually), but are classified in their own order due to other morphological differences. Originating in the late Paleocene, their natural distribution is worldwide except for Oceania, where they have latterly been introduced by modern humans. Pikas prefer colder climates and are mostly found in parts of Asia, Eastern Europe, and North America.

Lainyamok (Location 1°47'S, 36°11'E, Kenya; etym. Lainyamok means “place of thieves” in the local, Maa, language) History and general description Lainyamok lies in **Middle Pleistocene**

sediments in the East African Rift Valley in southern Kenya, 40 km/25 miles southwest of **Ologesailie** and about 8 km/5 miles northwest of Lake Magadi. W.W. (“Bill”) **Bishop** commenced geological work and mapping of the site in 1976 and a team led by Phillip Leakey and Kamoya **Kimeu** made a collection of artifacts and fossils including three associated hominin teeth. Additional fieldwork by Richard Potts, Pat Shipman, and colleagues in 1984 refined the stratigraphy, found vertebrate fossil localities possibly indicative of butchery by hominins, and a hominin femoral fragment. Temporal span and how dated? c.0.39–0.36 Ma on the basis of tephra bracketing the primary fossil layer dated by **single-crystal argon-argon dating** plus an obviously more modern fauna than that collected from Members 1–7 of the Ologesailie Formation (c.0.9–0.7 Ma) at **Ologesailie**. Hominins found at site A fragment of the diaphysis of a left femur (KNM-WM 13350) and associated right P⁴-M². The femur and the teeth are consistent with attribution to either *Homo sapiens* or *Homo heidelbergensis*. Archeological evidence found at site Fossils and artifacts at Lainyamok occur in layer “Khaki 2,” a 1–2.5 m-thick, poorly sorted **silt** and **cobble** layer near the middle of the section of Middle Pleistocene sediments. The layer appears to be the result of mudflows that redeposited material from the highlands, including stone tools and animal bones, to the lowlands around Lake Magadi. Denser concentrations of fauna appear to have accumulated within hyena burrows into these redeposited sediments. Thus, most of the dense bone accumulations at Lainyamok are likely the result of the bone-accumulating activities by hyenas rather than traces of hominin activities. Erosion and deflation of sediments at Lainyamok produced a few locally dense surface scatters of lithics (**flakes**, **discoidal** cores, **handaxes**, and **spheroids**, largely fashioned of green lava or **quartzite**), but not dense concentrations *in situ* or in association with faunal remains. Key references: Geology, dating, and paleoenvironment Shipman et al. 1983, Potts et al. 1988, Potts and Deino 1995; Hominins Shipman et al. 1983, Potts et al. 1988; Archeology Shipman et al. 1983, Potts et al. 1988.

Lake Botsumtwi Lake Botsumtwi occupies a meteor-impact crater in Ghana. The 74 m-deep lake preserves a sedimentary record of paleoclimate for subtropical southern Africa stretching back c.1 Ma. Oxygen isotopes in carbonates preserve a

detailed record of changes in African monsoon strength. Decadal- to centennial-length droughts are common over the past three millennia, suggesting that droughts similar to, or worse than, recent Sahelian droughts would have been a factor affecting modern human ancestors in the region (Shanahan et al. 2009) and that on longer time-scales there is evidence for extreme aridity between 135 and 75 ka (Scholz et al. 2007). *See also megadroughts.*

Lake Mungo (Location 33°07'S, 143°10'E, Australia; etym. the site is named after the lake of the same name) History and general description Three gracile hominin skeletons (LM 1 and LM 2 in 1968 and 1969, respectively, and LM 3 in 1974) were recovered from this site; all were found in the core of an eroded lake-shore dune on the southern edge of the dry Lake Mungo, 100 km/62 miles northeast of Mildura. Two of the skeletons (LM 1 and LM 2) were cremated and buried in a conical pit, while the third was interred as a complete skeleton (LM 3). The specimens were buried in calcrete horizons within brownish grey sands. Temporal span and how dated? LM 1 and LM 2 were originally attributed to the Late Pleistocene by radiocarbon dating of collagen from LM 1 (*c.*25 ka) and from charcoal found with the burials (*c.*26 ka). There has been a great deal of debate surrounding the age of LM 3. Some researchers claimed this individual is the most ancient on the Australian continent, citing ages of *c.*62 ka from uranium-series dating and electron spin resonance spectroscopy dating of the skeleton and ages of *c.*61 ka from optically stimulated luminescence dating (or OSL) of the associated sediments. However, subsequent OSL analyses point to both LM 1 and LM 3 being *c.*40 ka. Hominins found at site LM 1 and LM 3 are remarkably gracile, especially when compared to the later but much more robust individuals from Kow Swamp and Willandra Lakes. Two competing explanations have been offered regarding the transition from the earlier gracile to the later robust crania and postcranial skeletons in Pleistocene Australia. The first interprets the fossil evidence as being consistent with a single evolving lineage that began by being relatively gracile and then over time it came to consist of more robust individuals, a change that some see as an adaptation to an increasingly harsh and arid environ-

ment. The second interprets the same fossil record as evidence for multiple migrations from Asia, with an early migration of gracile individuals from north Asia and a later migration of more robust individuals from southeast Asia. Genetic evidence from the site In 2001 it was reported that mitochondrial DNA (mtDNA) had been isolated from LM 3. The recovered mtDNA sequence is unknown among modern Australian Aboriginals and it was suggested that it represented one of the most ancient modern human mtDNA lineages. However, researchers who have re-examined the mtDNA evidence suggest that the “ancient mtDNA” purportedly isolated from LM 3 was most likely either a contaminant and/or was the result of degradation. Archeological evidence found at site Australian core-tool and scraper tradition. Key references: Geology, dating, and paleoenvironment Bowler et al. 1972, 2003, Thorne et al. 1999, Grün 2006; Hominins Bowler et al. 1970, Brown 2000, Thorne and Curnoe 2000; Genetics Adcock et al. 2001, Smith et al. 2003; Archeology Bowler et al. 1970.

Lake Nitchie (Location 33°40'S, 142°00'E, Australia; etym. the site is named after the lake of the same name) History and general description The site consists of the deflated surface of what was formerly a sand dune that had formed on the northern shore of Lake Nitchie, 90 km/56 miles northwest of Mildura, 870 km/540 miles west of Sydney, Australia, that in 1969 yielded a hominin skeleton. Temporal span and how dated? Radiocarbon dating of bone collagen indicates a Holocene age *c.*6860 years BP. Hominins found at site The robust modern human male skeleton was interred at the site in a semi-recumbent position with the body flexed and the face pointing downwards. The Lake Nitchie specimen may document the earliest evidence of ritual tooth avulsion. Archeological evidence found at site Cores and scrapers (but no microliths) were recovered from the upper stratigraphic unit of the site. The modern human individual was buried wearing a necklace of pierced canine teeth of Tasmanian devil (*Sarcophilus harrisi*). Key references: Geology, dating, and paleoenvironment Bowler 1970b; Hominins Macintosh et al. 1970; Archeology Bowler 1970b.

Lake Olduvai The name suggested by Hay and Kyser (2001) for the highly alkaline, shallow,

and saline paleolake that occupied the region of the Olduvai Main Gorge during the deposition of Beds I and II. It varied in size, but its persistent central portion, known as the Central Basin (or CB) was centered on the western part of the Olduvai Main Gorge. The extensive lake margin areas to the west are known as the Western lake margin (or WLM) and to the east they are referred to as the Eastern lake margin (or ELM). The period of greatest alkalinity was in Bed I times and Lake Olduvai was most extensive during lower Bed II times. *See also* **Olduvai Gorge**.

Lake Tandou (Location 32°37'S, 142°08'E, Australia; etym. the site is named after the lake of the same name) History and general description This site, which yielded a hominin skeleton in 1967, consists of the deflated surface of what was formerly a sand dune that had formed on the eastern shore of Lake Tandou, 150 km/93 miles northwest of **Lake Mungo**. Temporal span and how dated? The hominin skeletal remains were too few, fragmentary, and fragile to allow direct dating, but **radiocarbon dating** of shell middens in the immediate area yielded ages of *c.*15 ka. Hominins found at site The extremely fragmented gracile male skeleton belongs to a modern human individual estimated to be 20–5 years old at death. It was interred at the site in a kneeling position. The Lake Tandou cranium is most similar to the gracile individuals from **Lake Mungo**, **Lake Nitchie**, and **Keilor** and, like them, it contrasts with the more robust modern human crania from **Kow Swamp** and **Coobool Creek**. Archeological evidence found at site Shell middens, hearths and burial features. Key references: Geology, dating, and paleoenvironment Hope et al. 1983; Hominin Merrilees 1973, Freedman and Lofgren 1983; Archeology Hope et al. 1983.

Lake Turkana This lake, previously known as Lake Rudolf, occupies the southern part of the **Omo-Turkana Basin**. The lake has fluctuated in size through time becoming larger when inflow exceeds any outflow and evaporation and smaller when it does not. The major fossiliferous formations around Lake Turkana are the **Koobi Fora**, **Mursi**, **Nachukui**, **Nkalabong**, **Shungura**, and **Usno Formations**. The major fossil and archeological sites surrounding Lake Turkana are **Koobi Fora**, **Lothagam**, the **Omo** region, and **West Turkana**.

Lake Turkana Basin *See* **Turkana Basin**.

Lake Turkana Group *See* **Turkana Group**.

Lakonis Location 36°46'59"N 22°34'49"E, Greece; etym. named after the province of Lakonia) History and general description The site, which was discovered by an amateur archeologist, has been excavated systematically by the Ephoreia of Paleoanthropology and Speleology (Greek Ministry of Culture) since 1999. It consists of a cave and a series of collapsed karstic formations, of which Locality I is the richest. Temporal span and how dated? Uranium-series dating on **travertine**, and **AMS radiocarbon dating** on charcoal suggest a range of *c.*100–40 ka for the cave sediments. Hominins found at site Isolated lower M₃ (LKH1). Archeological evidence found at site **Middle Paleolithic (Mousterian)** and the Initial Upper Paleolithic. Key references: Geology, dating, and paleoenvironment Panagopoulou et al. 2002–4; Hominins Harvati et al. 2003, Richards et al. 2008, Smith et al. 2009; Archeology Panagopoulou et al. 2002–4, Elefanti et al. 2008.

Lamalunga Cave *See* **Altamura**; **Altamura 1**; **Grotta di Lamalunga**.

Lamarckism (and neo-Lamarckism) One of the first to argue that species are not fixed (this had been accepted dogma since the time of the Greek philosopher and naturalist Aristotle) was Jean-Baptiste de Lamarck whose theory of the “transmutation” of species was published in *Philosophie zoologique* in 1809. In this work Lamarck argued that through the combination of the principles of the use and disuse of organs and the inheritance of acquired characteristics, individuals could change over time until their descendants would no longer closely resemble them. It is important to note that for Lamarck it is not the species that changes, but individuals. Lamarck suggested that there was an inherent tendency for organisms to be transformed into “higher” (i.e., more advanced) forms, and that this tendency resulted in a kind of escalator effect where, over many generations, lower organisms would progressively be transformed, or transmuted, into more advanced taxonomic categories. However, Lamarck

believed that the major taxonomic categories (fishes, reptiles, birds, mammals, etc.) had always existed; there was no suggestion, as Darwinian evolutionary theory would later argue, that these categories emerged over time. In the early 19thC Lamarck's theory failed to garner adherents and was widely criticized. However, in his *Vestiges of the Natural History of Creation* (1844) the Scottish publisher Robert Chambers (1802–71) linked Lamarck's theory of transmutation with the then recent recognition by geologists of a progression in the fossil record (more advanced taxa appearing in more recent geologic strata) and with the equally recent description of the development of the embryo (which seemed to progress through stages corresponding to the succession of taxonomic categories, an idea that would later be described as phylogeny recapitulating ontogeny) to formulate a naturalistic and progressive history of life on Earth. Lamarck's transmutation theory remained an idea on the periphery of accepted science until the publication of Charles Darwin's *On the Origin of Species by Means of Natural Selection* in 1859. Darwin's convincing argument, supported by immense quantities of supporting evidence, gradually drew the support of many prominent European scientists during the last half of the nineteenth century. Many naturalists in France, Germany, and America accepted the fact of biological evolution but relied upon Lamarck's notion of the inheritance of acquired characteristics to explain how evolution occurred. Rather than random variations in a population being acted upon by natural selection ("survival of the fittest" as Darwin's friend Herbert Spencer referred to it) these scientists believed that a biologically beneficial trait could be acquired by an organism and then that trait could be passed on to the next generation. Moreover, these naturalists reintroduced the Lamarckian idea that evolution was goal-directed and that the history of life on Earth was a linear progression leading from simple to more complex forms. Darwin had rejected these ideas and had argued that evolution by natural selection was random rather than progressive or teleological. The neo-Lamarckian version of evolution made the idea of biological evolution more acceptable than Darwin's version because within the neo-Lamarckian framework it could be argued that evolution proceeded according to a natural, or divinely directed, plan that was still consistent with the history of life on Earth as recorded in

the fossil record. It was also consistent with a "progressive" interpretation (i.e., **orthogenesis**) that saw the appearance of modern humans in the world as the ultimate goal of evolution. Whereas for Darwin the traits shared between the extant apes and modern humans were derived from a recent common ancestor, neo-Lamarckians were more likely to argue that these traits had evolved independently. The British anatomist and physical anthropologist Frederic Wood Jones supported a neo-Lamarckian view of modern human evolution during the early decades of the 20thC as did Robert **Broom**. The German physical anthropologist Hermann **Klaatsch** relied upon a neo-Lamarckian model of evolution to explain the origin of bipedalism and invoked the same principles in his theory that modern human races had evolved independently, each from a separate early primate species. Neo-Lamarckian ideas remained appealing and influential in biology and among theories of human evolution until the importance of the role of natural selection and the Darwinian model of biological evolution was reasserted as part of the rise of the **modern evolutionary synthesis** in the 1940s.

lamellar bone *See* bone.

lanceolate (L. *lanœola*=the diminutive of *lanœa*=lance) A term used to describe long and relatively thin bifacially flaked pieces such as those found at many **Lupemban** sites in Africa. An inference implicit in the term lanceolate is that such pieces may have served as lance or spear points rather than points on smaller **armatures** such as arrows.

landmark (etym. *landmark*=a nautical term meaning a visible place onshore that sailors use as a reference point to help them fix a course into a harbor) A place on a bone or tooth that can be defined precisely enough so that independent observers are likely to agree on its location. For example, nasion is where the suture between the nasal bones meets the frontal bone and basion is the most posterior point on the anterior border of the foramen magnum in the sagittal plane. In the context of **geometric morphometrics** Bookstein (1991, p. 2) defines landmarks as loci that are homologous across individuals in a sample (i.e., the landmarks have the "same" location in every other member of the sample being investigated).

Their location can be recorded in one, two, or three dimensions. *See also* **coordinate data; geometric morphometrics.**

Langebaanweg (Location 32°57'41"S, 18°06'38"E, South Africa; etym. in Afrikaans Langebaanweg literally translates to "long path road," but here the "weg" refers to the railway stop and therefore Langebaanweg means "the railway station near the town of Langebaan") History and general description The paleontological site of Langebaanweg, located on the west coast of South Africa, approximately 120 km/74 miles north of Cape Town, is renowned for its exceptionally well-preserved and diverse faunal remains. The fossil deposits at Langebaanweg were discovered during phosphate-mining operations that began at Baard's Quarry in 1943 and later moved to "C" and "E" quarries in the 1960s. From the late 1950s until the late 1980s Langebaanweg was a major focus of research at the South African Museum (now the **South African Museum, Iziko Museums of Cape Town**) under the leadership of Brett Hendey. Hendey published extensively during this time period, on both the fossil fauna and the geology of the region. In the 1980s, following Hendey's departure from the museum, research slowed considerably, and mining of the area stopped in 1992. Following the establishment of the West Coast Fossil Park (or WCFP), the educational, research, and tourism institution that incorporates the Langebaanweg paleontological site, in 1998 research recommenced at Langebaanweg and excavations were resumed at "E" quarry. This has resulted in an influx of international researchers to the site and to study the collections, but much work remains to be undertaken as entire families of organisms are poorly understood. To date, over 230 vertebrate and invertebrate taxa have been described from these deposits that date to the terminal **Miocene**/earliest **Pliocene** (c.5 Ma). For many taxa, including carnivores, birds, and frogs, Langebaanweg is unique in terms of species number, specimens, and quality of preservation. Although no hominin fossils have been found at the site to date, Langebaanweg is important for understanding the emergence of early hominins, because it provides essential context for interpreting and dating hominin-bearing sites in other parts of Africa with comparable faunal assemblages. At the end of 2005, the WCFP became an independent institution, managed by the WCFP Trust, and separate from Iziko

Museums, although the collections currently remain housed at the South African Museum, Iziko Museums of Cape Town. The open-air archeological locality known as the **Anyskop Blowout** is also located within the boundaries of the WCFP, approximately 1 km/0.6 miles south of the Pliocene fossil beds. language (ME *language* from OF *langage* from L. *lingua*=tongue or speech) Communication is ubiquitous among animals, but most language experts subscribe to the view that modern human language is a unique form of **communication**. The study of modern human languages can be broken down into the following subareas. **Phonology** is the study of how specific sounds (or signs) encode meaning, semantics is the investigation of how this meaning is generated and constituted in language, grammar is the study of how the various elements of language are structured and organized into larger units, and pragmatics focuses on the way language is used socially. According to Hauser et al. (2002), the only unique feature of modern human language is **recursion**. They argue that "though bees dance, birds sing and chimpanzees grunt, these systems of communication differ qualitatively from human language. In particular... [they] lack the rich expressive and open-ended power of human language" (*ibid* p. 1570). Various studies have demonstrated that while apes as well as other mammals (e.g., dogs) and birds (e.g., parrots) may learn, for example, to recognize specific sounds (i.e., phonology) and associate these sounds with particular objects (i.e., semantics) and even recognize that the social context may change the meaning of these sounds (i.e., pragmatics), no non-modern human animal has shown evidence of stringing different sounds to generate new meaning (i.e., grammar) into a sentence (cf., Terrace et al. 1979, Hauser et al. 2002). So, for instance, while a dog may respond appropriately when asked to *fetch*

ball and when asked to *roll over*, it will be entirely perplexed when asked to *roll over the ball* even though such a command, while odd, would be immediately understood by a 2 year-old modern human. Researchers who focus on the evolution of modern human language try to understand how and when our ancestors acquired the facility for recursion. It is still unclear if the capacity for recursion gradually evolved or if it appeared “fully formed” relatively recently in our evolutionary history.

language, evolution of Discussion of the evolutionary origins of modern human language has focused primarily on the origins of its distinctive recursive **syntax**. There is evidence that, unlike modern humans, nonhuman primate species otherwise very good at detecting patterns of speech syllables cannot detect patterns generated by recursive rules (Fitch and Hauser 2004). Recursive syntax makes possible several important semantic features of modern human language. Modern humans can communicate about specific objects or events with which they can have had no acquaintance because they can use recursive syntax to generate descriptions of arbitrarily precise specificity (Bolender 2007). Few animal communication systems are capable of communicating information about spatiotemporally displaced referents, and none seem capable of specifying them with the precision that recursive syntax makes possible. Syntactic rules apply to parts of speech defined independently of their semantics (e.g., any noun phrase, referring to any object, combines with any verb phrase, referring to any action, to form a sentence). This makes possible two other powerful semantic properties: generality and domain independence. According to the so-called “generality constraint” (Evans 1982) to count as having mastered any word, one must be capable of understanding sentences that combine that word with *any* other word one counts as having mastered. This includes even rather unlikely word combinations (Camp 2004); thus, if you count as understanding the terms “cat,” “can of tuna,” and “eats” you must be able to understand not just the sentence “The cat eats the can of tuna” but also “The can of tuna eats the cat.” One of the advantages of this is that we can use language to represent situations that have never been perceived and perhaps never could be perceived (e.g., a can of tuna eating a cat). This is closely related to the

modern human capacity for metaphorical thought and language, including many scientific insights (e.g., the claim that light is a wave was a central insight of 19thC physics). Domain independence is a byproduct of such generality (e.g., noun phrases and verb phrases referring to members of disparate domains can be combined into sentences expressing domain-independent propositions). Given these biologically unique properties explaining the evolution of the capacity for distinctively modern human language is extremely challenging. The classic approach to this problem adopts the traditional philosophical understanding of modern human language as an expression of modern human thought (Pinker and Bloom 1990). According to this view, many of the problematic properties of language are actually properties of uniquely modern human thinking, inherited by modern human language because it functions to communicate modern human thought. Unfortunately, this strategy only kicks the problem “up a level,” for now, to explain the puzzling properties of modern human language we must explain how and why the thought of our immediate, pre-linguistic precursors acquired these properties. It is not clear how or why a group of hominins, not yet able to use a modern human-like language, would develop a capacity to think recursive, domain-independent, and fully general thoughts. Numerous species of primates have inhabited environments similar to those of our precursors without developing the capacity for such thought. Furthermore, archeological proxies of such thought, like geographically and temporally diverse toolkits and the integration of information from multiple domains in tools, weapons, and ornaments (Mithen 1996), date to *c.*200 ka, by which time our species with, presumably, the capacity for language, was already on the scene. This leads many to argue that the puzzling properties of modern human language are not inherited from a kind of thinking that evolved prior to it. Rather, structurally complex language evolved as a tool both for thinking *and* communication in the relatively recent past (Bickerton 1990, 1995, Hauser et al. 2002). Such views distinguish the faculty of language in the broad sense from the faculty of language in the narrow sense (Hauser et al. 2002). The faculty of language in the broad sense incorporates many capacities that modern humans share with nonhuman species, including the capacity to refer to objects and events using vocalizations, the

capacity to conceptualize objects and events, and the capacity to read the communicative intentions of others. The unique component of the modern human faculty of language – the faculty of language in the narrow sense – is the capacity to detect and produce recursively structured signals. Bickerton (1990, 1995, 1998, 2000) similarly distinguishes between “proto-language,” in which unstructured combinations of two to three distinct vocalizations communicate task-specific information, and fully grammatical language. According to Bickerton (1990) pidgins and the language of two-year-olds are linguistic fossils: relics of such proto-language. Fully grammatical language requires an appreciation of the various parts of speech and the recursive rules for combining them into sentences. This Chomskian perspective is hostile to Darwinian explanations of fully grammatical language. One problem is that there does not appear to be any plausible, biological function for which such an expressively powerful communication system could have been selected. As many followers of Chomsky note, many of the functions of quotidian communication can be achieved with proto-language, as they are even today among immigrant workers with no formal instruction in the languages of their host countries. These individuals communicate successfully with short, unstructured sequences of words drawn from the local language; a kind of linguistic competence that Klein and Perdue call “The Basic Variety” (1997). If we can meet our communicative needs without employing the fully recursive structure of language, what advantage can a mutant capable of such a language have had in human prehistory? Origi and Sperber (2000) raise and try to solve a closely related bootstrapping problem for Darwinian approaches. Namely, what advantages could accrue to a mutant individual capable of understanding and producing grammatically complex language if there were no others with this capacity in her group? Finally, Bickerton (1990) notes that many aspects of fully recursive grammar cannot be acquired piecemeal. Sentences cannot function without their component parts of speech, but these component parts of speech cannot function without playing roles in sentences. In short, fully recursive, grammatical language appears to be a highly complex structure, with many components that make no independent contributions to functionality and which have no obvious independent function. This undermines

the assumption that adaptive complexity is the product of incremental accumulation and adjustment of multiple components, each of which has some adaptive justification independent of the others. These problems lead many followers of Chomsky to propose biologically implausible hypotheses about the phylogeny of grammatically complex language, like catastrophic macro-mutation (Bickerton 1990), wholesale exaptation of other cognitive faculties (Bickerton 2000), or some kind of emergent byproduct of anatomical constraints. Darwinian theorists hotly dispute such proposals and the claims that motivate them (Pinker and Bloom 1990, Pinker 2003, Pinker and Jackendoff 2005). If grammar is a textbook adaptation to the task of communicating propositional thought then the interdependence of grammatical components is no more problematic than the interdependence of components of other adaptations, like the eye. Furthermore, according to these theorists, there is much more that is unique to the modern human faculty of language than just recursive grammar. So, the picture of language as largely continuous with the communicative capacities of other species, except for one glaring, non-adaptive, structurally complex component – recursion – is, according to these theorists, misleading. Some theorists argue that grammatical complexity is a product of cultural, not biological evolution. For example, Wray and Grace (2007) argue that grammatical complexity arose gradually as isolated hominin populations began interacting with each other in prehistory. The need for communication among individuals sharing little background knowledge or context, drove the development of increasingly context-independent languages, capable of conveying clear, unambiguous information between interlocutors of vastly different backgrounds. This proposal is consistent with recent ethnographic evidence from an Amazonian population, the Piraha, said to indulge in self-imposed isolation. Although it is currently a matter of controversy among linguists, the researcher who has studied the Piraha language the longest claims it lacks recursive structure (Everett 2005). Charles Darwin first proposed another possibility, namely that modern human language is descended from sexually selected mating song (Darwin 1871). This proposal receives some support from evidence that sexually selected birdsong approaches the structural complexity of human language (Okanoya 2002) and that the *FOXP2* gene which

is known from neuropathological evidence to play a role in the modern human capacity for structurally complex language (Lai et al. 2001) apparently plays a role in the capacity for sexually selected birdsong in some species (White et al. 2006a). The structural analogies between modern human language and music have long been appreciated (Lerdahl and Jackendoff 1996) and there is growing evidence of neural overlap between areas underlying modern human musical and linguistic competence (Patel 2010). Such evidence leads some contemporary theorists of human evolution to revive Darwin's proposal that modern human language is descended from a sexually selected, song-like proto-language (Miller 2000, Mithen 2006). There are other notable disputes among theorists of modern human language evolution. One of the most prominent debates concerns whether or not language had a manual origin (Corballis 2002). Voluntary control is one of the distinctive features of modern human communication. Vocalizations of other primates are emotion-triggered and involuntary, like the sighs, laughs, and groans of modern humans. In contrast, all primates have voluntary control of manual gestures. Assuming that the most recent common ancestor with chimpanzees/bonobos fits this pattern, it seems more likely that a voluntarily controlled communication system first evolved in connection with the hand. The discovery of mirror neurons in primate brains, including those of macaques (Rizzolatti et al. 1996) and modern humans (Mukamel et al. 2010), has been interpreted as evidence for the manual origins view of language evolution (Rizzolatti and Arbib 1998, Arbib, 2006). The reason is that a central feature of language is the linkage between productive and receptive competence, for to produce linguistic signals properly one must understand how they will be interpreted, and to interpret linguistic signals properly one must understand the intent with which they are produced. Mirror neurons fire both when the same action is observed and executed, suggesting a mechanism capable of implementing this Janus-faced property of modern human linguistic communication. Terrence Deacon's *The Symbolic Species* (1997) and Tecumseh Fitch's *The Evolution of Language* (2010) provide more extensive surveys of hypotheses about the origin of language.

language, hard tissue evidence for

Hard-tissue evidence that may potentially be related to spoken language can be divided into two cate-

gories: evidence related to the generation of spoken language and evidence related to its perception. With respect to the generation of spoken language only two of the four categories of potential neuroanatomical evidence suggested by Ralph Holloway (1983b) are relevant, namely evidence for the reorganization, or enlargement, of **Broca's area** and cerebral cortical **petalias**. Broca's area, which is located along the inferior gyrus of the anterior prefrontal cortex and which is generally enlarged in the left hemisphere of most modern humans (Amunts et al. 1999) is thought to play a role in the production of spoken language (Damasio and Damasio 1989). The lateralization of Broca's area, though it is present in apes, occurs less frequently than it does in modern humans (Holloway 1996). A recent survey of extinct and extant hominins showed that while asymmetrical enlargement does occur in transitional and pre-modern *Homo* taxa (i.e., *Homo rudolfensis*, *Homo erectus*, *Homo heidelbergensis*, *Homo neanderthalensis*) it is absent in *Australopithecus afarensis* (de Sousa and Wood 2007). However, doubt has been cast on the wisdom of using endocranial morphology as a proxy for identifying functional regions of the cortex (e.g., Holloway 2009). Petalias, or asymmetries in the cortical hemispheres of the brain, once thought to be peculiar to modern humans (and thus a sound way of imputing functions such as spoken language), have been identified in samples of higher primates other than modern humans (Hopkins and Marino 2000). Two other categories of hard-tissue evidence for speech production have been put forward. The first used the size of the vertebral canal to predict the presence of the "extra" neurons in the thoracic spinal cord that allows for the fine control of the muscles of respiration, thus facilitating spoken language in modern humans. Examination of thoracic spinal cords across a wide range of primates suggested their cross-sectional areas are correlated with the cross-sectional area of the matching part of the vertebral canal (MacLarnon 1995), and when the vertebral canal sizes were adjusted for body weight only the relative size of the thoracic canals of modern humans and Neanderthals were larger than their body sizes would predict (MacLarnon and Hewitt 1999). However, experience with other systems suggests that broad across-primate allometric relationships cannot necessarily be extrapolated to much narrower allometric contexts, such as that within the hominin clade. The second category of evidence used the size of the hypoglossal vertebral canal to predict

the presence of the “extra” neurons that facilitate the fine control of the muscles of the tongue. The initial results of attempts to infer the size of the hypoglossal nerve (the motor nerve to most of the extrinsic and all of the intrinsic muscles of the tongue) from the size of the hypoglossal canal seemed promising (Kay et al. 1998), but closer examination (DeGusta et al. 1999) revealed unwarranted assumptions, and thus flaws, in this approach. Potential hard-tissue evidence related to the perception of spoken language involves the external and the middle ear. The external ears of chimpanzees are both longer and smaller in cross-section than those of modern humans [the external auditory meatus of modern humans (mean = 115 mm²) is more than twice that of chimpanzees (mean = 45 mm²)] and what is known of the size of the external auditory meatus of early hominins prior to *Au. afarensis* suggests that they were also chimp-sized. Middle ear ossicles have been recovered at Swartkrans and Sterkfontein (an incus, SK 848, belonging to *Paranthropus robustus*, from the former, and stapes, belonging to *Australopithecus africanus* and *Homo habilis*, from the latter). Moggi-Cecchi and Collard (2002) showed there was a marked similarity in size between the footplates of the early hominin stapes and the stapes belonging to the living great apes, and that they were both substantially smaller than those of modern humans. But what, if anything, this implies about the speech perception capabilities of *Au. africanus* (and *H. habilis*) is unclear.

language vocalization See spoken language.

Lantian Chenjiawo (蓝田陈家窝子) (Location 34°14'N, 109°14'E, northwestern China; etym. named after the local village) History and general description An open-air site, discovered in 1963, located near the village of Chenjiawozi, 10 km/6 miles northwest of Lantian City, Shaanxi Province. Initially made the type specimen of *Sinanthropus lantianensis*, the mandible is now referred to *Homo erectus*. Together with the **Gongwangling** cranium, they are commonly referred to as “Lantian Man.” Temporal span and how dated? On biostratigraphic grounds, the fossil mandible is estimated to be c.300 ka. However, **magnetostratigraphy** and paleoclimatic data derived from deep-sea cores place Chenjiawo at c.650–500 ka. A more detailed magnetostratigraphic and loess-paleosol lithostratigraphic study conducted by Sheng and Kun (1989) suggests the locality dates to 650 ka. Hominins found at site Presumed to be

an older adult female the Chenjiawo (PA 102) **mandible** is generally well preserved, missing just parts of the rami, the right P₃ (antemortem), and both M_{3s} (congenitally). The crowns of several teeth on the left side (C–M₁) were damaged during excavation. Archeological evidence found at site A lithic **scraper** and nine **flakes** were found scattered near the fossil site. One of these, found 70 m away, was reported to be from the same stratum as the hominin mandible. Key references: Geology, dating, and paleoenvironment Aigner and Laughlin 1973, An and Ho 1989; Hominins Woo 1964, Aigner and Laughlin 1973, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Brown 2001; Archeology Aigner and Laughlin 1973, Wu and Olsen 1985, Schick and Dong 1993.

Lantian Gongwangling (蓝田公王岭) (Location 34°11'0.73"N, 109°29'38.94"E, northwestern China; etym. named after a hill near Gongwang village) History and general description An open-air site, discovered in 1964, located on the northern slope of a hill south of Gongwang village, 17 km/10.5 miles southeast of Lantian City, Shaanxi Province. Together with the Chenjiawo mandible they are commonly known as “Lantian Man,” or *Sinanthropus lantianensis* (now referred to *Homo erectus*); Temporal span and how dated? Gongwangling is considerably older than Chenjiawo. Earlier estimates using **biostratigraphy**, **magnetostratigraphy**, and correlation with deep-sea cores place the locality at c.700 ka, c.800–750 ka (or 1.0 Ma), and c.800–730 ka, respectively. Based on new **geomagnetic dating** evidence and the lithostratigraphic position of the fossil in the loess-paleosol sequence, Sheng and Kun (1989) infer an age of c.1.15 Ma, making Gongwangling one of the oldest hominin fossil sites in mainland East Asia. Hominins found at site Presumed to be a female over 30 years of age, Gongwangling (PA 105 [1–6]) is a partial **cranium** consisting of a complete frontal, much of both parietals, the right **temporal** without the **mastoid**, parts of both nasal bones, incomplete maxillae, and an isolated left M². The fossils are poorly preserved and heavily mineralized; very little ectocranial topography is preserved. Archeological evidence found at site Twenty **quartzite** and **quartz** artifacts (11 cores, five flakes, and four scrapers) made using a hard hammering technique with minimal flaking, were found in association with the fossil cranium. Since these artifacts were

distributed through a 13 m depth of deposits they cannot be considered a single archeological assemblage and it is assumed that the site was only temporarily occupied. From the nearby site of Pingliang, a thick, large, and **Acheulean-like handaxe** (measuring roughly 20 cm×10 cm) was collected on the surface; it is known as the “Lantian biface.” Key references: Geology, dating, and paleoenvironment Aigner and Laughlin 1973, An and Ho 1989, Zhu et al. 2003; Hominins Woo 1966, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Holloway 2000, Brown 2001, Shang et al. 2008; Archeology Aigner and Laughlin 1973, Wu and Olsen 1985, Schick and Dong 1993.

Lantian Man *See* Lantian Chenjiawo; Lantian Gongwangling; *Sinanthropus lantianensis*.

Laron syndrome A particular variety of dwarfism that results from a deficiency of growth hormone receptors in the liver, which, in turn leads to a deficiency of IGF-1, also known as somatomedin. The Laron phenotype includes short stature, a small and abnormally shaped skull, malformed and misaligned teeth, small extremities, and relatively as well as absolutely short limbs. Hershkovitz et al. (2007) suggested that the morphology seen in **LB1**, the **holotype** of *Homo floresiensis*, was consistent with the Laron phenotype, but Falk et al. (2007) show that LB1 departs in several significant ways from the phenotype seen in Laron syndrome. *See also* *Homo floresiensis*; **LB1**.

Lascaux (Location 45°03'15"N, 1°10'01"E, France; etym. unknown) History and general description This cave site was discovered by accident by several small boys in September 1940. The cave houses some of the most famous **Upper Paleolithic** cave paintings in Europe, with many scenes of animals, humans, and abstract designs. These paintings have been the subject of many interpretations, as evidence of sympathetic hunting magic, totem worship, astronomy, and/or shamanism. At one time open to the public, the cave has been closed since 1963, although an exact replica of two of the galleries, Lascaux II, is available for tours. Temporal span and how dated? **Radiocarbon dating** of charcoal and antler have provided a range of dates from 15,500 to 18,900 years BP;

stylistic interpretations of the art suggest it was created during the **Solutrean**. Hominins found at site None. Archeological evidence found at site A variety of artifacts were found at the site, including lamps, decorated bones, and more than 300 stone tools, some of which show evidence of having been used for engraving. Key references: Geology, dating, paleoenvironment, and archeology Delluc and Delluc 2003, Glory et al. 2008.

laser ablation Because enamel develops incrementally any bulk-sampling method will result in a stable isotope (e.g., $^{13}\text{C}/^{12}\text{C}$) or elemental (e.g., **strontium/calcium ratio**) signal that is subject to **time-averaging**. Laser ablation helps ameliorate time-averaging by focusing a thin laser beam on a small area of **imbricational enamel** on the outer surface of a whole tooth, or on enamel that has been exposed by the tooth having been naturally fractured or deliberately sectioned, and this much more precise sampling strategy can result in a $^{13}\text{C}/^{12}\text{C}$ or Sr/Ca signal that samples days to weeks rather than years of time. This greater precision enables researchers to examine whether the $^{13}\text{C}/^{12}\text{C}$ ratio changes during the development of a tooth, as would be the case if the diet differed from one season to another (e.g., Sponheimer et al. 2006) or to use the ratio of Sr/Ca ratio to detect when weaning occurs (Humphrey et al. 2008). However, laser ablation cannot eliminate time-averaging because we are still ignorant about the dynamics of enamel mineralization. Only approximately 15% of the mineral in enamel is laid down during enamel secretion; the rest is deposited during enamel maturation and the timing and patterning of that process is poorly understood. Enamel maturation does not even start until the full crown thickness is attained, and it may take three times as long as the process of enamel secretion. *See* **C₃ and C₄**; **enamel development**; **stable isotopes**; **strontium/calcium ratio**.

laser ablation inductively coupled plasma mass spectrometry (or LA-ICP-MS) This process uses lasers to convert a solid by ablation into a phase that can be sampled using inductively coupled plasma mass spectrometry. The energy in the laser transforms the solid into plasma and its elemental composition is measured by a mass spectrometer. The system can be used for determining stable isotope or trace element ratios. Laser ablation helps ameliorate the effects of

time-averaging by focusing a thin laser beam on a small area of **imbricational enamel** on the outer surface of a whole tooth, or on enamel that has been exposed by the tooth having been naturally fractured or deliberately sectioned, and this much more precise sampling strategy can result in a signal that samples days to weeks rather than years of time. Humphreys et al. (2008) have used this system to measure the strontium/calcium ratio in thin sections of enamel to detect when weaning occurs in extant animals. *See laser ablation; strontium/calcium ratio.*

laser ablation stable isotope analysis

last appearance datum (or LAD) The term refers to the date of that taxon's last occurrence in the fossil record and in paleoanthropology it is usually used in connection with a species (e.g., *Paranthropus boisei*) or a genus (e.g., *Homo*). For various reasons the LAD of a taxon is almost certainly earlier than when the taxon actually became extinct, or emigrated from that region. Just how much later than its extinction or emigration from that region is determined by two factors. The first is any error in the date and the second is the nature of the relevant fossil record after the LAD. The problem is the old adage that "absence of evidence is not evidence of absence." Hominins are such a rare component of the mammalian faunal record that researchers need to find a substantial number of nonhominin mammalian fossils (at least several hundred) without finding any evidence of a particular hominin taxon before it can be reasonably assumed that the hominin taxon in question was not part of the faunal assemblage being sampled. In such cases the LAD has an acceptably low 95% confidence interval, but in cases where there is a major unconformity spanning several hundred thousand years after the LAD of a taxon, so there is no fossil record during that time, then the LAD of that taxon at that location has an unacceptably high 95% confidence interval. *See also first appearance datum.*

last common ancestor *See most recent common ancestor.*

Last Glacial Maximum This is defined as "the most recent interval in Earth history when global ice sheets reached their maximum volume"

(Clark et al. 2009, p. 710). Clark and colleagues investigated glaciers in five regions of the world and concluded that some ice sheets reached their maxima at 33 ka, all of them reached their maxima by 26.5 ka, and then they remained at these maxima until 20–19 ka. Sea levels, which are inversely correlated with glacial maxima, fell during **Oxygen Isotope Stage 3** and reached their lowest level, called the Last Glacial Maximum low stand, between 26.5 and 19 ka.

Last Glacial Maximum low stand *See Last Glacial Maximum.*

Late Pleistocene (Gk *pleistos*=most and *kainos*=new) An informal younger division of the **Pleistocene** epoch, synonymous with the Tarantian Age (126–11.7 ka). The lower boundary of the Late Pleistocene is traditionally placed at the base of **Oxygen Isotope Stage 5e**.

Late Pliocene transition Shackleton (1967) argued that the $^{18}\text{O}/^{16}\text{O}$ ratio of **benthic foraminifera** in the oceans would fall when ^{18}O -rich water was locked up in expanded ice caps and enlarged glaciers. Glaciation intensified in the northern hemisphere, this is called the **Northern Hemisphere Glaciation** (or NHG) from the mid **Pliocene** to the late **Pleistocene**, but during this time there were two periods when the rate of reduction in the $^{18}\text{O}/^{16}\text{O}$ ratio was more pronounced, from *c.*3.2 to *c.*2.7 Ma and from *c.*1.2 to *c.*0.8 Ma. The first of these two shifts is called the late Pliocene transition (or LPT) and the second later shift in the ratio of $^{18}\text{O}/^{16}\text{O}$ is called the **Mid-Pleistocene transition** (or MPT). The end of the LPT marks the beginning of the 41 ka-long obliquity-driven climate cycles and it is when ice-rafted debris begin to appear in sediments in the North Atlantic.

Late Stone Age *See Later Stone Age.*

Later Stone Age The youngest period in the tripartite division of the African archeological lithic record formalized by A.J.H. Goodwin and C. van Riet Lowe (1929) in their *The Stone Age Cultures of South Africa*. Although it was developed for sequences in southern Africa, the terminology has subsequently been applied to sites across sub-Saharan Africa. There have been numerous calls

to abandon the tripartite division (e.g., Clark et al. 1966, Barham and Mitchell 2008), but it, and thus the term Later Stone Age, persists because of the latter's utility for describing a broad stage in the general trend toward a more sophisticated lithic record (i.e., a trend toward aspects of the manufacture of stone tools that are conceptually and technically more elaborate). The Later Stone Age is distinguished from the **Middle Stone Age** by the presence of small **microliths** with one blunted, or **backed** edge, small circular **scrapers**, and in later assemblages **ground stone** tools and **pottery**. Although the term Later Stone Age is frequently used to describe stone tool-equipped modern human **foragers**, the term may also encompass stone tool-using **pastoralist** populations. Recognizing that first and last appearance dates vary locally and are subject to change as new sites are found, existing dating methods are improved, or when new methods are introduced, the present evidence suggests the Later Stone Age began *c.*40 ka. Its last appearance dates are contentious, and some contemporary African populations still occasionally use stone tools.

lateral enamel *See* imbricational enamel.

lateral fissure *See* lateral sulcus.

lateral geniculate nucleus (L. *geniculum*=knee, knotted, or bent and *nux*=nut, kernel) A cluster of cells situated lateral to the main body of the **thalamus** on its ventroposterior aspect. The optic nerve conveys visual information from the retinal receptors via retinal ganglion cells to the lateral geniculate nucleus, and neurons in the lateral geniculate nucleus project to (i.e., communicate with) the **primary visual cortex** (also called the **striate cortex** or **Brodmann's area 17**) of the **occipital lobe** of the **cerebral hemisphere**. The lateral geniculate nucleus is one of three subcortical regions that receive direct input from the retina and the only one that processes information ultimately resulting in the conscious perception of visual information. The lateral geniculate nucleus contains a **topographic** representation of the contralateral half of the visual field. In primates, the lateral geniculate nucleus is divided into layers, each of which receives inputs from only one eye. In modern humans and great apes, there are six main layers: two ventral magnocellular (i.e., large-celled) layers, which process motion-

related information, and four dorsal parvocellular (i.e., small-celled) layers, which are concerned with processing color and fine details of form. Neurochemically distinctive koniocellular cells located between these main layers are involved in processing color information from short-wavelength "blue" cones in the retina. The lateral geniculate nucleus and the primary visual cortex are considerably smaller in modern humans than predicted by **allometry** for a typical primate of the same brain size. This has been interpreted as reflecting reorganization of the modern human cerebral cortex towards a greater emphasis on regions of the **association cortex** that focus on higher-order processing and function. *See also* **lunate sulcus**.

lateral longitudinal arch A mainly hard-tissue structure consisting of the calcaneus, cuboid, and the lateral two rays. It is not a structural arch *per se* in modern humans as the lateral side of the foot is often in contact with the ground during the stance phase of modern human walking. The lateral longitudinal arch mainly serves to stiffen the lateral side of the midfoot to increase propulsive capacity during bipedal walking. This stiffening is produced by the dorsal inclination of the calcaneus and it is stabilized by a locking mechanism between the calcaneus and the cuboid. Additionally, the long plantar ligament and the well-developed plantar aponeurosis, unique among extant primates to the modern human foot, prevent dorsiflexion at the cuboid-metatarsal joint, thereby eliminating the midfoot flexion (the **midfoot break**) in the modern human foot. A stiff lateral side of the foot may be quite ancient given the evidence for tarsometatarsal stability in *Australopithecus* and perhaps even in *Ardipithecus*.

lateral sulcus (L. *fissus*=split, cloven) The lateral fissure is the *Terminologia Anatomica* term for the structure some comparative neuroscientists refer to as the Sylvian fissure. This eponymous name commemorates its discover, Franz de le Boë (1614–1672), a Dutch physician and scientist whose Latinized name is Franciscus Sylvius. The lateral fissure is a prominent cleft, or sulcus, found in primates. It is located on the lateral surface of each **cerebral hemisphere** and it separates the **temporal lobe** from the **frontal lobe** and **parietal lobe**. The lateral fissure is evident early in development, appearing before most other sulci. Lateral fissure length has been demonstrated to be asymmetric

(with a longer fissure in the left than on the right side) in modern humans and in the great apes. Similar asymmetry of lateral fissure length has also been reported in several Old and New World monkey species, but not all studies of monkeys are consistent in finding this asymmetry. The greater length of the lateral fissure in the left hemisphere may be correlated with anatomical **lateralization** of the posterior lobe and possibly related to hemispheric specialization of auditory processing for vocal communication signals.

lateralization The term used for the parts of the **cerebral hemisphere** whose functions are asymmetric. The classical example is that of **Brodmann's areas 44 and 45** in the frontal lobe. These areas are involved with **speech** in the dominant hemisphere (the left in the majority of people, i.e., in those who are right-handed) and with spatial cognition on the non-dominant side.

Lautsch See **Mladeč**.

lava (L. *labi*=to fall) The term lava refers to molten material (magma) extruded at the Earth's surface by volcanic processes and to the rocks formed when this material cools. The character of lavas varies widely with chemistry and cooling rate. Rapid quenching of the molten material can yield the volcanic glass **obsidian**, usually at the base or at the front of a lava flow. The rate of cooling determines the texture of the lava, and the size of the crystals it contains. Slower cooling allows the growth of crystals, with exterior portions of a lava flow characterized by a mix of fine crystals and a glassy groundmass, whereas the inner portions of the flow are more coarse-grained with large crystals. Classification schemes for lavas rely primarily upon mineralogy, crystallinity, and chemical composition. The most abundant lava types are **basalt**, **andesite**, **rhyolite**, **trachyte**, and **phonolite**.

Lawley-Hotelling trace See **multivariate analysis of variance**.

Lazaret (Location 43°41'38"N, 7°17'21"E, France; etym. Fr. quarantine area; the cave may have been used as a quarantine area for the port of Nice or it may have resembled the quarantine area of a boat) History and general description A large cave on the Mediterranean coast of France on the western slope of Mount Boron in Nice. Long

known to amateur archeologists, it was first explored professionally by Emile Rivière in 1879 and then more fully excavated by C.F.E. Octobon in the 1950s and 1960s. The most recent excavations were undertaken by Henry and Marie-Antoinette de Lumley in the mid 1960s. The site contains abundant archeological and faunal remains as well as several fragmentary hominin remains. Though the site is on the coast, there is no evidence for consumption of marine resources. Temporal span and how dated? **Biostratigraphy** suggests an age of **Oxygen Isotope Stages 5d and 5c** for the archeological layers. The underlying beach deposits and the overlying flowstone have both been the object of a variety of dating methods, including **uranium-series dating** and **electron spin resonance spectroscopy dating**. Fauna from the archeological layers have been directly dated using uranium-series dating, but none of these dating methods have proved conclusive. The overall consensus for the archeological layers is roughly the beginning of Oxygen Isotope Stage 5. Hominins found at site Nine hominins have been discovered, three of which are complete enough to tell they resemble other material that is considered to be **pre-Neanderthal**. Archeological evidence found at site The archeological layer, layer C, is divided into three units. CI and CII contain **Acheulean** artifacts and CIII contains **Mousterian** items of Acheulean tradition with many flake tools. Key references: Geology, dating, and paleoenvironment Michel et al. 2000, de Lumley H. et al. 1976; Hominins de Lumley M.-A. and Piveteau 1969, Puech and Albertini 1981; Archeology de Lumley H. et al. 1976.

LB Prefix used for fossils recovered from **Liang Bua**, Flores, Indonesia.

LB1 Site Liang Bua. Locality Sector VII, Spits 59 and 62 (possibly also 61), and Sector XI, Spits 56B, 57A, and 58A. Surface/in situ *In situ*. Date of discovery 2003 (the right humerus, both ulnae, and left fibula were found in 2004). Finders Benyamin Tarus, Emanuel Wahyu Saptomo, and Rhokus Due Awe. Unit N/A. Horizon Dark-brown silty clay (Layer R) immediately above a clayey silt matrix with reworked conglomerate (Morwood et al. 2005, 2009). Bed/member N/A. Formation N/A. Group N/A. Nearest dated horizon Dated samples, ANUA-27116 and -27117 for **radiocarbon dating**, and LBS7-42 for **luminescence dating**, were taken from the same location as the LB1 associated skeleton. The 95% confidence intervals of the

former two samples were 18.7–17.1 ka and 19.0–17.9 ka, respectively, and the luminescence sample provided a minimum age of 6.8 ka (Roberts et al. 2009). Geological age *c.*18 ka. Developmental age Adult. Presumed sex Probably female based on pelvis. Brief anatomical description The associated skeleton comprises evidence of the cranium and mandible, and evidence of the clavicle, humerus, ulna, part of the hand, vertebrae, ribs, sternum, partial pelvis, femora, tibiae, fibulae, and most of the foot (Brown et al. 2004, Morwood et al. 2005). Endocranial volume Approximately 417 cm³ (Falk et al. 2005). Announcement Brown et al. 2004. Initial description Brown et al. 2004, Morwood et al. 2005. Photographs/line drawings and metrical data Brown et al. 2004, Falk et al. 2005, 2007, 2009, Morwood et al. 2005, Tocheri et al. 2007, Baab and McNulty et al. 2009, Brown and Maeda 2009, Jungers et al. 2009a, 2009b, Larson et al. 2009; Detailed anatomical description Falk et al. 2005, 2009, Tocheri et al. 2007, Brown and Maeda 2009, Jungers et al. 2009a, 2009b, Larson et al. 2009. Initial taxonomic allocation *Homo floresiensis*. Taxonomic revisions *Homo sapiens* Jacob et al. 2006. Current conventional taxonomic allocation *H. floresiensis*. Informal taxonomic category Pre-modern *Homo*. Significance The holotype of *H. floresiensis*. There are two interpretations of this specimen. The first concludes that its small overall size (the stature of LB1 is estimated to be 106 cm and its body mass to be 25–30 kg), its especially small brain (approximately 417 cm³) for an adult hominin, and its primitive, pre-modern *Homo* or transitional hominin-like morphology are most parsimoniously interpreted as evidence of a novel endemically dwarfed early *Homo* taxon. The second concludes that no new taxon needs to be erected for in this interpretation LB1 is viewed as a pathological *Homo sapiens* individual afflicted by, variously, endocrine disorders or a range of syndromes that include microcephaly. Both explanations are exotic, but the ones that support a pathological explanation for LB1 need to explain what pathology affecting a modern human results in an early African *Homo erectus*-like cranial vault, *Homo habilis*-like cranial, mandibular, dental, carpal, and pedal morphology, and a brain that while very small, apparently has none of the morphological stigmata of microcephaly. Location of original National Research and Development Center for Archaeology, Jakarta, Indonesia.

LB6 Site Liang Bua. Locality Sector XI, Spits 51–53. Surface/in situ *In situ*. Date of discovery 2004. Finders Emanuel Wahyu Saptomo, Thomas Sutikna, Rhokus Due Awe, Jatmiko, and Sri Wasisto. Unit N/A. Horizon A brownish clayey silt (Layer Q) (Morwood et al. 2005, 2009). Bed/member N/A. Formation N/A. Group N/A. Nearest dated horizon Two dated samples, ANUA-23610 and -27117 taken from Sector III and VII respectively for **radiocarbon dating**, potentially constrain the ages of the LB6 associated skeleton. The confidence intervals of these two samples are >15.7–17.1 ka and <17.1–18.7 ka, respectively. Geological age *c.*17 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The associated skeleton comprises 14 numbered fossils including a mandible, the right scapula, ulna and radius, bones from the digits of the hand, and three pedal phalanges. The mandible lacks the right ramus, and the left coronoid and condylar processes have suffered some damage. As for the teeth, all but the left I₁₋₂ and the right I₁ are preserved. The scapula is nearly complete, and the ulna lacks just the distal end. The radius is complete, but the distal end displays the type of deformity associated with a healed (but unreduced and unsplinted) fracture. Announcement Morwood et al. 2005. Initial description Morwood et al. 2005. Photographs/line drawings and metrical data Morwood et al. 2005, Brown and Maeda 2009. Detailed anatomical description Larson et al. 2009, Jungers et al. 2009b, Brown and Maeda 2009. Initial taxonomic allocation *Homo floresiensis*. Taxonomic revisions *Homo sapiens* (Jacob et al. 2006). Current conventional taxonomic allocation *H. floresiensis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance This, the second associated skeleton of *Homo floresiensis*, has a mostly well-preserved mandible that in general matches the morphology seen in the LB1 mandible. As for LB1, the primitive early *Homo*-like morphology of this specimen can either be interpreted as evidence of a novel endemically dwarfed early *Homo* taxon, or as the result of a second modern human individual afflicted by a congenital abnormality or endocrine disorder resulting in small stature and primitive mandibular, dental, and postcranial morphology. Location of original National Research and Development Center for Archaeology, Jakarta, Indonesia.

LCA Acronym for last common ancestor, sometimes also referred to as the hypothetical last

common ancestor. In the context of hominin evolution, the last common ancestor of the hominin clade would be the hypothetical last common ancestor of the clades whose extant members are, respectively, chimpanzees/bonobos and modern humans. *See also most recent common ancestor.*

LCN Prefix for fossils recovered from Lincoln Cave North, at Sterkfontein, in Gauteng Province, South Africa. *See Lincoln Cave; Sterkfontein.*

LCS Prefix for fossils recovered from Lincoln Cave South, at Sterkfontein, in Gauteng Province, South Africa. *See Lincoln Cave; Sterkfontein.*

LD Acronym for **linkage disequilibrium** (*which see*).

Le Fate *See Caverna delle Fate.*

Le Gros Clark, Wilfrid Edward (1895–1971) Wilfrid Le Gros Clark was born in Hemel Hempstead, England, and entered St. Thomas's Hospital Medical School in London in 1912. After qualifying in medicine in 1916 he joined the Royal Army Medical Corps in 1917 and was sent to France early in 1918 to take part in WWI. He was demobilized in 1919 and he returned to St. Thomas's to study surgery. After passing his surgical qualification exams he became the Principal Medical Officer in Sarawak, part of the island of Borneo, in 1920. There he developed his longstanding interest in natural history (for details see below and Le Gros Clark's autobiography) by studying tarsiers (*Tarsius*) and tree shrews (*Tupaia*) with a particular emphasis on their evolutionary relationship to the primates. In 1923 Le Gros Clark left Sarawak to accept a position as head of the Department of Anatomy at St. Bartholomew's Hospital Medical School in London where he remained from 1924 until 1929. He moved again in 1930 to become professor of anatomy at his alma mater, St. Thomas's Hospital Medical School, and again in 1934 when he accepted the Dr Lee's Professorship of Anatomy at the University of Oxford. In the same year he was elected as a Professorial Fellow of Hertford College, Oxford. Through Le Gros Clark's studies of the tree shrew he concluded that they are the closest living example of the earliest primate to become differentiated from the mammalian/insectivore stem. New evidence has caused this interpreta-

tion to be rejected, but at the time Clark's research represented state-of-the-art comparative primatology, and it influenced many researchers. In 1934 Le Gros Clark published *Early Forerunners of Man*, which discussed human evolution and used his deep knowledge of the anatomy of living and fossil primates to review the pertinent comparative evidence. Because he believed that parallel evolution was common in primates he argued that the hominin and anthropoid lines could have separated very early. Non-Darwinian models of evolution were common throughout the early 20thC and Clark initially supported the idea of **orthogenesis** (i.e., that evolution was directional) as opposed to a strictly Darwinian conception of evolution driven solely by natural selection. Also, like many of his colleagues, Clark initially considered the australopiths discovered by Raymond **Dart** and Robert **Broom** in southern Africa to be anthropoid apes and not closely related to our own evolution. Le Gros Clark's experiences in WWI led him to be a pacifist, so that in WWII he contributed to the war effort through his research on muscle and nerve regeneration. Le Gros Clark attended the First **Pan-African Congress on Prehistory** held in Nairobi, Kenya, in 1947 and while he was in Africa he traveled to South Africa to inspect the australopith fossils that had been collected by Dart and Broom. Clark, who was one of the few Europeans to actually inspect the full collection thoroughly, became convinced that Dart and Broom had been correct in their interpretation that *Australopithecus* represented a hominin intermediate between anthropoid apes and modern humans and ancestral to modern humans. His article "Observations of the anatomy of the fossil australopithecine" published in the *Journal of Anatomy* in 1947 marked a turning point in the general acceptance of australopiths as at least potential, if not actual, human ancestors. Le Gros Clark was drawn into the controversy over **Pitldown Man** by his Oxford colleague Joseph Weiner who, together with Kenneth **Oakley**, began in 1953 to re-examine the Pitldown fossils and their context. The Pitldown (*Eoanthropus dawsoni*) fossils were found between 1908 and 1915 in Sussex, England, by Charles Dawson, an amateur archeologist. The large cranium, but ape-like jaw, of the specimen differed from the other fossil hominins that were becoming known by that time, but Pitldown had many supporters as a human ancestor. While some physical anthropologists had been skeptical of the specimen, it was not until 1953 that Weiner, Oakley, and Le Gros Clark used

fluorine dating to show that the fossils were forgeries and thus were able to finally remove Piltdown Man from the accepted ranks of valid hominin species. The removal of Piltdown Man from modern human evolutionary history had implications for the way other controversial hominin species, especially those assigned to the genus *Australopithecus*, were viewed. Le Gros Clark re-examined human evolution in *The Fossil Evidence for Human Evolution: an Introduction to the Study of Palaeoanthropology* (1955). This influential work discussed the hominin fossil record and contemporary debates over primate taxonomy and phylogeny, and in it the australopiths are treated as important links in the human lineage. By backing away from the centrality of parallel evolution and by drawing upon the work of the American paleontologist George Gaylord Simpson, Le Gros Clark helped reform **paleoanthropology**. Simpson had revolutionized paleontology by integrating the new emphasis on Darwinian evolutionary mechanisms and population genetics that were part of the **modern evolutionary synthesis** into paleontology. Le Gros Clark's 1955 book rejected theories, common during the early 20thC, suggesting modern human races had separate evolutionary histories. In 1959, in perhaps his best-known book, *The Antecedents of Man*, Le Gros Clark discussed primate comparative anatomy, including their embryology and dental and cranial anatomy. In it he examined the known hominin fossils, including treatments of the recent discoveries made by Louis Leakey in East Africa. This work went through three editions by 1971 and was widely used by students of primatology and paleoanthropology. Le Gros Clark retired as Dr Lee's Professor of Anatomy at the University of Oxford in 1962, but he was elected an Honorary Fellow of Hertford College, Oxford, in 1962 and he retained that appointment until his death. After his retirement he continued to conduct research and write books, including a second edition of *The Fossil Evidence for Human Evolution: an Introduction to the Study of Palaeoanthropology* (1964), *Man-apes or Ape-men? The Story of Discoveries in Africa* (1967), and an autobiography, *Chant of Pleasant Exploration* (1968). Le Gros Clark was elected a Fellow of the Royal Society in 1935, he was the President of the International Anatomical Congress in 1950, and he was elected the President of the Anatomical Society of Great Britain and Ireland in 1951. In 1955 he was made a Knight Commander of the British Empire.

Le Moustier (Location 44°59'38''N, 1°03'35''E, France; etym. named after the nearby town) History and general description A site along the Vézère river consisting of two shelters. The upper shelter was excavated in the late 19thC by Edouard Lartet and Henri Christy and the material they recovered led Gabriel de Mortillet to define the **Mousterian** technocomplex. Otto Hauser explored the much deeper deposit in the lower shelter in the early 20thC and found a deliberately buried associated skeleton of a young individual (Le Moustier 1) and a skull fragment (Le Moustier 3). Denis Peyrony excavated the remains of the lower shelter and found at least 11 different archeological layers. He also discovered the remains of an infant (Le Moustier 2). Temporal span and how dated? **Thermoluminescence** and **electron spin resonance spectroscopy dating** of the lower shelter suggest an age range of *c.*55.8–40.3 ka for the Mousterian levels and *c.*42 ka for the **Châtelperronian** level. Hominins found at site **Le Moustier 1**, the cranium, mandible, and a few postcranial remains of a young male *c.*10.5–12.1 years of age, attributed to *Homo neanderthalensis*; **Le Moustier 2**, a nearly complete neonatal skeleton, likely also intentionally buried; and **Le Moustier 3**, a cranial fragment. Archeological evidence found at site The deep Mousterian deposit contained several layers that Francois Bordes attributed to different types or facies of the Mousterian (e.g., Mousterian of Acheulean Tradition, Denticulate Mousterian, Typical Mousterian, etc.). These layers were topped by thin Châtelperronian and **Aurignacian** levels. Key references: Geology, dating, and paleoenvironment Mellars and Grün 1991, Valladas et al. 1986; Hominins Hauser 1909, Klaatsch and Hauser, 1909, Archeology Peyrony 1930.

Le Moustier 1 Site **Le Moustier**. Locality N/A. Surface/in situ *In situ*. Date of discovery March 7, 1908. Left radius and ulna and lower extremities removed on that date. Vertebrae and part of the pelvis disintegrated when an attempt was made to excavate them (Hauser 1909); the cranium and mandible were excavated on August 12 by anatomist Hans Klaatsch at Otto Hauser's invitation. Finders Otto Hauser and crew. Unit N/A. Horizon Probably layer J (Typical **Mousterian**). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*40 ka. Developmental age *c.*10.5–12.1 years (Smith et al. 2010). Presumed sex Male (Thompson and Nelson 2005a). Brief

anatomical description Nearly complete cranium, now missing parts of the midface and the upper right central incisor lost some time after 1945, and fragments of the postcranial skeleton (some bones were damaged in a fire in 1945 but these burned fragments were subsequently recovered from the rubble of the museum). Casts of the original postcranial remains made soon after discovery retain important morphological and diagnostic information. The elements cast include the left clavicle, fragment of the right scapula, left second rib, right radius and ulna (missing epiphyses), left femur and tibia, left patella, both fibulae (fragments of diaphyses), and the left first metatarsal. Burned fragments that remain include left femur diaphysis (incomplete), a fragment of the diaphysis of the right humerus, a fragment of the right scapula, a fragment of the proximal diaphysis of the right ulna, a fragment of the distal end of the left radius, fragments of the pelvic bone, a fragment of the left talus, a fragment of a rib, several diaphyseal fragments of long bones, fragments of epiphyses of several bones, and small unidentified bone fragments (Thompson and Nelson 2005b). Despite the individual's young age at death the specimen exhibits many features typical of *Homo neanderthalensis*. **Announcement** Hauser 1909. **Initial description** Klaatsch and Hauser 1909. **Photographs/line drawings and metrical data** Weinert 1925. **Detailed anatomical description** Weinert 1925, Bilsborough and Thompson 2005, Thompson 2005, Thompson and Bilsborough 1997, 2005, Thompson and Illerhaus 1998, Thompson and Nelson 2005b (see also papers in Ullrich 2005). **Initial taxonomic allocation** *Homo mousteriensis* (Klaatsch and Hauser 1909). **Taxonomic revisions** *H. neanderthalensis* (Weinert 1925). **Current conventional taxonomic allocation** *H. neanderthalensis*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** A fairly complete cranium and mandible of a late "classic" Neanderthal. The mandible shows evidence of having been broken some time prior to the death of the individual (MacGregor 1964; see also Ullrich 2005). The individual is a juvenile and so provides important information about patterns of Neanderthal growth and development. Estimates using synchrotron virtual histology provide a dental age of 11.6–12.1 years (Smith et al. 2010), which contrasts with estimates of 15–16 years based on modern rates of dental formation. This new dental age is consistent with the postcranial age estimates (Nelson and Thompson 2005), particularly that based on the length of the femur (10.5 years) and indicate that Neanderthal growth was accelerated compared to modern humans.

Given that Le Moustier 1 had completed about 85% of his skeletal and dental growth at the time of death it is estimated that Neanderthals had a total duration of growth of 13–14 years, much shorter than seen in most modern human populations. The implication is that the modern human pattern of growth and development is recent. **Location of original** Although the postcranial skeleton was damaged in a fire at the end of WWII, fragments were recovered from the building rubble (Ullrich 2005). The cranium, mandible, and remaining postcranial fragments are housed at the Staatliche Museen zu Berlin, Museum für Ur- und Frühgeschichte, Berlin, Germany.

Le Moustier 2 **Site** Le Moustier. **Locality** N/A. **Surface/in situ** *In situ*. **Date of discovery** May 19, 1914. **Finder** D. Peyrony. **Unit** N/A. **Horizon** Probably layer J (Typical **Mousterian**). **Bed/member** N/A. **Formation** N/A. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** *c.*40 ka. **Developmental age** Neonate *c.*4 months or less (Maureille 2002) **Presumed sex** N/A. **Brief anatomical description** Almost complete cranium and deciduous dentition (missing left temporal) and fairly complete postcranial skeleton (missing scapulae and pubes) of a neonate. **Announcement** Peyrony 1921, 1930. **Initial description** Maureille 2002a, 2002b. **Photographs/line drawings and metrical data** Maureille 2002a, 2002b, 2005. **Detailed anatomical description** Maureille 2005. **Current conventional taxonomic allocation** *Homo neanderthalensis*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** A fairly complete neonate skeleton of a late "classic" Neanderthal. **Location of original** Musée National de Préhistoire (Les Eyzies-de-Tayac), France.

Le Moustier 3 **Site** Le Moustier. **Locality** N/A. **Surface/in situ** *In situ*. **Date of discovery** 1910. **Finder** O. Hauser. **Unit** N/A. **Horizon** N/A. **Bed/member** N/A. **Formation** N/A. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** *c.*40 ka. **Developmental age** N/A. **Presumed sex** N/A. **Brief anatomical description** Cranial fragment. **Announcement** Hauser 1911, 1925. **Initial description** N/A. **Photographs/line drawings and metrical data** N/A. **Detailed anatomical description** N/A. **Current conventional taxonomic allocation** *Homo neanderthalensis*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** A cranial fragment from

Le Moustier site was mentioned in two of Hauser's publications but there is no formal description of the specimen. Hauser noted that the skull fragment was from the "lower grotto" at Le Moustier and in the travel diaries of Dr F. Krantz Le Moustier 3 is mentioned as "a small skull fragment isolated from a Moustier layer" (Rosendahl 2005, p. 75). Location of original Unknown.

leaf waxes Leaf waxes are the waxy molecules on the surface of terrestrial plant leaves. They are resilient to degradation and thus they are preserved in the geological record and can act as a proxy for past vegetation and climate. The carbon and hydrogen isotope ratios in individual leaf wax molecules (such as *n*-alkanes and *n*-alkanoic acids) can be analyzed by gas chromatography isotope ratio mass spectrometry dating and used for paleoclimate reconstruction. This approach has been used to measure C₃ and C₄ vegetation changes on Mount Kenya (Huang et al. 1999b), off northwest Africa (Huang et al. 2000), in the Congo fan (Schefuß et al. 2003), in the Namib margin (Rommerskirchen et al. 2006), in the Gulf of Aden (Feakins et al. 2005), and in the Turkana Basin (Feakins et al. 2007). Based on the carbon isotopic composition of plant leaf wax biomarkers in marine sediments researchers have reported repeated shifts between forest and grassland conditions in northeast Africa over the past 4 Ma. **Hydrogen isotope analysis** in plant leaf waxes has been applied to the Congo fan (Schefuss et al. 2003), Lake Tanganyika (Tierney et al. 2008), and Lake Wandakara in Uganda (Russell et al. 2009). *See* C₃ and C₄; stable isotopes.

Leakey, Louis Seymour Bazett (1903–72)

Louis Leakey was born at the Kabete missionary station near Nairobi, in what was then the British East Africa Protectorate (it became the Kenya Colony in 1920). The outbreak of WWI prevented Louis from attending school in Britain, but at the end of the war in 1919 he completed his education at Weymouth College in England. In 1922 he was admitted into St. John's College, Cambridge, where he studied anthropology and archeology with Alfred C. Haddon and Miles Burkitt. During a

break in his studies at Cambridge in 1924, Leakey joined the British Museum East African Expedition to what was then Tanganyika Territory to look for dinosaurs with Hans Reck at Tendaguru. Leakey completed his degree in 1926 and resolved to organize "an expedition to Kenya Colony to commence the scientific investigation of the history of the country during Stone Age times" (Leakey 1937, p. 179). He was appointed to a Research Studentship, also at St. John's College, and in July 1926 he returned to East Africa as the leader of the East African Archeological Expedition and between 1926 and 1935 Louis Leakey led four archeological expeditions to investigate the prehistory of Kenya and Tanganyika. By 1927 he had recovered sufficient human skeletal material from Nakuru, Elmentaita, and Gamble's Cave to justify their description and analysis. Leakey approached Sir Arthur Keith, by then the Conservator of the Royal College of Surgeons of England, to do this; Keith declined, but offered Louis space at the College so that he could do it himself. In 1931 Leakey traveled with Hans Reck to Olduvai Gorge; this was the first time Reck had been to Olduvai since the outbreak of WWI had prevented him from returning in 1914. Leakey was joined on that expedition by Hopwood, Donald MacInnes, and Vivian Fuchs. Subsequent expeditions also included visits to Olduvai Gorge, where, with his first wife Frida Leakey, Louis found and mapped many sites. The results of these early expeditions were published as *The Stone Age Cultures of Kenya Colony* (1931) and *Stone Age Africa* (1936). Leakey had completed his PhD at Cambridge in 1930, and while lecturing at the Royal Anthropological Institute in 1933 he met Mary Nicol, a student of archeology and an artist who worked on the illustrations for Gertrude Caton-Thompson's book *The Desert Fayum* (1934). Impressed by her work, Leakey asked her to illustrate his *Adam's Ancestors* (1934). Louis and Mary Nicol were married in 1936 and thus began a remarkably productive professional partnership. As well as resuming work at Olduvai Gorge in 1942 Louis and Mary Leakey relocated the site at Olorgesailie where hundreds of naturally unearthed handaxes had been reported some 30 years earlier by the geologist and explorer John Walter Gregory. They also explored Miocene sites on the shores of Lake Victoria, and in 1948 they discovered on Rusinga Island the partial skull and jaw of a Miocene primate they named *Proconsul africanus*. In the meantime Louis Leakey had accepted a position in 1945 as Curator of the Coryndon Memorial Museum in

Nairobi, a post he held until 1961. Louis also organized the First **Pan-African Congress on Prehistory**, which was held in Nairobi in 1947. The meeting brought together archeologists, geologists, and paleontologists from across Africa as well as Europe to discuss African prehistory. Louis served as the general secretary of the Pan-African Congress on Prehistory from 1947 to 1951, and was its president from 1955 to 1959. Excavation work at Olduvai Gorge initially progressed slowly due to lack of funds and the limited amounts of time the Leakeys could spend in the field, but this changed in 1951 when Charles **Boise** provided long-term financial support for their research at Olduvai. Excavations at Olduvai Gorge produced considerable quantities of prehistoric artifacts that were described in *Olduvai Gorge: A Report on the Evolution of the Hand-Axe Culture in Beds I-IV* (1951). But despite decades of searching, and apart from some isolated hominin teeth that at the time were not considered of sufficient moment to report, no well-preserved fossils of the tool makers had been discovered. However, in July 1959 Mary **Leakey** found the cranium of a fragmented robust hominin (**OH 5**) in association with **Oldowan** tools and what was interpreted as a “living site.” Leakey named the specimen *Zinjanthropus boisei* (the species name recognizes the support given by Charles Boise), and concluded that *Zinjanthropus* made the tools that were found with it. Specimens of volcanic rock from adjacent deposits were analyzed by a team of physicists, Garniss Curtis and Jack Evernden, from the University of California at Berkeley using a new technique called **potassium-argon dating**, and they established that *Zinjanthropus* had lived *c.* 1.75 Ma; this was the first use of this dating method to establish the age of a fossil hominin. In May 1960 Jonathan Leakey found a hominin tooth, and this led to the recovery of the skull (**OH 7**) and the postcranial bones (**OH 8**) of a more gracile form of hominin in deposits that also contained artifacts and processed animal bones; more evidence was found in 1960 and in 1963. Louis enlisted the help of South African paleoanthropologist Phillip **Tobias** (who was already undertaking the detailed description of OH 5 for the Leakeys) and British primatologist John **Napier** to analyze the post-1959 hominin discoveries, and in 1964 the three authors published a paper that introduced and described a new hominin taxon, *Homo habilis*. *H. habilis* possessed a larger brain than *Zinjanthropus* as well as other anatomical traits more akin to modern humans, and this led Louis to suggest that it was *H. habilis* and not *Zinjanthropus* that made

the Oldowan tools found at Olduvai Gorge. In 1961 Leakey discovered an upper jaw and teeth of a Miocene primate in western Kenya. This specimen, which he named *Kenyapithecus wickeri*, was followed in 1965 by fragments of another jaw and teeth that Louis referred to *Kenyapithecus africanus*. Louis and Mary Leakey’s excavations at Olduvai Gorge transformed **paleoanthropology**, through both the hominin specimens they recovered and the archeological evidence they discovered there. Moreover, because the geology and paleontology at Olduvai needed to be properly studied Louis and Mary enlisted the assistance of specialists (e.g., Shirley Coryndon, Richard **Hay**, Dick Hooijer) to conduct the work. Likewise, they relied upon the assistance of Phillip **Tobias**, John **Napier**, Michael **Day**, and Peter Davis to describe and analyze the hominin fossils; the archeological evidence was the bailiwick of Mary Leakey. The immense productivity of the team of researchers assembled by the Leakeys is evident in the publications produced during this period, which include *The Progress of Man in Africa* (1961), *Olduvai Gorge, 1951–1961. Volume 1. A Preliminary Report on the Geology and Faunas* (1965), *Fossil Vertebrates of Africa* (1969 and 1970), *Olduvai Gorge, Volume 2. The Cranium and Maxillary Dentition of Australopithecus (Zinjanthropus) boisei* (1967), *Olduvai Gorge, Volume 3. Excavations in Beds I and II* (1971), *Olduvai Gorge, Volume 4. The Skulls, Endocasts and Teeth of Homo habilis* (1991), and *Olduvai Gorge, Volume 5. Excavations in Beds III, IV and the Masek Beds* (1994). The **L.S.B. Leakey Foundation** was established in California in 1968 to support the research of Louis (and Mary) Leakey and to encourage further cognate research in Africa and elsewhere, and after Louis’ death in 1972 the International Louis Leakey Memorial Institute for African Prehistory (or TILLMIAP) was established at the National Museums of Kenya in recognition of Louis Leakey’s immense impact on paleoanthropology and African prehistory. In addition to his paleoanthropological contributions Louis Leakey published many seminal scholarly articles on the ethnography and culture of the Kikuyu, and he initiated, with Mary Leakey, programs that recorded Angolan String Figures and rock-shelter paintings in Tanzania. Louis Leakey was also instrumental in instigating the primate research of Jane Goodall, Dianne Fossey, and Birute Galdakis. *See also* Charles **Boise**; *Homo habilis*; *Olduvai Gorge*; *Paranthropus boisei*.

Leakey, Mary Douglas Nicol (1913–96)

Mary Nicol was born in London, England, the daughter of Erskine Nicol, a well-known painter, and Cecilia Frere, whose ancestor was the British antiquary, John Frere. In 1800 Frere had argued that a flint axe he had found several years earlier was of great antiquity, and was evidence that modern humans were more ancient than conventional wisdom suggested. The Nicol family lived for a time in the Dordogne region of France where Mary visited the prehistoric sites of the region with French prehistorian Elie Peyrony. When her father died in 1926, Mary and her mother returned to London. Mary had been unable to gain admittance to university, but in 1930 she began attending archeology and geology lectures at The University of London, as well as the archeology lectures of Mortimer Wheeler at the London Museum. She also worked with Dorothy Liddell on excavations at the Neolithic site of Hembury in Devon. Mary, who was a skilled artist, not only gained experience in archeological excavation, but also made fine drawings of the flint tools unearthed at the site. The drawings came to the notice of British archeologist Gertrude Caton-Thompson, who asked Mary to illustrate her book *The Desert Fayum* (1934). Mary and Caton-Thompson developed a close friendship and it was Caton-Thompson who, in 1933, introduced Mary to Louis Leakey, who was in London lecturing at the Royal Anthropological Institute. During the early 1930s Mary joined Dorothy Liddell in the excavation at Stockbridge in Hampshire and in 1934 Mary conducted excavations on her own at Jaywick Sands in Essex. Mary and Louis Leakey were married in 1936, and later in that year she joined Louis in Africa. During the early 1940s Mary along with Louis explored many prehistoric sites including **Olorgesailie**. While excavating on Rusinga Island in Lake Victoria in 1948 Mary discovered the partial skull of a **Miocene** primate later named *Proconsul africanus*. When Louis and Mary began more intensive work at **Olduvai Gorge** in 1951, they directed their efforts to the lowermost deposits of the gorge where they found numerous stone artifacts and processed animal bones. After years of excavating at Olduvai, in July 1959 in Bed I Mary found a fragmented cranium belonging to a robust looking hominin. Louis assigned the specimen to a new genus and species, *Zinjanthropus boisei*, and assumed it had made the tools found along with it. Mary mapped the

archeological sites and studied the stone artifacts found in the various deposits at Olduvai. Working with a team of Kenyan assistants and with geologist Richard Hay of the University of California at Berkeley, Mary devised a systematic way of classifying the sequence of stone tool industries at Olduvai, as well as suggesting the sources of the raw material for the stone tools. Mary's careful studies of what she interpreted as an apparent camp or living floor found in the *Zinjanthropus* deposits were at the time judged to be important information about the social life of these hominins. The results of Mary's archeological investigations were reported in detail in the third and fifth volumes of the *Olduvai Gorge* series, respectively: *Excavations in Beds I and II, 1960-1963*, published in 1971, and *Excavations in Beds III, IV and the Masek Beds*, published in 1994. Mary continued to conduct research at Olduvai after Louis' death in 1972. In 1974 she began work at a site called **Laetoli** and in 1975 she discovered fragmentary hominin remains including several jawbones, which have been dated to *c.*3.8–3.6 Ma. These remains were attributed to *Australopithecus afar-ensis*, although Mary demurred from this interpretation. Between 1974 and 1981 more hominin fossils were found at Laetoli and in 1978 trails of fossil footprints left by at least two hominin individuals were found in deposits of hardened volcanic ash; the **Laetoli footprints** indicate that hominins were walking upright at least 3.6 Ma. Mary Leakey retired from fieldwork in 1983 and moved back from Olduvai to the family home in Langata, near Nairobi. In 1984 she published an autobiography entitled *Disclosing the Past*.

Leakey, Meave (1942–) Meave Epps was born in London, England. She attended the University of North Wales where she completed a BSc in zoology and marine zoology. In 1965 she began her PhD work in zoology at the University of North Wales and later that year she took a staff position at the Tigoni Primate Research Centre near Nairobi, Kenya. Meave completed her PhD in 1968, and early the following year, she returned to Kenya to take a temporary position as the Director of the Tigoni Primate Research Centre. Later that year she joined Richard Leakey's team of researchers who were searching for hominin fossils at **Koobi Fora** on the eastern shores of Lake Rudolf (now called Lake Turkana) in northern Kenya. Richard and Meave were married in

1970 and Meave became an important contributor to the **East Rudolf Research Project**, the precursor of the **Koobi Fora Research Project**. Glynn Isaac, the co-leader of the Koobi Fora Research Project, had died in 1985, and when in 1989 Richard Leakey undertook other responsibilities Meave took over the leadership of the field project. Meave accepted a position at the **National Museums of Kenya** in 1969 and from 1982 to 2001 she was the head of the museum's paleontology division. Meave Leakey's research in the Turkana Basin has focused on the evolution of East African mammals, especially monkeys, and the discovery of fossil remains of early human ancestors. She collaborated on the reconstruction of the **KNM-ER 1470** skull discovered in 1972 at East Rudolf and assisted with the recovery and reconstruction of the **KNM-ER 3733 *Homo erectus* (*Homo ergaster*)** cranium discovered in 1975, as well as the cranium **KNM-ER 1813**, and others. Meave Leakey's role in the Koobi Fora Research Project expanded in 1989 when she became the coordinator of research. It was under her leadership between 1994 and 1997 that fragments of upper and lower jaws, a number of associated isolated teeth, and a proximal tibia, now classified as *Australopithecus anamensis*, were found at **Kanapoi** and **Allia Bay** in the Turkana Basin. This was followed in 1999 by the discovery at **West Turkana** of a mostly complete cranium (**KNM-WT 40000**) of a hominin that was assigned to a new species and genus, *Kenyanthropus platyops*. The specimen was dated at *c.*3.5 Ma, thus making it the contemporary of *Australopithecus afarensis*, and thereby challenging the notion that *Au. afarensis* is necessarily the ancestor of later hominins. In addition to publishing numerous research articles Meave Leakey also co-authored, with Richard Leakey, the first volume of the Koobi Fora Research Project series titled *The Fossil Hominids and an Introduction to Their Context, 1968-1974*, published in 1978. In 2003 John Harris and Meave Leakey published *Lothagam: The Dawn of Humanity in Eastern Africa* that surveys the geology, dating, and fossil fauna of **Lothagam**, a site on the western side of Lake Turkana, which documents the late Miocene/early Pliocene faunal turnover and the associated spread of grasslands. Meave Leakey continues to conduct field research in the Turkana Basin, and now co-leads the Koobi Fora Research Project with her daughter Louise Leakey who completed her PhD in paleontology from

University College London. *See also* **Kanapoi**; **Lothagam**; **Koobi Fora**.

Leakey, Richard Erskine Frere (1944–)

Richard Leakey was born in Nairobi, Kenya, the middle of the three sons of Louis and Mary **Leakey**. Initially Richard Leakey had no interest in pursuing human origins research and after dropping out of high school he began trapping animals to supply skeletons to universities and museums and later started his own safari business. But while flying over Lake Natron on the border between Kenya and Tanganyika (now Tanzania) in 1963 he noticed geological deposits that looked promising possible locations for vertebrate fossils. Richard explored the **Peninj** region early in 1964, and was later joined by archeologist Glynn Isaac. In sediments exposed by the Peninj river Kamoya **Kimeu** discovered an exceptionally well-preserved hominin mandible that belongs to what is now called *Paranthropus boisei*. Leakey took a decisive step into paleoanthropology in 1967 when he represented Louis Leakey on the the **International Omo Research Expedition** that had been organized to explore the lower reaches of the Omo River valley in southern Ethiopia. During that expedition he was loaned the expedition's helicopter to inspect the sediments exposed on the eastern shore of Lake Turkana (then called Lake Rudolf) in northern Kenya. Despite recovering two early *Homo sapiens* crania that are now considered to be among the earliest fossil evidence for anatomically modern humans in sediments exposed at **Omo-Kibish**, Leakey determined that the exposures along the eastern shore of the lake were more promising than the exposures the Kenyan contingent had been allocated to the east of the Omo River, so he withdrew from the International Omo Research Expedition to concentrate on the sites in northern Kenya. In 1968, with support from the National Geographic Society, Leakey and a team of colleagues conducted their first survey of the area in 1968 and quickly began to discover artifacts, animal fossils, and some hominin cranial and postcranial fragments including a partial *P. boisei* jaw. When Richard Leakey returned to work at Lake Turkana in 1969 he focused his attention on a site called **Koobi Fora**, which together with exposures on the western side of the lake, has become one of the most productive hominin sites in the world. In 1969 Leakey invited Glynn Isaac, his partner in the Lake Natron expedition, to join

him as co-director of what became known as the **East Rudolf Research Project**. Over the next two decades Leakey and a team of researchers, together with a team of experienced fossil hunters lead by Kamoya Kimeu, explored the fossil-rich exposures along the eastern shore of Lake Turkana and their efforts resulted in the recovery of a number of important hominin fossils. The first of the relatively complete hominins to be recovered was in 1969 when Leakey and Meave Epps discovered an adult *P. boisei* cranium, **KNM-ER 406**. The following year a partial cranium (**KNM-ER 732**) was found that resembled *P. boisei*, but it was smaller and lacked a sagittal crest. In 1972 in deposits originally thought to be 2.6 Ma Bernard Ngeneo discovered a relatively large-brained hominin cranium, **KNM-ER 1470**, and in 1973 Paul Abell discovered a small-brained hominin skull, **KNM-ER 1805**; that skull together with a cranium with an even smaller brain **KNM-ER 1813**, discovered by Kamoya Kimeu, contributed to the debate about the validity of the taxon *H. habilis*. In 1975, Bernard Ngeneo found yet another hominin cranium, **KNM-ER 3733**, that resembled *Homo erectus* specimens from Indonesia and China. The specimen was also significant since it was found in deposits that were of the same age as the deposits where the **KNM-ER 406** *P. boisei* cranium had been found, which meant that at least two species of hominin had lived in the Turkana Basin at the same time. During the late 1970s Leakey's team began to expand beyond sites at Koobi Fora to explore the potential of sites on the west side of the lake. Important discoveries continued to be made at in the Turkana Basin and in 1984 Kamoya Kimeu discovered a skeleton of an adolescent male at West Turkana (**KNM-WT 15000**), which provided important information about the stature, body size, and limb proportions of early pre-modern *Homo*. This find was followed by the discovery in 1985 by Alan Walker of an almost complete *c.*2.5 Ma cranium of a megadont archaic hominin, **KNM-WT 17000**. Leakey left his position as director of the National Museums of Kenya in 1989 when he was appointed as director of the Kenya Wildlife Service. During his tenure he worked to prevent elephant and rhinoceros poaching and to reform Kenya's park service. He was forced to resign in 1994 due to political opposition and he published a book about his experience titled *Wildlife Wars: My Battle to Save Kenya's Elephants* (2001). As a result of a plane crash in 1993 both of Leakey's legs

had to be amputated below the knee, and this made continued fieldwork difficult. Leakey's interests became increasingly political during the 1990s, and he joined a group of Kenyan intellectuals in 1995 to form a new political party called the Safina Party. Kenya's President, Daniel arap Moi, appointed Leakey to Head the Civil Service in 1999, but he was forced to resign in 2001. In addition to many papers in scientific journals announcing and describing the hominin and nonhominin fossils from the Turkana Basin, and elsewhere, Leakey published two popular books about his field research and ideas about human origins, *Origins* (1977) and *People of the Lake* (1978) and together with Meave Leakey they authored the first volume in the Koobi Fora Research Project series entitled *The Fossil Hominids and an Introduction to their Context, 1968-1974* that appeared in 1978. Although Richard Leakey became less involved in fieldwork in the Turkana Basin after 1989, he continued to write on the subject. He published two general works on human origins during the early 1980s, *The Making of Mankind* (1981) and *Human Origins* (1982) and following the discoveries at Lake Turkana during the 1980s Leakey joined with Roger Lewin to write *Origins Reconsidered* (1992). He is presently a Professor at Stony Brook University, where he is working to establish and develop the Turkana Basin Institute as a focus for a wide range of research programs, including paleoanthropology, in an effort to foster sustainable development in the Turkana Basin. *See also* **Koobi Fora; Koobi Fora Research Project; Omo-Kibish; West Turkana.**

least squares regression *See* ordinary least squares regression.

lectotype (Gk *lectos*=chosen and *typus*=image) If a **holotype** was not designated at the time of the original description of a **taxon**, one of the specimens (or **syntypes**) listed in that description can subsequently be designated as the type. This is then referred to as the lectotype of that taxon. For example, because Alexeev (1986) did not specifically name a holotype of *Pithecanthropus rudolfensis*, Wood

(1999) formally named **KNM-ER 1470** as the lectotype of that taxon.

Ledi-Geraru Research Project This paleo-anthropology project was begun in 2002 and was originally known as the Middle Ledi Research Project. The project was organized by the late Charles Lockwood (paleoanthropology), Ramon Arrowsmith (geology), and Kaye Reed (paleoecology/paleontology). In 2002, the researchers collected material in what Jon Kalb (see the **International Afar Research Expedition and Rift Valley Research Mission in Ethiopia**) referred to as the **Middle Ledi**, but research in 2002 focused on the Hawoona Dora and Leadu Basins, which are Afar names for the dry drainages in the area. Two *Australopithecus afarensis* teeth were recovered from the Kada Hadar Member of the **Hadar Formation** near the Hawoona Dora Basin. Other fauna from the western region was attributable to taxa also found in the **Hadar** and **Dikika** study areas of the same age. Subsequent surveys from 2003 through 2008 expanded the boundaries of the research area and the name was changed to the Ledi-Geraru Research Project to better describe the broader region. These later expeditions included a comprehensive study of the geology (DiMaggio et al. 2008, Dupont-Nivet et al. 2008) and identification of potential paleontological and archeological sites. These include regions such as Grufaitu in which there are conformable sediments less than 2.95 Ma, as well as Geraru and Asbole in which there were numerous fossils and stone tools. No fossils were collected during the surveys of 2003–8. Researchers on this expanded project include Lars Werdelin (paleontology), Guillaume Dupont-Nivet (paleomagnetic dating), Chris Campisano (sedimentology, spatial analysis), Erin DiMaggio (geology), Mark Sier (geology), and Andy Cohen (geology, continental drilling).

Ledi-Geraru study area (Location 11°20'N, 40°45'E, Ethiopia; etym. Ledi and Geraru are Afar names for the river beds that extend to the west and east in this area) History and general description Early research in this area was accomplished by the **International Afar Research Expedition** (or I.A.R.E.) from 1972 through 1974 and by the **Rift Valley Research Mission in Ethiopia** (or RVRME) from 1975 to 1978. Paleoanthropological and geological research was restarted in the area in 2002 by the **Ledi-Geraru Research Project**

and is ongoing. The area is between the Awash and Mille River basins in northeastern Ethiopia. Fossil exposures are directly east and somewhat north of the Hadar site, to the north of the Dikika site, and to the south of the Woranso-Mille study area. Temporal span and how dated? Tephrostratigraphic correlation with argon-argon dated units of the Hadar and Busidima Formation as well as direct **argon-argon dating** (Roman et al. 2008) suggest the deposits in the Ledi-Geraru range from slightly less than 3.4 to 1.7 Ma. Thus, the sediments encompass much of the **Hadar Formation** and **Busidima Formation**. Hominins found at site Left M₃ (HD 117-1) and left M₃ fragment (HD 118-1); both teeth have been attributed to *Australopithecus afarensis*. Archeological evidence found at site Evidence of **Oldowan**, **Acheulean**, and **Middle Stone Age** technologies has been found in the study area. Key references: Geology, dating, and fauna DiMaggio et al. 2008, Dupont-Nivet et al. 2008, Roman et al. 2008.

Levallois (etym. the Levallois industry takes its name from Levallois-Perret, a Paris suburb, the location of the archeological site where this method of stone tool manufacture was first recognized) Levallois refers to a distinctive strategy or approach to the manufacture of stone tools that involves the production of large, relatively thin, flakes (called Levallois flakes) from carefully prepared cores (Boëda 1994, 1995, Inizan et al. 1999, Van Peer 1992). Levallois cores have an upper surface from which Levallois flakes are removed

and a lower surface containing the “unflaked” volume of the core that diminishes in volume as successive flakes are removed. The two surfaces are separated by a **striking platform** that may extend around the full perimeter of the core. The “preparation” involved in a prepared core consists of removing multiple small flakes to shape the various convexities on the “upper” surface of the **core**; it is these convexities that determine the size and shape of the resulting Levallois flakes. Preparation also involves carefully shaping the striking platform to ensure successful flake removal; this latter phase of the preparation results in the characteristic **faceted platforms** of Levallois flakes. The Levallois production strategy is capable of producing Levallois flakes, **blades**, or **points**, and it can be preferential or recurrent depending on whether one, or several, Levallois flakes, points, or blades are removed from the upper surface before further preparatory flakes are removed to reshape it. Levallois technology first appears in **Acheulean** sites in Africa and Eurasia, and it is seen commonly in many **Middle Stone Age** or **Middle Paleolithic** assemblages (e.g., the **Kapthurin Formation**; see Monnier 2006 and Tryon et al. 2005). The Levallois technology may have been invented once, but more likely it was developed independently on several occasions (cf. Foley and Lahr 1997, Brantingham and Kuhn 2001).

Levant (MFr. *levant*=the Orient from L. *lever*=to rise) Its first recorded use according to the *Oxford English Dictionary* is in 1497 for “the Mediterranean lands east of Italy,” but today it refers to the lands on the shores of Mediterranean that are in the direction of the sunrise as seen from the sea. Today the Levant comprises Israel, Lebanon, and Palestine. So “Levantine Neanderthals” is an inclusive term for *Homo neanderthalensis* remains from sites in those countries.

Levantine Neanderthals See Levant.

Levene test Sometimes known as Levene’s test, a statistical test for the equality of two variances that is not as sensitive to non-normality as an *F* test. Rather than determining whether a ratio of two variances differs significantly from 1 like the *F* test, the Levene test calculates the absolute value of observations from their group mean for

two groups and compares the resulting absolute values of the deviations. If variances in the two groups are equal, then on average the observations should be the same distance from their group mean for both groups. If one set of absolute values is significantly greater than the other as identified by a *t* test or **analysis of variance**, then that group has a significantly greater variance. Variants of this test calculate deviations from the median rather than the mean, and may use **randomization** to determine whether average deviations differ between groups.

lever A lever is a rigid bar with a fulcrum (pivot, or point of rotation). Power (or force) arm length refers to the distance between the fulcrum and the point of application of the force; load arm length refers to the distance between the fulcrum and the load. A lever is a simple machine that can be used to multiply the mechanical force that can be applied to an object (load), based on the simple principle that the moments ($M = \text{force} \times \text{distance}$), or torques, will be equivalent about the fulcrum. For example, if the power arm is five times longer than the load arm, then the force applied to the load will be five times greater than the applied (power) force. Levers are commonly found in musculoskeletal systems. For example, in the modern human foot, the triceps surae (calf) muscles contract and pull on the calcaneus via the Achilles tendon (the force), which rotates about the ankle joint (the fulcrum) to apply a force through the forefoot (the load). A longer calcaneus would allow the foot lever system to generate greater forces at the forefoot; however, but that enhanced force is achieved at the expense of speed.

levo (L. *laevus*=left) Refers to the L- or left-handed form of a complex molecule. See **epimerization**.

LGM Acronym for the **Last Glacial Maximum** (*which see*).

LH (or L.H.) Acronym for Laetoli hominid and the prefix used for hominin fossils recovered from **Laetoli**, Tanzania.

LH 2 Site Laetoli. Locality Locality 7. Surface/ *in situ* In situ. Date of discovery 1974. Finder Maundu Muluila. Unit N/A. Horizon Found within aolian tuff “b” deposits (Leakey et al. 1976, Fig. 3). Bed/ member Laetoli Beds. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff c.

Nearest underlying dated horizon “Two dates, 3.82 ± 0.16 Ma and 3.71 ± 0.12 Ma, (from a 60 cm thick tuff lying approximately 50 m below tuff *c*) average 3.77 and give a lower limit to the age of the hominid remains” (*ibid*, p. 463). Geological age If LH 4 (which is within the tuff *b*, the tuff immediately below tuff *c*) is approximately the same age as a biotite crystal from tuff *b* “approximately 1–2 m below...tuff *c*” (*ibid*, p. 463) then it is *c.*3.59 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description An immature mandible unfused at the midline. It preserves most of the alveolar process on the right side, but less than half is preserved on the left side. The crown of the right dc, most of the right dm₁ crown, the crowns of the right dm₂ and M₁, and the crowns of the left dm₁, dm₂, and M₁ are preserved. Announcement Leakey et al. 1976. Initial description Leakey et al. 1976. Photographs/line drawings and metrical data Leakey et al. 1976. Detailed anatomical description White 1977. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Australopithecus afarensis* (Johanson et al. 1978). Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance One of the better preserved juvenile *Au. afarensis* mandibles. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

LH 4 Site Laetoli. Locality Locality 7. Surface/in situ Surface. Date of discovery 1974. Finder Maundu Muluila. Unit N/A. Horizon Found within aolian tuff “*b*” deposits (Leakey et al. 1976, Fig. 3). Bed/member Laetoli Beds. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff *c*. Nearest underlying dated horizon “Two dates, 3.82 ± 0.16 Myr and 3.71 ± 0.12 Myr, (from a 60 cm thick tuff lying approximately 50 m below tuff *c*) average 3.77 and give a lower limit to the age of the hominid remains” (*ibid*, p. 463). Geological age If LH 4 (which is within the tuff *b*, the tuff immediately below tuff *c*) is approximately the same age as a biotite crystal from tuff *b* “approximately 1–2 m below...tuff *c*” (*ibid*, p. 463) then it is *c.*3.59 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A mandibular corpus. The crowns of the right P₃–M₃ and the left P₄–M₂ are well preserved, plus the damaged crown of the right canine crown, the damaged root of the left canine, and the root only of the left P₃. The internal mandibular contour is narrow and

the anterior surface of the symphysis slopes posteriorly. Announcement Leakey et al. 1976. Initial description Leakey et al. 1976. Photographs/line drawings and metrical data Leakey et al. 1976 [NB: the occlusal view of LH 4 (Fig. 7) is mislabeled as LH 2], White 1977. Detailed anatomical description White 1977. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Australopithecus afarensis* (Johanson et al. 1978). Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance The distinctive symphyseal morphology of the LH 4 mandible was central to the argument for recognizing a new species of *Australopithecus* for the hominin fossils from Laetoli and Hadar and it was probably because of this that LH 4 was chosen as the **holotype** of *Au. afarensis*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

LH 18 Site Laetoli. Locality Locality 2. Surface/in situ *In situ*. Date of discovery 1976. Finder E. Kandini. Unit “Water-worked vitric tuff” (Day et al. 1980, p. 55). Horizon N/A. Bed/member Ngaloba Beds. Formation N/A. Group N/A. Nearest overlying dated horizon Eroding out of an exposure of a horizon that includes a trachytic tuff correlated with “the marker tuff in the lower unit of the Ndotu Beds at Olduvai Gorge” (*ibid*, p. 55). Nearest underlying dated horizon Lavas overlying the Ndolanya Beds. Geological age The vitric tuff has been “tentatively correlated with the marker tuff in the lower unit of the Ndotu Beds at Olduvai Gorge,” (*ibid*, p. 55) the age of which has been estimated to be 120 ± 30 ka (*ibid*, p. 55). Manega (1993) revised the date to 200 ka based on **amino acid racemization** dating. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A cranium comprising a calvaria and a face, with no contact between them. The vault is well preserved, but much of the midline of the cranial base and most of the medial wall of the left infratemporal fossa are missing. The facial fragment includes the maxillary bones, and much of the hard palate. All of the postcanine teeth are represented on at least one side. The heavily worn crowns of the left M¹ and M³ and the right P³, P⁴, and M¹ are affected by post-mortem damage and no useful occlusal morphology is preserved. It has a rounded occipital that is modern in configuration, expanded parietals, and small mastoid processes, but a strongly receding

frontal bone makes the specimen recognizably archaic. Endocranial volume Approximately 1200 cm³. Announcement Day et al. 1980. Initial description Day et al. 1980. Photographs/line drawings and metrical data Day et al. 1980, Magori and Day 1983a, 1983b, Schwartz and Tattersall 2003. Detailed anatomical description Magori and Day 1983a, 1983b, Cohen 1996, Schwartz and Tattersall 2003. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions Late archaic *Homo sapiens* (Bräuer 1984). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance The initial description of LH 18 said that “its anatomical features are mixed in that it has some modern characters and some that are archaic” (Day et al. 1980, p. 56). The modern part included an expanded vault, a rounded occipital, and low inion, and the archaic features included frontal flattening, an obvious supraorbital torus, small mastoid processes, an occipitomastoid crest, and a thick vault. The cranium has been likened to **Omo I** and **II** and the Ndutu cranium. Until the discovery of the **Herto** crania, and the redating of Omo I and II from **Omo-Kibish**, many regarded this cranium as the best-preserved and earliest evidence of *H. sapiens* in Africa. Location of original National Museum, Dar es Salaam, Tanzania.

Liang Bua (Location 08°31'50.4"S, 120°26'36.9"E, Flores, Indonesia; etym. Liang Bua in the local Manggarai language means “Cool Cave”) History and general description The cave is 30 km/18.6 miles from the north coast of Flores and is 7 km/4.3 miles northwest of Ruteng. Some 500 m above sea level it is a karstic solution cavity 30 m wide and 25 m high at the entrance and extends 40 m into Miocene limestone. Its north-facing entrance was exposed by the Wae Racang river, but this feature now lies 30 m below and 200 m distant from the cave entrance. The first large-scale excavations at the cave were carried out by Father Theodor Verhoeven in 1965. The next substantial investigation of the cave was carried out by R.P. Soejono, who between 1978 and 1989 excavated 10 squares (Sectors I–X). Between 2001 and 2004 a team directed by Soejono and Michael Morwood removed the backfill from the previous excavations of Sectors I, III, IV, and VII and extended the excavations in those sectors, and in 2003 they recovered the *c.*18 ka

associated skeleton, **LB1**, the **holotype** of *Homo floresiensis*, from Sector VII. The following year Morwood et al. excavated deeper into Sector VII and at a depth of 11 m they had not reached bedrock. In the same year they also excavated the adjacent Sector XI and recovered more evidence of LB1 (right humerus, both ulnae, and left fibula) as well as additional hominin remains (e.g., **LB6**). Most recently, Morwood and his colleagues have investigated Sectors V, XII, XIII, and XIV. Morwood et al. (2009) provide a detailed history of the research at Liang Bua. Temporal span and how dated? The *c.*190 ka conglomerate at the rear, which contains stone artifacts but no faunal/hominin remains, documents the original reopening of the cave by the river. The sediments that contain the artifacts and skeletal remains attributed to *Homo floresiensis* range in age from those in the basal layer of Sector IV (95–74 ka) to around 17 ka, the approximate date attributed to the black tuffaceous sands in Sector XI. Remains of modern humans and other non-endemic fauna are found in the upper layers that lie above the white tuffaceous silts, which are dated to between 11 and 13 ka. Radiocarbon dating, various luminescence dating techniques (infrared-stimulated luminescence, optically stimulated luminescence dating, and thermoluminescence dating) and coupled electron spin resonance spectroscopy and uranium-series dating were the main methods used. Hominins found at site A formal analysis of the minimum number of *Homo floresiensis* individuals has yet to be presented, but estimates range between six and 12. The different estimates are due to uncertainties regarding particular aspects of the stratigraphy, but further excavations may help resolve these issues. Archeological evidence found at site Thirty-two artifacts were found at the same level as LB1, but the greatest concentration of artifacts is in Sector IV, where the density reaches 5500 per m³. Most are **flakes** made from volcanics and **chert**, large flakes of which were bifacially and centripetally reduced using freehand, burination, truncation, and bipolar techniques (Moore et al. 2009). Many stone atreifacts are found in association with the remains of a dwarf variety of *Stegodon*. The *Stegodon* at the site, *Stegodon floresiensis insularis*, is a subspecies of *Stegodon florensis* known from the Soa Basin of central Flores between 880 and 680 ka and is 30% smaller than *Stegodon florensis*. life expectancy The average future time remaining for a person at age t to live. At age zero the life expectancy is referred to as the life expectancy at birth. For a **stationary population** (i.e., a population that is neither increasing or decreasing in size) the life expectancy at birth is equal to the **mean age at death**, and the mean age at death for those who survive to age t is equal to the life expectancy at that age plus the age (e.g., if the life expectancy at age 50 is 7.8 years, then the mean age at death for those alive at age 50 will be 57.8 years). In a stationary life table the life expectancies are found by dividing the total people-years to be lived (T_x) by the **survivorship** (l_x). This amounts to dividing people-years to be lived by the number of people to do the living, resulting in an average number of years to be lived. So, for example, in a population where 1000 individuals are born, 800 survive to age 20 years, and these 800 individuals accumulate 27,200 years of life past age 20, the life expectancy at age 20 will be $27,200/800=34$ years. Similarly, the mean age at death for those who reach age 20 will be $20+34=54$ years. In a hazard model the life expectancy at age t is the integral of the survivorship ($S(t)$) from age t up until the age at which survivorship equals 0.0 (i.e., up until the age by which all individuals are dead, the **maximum life span**). For nonstationary populations the life table or hazards analysis calculations must be adjusted using the population growth rate.

life history Individuals, populations, and **species** all have life histories. However, the term is usually used to describe the relative rate at which members of a species proceed through important developmental, maturational, and reproductive milestones. Life histories reflect the ways taxa have adapted to their ecological context by dividing the energy of individuals between maturation, the maintenance of the individual, and its reproduction, with the latter component being further subdivided between the production of offspring and their subsequent maintenance. An organism's

life cycle is punctuated by events that reflect "decisions" regarding the allocation of resources such as time and energy expenditure, and trade-offs such as those between growth and reproduction. It is the sum of the average of these decisions that define the life history strategy of a taxon. For mammals, this includes when to be born, when to be weaned, how many stages of development to pass through on the way to reproductive competence, when to procreate, and when to die. The life history of modern humans can be divided into six recognized life history stages: infancy, childhood, juvenile, adolescence, adult, and grandmotherhood/postmenopausal. On the basis of comparative physiological and behavioral data, childhood, adolescence, and grandmotherhood are proposed to be unique to modern humans (Bogin 1999a). In modern humans the total life span is relatively long, and the intervals between developmental and reproductive milestones are also relatively long. Modern humans are exceptional because they wean their infants early, their age at first birth is later than would be expected for a great ape of the same body mass, they have an absolutely long life span, and they decouple female fertility and mortality so that females have a long post-reproductive lifespan. Measures of life history include length of gestation, age at first molar eruption, age at weaning, age at sexual maturity, ages at first and last birth, interbirth interval, mean lifespan, and length of post-reproductive lifespan. *See also* **grandmother hypothesis**.

life table A statistical method used to describe mortality such that it can be summarized within various age categories. Shryock and Siegel (1976, p. 251) note that the "basic life table functions" are ${}_nq_x$, l_x , ${}_n d_x$, ${}_n L_x$, T_x , and e_x , which correspond respectively to the **probability of death** (age-specific) between age x and age $x+n$, the **survivorship** at age x , the number of deaths out of the **radix** between ages x and $x+n$, the number of person-years lived between ages x and $x+n$, the **total person-years to be lived in an age interval** at and beyond age x , and the **life expectancy** (average years of life remaining) at age x . The age categories are usually listed in the first column of a life table, while the "basic life table functions" are listed in subsequent columns. The most basic data in life tables used in **paleodemography** are the age intervals and the counts of the number of deaths observed in each age interval (often symbolized as ${}_n D_x$ to differentiate it from the ${}_n d_x$ used

as a standardized count based on a radix of 100 or 1000). Note that a life table has the appearance of a spreadsheet, with the age intervals forming the rows and the life table functions forming the columns. Indeed, computer spreadsheets can easily be used to calculate life tables.

ligaments (L. *ligamen*=a bandage, or “something that binds structures together”) The term ligament refers to any connective tissue that apparently connects one structure to another. These connections range from insubstantial layers of mesothelium within the body cavities (e.g., the gastro-splenic ligament runs from the stomach to the spleen) to thick bands of collagen (e.g., the ilio-femoral and sacro-iliac ligaments). Only this latter use of the term ligament is relevant to paleoanthropology. *See also* joints.

limbic cortex *See* limbic system.

limbic system (L. *limbus*=border or interface) A group of interconnected structures some of which are in the cerebral cortex and some of which are beneath the cerebral cortex (hence they are called subcortical). The limbic system includes the amygdala, hippocampus, septum, basal ganglia, and cingulate gyrus. The cingulate gyrus is the part of the cerebral cortex that wraps around the corpus callosum (also referred to as the limbic lobe). The limbic system is involved in memory, emotion, motivation, learning, and some homeostatic regulatory functions.

limestone (OE *lim*=birdlime) A sedimentary rock rich in calcium carbonate (CaCO₃) usually derived from the shells of microorganisms. It is easily dissolved by acidic water percolating through cracks to produce solution cavities and when this happens over a long period of time these solution cavities develop into caves. If these caves connect with the surface soil may be washed in. When this is mixed with stone fragments falling from the roof of the cave, it results in a rock called **breccia**. The early hominin cave sites in southern Africa are formed in a variety of limestone rich in magnesium called **dolomite**. Most of the fossil hominin cave sites in southern Africa (e.g., **Taung**, **Sterkfontein**) were initially mined commercially for limestone which was used as either a building material or for the local manufacture of cement.

Lincoln Cave (etym. Justin Wilkinson, who explored the Sterkfontein Cave system, named this particular cave after a friend of his whose family name was Lincoln) Part of the Lincoln-Fault cave, it is part of the **Sterkfontein** cave system. Two deposits, Lincoln Cave North (LCN) and South (LCS) are separated by a rubble ramp built by lime miners. Excavations in 1997 and 1998 suggest that the **breccia** is reworked and probably derives from the Sterkfontein Member 5 breccia via a connection between the two cave systems in or close to the L/63 grid square of the Sterkfontein excavation. There is also evidence that the cavity in the cave has been filled by **Middle Stone Age** deposits that Kuman and Clarke (2000) have referred to as “Post-Member 6.” The **Acheulean** artifacts found in both LCN and LCS deposits and the *Homo cf. ergaster* remains found in the LCS deposit almost certainly come from Sterkfontein Member 5 West breccia, and a *Paranthropus* incisor in the LCS sample most likely eroded out of the Sterkfontein Member 5 East **Oldowan** deposit (Reynolds et al. 2003).

LINE Acronym for long interspersed nucleotide element. Long interspersed nucleotide elements are DNA sequences of more than 5000 base pairs that are dispersed throughout the genome. They are a class of mobile genetic elements or transposons that are derived from the reverse transcription of RNA molecules. Because LINEs typically contain two genes, which encode reverse transcriptase and integrase, they are able to copy themselves (as well as other elements such as short interspersed nucleotide elements, or **SINEs**) into DNA and thus insert themselves into the genome. The L1 element, the most common LINE in modern humans, is estimated to make up approximately 20% of the modern human genome. LINEs are significant for studies of evolution because, like SINEs, they can be used to study population and species relationships. In addition, when LINEs copy themselves and insert the copy into the genome, neighboring DNA which may contain regulatory elements, genes, or gene fragments may also be copied and inserted. This DNA may then affect the regulation or sequence of a gene in the new location.

lingual (L. *lingua*=tongue) The aspect of the upper and lower tooth crowns that is closest to the tongue. Therefore, the lingual side of a tooth crown is the inner side of the crown.

lingual accessory cusp *See* postmetaconulid; tuberculum intermedium.

lingual paracone tubercle A term used by Kanazawa et al. (1990) for an accessory cusp on the occlusal surface of a maxillary molar that is located mesial to the median ridge of the paracone, but which is separate from the **mesial marginal ridge**. *See also* epicristoconule.

lingual pillar *See* median ridge.

lingula (L. *lingua*=tongue) A small tongue-like spicule of bone that forms the anterior border of the mandibular foramen. It is the inferior attachment of the sphenomandibular ligament and, like the latter ligament, it is a remnant of the first branchial arch. *See* branchial arches.

linkage When two loci are physically near each other the alleles present at those loci are inherited together as a "linked" unit (i.e., they are not separated during **recombination**). Linkage strength increases as the physical distance between the alleles decreases, and because of this linkage strength can be used to calculate the relative distance between loci, and from these data genetic maps can be generated. The relative distance between two loci is calculated using the frequency of recombination between them and it is measured in centimorgans (cM). One centimorgan equals the distance between two loci for which one recombination occurs out of 100 meioses. Examples of linkage in modern humans include the Rhesus blood group and the enzyme 6-phosphogluconate dehydrogenase (an enzyme found in blood) on modern human chromosome 1. Before other polymorphic markers such as microsatellites were discovered the linkage between phenotypic traits was used to create a crude map of the modern human genome. *See also* linkage disequilibrium.

linkage analysis An analysis which assesses the position of a locus (or loci) relative to known loci by estimating the **recombination** frequency (or **recombination fraction**) between them. This information can then be used to create a **genetic map**. A common method of linkage analysis is the LOD score, which stands for logarithm of the odds. It compares the likelihood of obtaining the observed data if the loci are linked to the likelihood of obtaining those data by chance.

Generally, a LOD score greater than 3 is considered evidence for linkage because this corresponds to 1000-to-1 odds that the observed data are not the result of chance.

linkage disequilibrium This refers to the nonrandom association of alleles at two or more loci. The degree of association, or the **linkage**, between two loci is measured by the frequency with which recombination separates the alleles (this is also known as the crossover frequency). The farther apart two loci are the greater the chance they will be affected by **recombination**. Linkage disequilibrium occurs when a combination of alleles at different loci is found more often than expected from a random combination of alleles based on their frequencies in a population. Linkage disequilibrium is important in studies of modern humans because it can indicate the presence of positive selection in a portion of the genome (e.g., Sabeti et al. 2002). It can also be used to research population history since "young" populations show greater linkage disequilibrium in the genome than "older" populations (this is because in the latter "older" populations recombination has had more time to break up linkage disequilibrium) (e.g., Tishkoff et al. 1996, Reich et al. 2001, Kaessmann et al. 2002). For example, sub-Saharan Africans typically have less linkage disequilibrium in their genomes than do Europeans.

Linnaean binomial Refers to the combination of the generic name and the species name (e.g., *Australopithecus afarensis*) that make up the proper scientific name of a species. The genus name is always capitalized and both names are always italicized. The genus can be abbreviated by reducing it to the first letter, or to the first few letters in cases where confusion may arise (e.g., *Au. afarensis*), but the species name must always be spelt out (e.g., *Homo sapiens* is abbreviated as *H. sapiens* and not as *Homo s.*).

Linnaean taxonomy A taxonomy based on the principles introduced by Carl Linnaeus. The two names (hence it is called a binomial) used for a species are a unique combination of a genus and a species name (e.g., *Homo sapiens*, *Pan troglodytes*, etc.).

lithic (Gk *lithos*=stone) An adjective used to describe artifacts made of stone. Its use as a noun

is common, but incorrect. Lithic artifacts are durable, and the oldest known artifacts (from the site of **Gona**, Ethiopia) are made of stone.

lithic analysis Analyses undertaken to derive information about hominin behavior and site-formation process from lithic assemblages (i.e. collections of stone tools and their manufacturing debris). Depending on the research objectives, lithic analysis may include typological classification, metric and nominal trait analyses, quantification and/or description of flake scar patterns, refitting, microwear and residue analysis, and raw-material studies (see Odell 2004 for overview). Typological classification has a long history and remains important for description and communication; however, its classical use to infer cultural affiliations and behavior on the basis of archeologically recognized tool types (e.g., a “Mousterian point”) has been vigorously questioned (e.g., Rolland and Dibble 1990, Toth 1985). In contrast, the use of technological types, such as flakes, cores, fragments, etc., to subdivide and describe lithic assemblages remains a fundamental step in virtually all lithic analyses. A special case is the system of **flake types** often used in studies of **Mode I** technology (Toth 1987). The relative representation of different technological types may be compared to experimentally derived expectations to make inferences about site-formation processes, the representation of different stages within a **reduction sequence**, and artifact transport patterns. Different technological artifact types are subjected to various different metric and nominal trait analyses. The distribution of maximum dimension and/or weight of all artifacts may be used to identify evidence of winnowing or other disturbance (Schick 1986). For cores, original form (e.g., block, cobble, large flake), linear dimensions, number and size of ‘scars’ left by flake removals, and amount of remaining cortex (original exterior surface) are commonly recorded and used to make inferences about knapping methods and reduction intensity. Analysis of detached pieces usually focuses on whole flakes rather than fragments and typically includes measures of length, breadth, and thickness. Often the dimensions of the “striking platform” (the surface surrounding the point of percussion) and the angles formed between the platform and the interior and exterior surfaces of the flake will be measured. On the exterior surface of the flake, the amount of cortex and number and size of flake scars may be recorded. Nominal traits might include flake shape,

platform type, and the occurrence of retouch. Artifact counts and metric and nominal data are used to make a wide range of inferences regarding knapping methods, techniques and skills, artifact transport patterns, and reduction intensity (e.g., Stout et al. 2010). The patterning and orientation of flake scars on cores and flakes may be used to infer knapping strategies. This form of “lithic reading” is particularly important in the *chaîne opératoire* tradition of lithic analysis, and where possible is complemented by actually **refitting** of pieces. Lithic reading proceeds through qualitative “mental reconstruction” based on personal knapping expertise (Pelegrin 2005), or by quantification of the frequency of different scar pattern types (“diacritic schemes,” e.g., de la Torre and Mora 2005). Characteristic microwear “polishes” and macroscopic damage patterns identified through experimental replication are used to infer artifact function (Keeley 1980), including the materials tools were used on, evidence of hafting, and use as projectiles (Shea 1988). Under favorable preservation conditions, organic residues may also provide an indication of artifact function (Wadley et al. 2004). Raw-material analyses are most commonly undertaken to identify the sources, transportation, and/or trade of lithic resources (e.g., Braun et al. 2008), but may also investigate the influence of raw-material performance characteristics on technological systems (e.g., Brantingham et al. 2000) and the preferences expressed by ancient tool makers (e.g., Stout et al. 2005).

lithic assemblage (Gk *lithos*=stone) A collection of stone artifacts, from some temporally and spatially bounded interval, typically a stratigraphic or excavation unit. This scale varies, such that, for example at **Blombos Cave** archeologists may use the term lithic assemblage to refer to the artifacts recovered from layer CD, or to refer the **Still Bay** lithic assemblage from phase M1.

lithology (Gk *lithos*=stone and *ology*=study) The part of earth science that deals with the physical appearance of rocks (e.g., color, grain, or particle size, etc.).

lithostratigraphy (Gk *lithos*=stone, and see the etymology of **stratigraphy**) Recognition and correlation of sedimentary strata based on the appearance of the rock layers as seen through the naked eye, with a lens, or by using a microscope.

"LITTLE FOOT"

"Little Foot" Informal name for Stw 573 (*which see*).

Little Ice Age *See* Holocene.

living age distribution (or c_x) The proportion of individuals alive in each age interval or the **probability density function** for ages in the living. The living age distribution is either observed from a census, or it is the distribution of ages among the living that is implied by the deaths analyzed in a **life table**, or in a hazards analysis. For a stationary life table the living age distribution is given by L_x divided by the life expectancy at birth. For a stationary hazard model the probability density function for age in the living is the survivorship at exact age t divided by the integral of survivorship across age. For a nonstationary life table or hazard model the estimated living age distribution needs to be adjusted by the growth rate. *See also* **stationary population**.

LK Acronym for Loruth Kaado, one of several groups of localities within the site of West Turkana named after ephemeral river drainages. *See* **Loruth Kaado**.

LKH Prefix for fossils recovered from Lakonis, Greece.

LKH1 Site Lakonis. Locality Locality 1. Surface/in situ *In situ*. Date of discovery 2002. Finder Maria Ntinou. Unit Unit 1a. Horizon Layer 3. Nearest underlying dated horizon Base of Unit 1a. Geological age *c.*40 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Left lower third molar. Announcement Harvati et al. 2003. Initial description Harvati et al. 2003. Photographs/line drawings and metrical data Harvati et al. 2003. Detailed anatomical description Harvati et al. 2003. Smith et al. 2009. Initial taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The only published Neanderthal fossil from Greece, apparently associated with an initial **Upper Paleolithic** industry. Location of original Ephoreia of Palaioanthropology and Speleology, Athens, Greece.

LLK Acronym for Louis Leakey Korongo. A locality at **Olduvai Gorge**, where, in 1961, Louis

Leakey discovered the **OH 9** calvaria. Matrix attached to the calvaria is consistent with it originating from Upper Bed II. *See also* **Olduvai Gorge**.

LM Acronym for La Madeleine and Lake Mungo and the prefix for fossils recovered from **La Madeleine** and **Lake Mungo**. *See* **Lake Mungo**; **La Madeleine**.

LM4 Site La Madeleine. Locality Base of Capitan and Peyrony's upper level (Magdalenian IV). Surface/in situ *In situ*. Date of discovery 11 December 1926. Finder D. Peyrony. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 10,190±100 years BP. Developmental age 3–4 years. Presumed sex Unknown. Brief anatomical description Nearly complete, but very fragmented, calotte, mandible, and most postcranial elements except the right lower leg and foot. Announcement Peyrony 1928. Initial description Capitan and Peyrony 1928. Photographs/line drawings and metrical data Heim 1991. Detailed anatomical description Heim 1991. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance This young child was buried with over 1000 shells, beads, and decorated animal teeth that were probably attached to clothes it wore during life, indicating a high level of social stratification (Vanhaeren and d'Errico 2001). Radiocarbon dating for this individual suggests it belongs in the Azilian period, but the shells and other grave goods are consistent with a late **Magdalenian** date. Location of original Musée National de Préhistoire, Les Eyzies-de-Tayac, France.

LO Abbreviation for Lomekwi one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* **Lomekwi**.

local enhancement Local enhancement is a type of **enhancement** effect associated with a suite of cognitively primitive attention and motivation mechanisms that affect **learning**. Specifically, local enhancement describes learning in situations where the presence of a conspecific directs an observer's attention to a particular location such as a water hole or a termite mound (Thorpe

1963). This type of enhancement is seen in mammals and birds alike, and may result in behavior matching, which can resemble learning by imitation.

locality A location within a large fossil site where fossils have been found. At small sites and at excavated cave sites (e.g., the **Gran Dolina** cave at **Atapuerca**) there is no need to do other than specify within which grid square and from what level in that square a fossil came from. But in large fossil sites (e.g., **Koobi Fora**, Middle Awash, **Olduvai Gorge**) the locations where one, or more, fossils have been found, are described as localities (e.g., **FLKNN I** and **MNK I** are two localities within Olduvai Gorge, and **ARA-VP-1** is a fossiliferous locality within the **Central Awash Complex** of the **Middle Awash study area**).

Locality 1 See **Zhoukoudian Locality 1**.

Locality 53 See **Zhoukoudian Locality 1**.

locomotion (L. *loco*=place and *motivus*=to cause motion) Refers to the various ways that animals use their anatomy to move from one place to another. Locomotion allows an individual to acquire food, find mates, avoid predators, move to safe resting places, and interact socially with other members of a group. Virtually all primates use a repertoire of different types of locomotion in a given day to move from place to place. Compared to that of other mammals, primate locomotion tends to be hindlimb-dominated, meaning that peak vertical forces experienced by the hindlimbs are greater than those on the forelimbs (Demes et al. 1994). If an animal locomotes with its trunk upright and supports itself exclusively on its hindlimbs, then its locomotion is described as bipedal. The locomotion practiced by a primate species has an impact on the architecture of most of the postcranial musculoskeletal system, as well as on aspects of cranial anatomy (e.g., Fleagle 1977). Thus, the anatomy of the skeleton, especially the postcranial skeleton, provides information about the locomotor adaptations and behaviors of fossil hominins. See also **bipedalism**.

locus (L. *locus*=place) The physical location of a **gene** or **nucleotide** in the genome. The locus of a gene is analogous to an individual's street

address. So, for example the gene for phenylthio-carbamide (PTC) tasting is called *TAS2R38* and it is on the long arm of chromosome 7 at position 141,318,900–141,320,042 according to the March 2006 assembly of the modern human genome.

LOD score A method for estimating recombination frequency in a **linkage analysis**. It is the logarithm (base 10) of the odds of linkage (i.e., the ratio of the likelihood that loci are linked to the likelihood that they are not) for a set of markers in a pedigree. Typically, a LOD score of greater than 3.0 is considered evidence for linkage.

loess (Ge. *loess*=loose) A deposit of wind-blown silt that typically forms an extensive blanket over mid-latitude landscapes during a period of cold, dry climate. The windy, dry environment of periglacial terrains and ample sediment supply from glacial meltwater streams afforded ideal conditions for silt to mobilize and form a mantle over extensive areas. About 10% of present-day continental terrain is covered by loess. Eastern and central Europe and China, in particular, have significant deposits. Cycles of alternating loess and soils, indicative of climate fluctuation between cold/dry and warm/moist conditions, have produced a long stratigraphic record of paleoclimate back to *c.*2.5 Ma over most of the Loess Plateau of north-central China, and as far back as *c.*22 Ma in the western part of this region (Kukla 1987, Guo et al. 2002). Connections between the climate history of the Loess Plateau and the Nihewan Basin have been implicated in the dispersal of early Pleistocene hominins to northeast Asia (Ao et al. 2010). Loess deposition during the Last Glacial Maximum extended in China as far south as the Bose Basin. See also **Bose Basin**; **Nihewan Basin**.

logistic population growth A model of population growth that, unlike exponential population growth, will bring a population to its **carrying capacity**. The carrying capacity (usually symbolized with a *K*) is included in the equation for logistic population growth along with the exponential rate of increase (*r*) found in the exponential model. Under the assumption that the exponential rate of increase must be positive, the equation for population size at time *t*+1 given the population size at time *t* is $N_{t+1} = N_t \times \exp(r(1 - \frac{N_t}{K}))$. Note that if $N_t = K$, then $N_{t+1} = N_t$; in other words, a population at its carrying capacity will stay at its carrying capacity.

If $N_t > K$, then $N_{t+1} < N_t$; in other words, a population above its carrying capacity will "downregulate" (decline in size) to reach its carrying capacity. If $N_t < K$, then $N_{t+1} > N_t$; in other words, a population below its carrying capacity will "upregulate" (increase in size) to reach its carrying capacity.

Lokalalei (or LA) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) Refers to a complex of fossil localities in the Kalochoro Member of the Nachukui Formation within the Lokalalei drainage in **West Turkana**, Kenya. Some of the earliest known archeological sites (i.e., LA1, LA2C, and LA1 α) are within the Lokalalei drainage. *See also* **West Turkana**.

Lokochot Tuff A 3.61 ± 0.09 Ma tuff known from the **Koobi Fora Formation**. Tuffs with the same geochemistry have been located in Uganda (Pickford et al. 1991) and Ethiopia (Deino et al. 2010), and in deep-sea cores from both the Arabian Sea (deMonacal and Brown 1999) and the Gulf of Aden (Brown et al. 1992).

LOM Abbreviation of the Lomweki Member in the Nachukui Formation, **West Turkana**, Kenya.

Lomekwi (or LO) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) Refers to a complex of fossil localities in the Kaitio, Lomekwi, Kataboi, and Lokalalei Members of the **Nachukui Formation** within the Lomekwi and Topernawi drainages in **West Turkana**, Kenya. The early hominin crania **KNM-WT 17000** and **KNM-WT 40000** were recovered from Lomekwi localities. *See also* **West Turkana**.

LON Abbreviation of the Lonyumum Member in the **Koobi Fora Formation**, **West Turkana**, Kenya.

long distance transport *See* carcass transport strategy.

long interspersed nucleotide element *See* LINE.

long-period incremental lines Incremental features in tooth enamel or dentine that have an intrinsic temporal secretory rhythm of

greater than 1 day. They are called **striae of Retzius** and **perikymata** in enamel and **Andresen lines** and **periradicular bands** in dentine. In primates, these lines have been reported to range between 2 and 12 days (reviewed in Smith et al. 2003), with a consistent **periodicity** within each individual (FitzGerald 1996). Counts and measurements of these features facilitate estimation of the **crown formation time**, root formation time, or the root **extension rate** (reviewed in Smith et al. 2006). *See also* **enamel development**; **enamel microstructure**; **dentine development**.

long-period markings *See* long-period incremental lines.

Longgushan *See* Zhoukoudian Locality 1.

longitudinal arch A structure unique among extant taxa to modern humans, the longitudinal arch runs along the length of the foot and serves both to stiffen it and to store and return elastic energy during the stance phase of walking (Ker et al. 1987). The longitudinal arch has two components, the **medial longitudinal arch** and the **lateral longitudinal arch**, formed by articulations between bones in the hind and midfoot. It is reinforced by four soft-tissue structures: the short and long plantar ligaments, the calcaneonavicular (spring) ligament, and the plantar aponeurosis. The short plantar ligament binds the cuboid to the calcaneus and the long plantar ligament anchors the calcaneus to the bases of the lateral four metatarsals. The calcaneonavicular (spring) ligament anchors the medial navicular to the sustentaculum tali and prevents plantar flexion of the talar head. Functionally, the important plantar aponeurosis tightens during dorsiflexion of the metatarsophalangeal joints and helps convert the foot into a stiff and effective lever during the final stage of toe-off. The longitudinal arch is also supported by intrinsic muscles of the foot (e.g., abductor hallucis, flexor hallucis brevis, flexor digitorum brevis, quadratus plantae, and abductor digiti minimi). It achieves its greatest height at the second metatarsal. The long flexors (flexor hallucis longus and flexor digitorum longus), fibularis longus, and tibialis posterior also help support the arch. Modern human foot arches can be excessively high (pes cavus) or low/flat (pes planus). Apes do not possess a longitudinal arch. Fossil footprints from Ileret, Kenya, indicate that the

arch had evolved in its modern form by 1.53 Ma, although some suggest that the 3.66 Ma footprints from **Laetoli** provide evidence for an arch much earlier in hominin evolution. *See* **foot movements**; **Koobi Fora hominin footprints**; **Laetoli hominin footprints**; **walking cycle**.

longitudinal data Data derived from measurements taken from a series of observations on a single individual, or a group of individuals. Longitudinal data are preferable to cross-sectional data for studies that wish to examine how individuals change over time, although studies using longitudinal data obviously take longer to conduct and longitudinal data are methodologically more difficult to collect.

Lordkipanidze, David (1963–) Born in Tbilisi, Republic of Georgia, in 1963, David Lordkipanidze claims it was an early love of detective stories that determined his early interest in anthropology. After completing his undergraduate degree in geology and geography at Tbilisi State University in 1985, a year later Lordkipanidze registered as a graduate student in the Russian Academy of Sciences where he studied the reconstruction and distribution of early human settlements in montane regions, receiving his PhD in geography in 1992. It was during that time that Lordkipanidze was selected by the Georgian paleontologist Leo Gabunia to take part in the excavations at **Dmanisi**; Lordkipanidze was subsequently selected to succeed Gabunia as the Director of the project. In 1992 Lordkipanidze was appointed Senior Researcher in the Georgia Academy of Sciences and he stayed there until his appointment in 1997 as Head of the Geology and Paleontology Department in the Georgia State Museum. In early 2002 Lordkipanidze was awarded a Fulbright Scholarship, which enabled him to visit a number of universities in the USA. When he returned to Georgia he became the Deputy Director of the Georgian National Museum, a post he held until 2005 until his appointment as General Director of the Georgian National Museum, where he is currently overseeing a large-scale reorganization and renovation. In 1991, during Lordkipanidze's first field season as leader of the excavations at Dmanisi, the first of many hominin remains (the **D211** mandible) was recovered and the during the subsequent years under his leadership the Dmanisi research team has grown into a large multinational enterprise and its activities over many years have resulted in many more

important hominin discoveries. In recognition of the importance of his longstanding and extraordinarily productive research at Dmanisi, in 2007 David Lordkipanidze was elected as a foreign associate of the United States National Academy of Sciences. *See also* **Georgian National Museum**.

lordosis (Gk *lordos*=bent backwards) The term lordosis, and its antonym, **kyphosis**, refer to the angular relationship within or between sections of a compound structure (e.g., the vertebral column), or between two planes (e.g., the anterior and posterior components of the **cranial base**). Thus, the parts of the adult modern human vertebral column that are concave posteriorly (i.e., the cervical and lumbar regions) are referred to as being lordotic, whereas the parts of the vertebral column that are concave anteriorly (i.e., the thoracic and sacral) are referred to as being kyphotic. Adult modern humans are distinctive among the extant great apes in normally having a pronounced lumbar lordosis, and it has been suggested that this is related to our habitual upright posture, and specifically to cope with anteriorward migration of the trunk's center of mass that occurs in pregnant females (Whitcombe et al. 2007). With respect to the cranial base, organisms or individuals with a larger, more obtuse (i.e., more chimpanzee-like) **cranial base angle** are described as having a more lordotic basicranium, whereas organisms or individuals with a smaller, more acute (i.e., more modern human-like) cranial base angle have a more kyphotic basicranium.

Loruth Kaado (or LK) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) Refers to a complex of fossil localities in the Kaitio, Kataboi, and Nattoo Members of the **Nachukui Formation** within the Loruth Kaado drainage in **West Turkana, Kenya**. *See also* **West Turkana**.

Los Azules (Location 43°21'N, 5°08'W, Spain; etym. Sp. for "the blues," as in the color) History and general description This cave lies in the Lluèves mountain, to the north of the village of Cangas de Onis in the province of Asturias, only about 15 km/9 miles from the Cantabrian sea. It was excavated between 1973 and 1988 by a team led by Fernández-Tresguerres. It is one of few Spanish sites that documents the end of the **Upper Paleolithic**, with layers dating to the

Magdalenian and Azilian, and includes a burial from the Azilian period. Temporal span and how dated? The Azilian burial was dated using conventional **radiocarbon dating** to between 9430 and 9540 years BP. Hominins found at site The Azilian-age burial of an adult presumed male was found close to the cave mouth, against the left wall. The skeleton of this individual is robust and tall, and it has congenitally fused foot bones and, likely, a bilateral claw foot. The grave was surrounded by **ochre**, and several artifacts were found in close association with the burial, including two bone **harpoons**, a deer antler, shells, and stone tools. Archeological evidence found at site Several archeological layers were uncovered which record the long-term presence of hominins, presumably *Homo sapiens*, through the middle and end of the Upper Paleolithic. The Azilian layers are represented by flat bone harpoons and small “thumbnail scrapers.” Key references: Geology, dating, and paleoenvironment Fernández-Tresguerras 1980, Fernández-Tresguerras and Rodríguez Fernández 1990; Hominins Fernández-Tresguerras 1976, Garralda 1986; Archeology Fernández-Tresguerras 1980, Fernández-Tresguerras and Rodríguez Fernández 1990.

Lothagam [Location 2°54'N, 36°03'E, Kenya; etym. the local Turkana people call the hill, or horst, that forms the eastern boundary of the site, Lothsagam. Leakey (2003) explains that in Turkana “lothsagam” refers to something that is “rough, varied and heterogeneous” and in the case of Lothagam “it is a reference to the many different rocks that make up the horst” (*ibid*, p. 2)] History and general description The first time the sediments at Lothagam were noted to be fossiliferous was in 1965 when Lawrence Robbins was excavating early to middle **Holocene** archeological sites (traces of hunter-gatherers and fishers) in the area. He recovered the remains of 29 buried individuals and many of these are stored at the Smithsonian Institution’s **National Museum of Natural History**. These reports caught the attention of Bryan Patterson and he and his colleagues prospected for fossils at Lothagam in 1967–8; the Lothagam mandible, **KNM-LT 329**, was recovered by Patterson’s group in 1967. A group from Princeton worked at the site in 1972–3. Personnel from the **Koobi Fora Research Project** (or KFRP) visited the site in 1980 and recovered evidence of fossil mon-

keys. A more deliberate survey conducted by Meave **Leakey** in 1989 resulted in the discovery of catarrhine and carnivore fossils, and in 1990 the same researchers spent a month at Lothagam. The KFRP focused their field research at Lothagam in 1991–3, and between 1989 and 1993 researchers recovered approximately 1700 vertebrate and other tetrapod fossils. Temporal span and how dated? Vertebrates have been recovered from exposures of the **Nachukui Formation** and **Nawata Formation**. The lower member of the Nawata Formation is *c.*7.4–6.5 Ma, the upper member of the Nawata Formation is *c.*6.5–5.23 Ma, and the Apak Member, the oldest member in the Nachukui Formation, is between approximately 5.0 and 4.2 Ma. The sediments have been dated using **potassium-argon dating**, **argon-argon dating**, and **magnetostratigraphy**. Hominins found at site Two teeth, a left partial M³ (KNM-LT 22930), and a right I₁ (KNM-LT 25935), have been recovered from the upper member of the Nawata Formation, a fragment of the right side of the mandibular corpus (KNM-LT 329) from the Apak Member, and four isolated teeth [a fragment of the crown of a right dm² germ (KNM-LT 23181), most of the crown of a right M₃ (KNM-LT 23182), a left M₂ crown (KNM-LT 23183), and a premolar crown fragment (KNM-LT 25936) from the Kaiyumung Member of the Nachukui Formation]. The former two hominins have been assigned to Hominidae *indet.* and the four isolated teeth to *Australopithecus cf. Australopithecus afarensis*. Archeological evidence found at site None have been found in the sediments from which the hominin fossils were recovered. Key references: Geology, dating, and paleoenvironment Patterson et al. 1970, Feibel 2003, McDougall and Feibel 2003; Hominins Patterson et al. 1970, McHenry and Corruccini 1980, Kramer 1986, White 1986b, Hill et al. 1992, Leakey and Walker 2003; Archeology N/A.

Lothagam (LSA site) (Location approximately 2°55'N, 36°03'E, Kenya; etym. named after Lothagam Hill, around which a series of burials were discovered, but *see* **Lothagam** for the full etymology) History and general description Lawrence Robbins excavated a series of **Later Stone Age** (or LSA) sites around Lothagam Hill on the western side of Lake Turkana in 1965–6. Temporal span and how dated? Conventional **radiocarbon dating** suggests 6–9 ka. Hominins found at site Twenty-nine

burials, including eight adult males, six adult females, one female subadult, two adolescents, and 12 individuals too poorly preserved or fragmentary to be identified. The burials include no infants or young children. The skeletons belong to tall people with a linear physique and long, narrow crania generally resembling modern Nilotic populations, but with larger and more robust jaws. Archeological evidence found at site Cultural traces included barbed bone harpoons, a lithic industry dominated by scrapers and crests, and pottery. Faunal remains at the site suggest the occupants of the site exploited Nile perch, catfish, and other aquatic species including crocodiles and turtles; similar faunal profiles are found at sites on the eastern side of the lake, including at Koobi Fora and Loengalani. The remains are associated with highstands of Lake Turkana between 9.5 and 7.5 ka and between 6.6 and 4.4 ka (Butzer et al. 1972). Key references: Geology, dating, and paleoenvironment Robbins 1974, Butzer et al. 1972; Hominins Angel et al. 1980; Archeology Robbins 1974, Angel et al. 1980.

low-ranking prey Within an **optimal foraging theory** framework low-ranking prey are those taxa or food resources that provide below-average energetic returns. The **prey-choice model** predicts that low-ranking prey will only enter the diet when encounter rates with **high-ranking prey** decline and overall foraging efficiency declines, a phenomenon known as **resource depression**. In archeological contexts prey rankings are often determined according to body size since larger taxa tend to provide greater energetic returns than small taxa. For example, small mammals such as rabbits and hares are typically regarded as low-ranking prey. However, a growing body of ethnographic evidence suggests that other factors (e.g., prey mobility) may play an important role in explaining human foraging decisions and prey rankings. *See also* **high-ranking prey**.

low-survival elements A term that refers to a subset of skeletal elements known to be particularly sensitive to destructive taphonomic processes. These include elements with thin cortical walls and substantial low-density, grease-rich, cancellous portions. For most ungulates, these include the vertebrae, ribs, pelvis, scapulae, and long-bone epiphyses. Phalanges, carpals, and tarsals of size 1–2 ungulates are also considered low-survival elements, given their tendency to be consumed by carnivores.

Because low-survival elements are readily destroyed following hominin discard, they are of relatively little utility when examining **carcass transport strategies** in bone assemblages that have been subjected to destructive processes. *See also* **skeletal element survivorship**.

low-utility bones *See* **economic utility index**.

lower bank *See* Swartkrans.

Lower Cave *See* Zhoukoudian Locality 1.

lower fissure One of the three main areas within Zhoukoudian Locality 1. *See* Zhoukoudian Locality 1.

Lower-middle tuffs *See* Okote Tuff Complex.

Lower Omo Basin The depression through which the lower reaches of the Omo River runs. The Omo River rises in the Ethiopian Highlands and ends by draining into the northern end of Lake Turkana. The last part of its course and Lake Turkana occupy the low country between the Ethiopian and Kenyan domes to the north and south, respectively, and between the western and eastern walls of the East African Rift. It was the mammalian fossils collected in 1902 by the Bourg de Bozas expedition that prompted Camille Arambourg to re-explore the region in 1933. Arambourg (1934) recognized that the fossils he had recovered were Plio-Pleistocene in age, but he had to wait until 1967 to return to the region as the first head of the French contingent of the **International Omo Research Expedition** (or IORE) that worked in the Lower Omo Basin from 1967 to 1976. The most recent program of fieldwork in the Lower Omo Basin, by the **Omo Group Research Expedition** led by Jean-Renaud Boisserie, began in 2006–7. The sediments in the Lower Omo Basin were mapped by Fuchs (1939) and by Butzer and Thurber (1969), but the geology of the Lower Omo Basin is described in detail by Paul Haesaerts, Jean de Heinzelin, and Frank Brown in contributions to de Heinzelin (1983). The sediments are divided into the **Omo Group** and the **Lake Turkana Group** (also called the **Turkana Group**). Fossils recovered from the Lower Omo Basin during the research campaigns conducted by the IORE were allocated to

collecting localities under several systems (see Appendix III in de Heinzelin 1983). Within the **Shungura Formation**, fossils collected by the French team were referred to “Omo” (or “O”) localities and these were given numbers (e.g., Omo 18); the American contingent also numbered localities, but used the letter “L” for locality (e.g., L. 396). Within each of these numbered localities fossils are themselves assigned a number (e.g., L. 40-19), and for the specimens collected by the French the year of discovery is inserted between the locality number and the fossil number (e.g., **Omo 18-1967-18**). In the **Usno Formation**, fossil hominins come from either **Brown Sands** (or “B”) or **White Sands** (or “W”). Within each of these fossiliferous regions there are numbered localities, and within each numbered locality fossils are assigned a number (e.g., B 8-27 and W 7-508). Additionally, some localities were recorded as “F” (by Frank Brown) or P (for Fr. *point*) by Jean de Heinzelin. Details of the history of the exploration of the Lower Omo Basin are given in Howell and Coppens (1983) and details of the geology are found in various contributions to de Heinzelin (1983). *See also* **Omo Group**; **Omo-Turkana Basin**; **Turkana Group**.

Lower Omo Valley *See* Lower Omo Basin.

Lower Paleolithic A term used to describe a stage of the European and Near Eastern **Paleolithic** that is defined predominantly by the stone tool technology (**mode 1** and **mode 2**, including the **Acheulean**, the **Oldowan**, and those Plio-Pleistocene technocomplexes that typically do not include handaxes) that appears from *c.* 2.5 Ma to 200 ka. The term is somewhat problematic since it encompasses a large period of time (at least 2 Ma) during which there were significant biological and behavioral shifts, as well as several distinct technocomplexes. The equivalent term for African sites with similar technologies is the **Early Stone Age**.

Lower Pubu *See* Bubing Basin.

lower scale Sometimes used for the lower part of the squamous part of the occipital bone (syn. **nuchal plane**).

Loyangalani Site Loyangalani. Locality N/A. Surface/in situ Surface. Date of discovery 1976. Finder Olivier Braun. Unit N/A. Horizon N/A.

Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age N/A. Developmental age Adult. Presumed sex Male. Brief anatomical description Mandible and fragment of maxilla of the same individual. The robust mandible points to archaic *Homo sapiens* rather than modern humans, but there is a chin. Initial taxonomic allocation *Homo sapiens*. Announcement Twisselmann 1991. Initial description Twisselmann 1991. Photographs/line drawings and metrical data Twisselmann 1991. Detailed anatomical description Twisselmann 1991. Location of original Original is lost, but there is a cast in the Institute royal des Sciences naturelles de Belgique (Royal Belgian Institute of Natural Sciences), Brussels, Belgium.

LPT Acronym for the **Late Pliocene transition** (*which see*).

“Lucy” Nickname for A.L. 288-1, the partial skeleton of *Australopithecus afarensis* discovered by Donald **Johanson** and his research team at **Hadar**, Ethiopia, in 1974. During a camp celebration of the discovery, The Beatles’ album *Sergeant Pepper’s Lonely Hearts Club Band* was playing and expedition member Pamela Alderman suggested calling the presumed female skeleton “Lucy” after the song “Lucy in the Sky with Diamonds.”

LSA Acronym for the Late Stone Age and Later Stone Age. *See* **Later Stone Age**.

L.S.B. Leakey Foundation Formed in 1968 to foster research into human origins. The Foundation awards more than US\$600,000 annually in grants, and it is the only privately funded granting organization wholly committed to human origins research in the USA. It was established by a group who wanted to establish an eponymously named organization to support the type of research carried out and promoted by Louis **Leakey**. For a long time it was called the L.S.B. Leakey Foundation and it is only recently that it has styled itself The Leakey Foundation. The Foundation is an endowed, independent, nonprofit institution whose mission is to increase scientific knowledge, education, and public understanding of human origins, evolution, behavior, and survival. Its headquarters is in San Francisco, California, and the

organization partners with other major science institutions throughout the USA to produce an annual, national, lecture series. In keeping with Louis Leakey's philosophy, the Foundation promotes a multidisciplinary approach to investigating human origins (i.e., research into the paleoenvironments, archeology, paleontology, and paleoanthropology of the Miocene, Pliocene, and Pleistocene). Research funded by the Foundation embraces the reconstruction of the behavior, biology, and ecology of hominins. The Foundation also supports projects that can shed light on the behavioral ecology of modern hunter-gatherers and the genetics and behavior of our closest living relatives, the great apes, in the belief that they provide important behavioral analogues for hominin evolution. Within the first decade of its existence the Leakey Foundation provided grants to many of the seminal studies that have informed our understanding of human prehistory, including the field research and discoveries of the Leakey family, Donald Johanson, Jane Goodall, Dian Fossey, and Biruté Mary Galdikas. Today, the Foundation continues to support the work of researchers including Zeresenay Alemseged, Jill Pruetz, Fred Grine, Sileshi Semaw, David Lordkipanidze, and many more. Since 1968 the Foundation has provided about \$14 million to more than a thousand grantees in over 100 countries. The major funding streams are General Research Grants and Franklin Mosher Baldwin Memorial Fellowships. General Research Grants are awarded in competitions that are held twice annually, constitute the majority of the Foundation's grant program; priority for funding is given to the exploratory phases of promising new research projects. The Franklin Mosher Baldwin Memorial Fellowships are intended for scholars and students from emerging nations who wish to obtain an advanced degree or specialized training in an area of study related to human origins research. Since 1977 more than 90 Baldwin Fellowships have been awarded to scientists from developing countries to complete their graduate work and pursue careers in human origins research. Recipients include young researchers from countries including Egypt, Ethiopia, Eritrea, Iran, Kenya, Madagascar, Malawi, Nigeria, Democratic Republic of the Congo, Somalia, South Africa, Sudan, Tanzania, Togo, Uganda, Zambia, and Zimbabwe. Details of the Leakey Foundation's programs and information on how to apply can be found at www.leakeyfoundation.org.

Lukeino (Location 00°48'N, 35°52'E, in Kenya; etym. local, Tugen, name for the area) History and general description Name of a complex of localities in the Tugen Hills in the Baringo District, Kenya. More than 44 fossiliferous localities have been mapped within the **Lukeino Formation**. Temporal span and how dated? Underlain by Kabarnet Trachytes (*c.*6.2 Ma) and overlain by Kaparaina Basalts (*c.*5.7 Ma); the trachytes and basalts have both been dated using potassium-argon dating. Hominins found at site Fossils assigned to *Orrorin tugenensis* have been recovered from at least four localities: **Aragai**, **Cheboit**, **Kapcheberek**, and **Kapsomin**. Archaeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Pickford and Senut 2001; Hominins Senut et al. 2001; Archeology N/A.

Lukeino Formation (etym. Local, Tugen, name for the area) General description Late Miocene formation consisting primarily of lacustrine and fluvial sediments that outcrop extensively in the eastern foothills of the Tugen Hills, west of Lake Baringo, Kenya. Deposits are located between the underlying Kabarnet Trachyte Formation and overlying Kaparaina Basalts Formation; the sediments are divided into four members. The oldest is the Kapgoya Member. Overlying this is the Kapsomin Basalt Member, followed by the Kapsomin Member (NB: most of the *Orrorin tugenensis* specimens were recovered from sediments within the Kapsomin member). The Kapcheberek Member is the youngest member (Sawada et al. 2002). Sites where the formation is exposed **Aragai**, **Cheboit**, **Kapcheberek**, **Kapsomin**. Geological age *c.*6.0 Ma to *c.*5.7 Ma. Most significant hominin specimens recovered from the formation The current hypodigm of *Orrorin tugenensis*, including KNM-LU 335, BAR 349'00, **BAR 1000'00**, BAR 1001'00, BAR 1002'00, BAR 1003'00, BAR 1004'00, BAR 1215'00, BAR 1390'00, BAR 1425'00, BAR 1426'00, and BAR 1900'00, has been recovered from sediments within the Lukeino Formation. Key references: Geology, dating, and paleoenvironment Dagley et al. 1978, Deino et al. 2002, Hill et al. 1985, Pickford 1974, 1975, Pickford and Senut 2001, Sawada et al. 2002; Hominins Pickford 1975, Senut et al. 2001.

"Lukeino molar" An isolated mandibular molar found in 1975 in the **Lukeino Formation**

in the Tugen Hills. The molar is the **holotype** of *Orrorin tugenensis*. See also KNM-LU 335; *Orrorin tugenensis*.

Lukenya Hill (Location 1°29'S, 37°03'E, Kenya; etym. the local name for the hill) History and general description During a survey of archeological sites around the base of Lukenya Hill in March 1970, R.M. Gramly dug a test pit in the rock-shelter and recovered a hominin frontal bone 140 cm below the surface in association with a **Later Stone Age** (or LSA) industry. The specimen was found at the junction of two semi-concreted limestone breccias containing bones and stone tools referred to as strata IV and V. More extensive excavations in 1971 produced no additional hominin remains. Temporal span and how dated? 17.7 ka radiocarbon years for the hominin layer based on conventional **radiocarbon dating** on animal bone. Hominins found at site Partial calotte comprising two-thirds of the frontal bone and the left parietal. It has a more robust supra-orbital torus and a more receding forehead than is usual in living Africans, but the calotte is clearly that of an anatomically modern human. Archeological evidence found at site A microlithic LSA industry featuring scrapers of various kinds made on blades and flakes, perforators, backed pieces, and many bladelets. The most common raw materials were fine-grained quartz followed by chalcedony, opal, obsidian, and white quartz. Strata IV and V also featured stone tools made from gneiss and sandstone and traces of ochre adhere to many of the grinding implements. No bone tools were encountered, but a few perforated ostrich eggshell beads were found. Extant taxa including zebra, eland, wildebeest, hartebeest, and impala dominated recognizable teeth in the fauna. Key references: Geology, dating, and paleoenvironment Dating of questionable reliability by Rainer Protsch is reported in Gramly and Rightmire 1973; Hominins Gramly and Rightmire 1973; Archeology Gramly and Rightmire 1973.

Luleche (Location 25°49.99'S, 27°51.36'E, North West Province, South Africa; etym. named for a nearby farm property) History and general description The site is an abandoned lime-works based on a cave system within Precambrian **dolomite** near the **Gondolin** Plio-Pleistocene locality in the Schurveberg mountain range, 15 miles northwest of **Sterkfontein**. Geologic description of

the cave system is limited because of extensive lime mining obliterated all but small *in situ* remnants of the original infillings. Field collections from the site in 2005–6 concentrated on the extensive *ex situ* dumpsites that contained decalcified sediments and a small ($n=365$) sample of heavily manganese-stained fossil specimens. Temporal span No depositional age could be assigned; however, the identifiable faunal remains (exclusively Bovidae) suggest accumulation in the Pleistocene. Hominins found at site None. Archeological evidence found at site None. Key references: Geology, fauna, and taphonomy Adams et al. 2007.

lumbar lordosis (*L. lumbus*=loin and *Gk lordos*=bent backwards) Refers to the characteristic curvature in the small of the back near the base of the vertebral column seen in adult modern humans. Because the lumbar region of the vertebral column in adult modern humans is concave posteriorly it is referred to as being lordotic. The **lordosis** is due to the wedge-shaped (anteriorly tall and posteriorly short) vertebral bodies and intervertebral discs in the lumbar region. This configuration of the lumbar spine is seen in modern humans, in all extinct pre-modern *Homo* taxa, and in individuals assigned to *Australopithecus africanus* (e.g., **Sts 14** and **Stw 431**). In modern human females lumbar lordosis is exaggerated during pregnancy and Whitcombe et al. (2007) suggest that this helps compensate for the anteriorward migration of the center of mass that occurs in pregnant females in habitually bipedal hominins.

lumbar vertebral column (*L. lumbus*=loin) The lumbar vertebral column, which is the region between the rib-bearing thorax and the sacrum, has a considerable influence on the degree and pattern of motion between the fore- and hindlimbs. Traditionally defined, lumbar vertebrae lack ribs and do not articulate with the sacrum. An alternative functional definition is based on the orientation of the synovial (or zygapophyseal) joints between the vertebrae. In thoracic-type articulations the joint surfaces form arcs of a circle the center of which lies ventral (i.e., anterior or inferior) to the vertebral canal, whereas in lumbar type articulations the joint surfaces form arcs of a circle the center of which lies dorsal (i.e., posterior or superior) to the vertebral canal. But these are ideal types and intergradations exist. In pronograde quadrupeds, primates and many other mammals, the most caudal two or three rib-bearing vertebrae

frequently bear lumbar type articulations. Traditionally defined lumbar vertebrae in most anthropoid pronograde quadrupeds generally number six or seven, whereas functionally defined lumbar vertebrae may total nine or ten. For the majority of extant hominoid individuals the two definitions coincide. The modal number of traditionally defined lumbar vertebrae is four in the living great apes, five in smaller-bodied hylobatids, and four or five in the larger siamang species. The modal number of traditionally defined lumbar vertebrae in modern humans is five, but six functionally defined lumbar vertebrae are frequent (e.g., up to 43% in some modern human populations). **Lordosis**, or posterior concavity, of the modern human lumbar region is an adaptation to **bipedal** positional behaviors, and is achieved by vertebral wedging, with dorsal vertebral margins being shorter than ventral margins. Modern humans are dimorphic, with females having three wedged vertebrae, males only two, as well as differences in relative size and orientation of lumbar zygapophyses between the sexes. These differences reflect the need to accommodate shifts in the position of the trunk's center of mass during pregnancy by increasing lumbar lordosis (Whitcome et al. 2007). The fossil records of three early hominin specimens, two belonging to *Australopithecus africanus* and one to *Homo erectus*, and several *Homo neanderthalensis* individuals, are sufficiently complete to infer the number of lumbar vertebrae. The Neanderthal specimens have five lumbar vertebrae, one *Au. africanus* specimen (Sts 14) has six functional lumbar, the most cranial of which bears a unilateral rib. The lumbar counts of the second *Au. africanus* and the *H. erectus* specimen (i.e., whether there are five or six lumbar vertebrae) are disputed (Haeusler et al. 2002).

luminescence dating One of the radiogenic group of dating methods, luminescence dating relies on either a thermal (**thermoluminescence dating** or TL) or an optical (optically stimulated luminescence dating or OSL) signal, the strength of which is related to the numbers of electrons trapped within defects in the crystal lattice of minerals. The electron trapping results from nuclear radiation from both within, and without, the mineral. The populations of electrons in the minerals under investigation must be capable of being reset to zero. For TL this happens when temperatures exceed 400°C. In the case of OSL, trapped electrons are eliminated by prolonged exposure to daylight (i.e., when sediments are trans-

ported, by wind or water, or if they lie for long periods on the surface). If these methods are to be of value for dating events in hominin evolution the “resettings” must be brought about by events that are the result of hominin activity, and not the result of natural events. For example, when TL is used on burnt flint artifacts researchers assume the flints were burned in a fire not long after they were fashioned, so the TL date provides a conservative, minimum date, or *terminus post quem* for the manufacture of the flint artifacts. These methods can be applied to minerals such as **quartz**, **flint**, and **feldspars** that are relevant to the chronology of the later stages of hominin evolution and they can be used up to c.100 ka and in certain circumstances more than 500 ka. Analytical problems with respect to OSL include inadequate exposure to sunshine so that previously acquired luminescence is retained and with respect to TL the long-term instability of the signal. Examples of OSL application include its use to date quartz grains from the M1 phase of the **Middle Stone Age** levels at **Blombos Cave** (Jacobs et al. 2003) and TL has been used to date two burned stone artifacts from the M2 phase at Blombos Cave (Tribolo 2003).

lumper (ME *lumpe*=to aggregate) A researcher who favors fewer, more inclusive, taxa [e.g., Milford **Wolpoff**, who advocated lumping all extinct *Homo* species into a single species, *Homo sapiens sensu lato* (Wolpoff et al. 1992)].

Luna See **Bubing Basin**.

lunate sulcus (L. *lunatus*=to bend like a crescent and *sulcus*=a deep furrow or groove) A prominent **sulcus** found on the lateral surface of the occipital lobe of the **cerebral hemispheres** of some monkeys, all extant ape taxa, and a small percentage of modern humans. In general, it marks the anterior-most limit of the **primary visual cortex**. Compared to the terminus of the **Sylvian fissure**, the lunate sulcus in modern humans (when present) is in a more posterior position relative to other primates. This is thought to reflect reorganization of the cortical areas to the extent that the parietal association cortex that lies immediately in front of the lunate sulcus has expanded in size relative to the primary visual cortex. Because the endocasts of fossil hominins, both natural and those prepared by researchers, occasionally preserve evidence of the lunate sulcus, its position has historically been a focus of debate about when in hominin

evolution cortical reorganization occurred. Raymond Dart (1925) argued for the hominin status of the Taung 1 child, in part on the basis of his assessment of a modern human-like position of the lunate sulcus on the specimen's natural endocast. While there is general consensus that the lunate sulcus is in a modern human-like position in endocasts from early *Homo* and pre-modern *Homo*, the position of the lunate sulcus in *Australopithecus afarensis* and *Australopithecus africanus* endocasts has proven to be more difficult to determine conclusively. Ralph Holloway has argued that A.L. 162-28, Taung, and Stw 505 all show the lunate sulcus in a posterior, modern human-like position, signaling evidence of brain reorganization in Pliocene hominins (Holloway 1983a, 1985a, 1991). In contrast, Dean Falk has claimed that the lunate sulci of Taung and A.L. 162-28 are in a more anterior, extant ape-like, position (Falk 1983a, 1986a, 1991).

Lupemban A Middle Stone Age archeological industrial complex, sites of which are widespread in central Africa, particularly the Congo River basin, from Angola to as far north as western Kenya. The type collections derive from mining operations along the Lupemba River in southern Democratic Republic of the Congo, near the Angola border, with the best-described collections and dated collections found at **Kalambo Falls** and **Twin Rivers** in Zambia, with an estimated age of *c.*200 ka (Barham 2000, Clark 2001). The diagnostic stone tools of the Lupemban are

“lanceolate” points, long (>20 cm in length), relatively thin **bifacially worked** tools whose function is unknown, and the more robust “core axes,” tools surmised to have served heavy-duty functions such as woodworking.

L_x The total number of years (based on the **radix**) lived in an age interval is represented in a **life table** as L_x or ${}_nL_x$. *See* **person-years lived in an age interval**.

Lydekker's Line Richard Lydekker (1849–1915) was a naturalist and an early biogeographer. He worked for the Geological Survey of India and then at the British Museum (Natural History). In 1895 he delineated the eastern boundary of the biogeographical region known as Wallacea (i.e., the boundary between Wallacea and **Sahul**) that is now referred to as Lydekker's Line. *See also* **Wallacea**.

Lyonization *See* **X-inactivation**.

Lyttelton Formation (etym. Named after local town near the type section) General description. Part of the Malmani Subgroup, which collectively are dolomites of the late Archaean (2.6–2.5 Ga). The Malmani Subgroup sequence is (from bottom to top): Oaktree Formation, Monte Christo Formation (includes **Swartkrans**, **Sterkfontein**, **Kromdraai**, and **Drimolen**), Lyttelton Formation (includes **Malapa**), Eccles Formation (includes **Gondolin** and **Gladysvale**), Frisco Formation.

M

Ma Abbreviation of millions of years ago, which is an age determination, or **age estimate**, expressed in millions of years. For example, “the approximate age of **KNM-ER 3733** is 1.8 Ma.” The terms “my” or “myr” should be used to describe periods of time, as in “2 myr have elapsed since hominins first appeared in Africa.” *See also* **age estimate**.

MA Acronym for **major axis regression** (*which see*).

Maba (马坝) (Location 24°40′28.51″N, 113°34′48.68″E, southern China; etym. named after the local town) History and general description This limestone cave site is situated in Shizishan (Lion Hill) about 2 km/1.2 miles southwest of the town of Maba, Qujiang County, Guangdong Province. Local farmers discovered hominin and non-human mammalian fossils in 1958 while digging for natural fertilizers. Several authors (e.g., Wu Xing Zhi and Geoffrey Pope) have commented on the morphology of the right orbit (rounded orbit with medially thick supraorbital torus and no supraorbital notch) and its similarity to *Homo neanderthalensis*. Temporal span and how dated? Uranium-series dating of calcite deposit and animal teeth produced an age estimate of $129 \pm c.10$ ka. Hominins found at site A calotte (PA 84) consisting of partial parietal bones, a frontal bone with fairly complete nasals, and most of the right orbit (frontal process of the zygomatic bone). Sutural fusion is consistent with it being an aged adult and ectocranial rugosity suggests the individual is male. Archeological evidence found at site None. Repository **Institute of Vertebrate Paleontology and Paleoanthropology**, Beijing. Key references: Geology, dating, and paleoenvironment Yuan et al. 1986; Hominins Woo and Peng 1959, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Brown 2001.

MacClade A piece of computer software written by Wayne and David Maddison (Maddison

and Maddison 2008) that is used as an aid in **cladistic analysis**. The main function of MacClade is as a tool for exploring the consequences of tree topology on patterns of **character evolution**; it does *not* search for the **most parsimonious tree** that can be generated from a given character matrix.

Machiavellian intelligence *See* **social intelligence**.

macrodont (Gk *macros*=large and *odont*=tooth) Literally having large teeth, but in paleoanthropology it usually refers to the relative size of the crowns of the postcanine teeth. It was used by Phillip Tobias (1967) to describe the large postcanine tooth crowns of *Paranthropus robustus*. Unlike the term megadont, which has been given a quantitative definition, macrodont is only a qualitative term. *See also* **megadont**.

macrostructure *See* **morphology**.

MAD Acronym for **mean age at death** (*which see*).

Magdalenian (etym. Named after the site of La Madeleine, France) A European **Upper Paleolithic** technocomplex, characterized by unretouched stone blades, bone needles, bone harpoons, and other bone tools, as well as figurative engravings of humans and animals, jewelry, and complex burials with many grave goods. It dates to between 17 and 11.5 ka.

Maghreb (etym. "The place where the sun sets" or "western" in Arabic) The northern lowland regions of Morocco, Algeria, and Tunisia (i.e., the parts of those countries that lie between the Atlas massif and the Mediterranean Sea).

magnetic anomaly time scale *See* **geomagnetic polarity time scale**.

magnetic polarity time scale *See* geomagnetic polarity time scale.

magnetic resonance imaging *See* functional magnetic resonance imaging.

magnetostratigraphy *See* geomagnetic polarity time scale.

magnetostratigraphy The use of the magnetic polarity of a stratum, or a sequence of magnetic polarities of a longer section, to date sediments or igneous rocks. *See* geomagnetic polarity time scale.

magnetozone *See* geomagnetic anomaly.

Magosi rock-shelter *See* Magosian.

Magosian The term formerly used to describe artifact assemblages attributed to the “Second Intermediate,” a transitional period considered to occur between the **Middle Stone Age** (or MSA) and the **Later Stone Age** (or LSA) in Africa. The type site occurs at Magosi rock-shelter, a sediment-filled cistern at the base of a granite cliff in otherwise arid easternmost Uganda (2°35′N, 30°25′E). Early descriptions (Wayland and Burkitt 1932, Clark 1957) emphasized the co-occurrence of **points**, considered diagnostic of the MSA, and backed pieces or **microliths**, typical of the LSA. However, subsequent excavations demonstrated the presence of steeply dipping strata at Magosi. The intersection of these tilted strata during initial excavation in horizontal layers resulted in the accidental admixture of formerly discrete MSA and LSA levels (Cole 1967). As the “transitional” nature of the Magosian was demonstrably the result of excavation methods rather than past human behavior, the term “Magosian” was subsequently abandoned, and with it the concept of the Second Intermediate as part of a general movement towards a better definition of African artifact assemblages (Clark et al. 1966).

Mahalanobis distance A measure of multivariate distance between a point and the **centroid** of data set. Mahalanobis distance differs from **Euclidean distance** in that it takes into account the correlation between variables in the data set as well as the difference in standard deviations between variables, whereas Euclidean distance does not. This distinc-

tion is potentially important in calculating multivariate morphological distances. For example, consider a data set with three variables: ulna length, radius length, and radial head diameter. While all of these variables will be correlated, the two length variables will be highly correlated and they are of much greater magnitude (and standard deviation) than radial head diameter. Thus a measure of multivariate distance that treats all variables equally (i.e., Euclidean distance) will be heavily weighted towards a difference in forearm length, and the variability in radial head diameter will contribute very little to the resulting distance. However, Mahalanobis distance effectively scales variables by standard deviation and correlation such that differences in variables of small magnitude and low standard deviations (e.g., radial head diameter) will be given equal weight with differences in variables with large magnitudes and large standard deviations (e.g., ulna and radius length) in the resulting distance. Furthermore, variables which are highly correlated with each other (e.g., radius and ulna length) will be given less individual weight in the resulting distance than variables which are less correlated with the rest of the data set (e.g., radial head diameter). Because Mahalanobis distance requires knowledge of standard deviations within each variable and correlations between variables, the distance cannot be calculated between two individual points in the absence of a reference group from which the standard deviations and correlations are calculated.

Maiko Gully *See* Olduvai Gorge.

main cusp *See* cusp (syn. primary cusp).

Main Deposit One of the three main areas within Zhoukoudian Locality 1. *See* Zhoukoudian Locality 1.

Main Ethiopian rift The middle of the three components of the **Ethiopian Rift System**. To the north is the Afar rift (also known as the Afar Depression) and to the southwest is the **Omo rift zone**. The main Ethiopian rift is divided into three sectors (WoldeGabriel et al. 2000). The southern sector is divided by the Amaro Horst into two basins and sites within it include Burji and **Konso-Gardula**. The central sector contains fewer areas of exposed sediments and the sites include **Gadeb**, **Gademotta**, and **Melka Kunturé**. The main site in the northern sector is **Kesem-Kebena**.

major axis regression A form of regression in which model parameters are fit by minimizing the sum of squared differences between observed values and the best-fit line as calculated by a perpendicular line from the best-fit line, thus taking into account error in both the independent and dependent variables. The best-fit line produced by major axis regression is identical to the axis of the first principal component in a **principal components analysis** (using a **correlation matrix**, not a **covariance matrix**). Major axis regression should only be used when independent and dependent variables are measured in the same units; otherwise, **reduced major axis regression** should be used. Because major axis regression takes into account error in all variables and not just the independent variable when fitting model parameters, it is an example of a **model II regression**.

major histocompatibility complex (or MHC) This system (known in modern humans as the **human leucocyte antigens**, or HLA, system) is a series of antigens on the cell surface that function as a part of the antibody processing that occurs during the immune response. The HLA system also identifies host cells as “self.” They are the most polymorphic system of inherited traits known in modern humans. HLA types are determined by several closely linked loci on chromosome 6 (i.e., HLA-A, HLA-B, HLA-C, HLA-D, and HLA-DR). The *HLA-A*, *-B*, and *-C* genes encode antigens (known as histocompatibility, or Class I, antigens) found on the surface of all nucleated cells, but they are *not* found on red blood cells, sperm, and some placental cells. The HLA-D region encodes Class II antigens and is composed of three subregions: HLA-DR, HLA-DQ, and HLA-DP. Class II antigens are structurally different from Class I antigens and are found only on the surface of B lymphocytes, macrophages, activated lymphocytes, and other specialized cells. The Class III genes, which are located between the HLA-B and HLA-D regions, encode the genes of the complement system, which is important in cell-mediated immunity. Each of these MHC loci has **alleles** for 8–40 antigens. Alleles are codominant, and **recombination** between loci is rare because of their close **linkage**. The set of alleles on one chromosome is referred to as a **haplotype**. The nomenclature for the alleles that code for different antigens at these loci first uses a letter (which refers to the locus) fol-

lowed by a number that signifies the allele. For example A1 was the first allele described at the A locus. Matching HLA types in modern humans is important for transplantation since these antigens are what identify “self” from “non-self.” Diseases such as type I diabetes, ankylosing spondylitis, and rheumatoid arthritis are associated with particular HLA alleles. Most of these diseases are associated with Class II alleles and are also referred to as autoimmune diseases. Many are inflammatory diseases and these disorders appear to be triggered by a combination of HLA and non-HLA effects, with environmental activation (possibly by infection by an agent that has antigens that mimic an HLA antigen; this type of mimicry is known as molecular mimicry). There is also evidence linking the MHC to mate choice. Due to its role in the immune system, mate choice for MHC genotype may provide several, non-exclusive fitness advantages, by providing offspring with increased (or optimal) MHC diversity and thus disease resistance, or by providing a “moving target” against infection by parasites that are themselves rapidly evolving. The exact patterns of mate choice vary, but they include choice for MHC-disparate partners or for a partner with an optimal set of MHC dissimilar alleles in taxa as diverse as birds, fish, and lizards, as well as nonhuman primates. Studies of whether our own species mates disassortatively with respect to MHC genes have yielded mixed results, which may be a reflection of context-dependent mate preference expression.

MAK Abbreviation of Maka and the prefix for fossils recovered from Maka, Ethiopia. *See* **Maka**.

MAK-VP-1/1 Site Maka in the Bodo-Maka fossiliferous subregion of the Middle Awash study area. Locality Maka Vertebrate Paleontology Locality 1. Surface/in situ Surface. Date of discovery 1981. Finder Tim White. Unit N/A. Horizon “Maka sands” (see White et al. 2000, p. 46). Bed/member N/A. Formation Matabaietu Formation. Group N/A. Nearest equivalent dated horizon MA 90–16 volcanic lens (see White et al. 2000, p. 47). Nearest underlying dated horizon VT-3 tuff. Geological age *c.*3.4 Ma. Developmental age Subadult. Presumed sex N/A. Brief anatomical description A well-preserved left proximal femur of a subadult lacking the head. The neck is preserved, as are the greater and lesser trochanters; the epiphyseal line of the latter is clearly seen. Announcement Clark et al.

1984a. Initial description Clark et al. 1984a. Photographs/line drawings and metrical data Clark et al. 1984a, Lovejoy et al. 2002. Detailed anatomical description Lovejoy et al. 2002. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance It is claimed that this well-preserved proximal femur confirms that *Au. afarensis* practiced a form of “habitual terrestrial bipedality” that differed “only trivially from that of modern humans” (Lovejoy et al. 2002, p. 97). Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

MAK-VP-1/12 Site Maka in the Bodo-Maka fossiliferous subregion of the Middle Awash study area. Locality Maka Vertebrate Paleontology Locality 1. Surface/in situ Surface. Date of discovery 1990. Finder Tim White. Unit N/A. Horizon “Maka sands” (see White et al. 2000, p. 46). Bed/member N/A. Formation Matabaietu Formation. Group N/A. Nearest equivalent dated horizon MA 90-16 volcanic lens (see White et al. 2000, p. 47). Nearest underlying dated horizon VT-3 tuff. Geological age *c.*3.4 Ma. Developmental age Sub-adult. Presumed sex N/A. Brief anatomical description An adult mandible assembled from many small fragments (White et al. 2000, Fig. 3). Both angles are damaged, but otherwise the bone of the mandible is well preserved, although inevitably there are minor distortions because of the need to glue the many fragments. The crowns of the left I₂-M₃ and the right P₃-M₃ are preserved in the alveolar process. Announcement White et al. 1993. Initial description White et al. 1993. Photographs/line drawings and metrical data White et al. 1993, 2000. Detailed anatomical description White et al. 2000. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance This mandible is another good example of the mandibular and dental morphology that is “typical” of *Au. afarensis* (Kimbel et al. 2004, Kimbel and Deleuzene 2009). The P₃s of MAK-VP-1/12 are two-rooted, but each root has a single root canal, thus they are unlike the dumbbell-shaped root cross-sections seen in many, but by no means all, specimens of *Paranthropus*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Maka (Location 3°54.03'N, 35°44.40'E, Ethiopia; etym. the name of the drainage in which the site is situated) History and general description The Maka site is located on the eastern side of the Awash River in the Middle Awash study area in the Afar Rift System; it is immediately south of Matabaietu and north of Belohdelie. Maka was first explored by Jon Kalb and his colleagues in 1975 and 1976 and then in 1981 by a multidisciplinary team led by Desmond Clark. Pleistocene hominin remains were recovered during a later survey and further surveying at Maka in 1990 resulted in the recovery of more hominin remains. Two localities within the Maka area have yielded archeological assemblages. Temporal span The horizon from which the hominin remains come is referred to informally as the “Maka sands.” The Maka sands were deposited disconformably *c.*6 m above the 3.74±0.023 Ma VT-3 Tuff (=Wargolo Tuff). Interdigitated within the Maka sands is a volcanic lens (MA90-16) whose glass chemistry is correlated with the 3.40±0.03 Ma Sidiha Koma Tuff of the Hadar Formation and with the 3.39±0.036 Ma MA90-28 Tuff at the nearby Wee-ee fossil locality. Thus, an age of 3.4 Ma is attributed to the hominin-bearing Maka sands horizon. Currently there are no dates available for the horizons bearing archeological assemblages How dated? Biostratigraphy and tephrocorrelation. Hominins found at site The first hominin fossil recovered at Maka, in 1981, was MAK-VP-1/1, a left proximal femur. Additional specimens from the Maka area recovered in the course of surface prospecting in 1990 include the right side of a mandibular corpus with M₁₋₃ (MAK-VP-1/2), a left humerus (MAK-VP-1/3), a right M₂ (MAK-VP-1/4), the left side of an endentulous mandible (MAK-VP-1/6), a nearly complete mandible with dentition (MAK-VP-1/12), a left M¹ (MAK-VP-1/13), a ramus from the left side of a hominin mandible found in 1990 (MAK-VP-1/83), and the proximal end of a left ulna (MAK-VP-1/111). The hominin remains from Maka are attributed to *Australopithecus afarensis* and they provided the first substantial sample of *Au. afarensis* material outside of Hadar and Laetoli. Archeological evidence found at site Two archeological localities were discovered at Maka in 1981. Locality MAK-A1 yielded evidence of an assemblage consisting of artifacts that are technologically and typologically analogous to Early Acheulean assemblages from East Africa. The artifacts are all surface finds and are scattered within lag gravels

of an uncertain age that cap Pleistocene sediments at MAK-A1. In 1991 further investigations of a low-density **Mode 2** occurrence at locality MAK-A2 yielded both surface and *in situ* lithic artifacts. The age of the artifacts at MAK-A2 is also uncertain, but they are most likely Late Acheulean. Key references: Geology, dating, and paleoenvironment Clark et al. 1984a, White et al. 1993, Renne et al. 1999; Hominins Clark et al. 1984a, White et al. 1993, 2000; Archeology Clark et al. 1984a, de Heinzelin et al. 2000.

Makah Mera Collection area within the **Woranso-Mille study area**, Central Afar, Ethiopia.

Makapansgat (Location 24°12'S, 29°12'E, South Africa; etym. in Afrikaans it means literally "Makapan's hole" and it commemorates the Ndebele Chief, Mokopane, or Makapan, who was besieged by the Boers in a cave in the valley in 1854) History and general description Makapansgat (its formal name is Makapansgat Limeworks; see below) is one of a number of cave complexes [others include Buffalo Cave, Cave of Hearths, Gwasa Cave (aka Makapan's Cave, Historic Cave), and Peppercorns] in the Makapansgat Valley, which is in the Highlands Mountains, 22.5 km/14 miles northeast of Mokopane in Limpopo Province (formerly Northern Province). The cave was mined as the "Makapansgat Limeworks" (hence the prefix "MLD" for "Makapansgat Limeworks Deposits/Dumps") from around the beginning of the 20thC. In 1925 a local teacher, Wilfred Eitzman, in response to the publicity surrounding the **Taung(s)** discovery, sent blocks of fossiliferous breccia collected from the dumps near the limekilns to Raymond **Dart**, who confirmed their antiquity. Other caves in the valley became the focus of attention, but in 1947 the Kitching brothers (James, Ben, and Scheepers) discovered a hominin brain case in the same dumps that Eitzman had examined. The brain case was sent to Dart who referred the new fossil to *Australopithecus prometheus* (Dart 1948). Partridge (1979) divided the Makapansgat Formation into five members (1–5) and he subdivided Member 4 into two deposits (A and B); subsequently M4 B became the CDP or central debris pile. Hominins that are now attributed to *Australopithecus africanus* derive mainly from Member 3, with one specimen (MLD 37/38) from Member 4A. Temporal span and how dated? Biostratigraphy and magnetostratigraphy suggest Member 3 (the source of all but two hominin fossils) is between *c.*2.85 and 2.58 Ma and

Member 4 is *c.*2.58 Ma. Herries (2003) suggests that the deposits in the Makapansgat Limeworks range in age between *>c.*4.3 and *c.*2.58 Ma and that the oldest fossiliferous deposits are *c.*3.0 Ma. Hominins found at site Raymond Dart suggested that the hominins he was aware of from Makapansgat should be assigned to a single new taxon, *Au. prometheus*, which is now regarded as a junior synonym of *Au. africanus*. However, others have suggested that more than one taxon is represented in the Makapansgat hominins; Aguirre (1970) proposed that the second taxon was *Paranthropus robustus* but Clarke (2008) opts for a second unnamed species of *Australopithecus* that is also sampled in Member 4 of the main Sterkfontein cave (e.g., Sts 1, Sts 71, Stw 252, Stw 505) and in the **Silberberg Grotto** (i.e., Stw 573). Archaeological evidence found at site Dart's osteodontokeratic culture has been discredited. Key references: Geology, dating, and paleoenvironment McFadden et al. 1979, Partridge 1979, 2000, Herries 2003; Hominins Dart 1948, Aguirre 1970, Tobias 2000; Archeology Dart 1957, Shipman and Phillips-Conroy 1977, Brain 1981, d'Errico and Backwell 2003.

Makapansgat Limeworks Deposit *See* Makapansgat.

MAL Acronym for **mean age in the living** (*which see*).

Malahuma One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Malapa (Location 25°53'39"S, 27°47'57"E, Gauteng Province, South Africa; etym. Sesotho for "homestead") History and general description The Malapa cave is *c.*15 km/9 miles northeast of a concentration of sites in the Blauwbank Valley that includes **Kromdraai**, **Sterkfontein**, and **Swartkrans**. It had been mined for lime in the 1930s, but the hominins exposed by mining were not found until 2008 when they were recognized in blocks removed from the excavated area, which is 3.3 m by 4.4 m and 3.5 m deep. Temporal span and how dated? The cave filling comprises five facies, with A and B below being separated by a layer of **flowstone** from C, D, and E above; the fossiliferous facies are D and E. The two specimens reported so far, **MH1** and **MH2**, come from facies D, but it is suggested that there are

“additional hominin remains in facies E” (Dirks et al. 2010, p. 205). Facies D is estimated to be within the range of 1.95–1.78 Ma. The dates of the fossiliferous facies are constrained by the **first appearance datum** of *Equus*, *Tragelephas* cf. *strepciceros*, *Felis silvestris*, and *Parahyaena brunnea* (*c.*2.36 Ma), and the **last appearance datum** of *Megantereon whitei* (*c.*1.5 Ma). There is normal magnetic polarity at the base of the flowstone, but most of the flowstone is reversed polarity and the facies above it (i.e., C, D, and E) are normal. Dates of 2.024 ± 0.062 and 2.026 ± 0.021 Ma using **uranium-series dating** (U-Pb) were obtained from the Bern and Melbourne labs, respectively, for specimens taken from flowstone 20 cm below MH2. Thus, the normal polarity at the base of the flowstone is interpreted as the Huckleberry Ridge subchron (2.06 ± 0.04 Ma) and the normal polarity in facies C–E is interpreted as the 1.95–1.78 Ma **Olduvai subchron**. **Hominins found at site** Two hominin associated skeletons: the juvenile MH1 and the adult MH2. **Archeological evidence found at site** None reported. **Key references:** Geology, dating, and paleoenvironment Dirks et al. 2010; Hominins Berger et al. 2010; Archeology N/A.

malar (L. *mal*=cheek) Refers to the region of the **face** corresponding to the cheek. That region of the bony face is called the malar region, and the external surface of the part of the maxillary bone that lies deep to the soft tissues of the cheek is called its malar surface.

malar visor *See* facial visor.

Malarnaud (Location $43^{\circ}01'08''N$, $1^{\circ}19'44''E$, France) **History and general description** This cave complex, consisting of several long interconnected galleries, has been explored by miners, treasure hunters, and amateur and professional archeologists since at least the late 1800s. A *Homo neanderthalensis* mandible was recovered in 1888, the first evidence for Neanderthals in France. **Temporal span and how dated?** Radiometric dating has not been attempted, but faunal analysis and correlation to glacial cycles suggests the Riss-Würm interglacial or the beginning of the Würm (*c.*100–50 ka) for the layer that contained the fossil. **Hominins found at site** A nearly complete mandible of juvenile, *c.*12 years old, but which is missing the crowns of all the teeth except the right M_1 and the unerupted left M_3 , which is still

visible in its crypt. **Archeological evidence found at site** The site was inhabited for a long period, and includes predominantly **Mousterian** deposits, but also **Aurignacian** and **Magdalenian** levels. **Key references:** Geology, dating, and paleoenvironment Heim and Granat 1995, Pales 1939; Hominins Heim and Granat 1995; Archeology Heim and Granat 1995, Pales 1939.

male-display model This model suggests that **Oldowan** sites were places on the landscape where scavenging and hunting opportunities were concentrated. It suggests that male *Homo erectus* displayed their fitness, and increased their mating success, by aggressively scavenging carcasses from carnivores in favored locations. These carcasses would then be transported to the nearest refuge, where taxonomically diverse archeologically visible assemblages would form over time (O’Connell 1997, O’Connell et al. 2002).

Malema (Location $10^{\circ}1'18.59''S$, $33^{\circ}55'51.53''E$, in Malawi; etym. named after Malema village) **History and general description** Discovered in 1992, Malema RC 11 is one of the many fossiliferous localities in the **Chiwondo Beds**. Its main significance is biogeographical, for it extends the range of the hominin taxon recovered from the site by more than 1000 km/620 miles to the south. **Temporal span and how dated?** *c.*2.5–2.3 Ma using **biostratigraphy**. **Hominins found at site** A maxillary fragment **HCRP RC 911** provisionally assigned to *Paranthropus boisei*. **Archeological evidence found at site** None. **Key references:** Geology, dating, and paleoenvironment Kullmer et al. 1999, Kullmer 2008; Hominins Kullmer et al. 1999; Archeology N/A.

Malladetes (Location $39^{\circ}01'19''N$, $0^{\circ}18'01''W$, Spain; etym. name of the local cave, also known as Cueva de les Malladetes) **History and general description** Malladetes cave lies on a hillside overlooking the town of Barx in Valencia. Excavations in the late 1940s under the direction of L. Pericot and F. Jordá uncovered a hominin occipital. **Temporal span and how dated?** Charcoal from the hominin level was dated by **AMS radiocarbon dating** to $25,120 \pm 240$ years BP (uncalibrated age). **Hominins found at site** A hominin occipital was found in level 12. The age at death has been approximated to 5–7 years. It has been suggested that the Malladetes occipital

supported the hypothesis of hybridization between *Homo neanderthalensis* and anatomically modern humans, but comparative studies indicate the specimen belongs to *Homo sapiens*. Archeological evidence found at site Some of the earliest tools have been characterized as **Aurignacian**. In upper layers, a **Gravettian** assemblage was recovered, including **points**, **scrapers**, and **burins**. Bone tools were also found. Key references: Geology, dating, and paleoenvironment Arsuaga et al. 2002; Hominins Arsuaga et al. 2002; Archeology Arsuaga et al. 2002.

malleus (L. *malleus*=hammer) *See* auditory ossicles; branchial arches; middle ear.

mammal size classes *See* bovid size classes.

mandible (L. *mandere*=to chew and *mandibular*=lower jaw) The bone of the lower jaw. Each side of the mandible consists of a horizontal **corpus** and a vertical ramus. In the adult the corpora are joined in the midline at the mandibular symphysis to form the body of the mandible. Each corpus has an **alveolar process** superiorly, a base inferiorly, and external and internal surfaces. The alveolar process contains the sockets, or alveoli, for the roots of the mandibular teeth. On the base, on either side of the midline, are the digastric fossae. The mental foramen perforates the external surface of the corpus and the mylohyoid line divides the internal surface into the sublingual fossa superiorly and the submandibular fossa inferiorly. The symphysis has the alveolar process superiorly, the external or mental surface anteriorly, the internal or lingual surface posteriorly, and a base. The external surface may have a **mental protuberance**, but to qualify as a **true chin** there must be a depression, called an *incurvatio mandibulae*, superior to it. The internal surface of the symphysis may have tubercles and fossae for the genial muscles. It may describe a smooth curve, or be reinforced by transverse bony buttresses. These may be separate, as superior and inferior transverse tori, or in the form of a single transverse torus. When the internal surface of the symphysis between the alveoli and the torus is flat it is called a post-incisive planum. The quadrilateral rami are attached to the corpora posteriorly. Each ramus has two surfaces, external and internal, four borders, superior and inferior, anterior and posterior, and two processes, condylar and coronoid, separated by the mandibular notch. The posteroinferior corner is called

the angle. The anterior border of the ramus can be straight or sinuous. The internal surface of the ramus is perforated by the mandibular foramen (for the inferior alveolar nerve and vessels). On the anterior border of the foramen the lingula marks the inferior attachment for the sphenomandibular ligament.

Mandible A *See* Kedung Brubus.

Mandible B *See* Sangiran 1b.

Mandible C *See* Sangiran 9.

Mandible E *See* Sangiran 21.

mandibular scaling *See* scaling.

Mann-Whitney U test A nonparametric statistical test used to determine whether the values of a **sample** of measurements are significantly larger or smaller than the values for a second sample. Used in the same situations as one would use a two-sample *t* test, the Mann-Whitney U test considers the relative ranking of the values in the two groups rather than the values themselves.

MANOVA Acronym for **multivariate analysis of variance** (*which see*).

manual digit (L. *manus*=hand and *digit*=finger) The separate fingers of the primate, and therefore the hominin hand, each comprise three bones, namely the proximal, the intermediate, and the distal phalanges. The manual digit is the distal component of a **manual ray**, which comprises a manual digit plus its associated metacarpal. The thumb has just two phalanges.

manual ray (L. *manus*=hand and *radius*=radiating line) The manual ray comprises a **manual digit** (i.e., the proximal, the intermediate, and the distal phalanges) plus its associated **metacarpal**. The thumb has just two phalanges.

manuport (L. *manus*=hand and *portare*=to carry) An unmodified stone found at an archeological site that is inferred to have been transported by hominins, perhaps for future use as raw material sources for the production of sharp-edge stone tools. Manuports are usually identified as such by a process

of eliminating other natural transport processes (e.g., deposition by streams) although this can be difficult in many ancient settings (e.g., de la Torre and Mora 2005).

Mapa *See* Maba.

marginal sinus (*L. margo*=edge) One of the dural venous sinuses belonging to the external component of the **intracranial venous system**. The marginal sinus, when present, runs from the inferior end of the occipital sinus around the margin of the posterior quadrant of the **foramen magnum** to drain into the superior jugular bulb and/or the **vertebral venous plexuses**. In most modern humans the superior sagittal sinus and the straight sinus (the latter drains venous blood from the deep cerebral veins) drain into the transverse sinuses. But in the majority of the crania belonging to *Australopithecus afarensis*, *Paranthropus boisei*, and *Paranthropus robustus*, the venous blood from the same sources drains into an **occipital sinus**, which in turn drains into the marginal sinuses. This pattern of intracranial venous drainage is known as the **occipito-marginal system** of venous sinuses, and individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., OH 5) are said to show occipito-marginal system dominance. *See also* **cranial venous drainage**.

MARGO *See* sea surface temperature.

marine isotope stages *See* Oxygen Isotope Stages.

marker bed A layer or stratum that is physically or chemically distinctive enough to be identified independently of its context. Marker beds are used to link isolated blocks of sediments in the same fossil site, or to provide a means of linking/correlating strata from one locality to another, or even from one site to another (e.g., the “grey tuff” and the “pumice tuff” in the **Kapthurin Formation**, Tugen Hills, Kenya; Tallon 1978). The ash spewed from each volcano has a unique mix of chemicals and even the ashes derived from different eruptions from the same volcano are chemically distinctive. The unique chemical profile of a tuff can be used to trace a tuff from one block of sediment to another and from one site to another. This technique is called **tephrostratigraphy**.

Mas-d’Azil Location 43°04′04″N, 1°21′16″E, France; etym. name of a nearby town) History and general description This late **Upper Paleolithic** site is located in the caves leading off the large tunnel created by the Arize river as it flowed through part of the Pyrenées. It is the type site of the Azilian, and was excavated in the 19thC by Edouard Piette. It contains many carvings on bone and antler of reindeer and horses, as well as humans and other animals. Temporal span and how dated? Based on the art style and stone tool technologies, as well as a **radiocarbon dating**, the site is thought to date to between 18 and 7 ka. Hominins found at site Piette discovered an incomplete modern human skeleton in 1895, and Vallois found a skull in the **Magdalenian** layers; both are attributed to *Homo sapiens*. Archeological evidence found at site Stone and bone tools and carvings attributed to the Magdalenian and Azilian; the latter is known for small scrapers and distinctive points. Key references: Geology, dating, and paleoenvironment Aleirac and Bahn 1982; Hominins Piette 1895, Vallois 1965; Archeology Cartailhac 1891, Péquart and Péquart 1941.

mastication (Gk *mastikhan*=to grind the teeth) The processes involved in **chewing** food by moving the lower teeth against the upper teeth to slice, fracture, or crush food into smaller pieces. This mechanical reduction, or **comminution**, of food in the mouth is a key feature of mammals and it was crucial for the relatively high energy consumption of mammals compared to reptiles of the same body mass. Mastication reduces the particle size of food, mixes it with saliva, and softens it so that it forms a bolus that can be transferred to the esophagus by the process called **swallowing**. *See also* **chewing**; **mandible**; **TMJ**; **mastication, muscles of**.

mastication, muscles of (Gk *mastikhan*=to grind the teeth) An informal term used for the group of striated muscles that moves the mandible during **mastication**. *Gray’s Anatomy* includes the masseter, temporalis, and the lateral and medial pterygoid muscles in its section on the muscles of mastication. The main action of the masseter is to elevate the mandible, but its obliquely orientated fibers also play a minor role in side-to-side and protraction and retraction movements of the mandible. The anterior temporalis fibers are involved in elevation of the mandible and the

posterior fibers with retraction. The pterygoids act as an integrated unit. When the medial and lateral pterygoids of the same side contract the condyle on that side is drawn anteriorly so that movements can then occur around an axis that passes through the opposite condyle. When the medial and lateral pterygoids of one side contract, followed by contraction of the medial and lateral pterygoids of the other side, the mandible is moved from side to side in a chewing movement. When the inferior fibers of the two lateral pterygoids contract together with the two medial pterygoids they draw both mandibular condyles and articular discs anteriorly onto the articular eminence to maximize the gape. When the superior fibers of the lateral pterygoids are involved instead of the inferior fibers, together with medial pterygoids, the mandible is protruded. The motor branch of the trigeminal nerve supplies all these muscles. Other muscles, including the buccinator supplied by the facial nerve, play an important role in mastication (e.g., the buccinator prevents masticated food collecting in the cheek) but they are not usually considered to be among the “muscles of mastication.”

masticatory apparatus (Gk *mastikhan*=to grind the teeth, plus L. *ad*=to and *parare*=to make ready) The soft (i.e., muscles) and hard (i.e., bones and teeth) parts of the skull involved in **chewing** food. With respect to the hard tissues it includes the upper jaw, the maxilla, plus the upper, or maxillary, teeth, and the lower jaw, the mandible and the lower, or mandibular, teeth. The jaws and the teeth are among the more dense parts of the skeleton, and for this and other reasons they tend to resist post-mortem damage and survive long enough to be fossilized. This results in the hard tissues of the masticatory apparatus dominating the hominin fossil record.

mastoid crest (Gk *mastos*=breast, *oides*=shape, and L. *crista*=crest) A bony crest that sometimes marks the lateral boundary of the attachment of the sternocleidomastoid muscle and two deep neck muscles (the splenius and longissimus capitis) to the lateral surface of the mastoid process. If the posterior-most fibers of the temporalis muscle are especially well developed, then the bony edge of that muscle in the region of the mastoid may be raised up to form a supramastoid crest, and in *Paranthropus*, in which the supramastoid crest and the mastoid

crests are usually distinct, they are separated by a supramastoid sulcus.

mastoid process (Gk *mastos*=breast and *oides*=shape) A bony prominence that projects inferiorly from the posterior part of the temporal bone. It is relatively large in modern humans (you can feel it just behind your ear). The shape and size of the mastoid process shows considerable inter-individual variation in all the higher primates, including extinct hominin taxa. However, there are trends in mastoid process size and shape that are reasonably consistent. In modern humans it is typically the only substantially pneumatized part of the temporal bone and its pyramidal shape is distinctive. Among pre-modern *Homo* taxa the mastoids of *Homo neanderthalensis* are distinctively small. In archaic hominins the mastoid is less distinct because it is just one part of a more general pneumatization of the temporal bone. The sternocleidomastoid muscle and two deep neck muscles (the splenius and longissimus capitis) are attached to its lateral surface and the bony edge of their attachment is sometimes raised up as a mastoid crest. If the posterior-most fibers of the temporalis muscle are especially well developed, then the bone may be raised up to form a supramastoid crest. In *Paranthropus* (and in most archaic hominin taxa assigned to *Australopithecus*) the mastoid normally projects further laterally than the supramastoid crest. In *Paranthropus* the supramastoid and mastoid crests are distinct and they are usually separated by a supramastoid sulcus. The posterior belly of the digastric muscle is attached in a groove (called the digastric notch) on the medial surface of the mastoid process. The sequence of the suite of structures that may be manifest posteromedially to the tip of a mastoid process are, from lateral to medial, the digastric fossa, the juxtamastoid eminence, a groove for the occipital artery, and the occipito-mastoid crest.

Mata Menge (Location 8°41'31"S, 121°5'43"E, Flores, Indonesia; etym. named after a local village) History and general description Mata Menge is the best known of a group of Early and Middle **Pleistocene** sites in the **Ola Bula Formation** located in the **Soa Basin** of central Flores. The first fieldwork was conducted between 1991 and 1994 by Paul Sondaar, John de Vos, Gert van den Bergh, and Fachroel Aziz. Michael

Morwood and colleagues began their investigations in 1997 and excavations in 1994, 1997, and 2004–5 resulted in the recovery of more than 500 artifacts, Temporal span and how dated? The age of the *c.*780 ka is based on **geomagnetic dating** and **fission track dating**. The artifact-bearing horizon is 3 m above what is assumed to be the reversed/normal transition of the Brunhes-Matuyama boundary. Zircons for fission track dating were collected from “the pink tuff immediately below the lowest fossils and stone artefacts” (MM1) and from a “white tuff” that “overlies *in situ* artefacts” (MM2) (Morwood et al. 1998, pp. 175–6); MM1 has been dated to 0.88 ± 0.07 Ma and MM2 to 0.80 ± 0.07 Ma (*ibid.*). Hominins found at site None. Archeological evidence found at site Excavations in 1994 resulted in the recovery of 14 chert artifacts, four of them with use wear consistent with being used to process plant remains. A few additional artifacts were recovered in 1997 and a more recent excavation campaign in 2004–5 recovered 487 *in situ* artifacts; roughly 50% of the combined sample of 507 artifacts are classified as “fresh/unabraded.” Aside from the intrinsic value of the archeological evidence, the site is significant for two other reasons. First, because Flores is separated from the Sunda shelf by at least three deep-sea channels – even when sea levels were lowered at times of global cooling – hominins would have had to face a sea crossing of *c.*20 km/12.4 miles to reach Flores from the Sunda shelf. Second, the similarities between the artifacts at Mata Menge and those at Liang Bua (some 50 km/31 miles to the west) strengthen the case that the latter were manufactured by hominins other than modern humans. Key references: Geology, dating, and paleoenvironment Morwood et al. 1998, O’Sullivan et al. 2001; Hominins N/A; Archeology Morwood et al. 1997, 1998, 1999, Brumm et al. 2006.

Matabaietu One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area**, in Ethiopia.

maternal effect This occurs when an organism’s phenotype is affected by the maternal genotype, environment, or condition. Sometimes an offspring will manifest aspects of the maternal phenotype, due to maternal effects resulting from a maternal supply of mRNA or proteins to the devel-

oping ovum. The maternal, or intrauterine, environment can affect offspring phenotype in ways such as intrauterine position: female fetuses located between male fetuses can experience effects of androgens on morphology, behavior, and reproduction. The condition of the mother can also affect her offspring. For example, in modern humans, uncontrolled gestational diabetes mellitus, in which the mother’s normal insulin response has been altered, is related to macrosomia (large size), delayed lung maturation, or problems with blood-sugar regulation.

maternal energy hypothesis Robert Martin (1996) suggested there is a causal link between the basic metabolic rate of the mother and the brain size of her developing offspring, such that “all mammals have the largest brains that are compatible with the metabolic resources available to their mothers” (*ibid.*, p.155).

matrix (L. *mater*=mother, in the sense of a substance from which something else originates) Biology The combination of water and polymers that, along with cells, fibers, and fibrils, makes up connective tissues. The more polymerized the matrix the stiffer the connective tissue. Earth sciences The rock in which a fossil is embedded. If the matrix is very mineralized it may adhere to the surface of the bone. Extreme changes in humidity and temperature can produce cracks in fossils and when matrix enters these cracks they undergo further expansion. Matrix-filled cracks can artificially increase the size of a structure like the corpus of the mandible. Statistics When raw data, or reformulations of raw data, are presented in a series of rows and columns. It is referred to as data matrix. More sophisticated matrices (e.g., correlation and covariance matrices) are used in **multivariate analysis** and in **Euclidean distance matrix analysis**.

Matupi Cave (Location $1^{\circ}13'53''N$, $29^{\circ}49'23''E$, in the Democratic Republic of the Congo; etym. unknown) History and general description Matupi Cave is one of approximately 40 caves formed in the Precambrian limestone and shale of Mount Hoyo in the Democratic Republic of the Congo. Archeological excavation of a 15 m² area in 1973–4 directed by Francis Van Noten exposed a 210 cm-deep sequence of loam formed by the combination of limestone bedrock decalcification and anthropogenic sediments; the excavation also exposed a number of **hearths**.

Later Stone Age artifacts, which occur from 25 cm below the surface to the base of the excavations, underlie strata attributed to the Iron Age. Many of the **speleothems** found in the cave complex at Matupi (but these are about 10–100 m distant from the archeological excavation) preserve a diverse pollen spectrum suggesting local shifts in the region throughout the **Late Pleistocene** between **savanna grasslands** and **montane forests**. This interpretation is also suggested by the pollen record recovered from the excavated sediments. Temporal span and how dated? Uncalibrated radiocarbon dating estimates (presumably on charcoal) suggest long-term presumably modern human occupation of Matupi Cave, with published values increasing with stratigraphic depth ranging from 0.72 ± 0.05 to more than 40.7 ka. A **thermoluminescence dating** age estimate of 21.35 ± 3.50 ka on burnt quartzite cobbles has also been reported. **Uranium-series dating** ($^{230}\text{Th}/^{234}\text{U}$) of the speleothems provide comparable Late Pleistocene estimates, ranging from 0.99 ± 0.28 to 50.33 ± 2.58 ka. Hominins found at site The Later Stone Age strata contain a single isolated lower tooth attributed to *Homo sapiens sapiens*. Archeological evidence found at site The artifact sample includes more than 8000 predominantly **quartz** artifacts attributed to the Later Stone Age, including early **microliths** in the basal layers that are associated with an infinite radiocarbon age estimate, ground pieces of **hematite** that are found throughout the sequence, and early (*c.* 20 ka) evidence for the use and manufacture of “bored” stones. More than 50,000 faunal elements were recovered, including a diverse mammalian and non-mammalian fauna that suggesting proximity to a forest-savanna **ecotone**. Key references: Geology, dating, and paleoenvironment Brook et al. 1990, Van Neer 1989, Van Noten 1977; Hominins Van Neer 1989; Archeology Van Neer 1989, Van Noten 1977.

Matuyama *See geomagnetic polarity time scale.*

Matuyama chron *See geomagnetic polarity time scale.*

MAU Acronym for **minimal animal unit** (*which see*).

Mauer (Location 49°21'N, 8°48'E, Germany; etym. Ger. for “wall,” the name of a nearby village,

and also of the “Mauer Sands”) History and general description The site is the Grafenrain commercial sandpit 16 km/10 miles southeast of Heidelberg. The stratified fluvial sands exposed there contain mammalian fossil fauna, but the only hominin from the site is a mandible discovered in 1907. Temporal span and how dated? Between *c.* 450 and *c.* 650 ka (i.e., **Oxygen Isotope Stages** 11 or 15), but probably OIS 15 based on **biostratigraphy** and **magnetostratigraphy**. Recent combined **electron spin resonance spectroscopy dating** and **uranium-series dating** on mammal teeth and infrared radiofluorescence on sand grains suggests an age of 609 ± 40 ka. Hominins found at site An adult mandible, the **holotype** of *Homo heidelbergensis*. Archeological evidence found at site None. Geology, dating, and paleoenvironment Howell 1960 (pp. 199–202), von Koenigswald and Tobien 1987, von Koenigswald 1992, Hambach 1996, Wagner et al. 2010; Hominins Schoetensack 1908, Howell 1960 (pp. 211–212), Kraatz 1992, Rosas and Bermudez de Castro 1998a, Mounier et al. 2009.

Mauer mandible Site Mauer. Locality Grafenrain pit. Surface/in situ *In situ*. Date of discovery October 21, 1907. Finder Workmen at the sandpit. Unit N/A. Horizon N/A. Bed/member Mauer Sands. Formation N/A. Group N/A. Nearest overlying dated horizon Rhine terrace volcanic tuffs postdating Mauer Sands (>400 ka from a **potassium-argon date**). Nearest underlying dated horizon N/A. Geological age Between 450 and 650 ka (**Oxygen Isotope Stages** 11 or 15). Recent combined **electron spin resonance spectroscopy dating** and **uranium-series dating** on mammal teeth and infrared radiofluorescence on sand grains suggests an age of 609 ± 40 ka (Wagner et al. 2010). Developmental age Adult. Presumed sex Presumed male, based on large size. Brief anatomical description When the mandible was found it was in two pieces having been broken at the symphysis (in Schoetensack 1908 it is illustrated as separate right and left sides of a mandible) and some perisymphyseal bone has been lost. Most of the lower teeth are preserved in good condition. The left coronoid process is broken at the tip and the left mandibular condyle is deformed. Announcement Schoetensack 1908. Initial description Schoetensack 1908. Photographs/line drawings and metrical data Schoetensack 1908. Detailed anatomical description Schoetensack 1908, Mounier et al. 2009.

Initial taxonomic allocation *Homo heidelbergensis*. Taxonomic revisions *Homo erectus* (Hrdlička 1927), *Homo neanderthalensis* (Hublin 1998), *incertae sedis* (Hublin 2009). Current conventional taxonomic allocation *H. heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance The oldest hominin fossil specimen known from north-central Europe. As it is the **holotype** of *H. heidelbergensis*, any specimens allocated to that hypodigm must be compatible with being included in the same species as the Mauer mandible. Mounier et al. (2009) provide the most detailed morphological and taxonomic analysis and consider the mandibles from **Arago**, **Montmaurin**, **Sima de los Huesos**, and **Tighenif** to be conspecifics of the Mauer mandible. While some argue that the Mauer mandible represents an early stage in the **accretion model** for the origin of *Homo neanderthalensis* (e.g., Arsuaga et al. 1997, Humphrey et al. 1999, Carbonell et al. 2005), others see no evidence of the derived morphology seen in later Neanderthals (e.g., Rightmire 2008, Mounier et al. 2009). If there is sufficient evidence in favor of the former view, then *H. heidelbergensis* would be a **junior synonym** of *H. neanderthalensis*. However, if the latter view prevails, then *H. heidelbergensis* would have priority as the name of the taxon that gave rise to both *H. neanderthalensis* and *Homo sapiens*, or to just *H. neanderthalensis*. Location of original **Geologisch-Paleontologisch Institute, University of Heidelberg**, Heidelberg, Germany.

MAVT Abbreviation for the Maoleem Vitric Tuff. See **BOU-VP-12/130**.

Max Planck Institute for Evolutionary Anthropology (or MPI-EVA) Founded in 1997, this research institute is one of many sponsored by the Max-Planck-Gesellschaft zur Förderung der Wissenschaften (Max Planck Society for the Advancement of Science), a nonprofit organization funded in large part by the German federal and state governments. The MPI-EVA aims to investigate the history of humankind with the help of comparative analyses of different genes, cultures, cognitive abilities, languages, and social systems of past and present human populations as well as those of primates closely related to human beings. The institute currently comprises five departments (listed here with their current heads): Primatology (Christophe Boesch), Developmental

and Comparative Psychology (Michael Tomasello), Linguistics (Bernard Comrie), Evolutionary Genetics (Svante Pääbo), and Human Evolution (Jean-Jacques Hublin). The MPI-EVA funds many research projects, including field sites investigating three of the four great ape species, and studies of captive populations of all four great ape species at the Wolfgang Koehler Primate Research Center, the Neandertal Genome project, archeological excavations (e.g., Jebel Irhoud, Willensdorf II, Jonzac), and isotope analyses to reconstruct diet and environment (in collaboration with the **Ancient Human Occupation of Britain Project**). What makes the MPI-EVA unique is that these diverse perspectives – behavioral, ecological, cognitive, cultural, linguistic, and genetic – are all housed under one roof. The MPI-EVA has close connections with local research institutions including the University of Leipzig, and together with the University of Leipzig the MPI-EVA runs the Leipzig School of Human Origins, an International Max Planck Research School. Contact address Deutscher Platz 6, 04103 Leipzig, Germany. Website www.eva.mpg.de/english/index.htm.

maxillary fossula The name used by Yoel Rak (1983, Fig. 16, p. 135) to describe the small hollowed area on the face of *Paranthropus robustus* at the inferomedial corner of the **maxillary trigon**. It is what remains of the **maxillary furrow** after the anterior advance of the infraorbital region in *P. robustus*, and it contrasts with the morphology seen in *Australopithecus africanus*.

maxillary furrow A modification of the canine fossa seen in archaic hominin taxa (e.g., *Australopithecus africanus*) that have **anterior pillars**. It is a sulcus that extends from the infraorbital foramina inferiorly to the alveolar process. It runs parallel and posterior to the superior end of the anterior pillar (e.g., MLD 6).

maxillary sulcus The name given by Franz Weidenreich (1943) to the hollowed area in the face of *Homo erectus* between the **canine eminence** and the zygomatic process of the maxilla.

maxillary trigon The name used by Yoel Rak (1983, Fig. 16, p. 135) to describe the triangular area of the mid-face of *Paranthropus robustus*. Its long sides are the **anterior pillars** medially and

the **zygomaxillary step** laterally and its base is the **zygomaticoalveolar crest**. There is often a hollowed area, the **maxillary fossula**, at the inferomedial corner of the maxillary trigon.

maxillary visor *See* facial visor.

maximum life span The greatest age to which a member of a group or species has lived. Carey and Judge (2000) is an excellent online source for the data that are available for comparative maximum life spans across many taxa. For modern humans the documented maximum life span was for Jeanne Calment, who was born on February 21, 1875 in Arles, France and died on August 4, 1997 at the age of 122 years and 164 days (Robine and Allard 1995). For nonhumans the maximum life span is much harder to obtain. While zoos keep good demographic records, the maximum life span for zoo animals can typically only be obtained if the animals were born in captivity. Further, animals that are born in captivity and live their entire lives in captivity can be subject to very different hazards of death compared to animals living in the wild. To measure maximum life span in the wild an observer must be present for both the birth and death of an individual animal and must be able to identify the animal as a unique individual so that the birth and death can be linked. A further complication is that the maximum life span represents an extreme event, so it is sample-size-dependent. In paleodemography and paleoanthropology the measurement of maximum life span is extremely difficult. This is because (a) ages at death must be estimated rather than observed by linking birth and death records, (b) ages at death for the old are particularly difficult to estimate, and (c) sample sizes are typically small, so the probability of someone dying at the maximum lifespan is extremely small. Because of these problems it is more common in paleodemographic studies to model **survivorship** (or mortality) and to determine the maximum life span from the model. Given the difficulties both in determining ages at death for fossils and the widely varying sample sizes for various paleoanthropological taxonomic units, any statements about the evolution of maximum life span are highly speculative.

maximum likelihood A method of inferring phylogenetic relationships. Unlike **cladistic analy-**

sis, the maximum likelihood method requires an explicit model of character evolution to be specified. It then calculates the probability or likelihood of phylogenetic trees given the observed character state data set and the chosen model of character evolution. The preferred phylogenetic tree is the one with the highest likelihood. Maximum likelihood is extensively used in DNA-based phylogenetic research but has had limited impact in paleoanthropology. This difference in popularity is due to a difference in availability of widely accepted models of character evolution for DNA and morphology. Several such models have been developed for DNA, including the Jukes–Cantor Model, which simply specifies an expected substitution rate, and the Kimura Model, which differentially weights transitions and transversions (*see* **mutation** for explanations). In contrast, so little is known about the processes of morphological evolution that a widely accepted model of morphological character evolution has yet to be developed.

MCBA Abbreviation for measured crown base area. This is measured from an enlarged print of a photograph taken from above the tooth with the optical axis of the camera perpendicular to the plane of the tooth cervix (e.g., Wood and Abbott 1983, pp. 199–200). This provides a two-dimensional measure of the total occlusal area of a tooth crown. When this estimate is corrected for interstitial wear it is abbreviated as “MCBA(C).” These raw or corrected measurements are always less than estimates of occlusal area that are computed from linear measures of the maximum breadth (buccolingual or B/L) and maximum length (mesiodistal or M/D) of a tooth crown.

MCBA(C) *See* MCBA.

Meadura One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area** in Ethiopia.

mean age at death (or MAD) The average age at which individuals die. In the analysis of a **stationary population** the mean age at death is equal to the **life expectancy** at birth. The inverse of the average age at death in a stationary population is equal to the **crude death rate** as well as the **crude birth rate**. For example, if the average age at death (life expectancy at birth) in a life table

is 25 years then the crude birth and death rates are 1/25, or 0.04. In a (stationary) hazards analysis the mean age at death is the integral of the product of age at death with the probability density function of death at that age. Consequently, the probability density function “averages” across all ages at death. More simply, the mean age at death can be found as the integral of the survivorship function.

mean age in the living The mean age in the living is the average age from a census or the average age among the living that is implied by the deaths analyzed in a **life table** or a hazards analysis. In the life table of a **stationary population** the average age of the living population is found by summing the product of the **living age distribution** with the mid-point of the age intervals. In a stationary hazards analysis the mean age in the living is the integral of the product of age and survivorship divided by the integral of survivorship. Nancy Howell (1982) has used arguments based on the implied age distribution in the living to argue that there may be deficits in paleodemographic analyses.

Mechta-Afalou *See Iberomaursian.*

Meckel's cartilage The cartilage of the first branchial (or pharyngeal) arch. Described by Johann Meckel in 1805. It does *not* develop into the mandible; it provides the cartilaginous scaffold around which the mandible develops. *See also branchial arches.*

medial longitudinal arch The medial longitudinal arch is a mainly hard-tissue structure consisting of the calcaneus, talus, navicular, cuneiforms, and the medial three pedal rays. It is higher than the lateral longitudinal arch, causing the medial side of the foot to be elevated off the ground during the stance phase of walking. Although the bones produce the shape of the arch, soft-tissue structures stabilize and support it. These include the calcaneonavicular (spring) ligament, the long plantar ligament, and the plantar aponeurosis. Intrinsic muscles of the foot, fibularis longus, tibialis anterior, and tibialis posterior are all instrumental in supporting the medial longitudinal arch.

median lingual accessory cusp *See tuberculum intermedium.*

median ridge An enamel crest present with variable degree of expression in the central part on the lingual face of the anterior teeth, that runs from the **cingulum** towards the incisal edge or, in the case of canines, to the cusp tip. In the postcanine teeth the median ridge indicates the most prominent enamel ridge running down from the cusp tip. *See essential crest.*

Medieval Warm Period *See Holocene.*

Mediterranean climate In contrast to **monsoonal** climates, Mediterranean climates receive predominantly winter-season precipitation. Mediterranean climates around the world are characterized by high floral diversity and a large number of **endemic** species. The northern coast of Africa has a Mediterranean climate that receives winter precipitation supplied by the mid-latitude westerly winds (Nicholson 2000). Inter-annual to inter-decadal variability is influenced by regional and global atmospheric connections associated with the North Atlantic Oscillation (Hurrell 1995) and to a variable extent by the **El Niño Southern Oscillation** (Knippertz et al. 2003). Greenland ice core data indicate these patterns of variability persist for several hundred years (Dansgaard et al. 1993).

Medjez (Location approximately 36°11'N, 5°42'E, Algeria) History and general description Sometimes known as Medjez II, this open-air Mesolithic archeological site east of Sétif and 4 km/2.5 miles north of El Eulma contains assemblages identified to the Upper Capsian tradition. The site was first professionally excavated by Camps (1974) and has been described as a typical example of a Capsian *escargotières*, or a site characterized by large numbers of whole and crushed land snail shells and large quantities of ash and fire cracked rock (Lubell 2001). Temporal span and how dated? **Radiocarbon dating** suggests a range of 8.9–6.5 ka, but the exact age of the site is controversial due to a disparity in radiocarbon dates determined by two different laboratories (Lubell et al. 1992). However, the artifact assemblage from Medjez does match a technological transition known from other Algerian sites to date to *c.*8000 years BP (Lubell 2001, Sheppard 1987). Hominins found at site A minimum number of 15 hominin individuals, including four adult and seven neonate skeletons, were recovered by Camps-Fabre (1975) and three adults and one infant from earlier unsystematic excavations were reported by Lubell

(2001). The hominin remains were deliberately buried in a range of flexed and unflexed positions, many in association with red ochre and other grave goods (Haverkort and Lubell 1999). The Iberomaurusian cultural practice of incisor evulsion is present in the Upper Capsian culture at Medjez, albeit with more variation in the specific teeth removed than in the earlier culture. Archeological evidence found at site Camps-Fabrer (1975) divided Medjez into four arbitrary units, all which were assigned to the Upper Capsian tool tradition. However, this interpretation has been challenged by Rahmani (2004) on the basis that two of the units lack pressure-flaked stone tools. Faunal remains include the aforementioned ubiquitous land snail shells and many vertebrate species, with larger examples including hartebeest, gazelle, and Barbary sheep. Key references: Geology, dating, and paleoenvironment Lubell et al. 1992, Rahmani 2004; Hominins Haverkort and Lubell 1999, Lubell 2001; Archeology Camps 1974, Camps-Fabrer 1975, Lubell 2001, Sheppard 1987.

megadont (Gk *megas*=great and *odont*=tooth) This term, that literally means having “very large teeth,” is used in paleoanthropology to refer to the size of the crowns of the postcanine teeth (i.e., premolars plus molars). The term was probably first used by William Flower in relation to his “dental index” that related the length of the postcanine tooth row to the distance between basion and nasion. If the index was more than 44 then Flower suggested such individuals should be referred to as “megadont.” Phillip Tobias reintroduced the term to describe the very large postcanine teeth of *Paranthropus boisei* (i.e., “a megadontic line (*A. boisei*) emerged with specialised dentition”, Tobias 1967, p. 243). In 1988 Henry McHenry introduced the “megadontia quotient” (or MQ) to relate postcanine tooth area to estimated body mass. By analogy with the **encephalization quotient**, $MQ = \frac{\text{observed tooth area}}{12.15 \text{ (body mass)}}$, where “observed tooth area” is the sum of the areas of the P_4 , M_1 , and M_2 (McHenry 1988, p. 144). The specifics of this formula are derived from data used to regress postcanine tooth area against estimated body mass (McHenry 1984, Table 1, p. 299 and Fig. 1, p. 300).

megadontia *See* megadont.

megadontia quotient *See* megadont.

megadroughts Droughts are periods of below-average rainfall and when such dry intervals last decades or more they are referred to as megadroughts. Drill cores from **Lake Botumtwi** and **Lake Malawi** indicate that periods of severe aridity between 135 and 75 ka were marked by 95% reduction in lake volume. This is notably drier than the conditions reconstructed for the **Last Glacial Maximum**, previously identified as a dry interval in the Late **Pleistocene**. Following the 135–70 ka extreme dry period, there was a shift to wetter climates around 70 ka. While the extreme arid period may have restricted the total area available for year-round habitation, the following wet interval may have facilitated the expansion and migration of early modern human populations (Scholz et al. 2007).

megafauna (Gk *megas*=large and L. *fauna*=in Roman mythology the sister of the Faunus, the god of nature) Literally “large animals,” but usually interpreted as animals with an adult body mass of more than 44 kg (approximately the size of a large Labrador retriever dog). Defined in this way, in the **Plio-Pleistocene** faunas of Africa the category megafauna would include not only elephants and rhinoceros, but also lions, Grant’s gazelles, and warthogs. In the more temperate faunas of Pleistocene Europe megafauna would include deer, boar, and bear. With an average body weight of around 67 kg **modern humans** are also megafauna, but they illustrate the problem of this category in an evolutionary perspective since the some of the earlier hominins almost certainly did not have a body mass over 44 kg and some populations of contemporary modern humans would not qualify, either.

Meganthropus (Gk *megas*=great and *anthropos*=human being) This genus name was introduced and used informally in the early 1940s by Ralph von Koenigswald for the **Sangiran D** (1941) mandible. The genus name was used by other researchers (e.g., Weidenreich 1942, 1944), but the correct citation for the first use of this genus name is von Koenigswald (1950) for it was in this paper that he formally introduced the species name *Meganthropus palaeojavanicus*. *Meganthropus* fell into disuse because researchers judged it to be a junior synonym of either *Homo erectus* (e.g., Le Gros Clark 1955, p. 155) or *Paranthropus* (e.g., Robinson 1954, p. 36).

Meganthropus A See Sangiran 6a.**Meganthropus africanus Weinert, 1950**

(Gk *me-gas*=great and *anthropos*=human being, and L. *africanus*=pertaining to Africa) The binomial introduced by Hans Weinert (1950) for the taxon represented by the maxilla found by Ludwig Kohl-Larsen in 1939 at the site then called Garusi and now called Laetoli. John Robinson (1953a, 1954) suggested that the Garusi maxilla “cannot be distinguished from the Sterkfontein apeman” (Robinson 1954, p. 195), but Remane (1954) took the view that the premolar morphology of the Garusi maxilla was more primitive than that of the Sterkfontein hominin, prompting him to “doubt whether the more pongid premolars of *Meganthropus africanus* are the same species as *Plesianthropus*” (*ibid.*, p.126). Most researchers now regard *Meganthropus africanus* as a junior synonym of *Australopithecus afarensis*.

Meganthropus B See Sangiran 8**Meganthropus palaeojavanicus von Koenigswald in Weidenreich, 1945**

(Gk *me-gas*=great, *anthropos*=human being, *palaios*=ancient, and L. *javanicus*=from Java) The taxon *Meganthropus palaeojavanicus* was mentioned by Weidenreich (1942, p. 62), who later referred to it as “von Koenigswald’s *Meganthropus palaeojavanicus*” (Weidenreich 1944, p. 2). In his 1945 monograph Weidenreich explains that the name *M. palaeojavanicus* was used in a letter dated January 15, 1942 sent to him by W.C.B. Koolhoven, Director of the Geological Survey of the Netherlands Indies, in which it was explained that it was von Koenigswald’s intention that the “1939” and the “1941” mandibles should both be given the name *Meganthropus palaeojavanicus*, the former mandible belonging to a female and the latter to a male of that taxon. However, von Koenigswald did not formally propose it as a hominin taxon until 1950 (von Koenigswald 1950). Arguably, the first formal attempt to justify the new taxon was made by Weidenreich (1945) so strictly speaking his name should be attached to the taxon, but von Koenigswald’s name was associated with it by Weidenreich, so *de facto* the taxon has become known as *Meganthropus palaeojavanicus* von Koenigswald, 1950. This is all theoretical for the species name is rarely, if ever, used now because most researchers (e.g., Le Gros Clark 1955, p. 155) regard *M. palaeojavanicus* as a junior synonym of *Homo*

erectus. John Robinson retained the species name, but suggested that it be transferred from *Meganthropus* to *Paranthropus* (e.g., Robinson 1954, p. 196), but von Koenigswald (1955) insisted that differences in the relative size of the mandibular premolars and in the details of their cusp morphology precluded *M. palaeojavanicus* being included in *Paranthropus*. First discovery Sangiran Mandible D (also known as the “1941” mandible). Holotype As above. Main site Sangiran. *See also* *Meganthropus*.

meiosis (Gk *meiosis*=diminution) The process of cell division in sexually reproducing organisms that reduces the number of chromosomes in reproductive cells by half to create haploid gametes (i.e., the egg and sperm). It is also known as reduction division.

Melanesia (L. *melan* from Gk *melas*=black, and Gk *nesos*=island, literally “black islands”) A group of islands in the southwest Pacific that extends southwest from Fiji to the Admiralty Islands. *See also* Oceania, peopling of.

melanin (L. *melan* from Gk *melas*=black) A dark organic pigment that gives brown coloration to skin, hair, feathers, scales, eyes, or other tissues. In hominins, melanin helps protect the skin from damage by ultraviolet radiation. *See also* pigmentation.

Melka Kontoure See Melka Kunturé.

Melka Kunturé (Location 8°42’N, 38°34’E, Awash River, Ethiopia; etym. unknown; alternate spellings: Melka Kunture, Melka-Kunturé, Melka Kontoure, and Melka Kontouré) History and general description Melka Kunturé is a complex of sites along approximately 6 km/3.7 miles of outcrops exposed along either side of the Awash River in Ethiopia. The complex cut-and-fill sequence of tuffaceous alluvial sediments was first explored and excavated by Jean Chavaillon, Marcello Piperno, and Maurice Taieb in the 1960s. Typologically, the sites range from Early Stone Age (Oldowan) to Later Stone Age. The site is currently a museum, housing a small permanent collection of artifacts with several excavations still open for viewing, and a detailed website is maintained (geo-server.itc.nl/melkakunture/index.asp). Temporal span and how dated? The numerous sites at Melka Kunturé remain poorly dated. Incompletely

published **potassium-argon dating** estimates suggest it is <1.8 Ma and a reversed to normal polarity shift in the sediments is most likely the Brunhes-Matuyama boundary (i.e., c.780 ka). **Hominins found at site** Five cranial fragments from more than one individual, two mandibular fragments, a distal left humerus, and a possible hominin phalanx from three excavations at sites (Gomboré II, Garba III, and Garba IV) within the Melka Kunturé site complex have been attributed to *Homo erectus*. **Archeological evidence found at site** Archeological sites have been identified at more than 13 localities in the Melka Kunturé area, each locality being named after a smaller tributary that drains into the Awash River. Sites at each location are designated by roman numerals with different strata within an excavation by capital letters. The primary localities are Garba (**Developed Oldowan**, a long sequence of **Acheulean**, and perhaps **Middle Stone Age** strata), Gomboré (Oldowan and Acheulean assemblages), Karre (Oldowan), and Wofi (Middle and Later Stone Age artifacts). More than 35,000 artifacts have been recovered from more than 500 m² of excavation, although many of the assemblages have been reworked by water. The stone artifacts were made of various locally available lavas such as basalt and trachyte, as well as obsidian derived from Balchit, 7 km/4.3 miles north of Melka Kunturé. Obsidian use is unusual in the Early Stone Age sites, and is a distinguishing feature of the Melka Kunturé assemblages. The only site where fauna are abundant is Garba IV, and the Garba IV assemblage includes rare taxa such as carnivores and primates, and the presence of *Pelorovis turkanensis brachyceras* and *Metridiochoerus modestus* suggest an Early Pleistocene age. The lack of tragelaphine and near lack of reduncine bovids, combined with the dominance of alcelaphine and antilopine bovids, suggest a dry, open environment at Garba IV. Pollen preserved at Gomboré I include evidence of a thicket or scrub vegetation with a nearby forest. Key references: **Geology, dating, and paleoenvironment** Bonnefille 1976, Chavaillon et al. 1979, Westphal et al. 1979, Chavaillon and Piperno 2004; **Hominins** Condemi 2004; **Archeology** Hivernel-Guerre 1976, Chavaillon and Piperno 2004, Negash et al. 2005, Piperno et al. 2008.

member A physically distinct subdivision of a geological formation (e.g., the Okote Member of the **Koobi Fora Formation**).

membranous labyrinth (L. *labyrinthus*=maze and *membrana*=skin or pliable layer) Endolymph-filled connective tissue sac suspended in perilymph and lying within the **bony labyrinth**. It has three parts, anteriorly the duct of the cochlea, next the saccule and utricle, and posterosuperiorly the semicircular ducts. The cochlear duct communicates with the saccule and the three semicircular canals with the utricle. *See also* **bony labyrinth**.

meme A term first used by Richard Dawkins (1976, p. 192) in the *Selfish Gene* to describe a “unit of cultural transmission,” which he viewed as “a new kind of replicator.” For Dawkins, memes were unique to modern humans and “were analogous to genetic transmission in that, although basically conservative, they can give rise to a form of evolution” (*ibid*, p. 192). For Dawkins, examples of memes include, “tunes, ideas, catchphrases, clothes fashions, ways of making pots or of building arches” (*ibid*, p. 192). And so, “Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called **imitation**” (*ibid*, p. 192). *See also* **imitation**.

memory (L. *memor*=to be mindful) Among contemporary cognitive scientists, memory is not viewed as a unitary psychological mechanism, but as a multi-faceted faculty that includes different memory systems (Schacter and Tulving 1994, Tulving 1972). Specifically, cognitive neuroscientists have demonstrated that there are at least two broad types of memory systems: long-term memory and short-term or **working memory**. Each of these systems has more specialized memory subsystems that include episodic or biographic memory and semantic or factual memory systems. It is widely accepted that all mammals and many birds have both long- and short-term memory. However, some have argued that certain memory subsystems such as episodic memory (Tulving 2005) and working memory (Coolidge and Wynn 2007) are unique to modern humans and are not shared with other mammals or other primate species including the great apes. However, this view is not widely accepted among comparative psychologists (Tomasello and Call 1997).

memory span This is a measure of an individual’s short-term memory, generally tested by

how many numbers or words an individual can remember immediately after seeing a list. A variety of animals have shown competency in delayed match-to-sample tasks involving sounds, objects, and two-dimensional images. In all these tasks, the general consensus is that the short-term memory span of both modern humans and nonhuman animals (birds and primates) is about five to seven items (Terrace 1987, 2005).

menarche (Gk *men*=month and *arkhe*=beginning) A **life history** variable that is the time of onset of the first menstrual period in females and since it represents the beginning of near-monthly cycles of egg release from the ovary it also represents the beginning of **fertility**. However, for variable lengths of time following menarche a female's cycles are usually irregular and can be anovulatory. The onset of menarche is influenced by a number of factors; nutritional status is thought to be particularly important and social factors such as the presence of a father or adult male have also been proposed to play a role. Over the past 200 years, statistics show a trend toward decline in the average age at menarche in various modern human populations across the world. The mechanism behind this apparent trend is debated. While some scholars argue that earlier attainment of a certain percentage of body fat is the main reason for the pattern, others have more recently argued that an early age at menarche is in fact a temporally old hominin trait. These scholars argue that high levels of disease and infection associated with increased population sizes worked in the past to hold off the beginning of regular menstrual cycling and that only recently, with improvements in nutrition and health care, have modern human populations started to move back to the younger age at menarche. Menarche generally occurs earlier in great apes and Old World monkeys than in modern humans, but there is some overlap among chimpanzees and modern humans (around 11 years of age). There is evidence to suggest that great apes and Old World monkeys, like modern humans, also pass through a phase of adolescent subfertility after menarche occurs.

Mendelian inheritance *See Mendelian laws.*

Mendelian laws These laws of inheritance were established by Johann Gregor Mendel, an Augustinian monk who experimented with simple

traits in pea plants. Mendel's work was initially published in 1865 and 1866 but was largely ignored until the early 20thC. As a result of his experiments, Mendel came to two conclusions that are now known as Mendel's laws. The first law is the law of segregation, which states that during **gamete** formation the two **alleles** of a **gene** segregate so that each gamete receives only one allele. This law is true because of the mechanism of **meiosis** where the pairs of chromosomes are separated so that each gamete receives one of each type of chromosome. The second law is the law of independent assortment, which states that alleles from different gene loci assort independently during gamete formation. Mendel examined simple traits that were located on different chromosomes so the second law was true in all of his experiments. However, the second law is not true if two genes are located close together on the same chromosome. In this case, the alleles may not sort independently because of **linkage**. In general, genes on the same chromosome that are more than 50 centimorgans apart will be unlinked, and thus for these genes the second law will apply. *See also linkage disequilibrium.*

meningeal arteries *See meningeal vessels.*

meningeal vessels (Gk *menin*x=membrane) The meningeal vessels (i.e., arteries and veins) run between the inner, or **endocranial**, surface of the **cranial vault** and the **dura mater** that lines it. They either supply blood to (the meningeal arteries) or drain blood from (the meningeal veins) both the cranial vault and the dura mater. They leave vascular impressions on the endocranial surface of the cranial vault and the pattern of these vascular markings has been explored for its taxonomic utility as well as to make inferences about the relative size of the components of the **cerebral hemispheres**. *See also middle meningeal vessels.*

meninges (Gk *menin*x=membrane) The term refers individually or collectively to the three membranes (the pia mater, the arachnoid mater, and the dura mater) that cover the components (i.e., the brain, the optic nerve, and the spinal cord) of the central nervous system. The innermost layer, the pia mater, adheres closely to the surface of the brain. The middle layer, the arachnoid mater, is separated from the pia by the **subarachnoid space** and from the outer dura by the subdural space.

The outer dura mater has two layers: the fibrous inner meningeal layer and the outer more vascular and osteogenic endosteal layer. The inner meningeal layer of the dura mater has two prominent folds. The **falx cerebri** and **falx cerebelli** in the sagittal plane separate the cerebral and cerebellar hemispheres, respectively, and the approximately horizontal **tentorium cerebelli** separates the posterior cranial (also called the cerebellar fossa) from the rest of the cranial cavity. The **dural venous sinuses** (e.g., superior sagittal, transverse, sigmoid, occipital, and marginal) are endothelium-lined spaces between the two layers of the dura. The endosteal layer of the dura is continuous at the foramina and sutures with the periosteum (or pericranium) that covers the outer surface of the cranium. The pia and arachnoid are derived from ectoderm and are called the **leptomeninges**; the dura mater develops from mesoderm and is also called the **pachymeninx**.

menopause (Gk *men*=month and *pausis*=pause) This life history variable is the time when ovulation ceases and it marks the permanent end of female reproductive fertility. In modern human females this occurs, on average, around 50 years of age, although substantial within- and between-population variation exists. Normal menopause is initiated when stores of oocytes (egg cells stored in the ovaries) built up before birth and depleted through a combination of monthly release, degeneration, and resorption diminish to the point where the hormones needed to initiate the monthly cycle are no longer stimulated. While other primates may also experience an end to fertility before death, modern humans differ in that the majority of populations now vigorously outlive their fertility by a significant margin. The extension of the life span beyond menopause in modern human women, compared to nonhuman primates and most other mammals, has been attributed to a number of factors. *See also* **grandmother hypothesis**.

mental protuberance (L. *mentum*=chin) A midline projection of bone near the base of the mandible on the external surface of the **symphysis**. For a mental protuberance to be classed as a **true chin** there must be a depression, called an *incurvatio mandibulae*, between it and the **alveolar process** superiorly. *See also* **mandible**.

mentum osseum *See* chin.

meristic (Gk *meristos*=divided) The term refers to morphology that develops from craniocaudally or mesiodistally serially arranged segmental units as well as to the number or position of those segmental structures. The **vertebral column** and the **dentition** are examples of meristic structures.

meristic variation (Gk *meristos*=divided) Variation in the number or nature of serial structures such as vertebrae or teeth. Additional vertebrae, sacralization of the fifth lumbar vertebra, additional teeth, etc., are all examples of meristic variation.

Mesgid Dora Collection area within the **Woranso-Mille study area**, Central Afar, Ethiopia.

mesial accessory cusplule *See* mesioconulid.

mesial accessory tubercle A generic term to indicate an accessory cusp on the **mesial marginal ridge** of a postcanine tooth crown; on a mandibular molar the equivalent accessory cusp is usually referred to as the **mesioconulid**. Several accessory tubercles have been identified on, or adjacent to, the **mesial marginal ridge** on the mesial portion of the occlusal surface of a maxillary molar. *See also* **mesial paracone tubercle**; **lingual paracone tubercle**; **protoconule**; **epicoconule**; **mesiostyle**.

mesial fovea (maxillary) *See* fovea anterior (maxillary).

mesial marginal accessory tubercle *See* mesial accessory tubercle.

mesial marginal ridge A crest of enamel that delineates the mesial border of the lingual face of an anterior tooth or the mesial border of the occlusal surface of a postcanine tooth crown. In a maxillary postcanine tooth crown it is an enamel crest running between the **protocone** and the **paracone**; in a mandibular postcanine tooth crown it is an enamel crest running between the **protoconid** and the **metaconid** [syn. anterior transverse crest, anterior trigon crest, crista nova, mesial margocrista (-id), precingulum, precingulid, protoloph].

mesial margocrista (-id) A term used by Schwartz and Tattersall (2002) for an enamel crest

on the anterior teeth more commonly referred to as the mesial marginal ridge. *See also* **mesial marginal ridge**.

mesial paracone tubercle A term used by Kanazawa et al. (1990) for an **accessory cusp** located on the occlusal surface of a maxillary molar on the **mesial marginal ridge** mesiolingual to the **paracone**. *See also* **mesial accessory tubercle**; **mesiostyle**.

mesial pit (mandibular) *See* **fovea anterior (mandibular)**.

mesial pit (maxillary) *See* **fovea anterior (maxillary)**.

mesic (Gk *mesos*=middle) An environment or habitat that is moist.

mesio Buccal cusp A term sometimes used for the primary cusp on a maxillary molar called the **paracone**, and for the primary cusp on a mandibular molar called the **protoconid**. *See also* **paracone**; **protoconid**.

mesioconulid A small **accessory cuspule** on the **mesial marginal ridge** of a mandibular postcanine tooth crown.

mesiolingual cusp A term sometimes used for the primary cusp on a maxillary molar called the **protocone**, and for the primary cusp on a mandibular molar called the **metaconid**. *See also* **protocone**; **metaconid**.

mesiostyle A term introduced by Vanderbroek (1961, 1967) and used by Grine (1984) for a small enamel feature on the **mesial marginal ridge** close to the tip of the **paracone** on the occlusal surface of a maxillary postcanine tooth. *See also* **parastyle**.

mesoconid A term used by Weidenreich (1937) for what most researchers refer to as the **hypoconulid**. *See* **hypoconulid**.

mesostyle A term used by Pilbrow (2003) for an **accessory cusp** on the buccal face of a maxillary molar, between the **paracone** and the **metacone**.

messenger RNA *See* **ribonucleic acid**.

meta-memory The ability to reflect on one's own knowledge or memory. This could include a reflection upon **semantic** facts such as "do I *know* the capital of the United States?" or episodic memory, such as "have I ever *experienced* meeting someone famous?" Studies with primates (rhesus macaques, capuchin monkeys, and the great apes) have suggested that meta-semantic-memory is shared and is, perhaps, phylogenetically ancient (Hampton 2001, Fujita 2009, Kornell et al. 2007, Call and Carpenter 2001). However, various authors have argued that meta-episodic-memory is unique to modern humans. This implies that other animals are unable to declaratively state or "re-experience" the past, an essential feature of all episodic memories (Carruthers 2006, Tulving 2005).

metacentric *See* **chromosome**.

metacone (Gk *meta*=behind or beyond; *konos*=pine cone) One of the terms proposed by Osborn (1888) for the main cusp of mammalian molar teeth. It refers to the main cusp distal to the **paracone** on a maxillary (upper) molar tooth crown. It is one of the components of the **trigon** (syn. **distocone**, **distobuccal cusp**, **tuberculum posterium externum**).

metaconid (Gk *meta*=behind or beyond and *konos*=pine cone) One of the terms proposed by Osborn (1888) for the main cusp of mammalian molar teeth. It refers to the main mesial cusp on the lingual aspect of a mandibular (lower) (hence the suffix "-id") molar tooth crown and to the lingual cusp of a bicuspid mandibular premolar. It was given its name because in the lower molar of a primitive mammal it is the cusp distal to, or behind, the **paraconid**. It forms part of the **trigonid** component of a mandibular postcanine tooth crown (syn. **epiconid**, **mesiolingual cusp**, **tuberculum anterium internum**).

metaconule A term introduced by Osborn (1907) for an **accessory cusp** on the crest between the **metacone** and the **protocone** of a maxillary molar crown. A synonym for this feature, a **plagioconule**, was introduced by Vanderbroek (1961, 1967) and has since been used by Grine (1984). **Metaconule** has been used by some researchers to refer to a different enamel feature most researchers refer to as the **C5** (e.g., Harris and Bailit, 1980). *See* **C5**; **distal accessory tubercle**.

metaconulid *See* **tuberculum intermedium**.

metaquartzite *See* quartzite.

metastyle A term introduced by Osborn (1892) for an **accessory cusp** distolingual to the metacone on the crown of a maxillary molar. It is equivalent to the structure other researchers (e.g., Grine 1984) refer to as the distostyle.

metastylid A term used by Schwartz and Tattersall (2002) for an **accessory cusp** on the occlusal surface of a mandibular molar that most other researchers refer to as **tuberculum intermedium** or **C7**. *See* **tuberculum intermedium**.

methylation The attachment of a methyl group to a substrate. In the genome, DNA methylation typically occurs at CpG sites (an acronym for cytosine-phosphate-guanine sites) and it can have a major impact on gene expression. For example, many genes have large clusters of CpG sites called “CpG islands” in or near the promoter region that influence gene expression. Methylation (or demethylation) of these sites is catalyzed by enzymes during certain phases of development and by environmental stimuli. In general, the addition of methyl groups turns genes “off.”

Metridiochoerus (Gk *metridios*=fruitful and *choerus*=pig) A genus of African Suidae which underwent an adaptive radiation in the later Pliocene and Pleistocene, during which five species arose and then went extinct. The earliest examples of *Metridiochoerus* are relatively small-bodied and have a more generalized dentition. Later examples follow the dental pattern of their modern descendant, the warthog *Phacochoerus*, in having extremely hypsodont third molars that outlast the other cheek teeth. The more derived *Metridiochoerus* species are large-bodied, having large heads with complex hypsodont third molars and, in mature individuals, no other cheek teeth. Canines were highly developed in some forms, particularly *Metridiochoerus compactus*, which had long, relatively straight canine teeth. *Metridiochoerus* fossils found at hominin sites have been used for biostratigraphy for the radiation of *Metridiochoerus* is relatively well dated at East African hominin sites, and the presence of particular species or evolutionary stages can be used to estimate the age of sites that are otherwise undatable.

Mezmaiskaya Cave (Location 44°10'N, 40°00'E, Northern Caucasus, Russia; etym. named

after the nearby village of Mezmay) **History and general description** This cave site was discovered in 1987 and excavations were directed by L. Golovanova until 1997. Well-stratified Middle and Upper Paleolithic deposits were recovered, recording the transition between these two periods. An infant *Homo neanderthalensis* was found in the lowest levels of the cave. **Temporal span and how dated?** **Radiocarbon dating** has suggested that the Upper Paleolithic layers date to *c.*32 ka, whereas the electron spin resonance spectroscopy dating shows that the Middle Paleolithic layers date to *c.*36–73 ka. The Neanderthal infant was directly dated using radiocarbon to 29 ka, in contrast to the date of the level in which it was found. **Hominins found at site** A partial skeleton of a neonate less than 7 months old was found in the lowest Middle Paleolithic layer, and included a damaged cranium and much of the upper body. This individual was the second Neanderthal to have its mitochondrial DNA examined. The size of the cranium allowed Ponce de León and colleagues to reconstruct Neanderthal life history as being as slow as that modern humans. Cranial fragments from a 1–2-year-old infant were recovered in a pit in the upper Middle Paleolithic layer. **Archeological evidence found at site** Four Middle Paleolithic layers attributed to the “East European Mousterian,” and three Upper Paleolithic levels, were recovered. Key references: **Geology, dating, and palcoenvironment** Ovchinnikov et al. 2000, Skinner et al 2005, Golovanova et al 1999; **Hominins** Ovchinnikov et al. 2000, Golovanova et al 1999, Ponce de León et al. 2008; **Archeology** Golovanova et al 1999.

MH Acronym for Malapa Hominin and used as the prefix for hominin fossils from the site of **Malapa** (e.g., MH1). *See* **Malapa**.

MH1 **Site Malapa**. **Locality** Excavation 3.3 m by 4.4 m in area and 3.5 m deep. **Surface/in situ** *In situ*. **Date of discovery** August 2008 and thereafter. **Finder** The first evidence of the MH1 associated skeleton (the right clavicle, U.W.88-1) was found by Matthew Berger on August 15, 2008. **Unit** N/A. **Horizon** Facies D. **Bed/member** N/A. **Formation** N/A. **Group** Malmani Subgroup. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** Flowstone (*c.*2.025 Ma). **Geological age** 1.95–1.78 Ma. **Developmental age** Juvenile. The second molars are in occlusion, the third molar crowns are close to crown complete with no radiological evidence of root formation, and the

distal humeral epiphysis is the only fused long-bone epiphysis. Presumed sex Male. Brief anatomical description This associated skeleton comprises much of a cranium with the right P³–M³, left I², and P³–M³, separate right I¹ and C, the right side of the mandibular body with M₁ and M₂ and an unerupted M₃, and the left C with an attached section of the corpus. The axial skeleton is represented by three cervical, three thoracic, and one lumbar vertebrae, plus vertebral and rib fragments. The pectoral girdle and the upper limb are represented by part of the right clavicle, all but the proximal epiphysis of the right humerus, the right proximal ulna, the right distal radial epiphysis, and the right third metacarpal, plus the proximal part of the right humeral diaphysis. The pelvic girdle and the lower limb are represented by substantial parts of the left ilium and ischium, part of the right ilium, the proximal half of the right femur minus the proximal epiphysis, most of the right tibia (but its attribution to MH1 is said to be “uncertain”) and the diaphyses of two left metatarsals. Endocranial volume *c.*420 cm³ (Berger et al. 2010). Announcement Berger et al. 2010. Initial description Berger et al. 2010. Photographs/line drawings and metrical data Berger et al. 2010. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus sediba*. Taxonomic revisions Its discoverers assign it to a new species, but the combination of its immaturity and the demonstration that it differs from samples of *Au. africanus* as opposed to the population from which those samples were drawn makes it possible that MH1 comes from a sample of *Au. africanus*. Current conventional taxonomic allocation *Au. sediba*. Informal taxonomic category Archaic hominin. Significance **Holotype** of *Au. sediba* and one of two associated skeletons attributed to that taxon. The researchers who have analysed this material suggest that despite its archaic hominin-like ankle and foot, it shares cranial (e.g., more globular neurocranium, gracile face), mandibular (e.g., more vertical symphyseal profile, a weak *mentum osseum*), dental (e.g., simple canine crown and small tooth crowns), and postcranial (e.g., **acetabulocrystal buttress**, expanded ilium, and short ischium) morphology with early and later *Homo* taxa. Its discoverers assigned it to a new species, but the combination of its immaturity and the demonstration that it differs from samples of *Au. africanus* as opposed to the population from which those samples were drawn makes it possible that MH1 comes from a sample of *Au. africanus*.

Location of original Bernard Price Institute for Palaeontological Research, University of the Witwatersrand, Johannesburg, South Africa.

MH2 Site Malapa. Locality Excavation 3.5 m deep and 3.3 m by 4.4 m in area. Surface/in situ *In situ*. Date of discovery September 2008 and thereafter. Finder The first evidence of the MH2 associated skeleton (the right humerus, U.W.88–57) was found by Lee Berger on September 4, 2008. Unit N/A. Horizon Facies D. Bed/member N/A. Formation N/A. Group Malmani Subgroup. Nearest overlying dated horizon N/A. Nearest underlying dated horizon Flowstone (*c.*2.025 Ma). Geological age 1.95–1.78 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description This associated skeleton comprises two maxillary teeth (left M^{2–3}), a fragment of the right side of the mandible with M₁–M₃, AND a fragment of the left side of the mandible with M₂–M₃. The axial skeleton is represented by one cervical and three thoracic vertebrae and rib fragments. The majority of the pectoral girdle and upper limb are preserved on the right side, including the scapula, humerus, radius, and ulna. On the left side all that remains is the proximal humerus and a few hand bones. The pelvis is represented by a fragment preserving both sides of the symphysis and part of the left ischiopubic ramus. The lower limb is represented by the proximal end and distal third of the right femur, the right distal tibia, a complete talus and calcaneum and phalanges of the right foot, and on the left side the proximal and distal fibula (but the latter’s attribution to MH2 is said to be “uncertain”) and part of the lateral tibial condyle. Announcement Berger et al. 2010. Initial description Berger et al. 2010. Photographs/line drawings and metrical data Berger et al. 2010. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus sediba*. Taxonomic revisions Its discoverers assign it to a new species, but the demonstration that it differs from samples of *Au. africanus* as opposed to the population from which those samples were drawn makes it possible that MH2 comes from a sample of *Au. africanus*. Current conventional taxonomic allocation *Au. sediba*. Informal taxonomic category Archaic hominin. Significance The **paratype** of *Au. sediba* and one of the two associated skeletons attributed to that taxon. The researchers who have analysed this material suggest that MH2 shares postcranial morphology (e.g., acetabulocrystal buttress, expanded ilium, and short ischium) with early and later *Homo* taxa, but the foot is acknowledged to be

like that of archaic hominins. **Location of original Bernard Price Institute for Palaeontological Research**, University of the Witwatersrand, Johannesburg, South Africa.

MHC Acronym for the **major histocompatibility complex** (*which see*).

MIC Acronym for **models of intermediate complexity** (*which see*).

microarray *See* array.

microcephaly (Gk *micro*=small and *kephale*=head) Refers in modern humans to a spectrum of pathologies, whose common denominator is that individuals have an unusually small brain for their body size. The defective growth of the brain results in a cranium with an unusually small head circumference. Some modern human microcephalic brains are relatively normally proportioned, but most have a disproportionately small cerebral cortex and hence a disproportionately large cerebellar cortex. Loss-of-function mutations at certain genetic loci have been identified that may cause primary microcephaly. Among them are *ASPM* and *microcephalin*, genes which show significant coding sequence changes in ape and human evolution. One interpretation of *Homo floresiensis* is that it samples a *Homo sapiens* population afflicted by a pathology that includes microcephaly, but if *H. floresiensis* samples a relic population of archaic or transitional hominins that at one time, or another, had undergone insular dwarfing, then its small brain would not be considered to be pathological.

micro-computed tomography (or micro-CT or μ CT) Based on the same principles as **computed tomography** (or CT), but using dedicated equipment (e.g., with a micro-focus X-ray tube) designed for the nondestructive testing of materials. The limit on sample size is in the order of 7 cm in diameter, and the spatial resolution ranges between 5 and 50 μ m. Micro-CT has been used to investigate the morphology of the enamel-dentine junction, enamel thickness, and enamel volume in single teeth. A special type of micro-CT, **synchrotron radiation micro-computed tomography** (or SR- μ CT) enables researchers to investigate microstructure of subsurface enamel. It makes use of synchrotron radiation, which is monochromatic and therefore it does not suffer from **beam-hardening**.

micro-CT *See* micro-computed tomography.

microfauna (Gk *micro*=small and L. *fauna*=in Roman mythology the sister of Faunus, the god of nature) In the context of **paleoanthropology** the term microfauna is usually used loosely to refer to *all* small animals, or *all* small vertebrates, or *all* small mammals (usually rodents and insectivores) found in a fossil **faunal assemblage**. Analyses of microfauna, principally small mammals (sometimes termed micromammals, i.e., mammals that weigh less than 1000 g) have contributed significantly to studies of **taphonomy**, **paleoenvironments**, and **biostratigraphy** relevant to human evolution. Note that the more common definition of microfauna outside of paleoanthropology is that the term applies to microscopic animals such as protozoa, bacteria, nematodes, etc., rather than to animals visible with the naked eye.

microlith (Gk *micro*=small and *lithos*=stone) Small **blades** or **flakes** that have been modified by removing even smaller flakes to form triangular or crescent-shaped pieces. One edge is typically blunted (or **backed**) for insertion into a prepared **haft** as part of a **composite tool**. Although abundant in some <40 ka artifact assemblages (e.g., **Enkapune ya Muto** in Kenya) similarly shaped, but larger, forms dating to the **Middle Pleistocene** are seen in some African sites (e.g., Ambrose 2002, Barham 2002a).

Micronesia (Gk *micro*=small and *nesos*=island, literally “small islands”) A group of small islands in the Pacific that extends east from the Phillipines; they all lie north of the equator. The islands in Micronesia include the Caroline, Gilbert, Mariana, and Marshall islands. *See also* **Oceania**, **peopling of**.

microsatellite (Gk *micro*=small and *satelles*=an attendant) Microsatellites, also known as short tandem repeats (or STRs) are repeated sequences that are between two and nine base pairs in length. The most common are dinucleotide, trinucleotide, and tetranucleotide repeats (i.e., two, three, and four base repeats, respectively). Some trinucleotide microsatellites have been linked to modern human diseases. These are called trinucleotide repeat disorders, and they include Huntington’s disease, fragile X, and myotonic dystrophy. Trinucleotide repeat disorders commonly have a threshold number

of repeats above which the microsatellite tends to become unstable and gains large numbers of repeats. A higher number of repeats above the threshold is correlated with more severe disease and an earlier age at onset. Microsatellites occur throughout the **genome** and are often highly **polymorphic**. This makes them useful for studies of recent modern human population history, for linkage analyses, and for individual identification. For example, Bowcock et al. (1994) used 30 microsatellites to investigate relationships among 10 modern humans. They found that microsatellite diversity reflected the geographic origin of each individual and was highest in Africa. In addition, the data could be used to generate a phylogeny of the relationships among individuals and of the different populations.

microstrain (or $\mu\epsilon$) *See* strain.

microstructure *See* enamel microstructure; incremental features.

microtomography *See* micro-computed tomography.

microwear *See* dental microwear; diet reconstruction; tooth wear.

Mid-Holocene Warm Event *See* Holocene.

Mid-Pleistocene transition (or MPT) Shackleton (1967) argued that the $^{18}\text{O}/^{16}\text{O}$ ratio of benthic foraminifera in the oceans would fall when ^{18}O -rich water was locked up in expanded ice caps and enlarged glaciers. Glaciation intensifies in the northern hemisphere (this is called the **Northern Hemisphere Glaciation**, or NHG) from the mid Pliocene to the late Pleistocene, but during this time the rate of reduction in the $^{18}\text{O}/^{16}\text{O}$ ratio is more pronounced in two periods, from *c.*3.2 to 2.7 Ma and from *c.*1.2 to 0.8 Ma. The second of these two shifts is called the MPT and the first earlier shift in the ratio of $^{18}\text{O}/^{16}\text{O}$ is called the **late Pliocene transition** (or LPT). The end of the MPT *c.*0.8 Ma marks the beginning of the *c.*100 ka-long climate cycles. *See* **astronomical theory**; **astronomical time scale**.

midbrain (ME *mitte* = middle and OE *braegen* = brain, most likely from the Gk *bregma* = the front of the head) The midbrain (or mesencephalon) is the middle of the three swellings, or vesicles, of

the developing neural tube that give rise to the brain. The midbrain houses important processing centers for coordinating movements of the head and saccadic eye (the superior colliculi) and auditory information (inferior colliculi). *See also* brain.

midcarpal joint The articulation between the proximal and distal carpal rows; it functions generally as a single ball-and-socket-like joint. The articulation between the capitate and lunate forms the crux of this joint, with the scaphoid (and os centrale if present) on the lateral side and the triquetrum-hamate articulation on the medial side. Together, these bones function to allow supination and pronation, adduction and abduction, and flexion and extension of the wrist. Each of these motions is accomplished via a complex set of movements among different combinations of carpals within the midcarpal joint (Moritomo et al. 2006).

midden An archeologically visible accumulation of household waste, which is usually a faithful record of daily activities. In many places, middens contain large numbers of shells, which make them alkaline and thus good preservers of organic remains.

Middle Awash *See* Middle Awash study area.

Middle Awash Research Project The Middle Awash study area extends along both sides of the modern Awash River in the Afar Depression of Ethiopia, north of Gewane town. Geological work in the study area began in 1938 with an Italian geological mission (Gortani and Bianchi 1973), but the first formal investigation of its paleontological potential was by Maurice Taieb, a French geologist who collected the first fossils and conducted pilot stratigraphic work, and this was followed by the work of the **Rift Valley Research Mission in Ethiopia** (or RVRME). In 1976, Antiquities Officer Alemayehu Asfaw discovered the study area's first hominin fossil in the Middle Pleistocene deposits at **Bodo** (Kalb et al. 1980, Conroy et al. 1978). The RVRME project ended in 1978 and the Middle Awash research project was initiated in 1981 under the leadership of the **Desmond Clark**; **Tim White**, and **Berhane Asfaw** (as a graduate student) joined Desmond Clark that year and went on to co-lead the project after Desmond Clark's retirement in 1986. A permit issued

by the Centre for Research and Conservation of Cultural Heritage (CRCCH) of the Ethiopian Ministry of Culture authorized the 1981 exploration of areas on both sides of the Awash River, north of Gewane and south of the Gona. Archeological excavations were undertaken at Bodo and **Hargufia**, radiometric dates for the area were determined and the first Pliocene hominins were recovered (Clark et al. 1984a). Planned Middle Awash field research was postponed from 1982 to 1990 while new Ethiopian antiquities legislation was formulated. With the new laws in place, the Middle Awash research project resumed fieldwork in 1990, concentrating on the better-known geological sequences east of the modern Awash River, but since 1992 the Middle Awash research project's primary attention has been directed to the western side of the modern Awash River. In addition to developing a comprehensive stratigraphic record for the basin the team's many significant fossil discoveries included the remains of *Ardipithecus ramidus* (White et al. 1994, 2009, WoldeGabriel et al. 1994), *Ardipithecus kadabba* (Haile-Selassie 2001, Wolde-Gabriel et al. 2001, Haile-Selassie et al. 2004), and *Australopithecus garhi* (Asfaw et al. 1999, de Heinzelin et al. 1999). The project's recent research publications include a monograph on the Acheulean of Bouri (de Heinzelin et al. 2000), monographs on *Ardipithecus kadabba* (Haile-Selassie and Wolde-Gabriel 2009) on the **Daka** *Homo erectus* calvaria (Gilbert and Asfaw, 2008), and papers on the **Asa Issie** *Australopithecus anamensis* (White et al. 2006b) and fossils from **Herto** representing some of the earliest evidence for *Homo sapiens* (White et al. 2003, Clark et al. 2003). The Middle Awash research project has arranged with the University of California Press to publish three more monographs on the Middle Awash during the next several years. Field research continues on both the eastern (e.g., Ala Kanasa, Andalee, **Gamedah**, **Maka**, and **Matabaietu**) and western (e.g., Hatayae Member, Esa Dibo, Bahroo Koma, upper Asa Issie, Burka, Guneta) sides of the study area. Stone tools belonging to the **Oldowan**, developed **Oldowan**, and a range of **Acheulean**, **Middle Stone Age**, and **Late Stone Age** archaeological technologies have been identified by the Middle Awash research project. Hominins and archeology were recovered since 2003 in the Talalak and Halibee areas in the northwestern quadrant of the study area. More than 70 scientists (from countries including Argentina, Australia, Belgium, Canada, China, England, Ethiopia, France, Greece, Guam, India, Italy, Japan, Kenya, Mexico, Spain, Tanzania,

Turkey, and the USA) and hundreds of local people are involved in the research.

Middle Awash study area The Middle Awash region (Kalb et al. 1978b refer to it as the Middle Awash valley) is one of the three informal divisions of the part of the **Awash River** valley that runs through the **Afar Triangle**. The Middle Awash region is more or less coextensive with the Middle Awash study area and extends from approximately Lake Yardi in the south towards the **Hadar study area** in the north. Major fossiliferous subregions within the Middle Awash include the **Bouri Peninsula**, **Central Awash complex**, and **Western Margin** on the west side of the **Awash River**, and **Bodo-Maka** on the east side of the river.

middle ear The term refers to the part of the ear between the external, or outer ear, and the **inner ear**. It comprises a cavity and the hard- and soft-tissue structures contained within it. The cavity lies within the **petrous** part of the temporal bone between the medial end of the outer ear (i.e., the tympanic membrane at medial end of the external auditory meatus) and the oval window of the **bony labyrinth**. It contains three small bones or **auditory ossicles** (from lateral to medial they are the malleus, the incus, and the stapes) that connect the tympanic membrane with the oval window, two small muscles that help dampen excessive movements of the auditory ossicles, blood vessels, and several nerves. It is about the size of three stacked 10 cents (US) or 1 pence (UK) pieces stood on end.

Middle Ledi See Ledi-Geraru study area.

Middle Ledi Research Project See Ledi-Geraru Research Project.

middle meningeal vessels (Gk *meninx*=membrane) The middle meningeal vessels (i.e., arteries and veins) supply blood to (the arteries) and drain blood from (the veins) both the **cranial vault** and the **dura mater** of the middle **cranial fossa**. They leave vascular impressions on the endocranial surface of the cranial vault (the transmitted pulsations of the arteries are responsible for this, although it is the vein that is immediately adjacent to the bone of the cranial vault). The pattern of these vascular markings has been explored for its taxonomic utility as well as to make inferences

about the relative size of the components of the **cerebral hemispheres**.

Middle Paleolithic A term used to describe a stage of the European and Near Eastern **Paleolithic** that is defined by the dominant stone tool technology (**Mode 3**, including the **Mousterian** and its regional variants). The Middle Paleolithic is usually associated with *Homo neanderthalensis* in Europe, but it has also been associated with some anatomically modern human fossils in the Near East (e.g., **Skhul**). The term has also been applied to sites in India and the Far East, but it is not clear what hominin was responsible for the artifacts at these sites. The equivalent term for African sites with comparable technologies (but not necessarily similar ages) is **Middle Stone Age**.

Middle Pleistocene (Gk *pleistos*=most and *kainos*=new) An informal division of the **Pleistocene** epoch and series, synonymous with the **Ionian age/stage** (781–126 ka). The lower boundary of the Middle Pleistocene is placed at the boundary between the **Matuyama** and **Brunhes** chrons.

middle-range theory See Binford, Lewis (1930–).

Middle Stone Age (or MSA) The intermediate period in the tripartite division of the African archeological lithic record formalized by A.J.H. Goodwin and C. van Riet Lowe (1929) in their *The Stone Age Cultures of South Africa*. Although it was developed for sequences in southern Africa, the terminology has subsequently been applied to sites across sub-Saharan Africa. There have been numerous calls to abandon the tripartite division (e.g., Clark et al. 1966, Barham and Mitchell 2008), but it, and thus the term Middle Stone Age, persists because of the latter's utility for describing a broad stage in the general trend towards a more sophisticated lithic record (i.e., a trend towards aspects of the manufacture of stone tools that are conceptually and technically more elaborate). The MSA was initially defined by its technological and stratigraphic position between **Early Stone Age** and **Later Stone Age** sites. The distinctive features of a MSA archeological site are the absence of the **handaxes** and/or **cleavers** that distinguish Early Stone Age sites, the absence of the **microliths** that are typical of the Later Stone Age, and the presence of **points**, presumably used to make

composite tools such as spears or similar hunting implements. Since the terminology was first introduced (Goodwin 1928) it has been recognized that MSA sites show spatial and/or temporal variation in the shape of the points and of other aspects of MSA artifact assemblages (Clark 1988, McBrearty and Brooks 2000). Flake production is often by **Levallois**, or comparable methods, and **blades** or elongated flakes are present in some assemblages, particularly in southern Africa. MSA artifacts are associated with the earliest fossil remains of *Homo sapiens* (e.g., **Omo-Kibish**). Recognizing that first and last appearance dates vary locally and are subject to change as new sites are found, existing dating methods are improved, or when new methods are introduced, the present evidence suggests the MSA began *c.* 300 ka and ended *c.* 30 ka.

middle trigonid crest An enamel crest in a mandibular molar that runs between the protoconid and the metaconid, distal to the **mesial marginal ridge** and mesial to the **distal trigonid crest**. The feature is illustrated in Zubov (1992) (syn. mid-trigonid crest, epicristid, accessory trigonid crest).

midfacial prognathism See prognathic.

midfoot break Bending (or dorsiflexion) at the calcaneocuboid and cuboid-metatarsal joints during the push-off phase of walking in nonhuman primates. This establishes a temporary fulcrum at the cuboid-metatarsal joint in nonhuman primates, and helps balance the demands of propulsion and grasping in the nonhuman primate midfoot. Notably, this flexibility in the midfoot allows the forefoot to maintain its grip on arboreal supports while the hindfoot and other hind limb elements propel the body during locomotion. Originally thought to occur solely at the transverse tarsal joint (as the midtarsal break), it is now recognized to be a more complicated foot motion involving both the transverse tarsal joint and the tarsometatarsal joints. A calcaneocuboid locking mechanism and the development of strong plantar ligaments that support the longitudinal arch prevent flexion of the midfoot in modern humans, producing a rigid structure that functions as an effective lever for push-off during bipedal locomotion. See also **midtarsal break**.

midtarsal break Bending (or dorsiflexion) at the midtarsal region during the push-off phase of walking in nonhuman primates. First identified and

studied by Elftman and Manter (1935) this flexibility in the mid-foot allows the nonhuman primate hind limb to move about the forefoot while the it maintains its grasp on arboreal supports. The bending was originally argued to occur at the transverse tarsal joint (i.e., the calcaneocuboid and talonavicular joints) and it was suggested that the interlocking mechanism between the calcaneus and the cuboid prevents the midtarsal break in modern humans. More recent work (DeSilva 2009) has found that the midtarsal break involves motion at both the transverse tarsal joint and the cuboid-metatarsal joints that would more accurately be termed **midfoot break**.

migration *See gene flow.*

Milankovitch cycles *See astronomical theory.*

Miles' method This method for determining ages at death from dental wear was first put forth by A.E.W. Miles (1962). Miles suggested that ages at death for subadults could be estimated using modern information on the timing of tooth development and eruption. This "known age" archeological or paleoanthropological sample can then be used as a baseline to establish the pattern of dental wear. Because the rate of dental wear is highly dependent on diet and methods of food preparation, it is necessary to do an "internal calibration" using the actual archeological or paleoanthropological sample. The "known" age sample of subadults allows for this calibration. Because the first, second, and third molars in modern humans typically erupt at 6, 12, and 18 years of age (respectively), a 12-year-old should exhibit 6 years of dental wear on their first molar. Similarly, an 18-year-old should exhibit 12 years of wear on their first molar and 6 years of wear on their second molar. Dental development and eruption are only useful in aging individuals up until their late teens, but from the "known" age sample it is possible to estimate more advanced ages from dental wear. For example, an individual with "6 years' worth" of dental wear on their third molar should be approximately 24 years old (the age of eruption plus the years of dental wear on the erupted tooth). This 24-year-old should display 18 years (24-6) of dental wear on their first molar. In turn, an individual with "18 years' worth" of wear on their third molar should be approximately 36 years old (18+18), and should have 30 years of wear on their first molar (36-6). An individual with 30 years of wear on their third molar should then be approximately 48 years old (30+18). This method

assumes constant rates of wear across teeth. Miles suggested that for at least some populations the third molar wears more slowly than the second molar, which wears more slowly than the first. To account for this, he suggested: (a) adding 8.33% years when "reading" wear on a second molar using first molar standards, (b) adding 16.67% years when "reading" wear on a third molar using first molar standards, and (c) adding 7.69% years when "reading" wear on a third molar using second molar standards. These percentages come from a presumed wear ratio of 6:6.5:7; in other words, that 6 years of wear on a first molar is equivalent to 6.5 years of wear on a second molar, which is equivalent to 7 years of wear on a third molar. As an example, Miles (1962) gives information on a burial with "31 years of M_1 wear" on the second molar, which gives an age estimate of $31 + 0.0833 \times 31 + 12$, or about 46 years old. This same burial had "28 years of M_1 wear" on the third molar giving an age estimate of $28 + 0.1667 \times 28 + 18$, or about 51 years old, and "29 years of M_2 wear" on the third molar giving an age estimate of $29 + 0.0769 \times 29 + 18$, or about 49 years old. Miles suggested averaging these ages to arrive at a final estimate of about 49 years old for this particular example.

Millennium Man A term used by the media for BAR 1000'00 from Lukeino, Kenya. *See BAR 1000'00.*

Minatogawa *See Ryukyu Islands.*

Mindel *See glacial cycles.*

Mindel-Riss *See glacial cycles.*

mineral The term is used for any naturally occurring, crystalline solid, with a fixed or limited range of chemical composition. Minerals form when a fluid cools, when chemicals precipitate from solutes, or when there is solid-state recrystallization from pre-existing phases. Minerals are the fundamental building blocks of most rocks, and in the context of biology they are the chemicals that are introduced into tissues during the process of calcification and **mineralization**.

mineralization The process whereby minerals are added to a soft tissue, such as immature enamel, that results in an increase in its hardness so much so that it is classified as a hard tissue. During tooth

formation, the primary organic matrix secreted by ameloblasts, cementoblasts, and odontoblasts is replaced by an inorganic crystalline lattice, which results in three of the body's hard tissues (**enamel**, **dentine**, or **cementum**). It is due to the highly mineralized nature of teeth that they are relatively common elements recovered as fossils. In effect the teeth of an organism are fossilized during its lifetime. *See also* **calcification**; **dentine development**; **enamel development**.

minicolumn Minicolumns are fundamental structural and functional units within the **cerebral cortex** made up of a single vertical row of neurons with strong vertical interconnections among the layers. The core of a minicolumn contains the majority of the neurons, their apical dendrites, and both myelinated and unmyelinated fibers, whereas the outer layer of each column has fewer neurons and more connections (e.g., dendrites, unmyelinated axons, and synapses). In modern humans there is bilateral asymmetry of minicolumn width in **Wernicke's area** (cytoarchitectonic area Tpt), with more space for neuronal interconnections in the left cerebral hemisphere. Similar analyses of minicolumns in area Tpt of chimpanzees and macaques have not revealed this asymmetry.

minimal animal unit (or MAU) A derived measurement used to quantify the frequencies of skeletal elements in a bone assemblage. The MAU is calculated as the **minimum number of elements** (or MNE) of a skeletal element divided by the number of times that element occurs in the complete skeleton (e.g., femur MAU=0.5, rib MAU=0.042). This standardization procedure makes MAU a useful measure for examining **skeletal element survivorship**, since elements that are rare in a skeleton may show disproportional frequencies within an archeological site. The MAU measure can help show how hominins differentially dismember and transport portions of an animal carcass. In archeological contexts, for example, MAU can be used to demonstrate that hominins preferentially transported certain classes of elements from the point of prey acquisition to the point of consumption. The MAU can also help establish the nature of an archeological site (e.g., as a kill/butchery site or home base/consumption site) or suggest whether hominins had access to fully fleshed carcasses or those largely defleshed by carnivores. *See also* **carcass transport**

strategy; **home base hypothesis**; **minimum number of elements**.

minimum number of elements (or MNE)

A derived measurement that refers to the minimum number of skeletal elements, or portions thereof, necessary to account for the observed specimens in a bone assemblage. The MNE measurement is used to quantify skeletal part frequencies. When fossil bone assemblages are heavily fragmented, MNE counts are used to estimate the minimum number of bones originally deposited by hominins, carnivores, or any other depositional agent. MNE counts allow faunal analysts to compare the relative abundances of skeletal elements to those in a complete skeleton to address questions of **skeletal element survivorship** or differential transport by hominins. The number of fragments that represent a complete element can be used for addressing taphonomic questions concerning bone fragmentation. For example, in an archeological context, one might compare ratios of the **number of identified specimens** (or NISPs) to the MNE to determine whether those bones with higher marrow contents were fragmented to a greater extent than those bones with low marrow contents. *See also* **minimal animal unit**.

minimum number of individuals (or MNI)

A derived measurement that is the minimum number of individuals of a particular taxon necessary to account for the number of observed skeletal elements, or portions thereof, in a bone assemblage. It provides an estimate of the minimum number of individual animals originally deposited by any depositional agent. The MNI measure can be used to quantify taxonomic abundances and, to a lesser extent, skeletal part frequencies. It can be a useful measure when comparing taxonomic abundances in a faunal assemblage where the bone accumulator may have deposited some species largely intact and only certain parts of another. To some extent, MNI can also correct for differential fragmentation and for the fact that some species have a greater number of taxonomically diagnostic bones than others.

minisatellite (It. *miniatura*=miniature illumination in a Medieval manuscript and L. *satelles*=an attendant) A **tandemly repeated sequence** that is 10 to over 100 **base pairs** in length. Minisatellites are located throughout the genome and are particularly common at centromeres and telomeres. They are often **polymorphic** and have been used

extensively for DNA fingerprinting (i.e., individual identification) and for **linkage** analysis.

Miocene (Gk *meion*=less and *kainos*=new) One of the five **epochs** that make up the **Tertiary** period, and the first of the two epochs that make up the **Neogene** period. Miocene refers to a unit of geological time (i.e., a geochronological unit) that begins 23.5 Ma at the end of the Oligocene and ends 5.2 Ma at the beginning of the **Pliocene**. It is usually divided in to three phases, Early, Middle, and Late.

miombo woodland (Swa. *miombo*=term for the many types of trees in the genus *Brachystegia*) The term is applied to woodland that is dominated by trees belonging to the genus *Brachystegia*. Other trees growing in miombo woodland include members of the genus *Isoberlinia* and *Julbernardia*. Miombo "woodlands" can vary from areas where the trees are spaced so far apart that there are substantial areas of open tropical, or C₄, grass between them, to patches of woodland where the canopy is more or less continuous.

mirror neurons *See* language, evolution of.

MIS Acronym for marine isotope stages. *See* Oxygen Isotope Stages.

mismatch distribution A histogram of the number of pairwise **nucleotide** differences within a sample. A population that is expanding in size shows a smooth curve, while a population with a long-term constant population size shows a ragged distribution. As a population expands, the "wave" generated moves from left to right (i.e., as the differences between lineages increase with time) and the timing of the initial population expansion can be estimated. This method has been used in analyses of **mitochondrial DNA** as well as other loci and the results suggest that the population of anatomically modern humans expanded approximately 50 ka (Sherry et al. 1994).

missense mutation *See* nonsynonymous mutation.

Mission Paléoanthropologique Franco-Tchadienne (French-Chadian Paleanthropological Mission, or MPFT) An international and interdisciplinary research program on the origin

and environment of early hominids in Chad. The project was founded by Michel **Brunet** in 1994 and is a collaboration among the University of Poitiers in France, the University of N'Djamena in Chad, and the Centre National d'Applui à la Recherche (C.N.A.R) of N'Djamena in Chad. It focuses on geological and paleontological research, the further education of Chadian students through PhD research and training, and it provides training in collections management. It enabled the construction of the Centre de Valorisation des Collections at the C.N.A.R. The MPFT has recovered fossil fauna and several fossil hominins, including two holotype specimens: the 3.5 Ma mandible assigned to *Australopithecus bahrelghazali* and a c.7 Ma cranium assigned to *Sahelanthropus tchadensis*.

Mission Scientifique de l'Omo *See* Arambourg, Camille Louis Joseph (1885–1969).

mitochondria (Gk *mitos*=thread and *khondrion*=small grain) The energy-producing organelles of the cell located in the cytoplasm. Each cell typically contains several hundred mitochondria, and each mitochondrion has several copies of its own **DNA**. Similarities in the genetic code of mitochondria and an endosymbiotic type of Proteobacteria suggest that the former may be derived from the latter. *See also* **mitochondrial DNA**.

"mitochondrial Eve" (also called "African Eve") A concept that arose from research conducted by Allan **Wilson**, Rebecca **Cann**, Mark Stoneking, and a group of collaborators at Wilson's laboratory at the University of California at Berkeley in the 1980s. From studies of the mitochondrial DNA (or mtDNA) of current human populations they concluded that all current humans can trace their matrilineal ancestry back to one common source, a modern human female who lived in Africa c.150–200 ka. This kind of genetic evidence, when combined with fossil evidence that is consistent with the evolution and earliest appearance of *Homo sapiens* in Africa (Stringer and Andrews 1988), forms the basis of the so-called **out-of-Africa hypothesis**. Wesley Brown et al. (1979) developed techniques for comparing mtDNA samples from different individuals and he successfully compared mtDNA taken from the placentas of 21 mothers of different populations. Brown and colleagues found that the samples differed only slightly in the number of mutations that they did not share in common, which they took to

indicate that contrary to the candelabra and multi-regional models, the different modern human races had diverged relatively recently. He even suggested that the amount of similarity in his samples might mean that all modern humans were descended from a single recent, small population. Meanwhile Douglas Wallace, a geneticist at Stanford University, who was the first to demonstrate that mtDNA is passed exclusively from mother to daughter, used a technique called **restriction mapping** to study mtDNA to reconstruct human phylogeny. Wallace collected mtDNA samples from over 200 individuals from diverse populations (Bantu and San from Africa, Native American, white, and east Asian). This study produced results similar to Brown et al.'s, namely that the remarkably few differences among the mtDNA of the different populations indicated a recent common origin. Furthermore, Wallace found much more variation in the mtDNA of different African populations than between African and non-African populations. By the time Wallace published the results of these studies he had joined Allan Wilson's team at Berkeley. Wilson had begun to use new techniques such as **polymerase chain reaction** (or PCR) and the **relative rate test** to build upon his earlier work on the phylogenetic relationships between mammals and his team was studying mutations in mtDNA in humans and primates (e.g., Brown et al. 1982, Wilson et al. 1951). During this time Brown met Rebecca Cann, a graduate student who had begun working in Wilson's laboratory in 1979 and was interested in mtDNA research. Cann decided to expand upon Brown's earlier research into human phylogeny for her dissertation research, but now with a larger population sample of mtDNA. Cann worked with Wilson and Mark Stoneking, who arrived at Wilson's laboratory in 1981, and began to collect mtDNA samples from placentas collected from local hospitals. By 1986 Cann and Stoneking had gathered samples from 147 individuals from Europe, Asia, and the South Pacific, although difficulties in collecting samples from Africa led them to rely upon African-American samples instead. Cann and Stoneking reconstructed a phylogenetic tree by using an algorithm to group together those samples with the greatest similarity according to their degree of difference in the quantity of mutations in their mtDNA. The result was a tree with two main branches, one a small branch containing only Africans and the other a large branch containing samples from every other geographical group, including some Africans. Since the branch containing only Africans connected with the other branch close to its base,

Cann, Stoneking, and Wilson concluded that all modern human populations, or at least their mtDNA, must have descended from a woman living in Africa. By arguing that mutations in mtDNA occur at a steady rate they had a possible means of determining approximately when this woman had lived. To estimate the mutation rate they studied the mtDNA of populations, such as Australian aborigines, whose ancestors had migrated to Australia (an event then estimated to be *c.*30 ka), and determined how many mutations had accumulated in this population as compared to others over that known period of time. Extrapolating from the mutation rate acquired from that research they estimated that the female mitochondrial common ancestor lived 140–290 ka, which they simplified to a figure of *c.*200 ka (Cann, Stoneking, and Wilson 1987). This hypothetical female common ancestor was dubbed Eve, and the research that led to the notion of the mitochondrial Eve was immediately seen as support for the out-of-Africa hypothesis, and was incompatible with the idea that *Homo sapiens* had evolved from regional populations of *Homo erectus*, as supporters of the **multiregional hypothesis** argue. Subsequently, there has been debate over mutation rates in mtDNA and about other factors that could affect the original interpretation of Cann et al.'s research, but its general conclusion is widely accepted. The paper helped to spark rapid growth in the application of molecular biology to the interpretation of recent human evolutionary history.

mitochondrial DNA (or mtDNA) Circular and approximately 16,570 **base pairs** (bp) in length. It contains 37 **genes**, 13 that encode **proteins** involved in cellular respiration (i.e., the synthesis of adenosine triphosphate, or ATP), two that encode rRNA subunits, and 22 that encode tRNAs specific to protein synthesis in the mitochondria. The mitochondrial DNA genetic code is slightly different from the **nuclear DNA** genetic code. For instance, the almost universal nuclear mRNA stop codon UAG in mtDNA codes for tryptophan in the nuclear DNA. Most of the mtDNA genome is coding sequence except for some short sequences between genes and the displacement loop (also known as the D-loop or hypervariable region). The mitochondrial genome has been examined extensively to investigate modern human population history worldwide (e.g., Di Rienzo and Wilson 1991, Horai et al. 1996, Lum et al. 1994, Mountain et al. 1995, Richards et al. 1996, Vigilant et al. 1989, Ingman et al. 2000) as well as

nonhuman primate population history (Morin et al. 1994, Wildman et al. 2004). Several important features of mtDNA make it useful for population genetic studies [e.g., it is typically maternally inherited, it does not undergo **recombination** (Giles et al. 1980), and it has a relatively fast mutation rate]. In modern humans, mtDNA analyses have largely focused on the two hypervariable segments of the control region, a noncoding “spacer” region where one of two origins of replication is located, on restriction sites located throughout the mitochondrial genome, and on a 9 bp deletion found in some populations in a small noncoding segment between the cytochrome oxidase subunit II gene and a gene coding for a lysine tRNA. Characteristic polymorphisms have been used to define mtDNA **haplogroups** (a group of similar mtDNA lineages). One limitation of mtDNA is that its lack of recombination means that it should be treated as a single locus (since everything is linked and passed from mother to child as a unit) in population genetic analyses. This reduces the statistical power of conclusions about population history that only use this locus. Although both men and women have mtDNA, only women usually pass it to their offspring, and therefore it is useful for examining female population history (including migration patterns and effective population sizes). For example, in the New World, research on mtDNA variation has included both restriction enzyme surveys and sequencing of the hypervariable regions. These data have been used as evidence for hypotheses about the timing, origins, and number of migrations from Asia into the Americas, about the size of the migrant population, and about local demographic history (e.g., Merriwether et al. 1996, Bonatto and Salzano 1997). Most analyses of **ancient DNA** focus on mtDNA because it has a much higher copy number (>700 copies) in each cell than nuclear DNA, making it much more likely to be recovered in samples where DNA quantity and quality are degraded. For example, several mtDNA hypervariable region sequences are available for Neanderthals (e.g., Krings et al. 1997, Krause et al. 2007b) as well the complete mtDNA genome (Green et al. 2008). Mitochondrial DNA has also been used extensively to generate primate phylogenies. Such analyses have primarily examined the *cytochrome B* gene and the cytochrome oxidase subunit II (*COII*) gene, but whole-genome data are becoming increasingly common (e.g., Disotell et al. 1992, Schrago and Russo 2003, Raaum et al. 2005).

mitochondrial genome *See* mitochondrial DNA.

mitogen (Gk *mitos*=warp thread and *genes*=born) Any substance that stimulates **mitosis**.

mitosis (Gk *mitos*=warp thread) The process of cell division that produces two identical **diploid** cells. It occurs in four stages (prophase, metaphase, anaphase, and telophase) followed by cytokinesis.

ML Acronym for **maximum likelihood** (*which see*).

Mladeč (Location 40°40'N, 17°00'E, Czech Republic, West of Litovel; etym. name of nearby village) History and general description Cave discovered, probably as early as 1826, while blasting for a quarry, and yielding some of the earliest *Homo sapiens* remains in Europe and evidence of **Upper Paleolithic** industries. The excavations conducted in 1881–2 yielded Mladeč 1–3 and other unnumbered bones. In 1903–4 Mladeč 4–7 and other unnumbered bones were recovered as part of salvage and/or amateur excavations. Mladeč 8–10 were recovered in 1922. All of these efforts also resulted in a rich faunal and archeological record. The process of converting the caves into a tourist attraction, starting in 1911, resulted in the disturbance and large-scale removal of sediments. Later systematic excavations conducted between 1958 and 1961 did not recover any additional hominins or Upper Paleolithic archeological remains. Temporal span and how dated? Uncalibrated radiocarbon dates on carbonates, faunal bone, and human bone. The modern human specimens have yielded dates between 26,330±170 and 31,500±420–400 years BP. Hominins found at site Mladeč 1 [adult cranium, Natural History Museum, Vienna, Austria (or NHMV)], Mladeč 2 (adult calvaria, NHMV), Mladeč 3 (child, calvaria, NHMV), Mladeč 4 (missing), Mladeč 5 (adult calotte, Moravian Museum, Brno, Czech Republic), Mladeč 6 (adult calotte, destroyed), Mladeč 7 (missing), and Mladeč 8–10 (missing), plus additional cranial and postcranial remains of several individuals, also missing (see Wolpoff et al. 2006 for the latest inventory). Archeological evidence found at site Lithic and bone industry described as **Upper Paleolithic (Aurignacian)**. Bone artifacts include **points**, awls, and perforated teeth and long bones. **Ochre**

markings on the wall have also been reported. Key references: Geology, dating, and paleoenvironment Svoboda 2006, Wild et al. 2005, 2006; Hominins Szobathy 1925, Vlček 1971, Teschler-Nicola 2006, Wolpoff et al. 2006; Archeology Szobathy 1925, Oliva 2006.

MLD Acronym for Makapansgat Limeworks Deposit and prefix for fossils recovered from the Makapansgat Limeworks Deposit, Limpopo Province, South Africa.

MLD 1 Site Makapansgat. Locality N/A. Surface/in situ Extracted from a piece of breccia that came from one of the dumps of Lower Phase I breccia discarded by the limeworkers. Date of discovery September, 1947. Finder John Kitching. Unit N/A. Horizon N/A. Bed/member Member 3. Formation Makapansgat Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.2.8 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Posterior part of a calvaria that preserves most of the occipital bone and the posterior parts of the parietal bones. Announcement Dart 1948. Initial description Dart 1948. Photographs/line drawings and metrical data Dart 1948. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus prometheus*. Taxonomic revisions Robinson (1954) proposed that a subspecies of *Australopithecus africanus*, *Australopithecus africanus transvaalensis*, be used to distinguish the australopiths from “Sterkfontein, Makapan and East Africa” (*ibid*, p. 196) from the australopith taxon, *Australopithecus africanus africanus*, represented by the Taung(s) skull. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance The holotype of *Au. prometheus*. Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa.

MN zones Acronym for mammal neogene. *See* European mammal neogene system.

MNE Acronym for **minimum number of elements** (*which see*).

MNI Acronym for the **minimum number of individuals** (*which see*).

MNK Acronym for Mary Nicol Korongo, a locality in **Olduvai Gorge**. It was discovered by Mary Leakey (Nicol was her maiden name) in 1935. Subsequently artifacts and faunal remains have been recovered, and in 1963 the juvenile cranium **OH 13** was recovered. *See also* **Olduvai Gorge**.

mobile art *See* art.

mobile genetic element *See* transposition; transposon.

mode (L. *modus*=manner) Archeology In his global review of world prehistory, Grahame Clark (1969) divided lithic technology into five categories, or modes, that characterized the dominant artifact form and the inferred underlying hominin behavior responsible for it. The approach obscures much of the variability of the lithic technological record at any time or place. Modes emphasize only the most complex, or derived tool forms, and this feature has occasionally led to its use for comparing change in the archeological and hominin fossil records (e.g., Foley and Lahr 2003). Evolution George Gaylord Simpson’s *Tempo and Mode in Evolution* (1944) helped push evolutionary biologists in the direction of recognizing these two components of the evolutionary process: rate (or **tempo**) and pattern (or mode) of evolution. The various evolutionary modes include **stasis**, **directional selection**, and **random drift**. Grey et al. (2008) provide good pictorial examples from invertebrate evolution. As one can see from the Grey et al. paper you need a lot of fossil evidence (i.e., many data points) to investigate evolutionary mode. Researchers who have attempted to investigate the mode of evolution within the hominin clade (e.g., Wood et al. 1994, Lockwood et al. 2000) suggest stasis is the dominant signal. *See also* **phyletic gradualism**; **punctuated equilibrium**; **sample statistics**.

Mode 1 The first of the five technological modes defined by Clark (1969) in his global review of lithic technology. Mode 1 artifacts were originally defined as “chopper-tools and flakes,” but they are now widely equated with “least-effort flake production.” Mode 1 assemblages are comparable to those of the **Oldowan**, characterized by the production of flakes from cobbles or similar naturally occurring rock forms by direct

stone-on-stone percussion or the use of an anvil. Sharp flakes are the desired products, cores are generally thought to be byproducts, and there is no elaborate knapping plan or predetermination of products. Mode 1 is exemplified by Oldowan sites from Bed I of **Olduvai Gorge** (Leakey 1971), **Koobi Fora** (Isaac et al. 1997), and **Gona** (Semaw 2000); by early sites in western Eurasia such as **Dmanisi** (Baena et al. 2010) and **Atapuerca** (Carbonell et al. 1999); and by a majority of Lower Paleolithic sites east of India (Schick and Zhuan 1993).

Mode 2 The second of the five technological modes defined by Clark (1969) in his global review of lithic technology. Mode 2 artifacts were originally defined as “bifacially flaked handaxes,” but it is generally considered to include cleavers as well. Mode 2 assemblages are comparable to those of the **Acheulean**, characterized by the production of handaxes and cleavers through bifacial flaking using stone or organic (e.g., wood or antler) hammers. The shaped core is the desired product, and the flakes produced in shaping are considered waste. There is substantial variation, but Mode 2 forms should usually be worked on both sides (bifacial) and have a recognizable, imposed form. They may be shaped from naturally occurring clasts (e.g., cobbles, nodules, blocks) or from large (>10 cm) flake blanks detached from boulder cores. Exemplified by Acheulean sites throughout Africa and western Eurasia, including Bed II of **Olduvai Gorge** (Leakey 1971), **Kalambo Falls** in Zambia (Clark 2001), **Geshen Benot Ya’aqov** in Israel (Saragusti and Goren-Inbar 2001), and **Boxgrove** in England (Roberts and Parfitt 1999).

Mode 3 The third of the five technological modes defined by Clark (1969) in his global review of lithic technology. Mode 3 artifacts were originally defined as “flake tools from prepared cores.” The classic example is **Levallois** technology. Cores are carefully shaped (prepared) so that one or more standardized flakes of a predetermined shape may then be produced. Cores and the flakes from shaping are considered waste. Exemplified by numerous **Middle Stone Age** sites from East (e.g., the **Kapthurin Formation**; Tryon et al. 2005) and North (Vermeersch 2001) Africa, and **Middle Paleolithic** sites in the Levant (e.g., **Tabun**, **Kebara**; Bar-Yosef 1998), and Europe (e.g., **Le Moustier**, **La Quina**, **Combe Grenal**; Mellars 1996)

Mode 4 The fourth of the five technological modes defined by Clark (1969) in his global review of lithic technology. Mode 4 artifacts were originally defined as “punch-struck blades with steep retouch,” but now it is often used to refer to blade production generally. Classically, a roughly cylindrical, conic, or wedge-shaped “prismatic” core is carefully prepared with long ridges around its circumference. Percussion above the ridges (often using a punch) produces multiple, uniform blades, which may then be retouched into a wide array of standardized tools. Prismatic blade production is exemplified by **Mayan** (Bordes and Crabtree 1969) and European **Upper Paleolithic** (e.g., **Etoilles**; Pigeot 1990) technologies. Other blade-production methods are more widespread (Bar-Yosef and Kuhn 1999).

Mode 5 The fifth of the five technological modes defined by Clark (1969) in his global review of lithic technology. Mode 5 artifacts were originally defined as the “microlithic components of composite artifacts.” Clark associated Mode 5 with the **Mesolithic**, but microlithic technologies are now well known from the later Paleolithic. Microlithic tools may be produced using microblades detached from diminutive cores or snapped segments of larger blades that are retouched into standardized geometric shapes and hafted to make composite tools. Classically exemplified by **Mesolithic** (e.g. **Maglemosian**) sites in Western Europe, microlithic technology is important in the late Pleistocene of East Asia (e.g., **Dyuktai**) and examples are found throughout the world by the mid-Holocene (see papers in vol. 12, issue 1 of *Archaeological Papers of the American Anthropological Association*, January 2002, Elston and Kuhn (eds)). Less classically, Mode 5 may include somewhat larger geometric forms from the **Middle Stone Age** **Howieson’s Poort** from South Africa (*ibid*).

model I regression A term applied to regression techniques which minimize residuals from the best-fit line in the independent variable alone (e.g., **ordinary least squares regression**). Model I regressions should be used when the goal is to predict values rather than identify **scaling** relationships.

model II regression A term applied to regression techniques which minimize residuals from the best-fit line in both independent and dependent

variables (e.g., **major axis regression** and **reduced major axis regression**). In general, model II regressions should be used when the goal is to identify **scaling** relationships rather than to predict values.

model organism A species that is intensively studied to understand particular biological processes or traits. These species usually are easy to work with in the laboratory setting. Such organisms include bacteria (e.g., *Escherichia coli*), nematodes (e.g., *Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), zebra fish (*Danio rerio*), and mice (*Mus musculus*). Model organisms have been important for studies of development, gene expression and function, and comparative genomics, and thus they have aided in our understanding of development, gene function, and the evolution of the modern human genome.

modeling (L. *modus*=standard) **Biology, general** Modeling is routinely used in the experimental sciences. The aim is to build a model that best explains the observed phenomena. Well-designed experiments enable researchers to refine and validate their models by comparing what is observed with what the model predicted. The principles of modeling can also be used in the historical sciences, but there are difficulties in applying modeling in the absence of the ability to experiment. Tooby and DeVore (1987) reviewed the use of models for reconstructing the evolutionary history of hominin behavior. They distinguished between **referential** and **conceptual modeling**. In a referential model the real behavior of one, or more, living animal(s) is used to reconstruct the behavior of a fossil taxon (the **referent**). For example, if in extant forms closely related to fossil hominins substantial levels of canine-crown-height **sexual dimorphism** are always associated with a **multimale social structure**, then the principles of referential modeling suggest it is reasonable to infer that a fossil hominin with similar levels of canine-crown-height sexual dimorphism had a multimale social structure. In contrast, in conceptual modeling the model is not so directly based on “real” observations. It is based on general principles that have been developed from observations of a wide range of animals (e.g., bees), not just those closely related or analogous to the referent. In conceptual models “individual taxa should be treated as sources of data points for comparative studies,

not as models” (Moore 1996). Therefore, for example, baboon behavior could be used as a literal referential model, or observations on baboons could be just one component of the information used to generate a conceptual model. Tooby and DeVore (1986) suggest a third category of model, **strategic modeling**, based on the principle of **uniformitarianism**. The premise of strategic modeling is that “species in the past were subject to the same fundamental evolutionary laws and ecological forces as species today, so that principles derived today are applicable throughout evolutionary history” and therefore “although no present species will correspond precisely to any past species, the principles that produced the characteristics of living species will correspond exactly to the principles that produced the characteristics of past species” (*ibid*, p. 189–90). **Biology, bone** In bone biology modeling refers to any change in the mass and/or external shape of bone (e.g., during growth or as the result of excessive use).

models of intermediate complexity (or MIC) Climate models that are more complex than “box models” but less complex than **general circulation models** (or GCMs). They are useful for paleoclimate reconstruction because their reduced computational demands (compared to GCMs) mean that, whereas the latter can only be run for “equilibrium” experiments, MIC models can be used for “time-transient” experiments (i.e., simulations through time). *See also* **general circulation model; paleoclimate**.

modern evolutionary synthesis The modern evolutionary synthesis emerged as the dominant model of biological evolution during the 1930s and 1940s. Charles **Darwin** unveiled his theory of evolution through natural selection in 1859 and while most biologists came to accept the idea that species evolved over time there was disagreement over the mechanisms that caused evolution. By the beginning of the 20thC a substantial number of biologists and paleontologists supported versions of evolution that differed from Darwin’s. These scientists tended to reject the idea of natural selection, and instead invoked either **neo-Lamarckism**, which stressed the role of the inheritance of acquired characteristics, or **orthogenesis**, which argued that biological properties internal to organisms caused certain groups to evolve along linear progressive lines. The German

biologist August Weissmann's studies of germ plasm and chromosomes during the 1880s and 1890s, and the experiments on heredity conducted by Gregor Mendel (published in 1865 but generally unknown until the turn of the 19thC) led to the emergence of the new disciplines of genetics and population genetics in the early 20thC. The relationship between evolution theory and genetics was explored by Ronald Fisher and J.B.S. Haldane in England and by Sewall Wright in the USA. Their mathematical approach to studying the frequency of genes in populations offered new ways of understanding how variation within populations originated and could be acted upon by natural selection. Fisher's *The Genetical Theory of Natural Selection* (1930) and Haldane's *The Causes of Evolution* (1932) demonstrated how Mendelian genetics and Darwin's theory of evolution by natural selection could be combined to explain how species change over time. At the same time the Russian geneticist Sergei Chetverikov was studying the impact of recessive genes in populations of organisms and their role in evolution. Chetverikov conducted this research within a Darwinian conception of how evolution operated and his research influenced a generation of Russian geneticists before they were purged by the Soviet leader Joseph Stalin. However, the ideas of this generation of Russian geneticists were introduced into America by Theodosius Dobzhansky who left Russia in 1927 to work in the genetics laboratory of Thomas Hunt Morgan at Columbia University. Dobzhansky combined population genetics and natural selection to explain the process of speciation, and his *Genetics and the Origin of Species* (1937) had a powerful impact on biological thinking during the middle of the 20thC. By the 1930s, among at least some biologists, Darwin's theory was enjoying a resurgence. The German ornithologist Ernst Mayr, who emigrated to the USA in 1931 to become the curator of the American Museum of Natural History's collection of birds, offered new insights into how new species emerge by analyzing the role of isolation. Dobzhansky nominated Mayr to present his ideas about speciation in animals at the Jesup lectures at Columbia University in March 1941 and these lectures were the basis of his *Systematics and the Origin of Species* (1942). In that work Mayr promoted a conception of evolution that was strongly Darwinian and yet integrated the latest biological knowledge, especially population genetics. This new thinking about the mechanisms of evolution was introduced into paleontology by George Gaylord Simpson,

curator of fossil vertebrates at the American Museum of Natural History. In his influential work *Tempo and Mode in Evolution* (1944) Simpson demonstrated that the kinds of small-scale evolutionary processes discussed by population geneticists could produce the kinds of large-scale evolutionary changes observed in the fossil record. He used evidence from the mammalian fossil record to show that the fossil series of many groups of organisms did not show the linear paths of evolutionary development as proponents of neo-Lamarckism or orthogenesis argued, but showed instead many diverging branches just as Darwin described. The best-known systematic survey of the new union of population genetics and Darwinian evolution theory was Julian Huxley's *Evolution: The Modern Synthesis* (1942). Reduced to its most critical components, the modern evolutionary synthesis argued that (a) evolution was the result of small genetic mutations accumulating in populations of organisms over long periods of time as well as the movement and recombination of genetic traits within populations, (b) natural selection was the primary mechanism by which species change over time, and (c) natural selection operating upon a population leads to adaptation to specific environmental conditions. Through their research, publications, and prominent institutional affiliations, Mayr at Harvard University, Dobzhansky at Columbia University, Simpson at the American Museum of Natural History, and Sewall Wright at the University of Chicago transformed modern thinking about the mechanisms underlying evolution. It was not long before the members of this group began to apply the principles of the modern evolutionary synthesis to the problem of human evolution. Dobzhansky addressed the question of human evolution and hominin species in an article titled "On species and races of living and fossil man" published in the *American Journal of Physical Anthropology* in 1944, in which he argued that *Sinanthropus* and *Pithecanthropus* are no more different than are what were then recognized as races of modern humans. As a result of this conception of a species, Dobzhansky argued that only one species of hominin had existed at any one time, and that there was often considerable variation within hominin species. He greatly expanded upon these issues later in *Mankind Evolving* (1962). The modern evolutionary synthesis was brought solidly into human origins research in 1950 at a symposium held at Cold Spring Harbor in New York. In a paper titled "Taxonomic categories in fossil hominids," Mayr sought to reform

hominin taxonomy to reflect the new population thinking about species. In Mayr's opinion, anthropologists had been too ready to name new species on the basis of very slight differences between fossils, and he argued that all of these species should be collapsed into a single genus (*Homo*) consisting of only three species: *Homo transvaalensis* (australopiths), *Homo erectus* (*Sinanthropus* and *Pithecanthropus*), and *Homo sapiens* (i.e., modern humans and Neanderthals). At this same meeting George Gaylord Simpson criticized the persistence of orthogenesis in many interpretations of about human evolution and explained how the hominin fossil record could be better interpreted from the perspective of the modern evolutionary synthesis. While there was some resistance among anthropologists and anatomists to the modern evolutionary synthesis (sometimes referred to as just "the synthesis"), by the 1980s the majority of human origins researchers had fully accepted this approach to the study of human evolution.

modern human (L. *modernus*=now and *humanus*=people) When used as a noun (e.g., as in "the Herto crania more closely resemble the crania of modern humans than they do any other hominin taxon") the term modern human is equivalent to either all *Homo sapiens*, or to just extant *H. sapiens*. When used as an adjective (e.g., as in "modern human morphology") this term refers to the morphology seen in contemporary populations of *H. sapiens*. "Human morphology" (i.e., the morphology seen in taxa within the genus *Homo*) is sometimes used when the writer really means "modern human morphology." See also *Homo sapiens*.

modern human behavior The suite of behavioral patterns that characterize behaviorally modern *Homo sapiens* and that distinguish them from living primates and other members of the hominin lineage. There is intense debate concerning the nature, timing, and geographical origin of modern human behavior. Disagreement stems in part from the difficulty of defining modern human behavior in the first place and then being able to recognize modern human behavior through the lens of the archeological record. Some behavioral patterns that are considered to be evidence of modern human behavior include symbolic behavior and personal adornment, effective exploitation of large mammals and dietary breadth, long-distance exchange networks, standardized lithic technology, and use of composite tools, among others. But there is a danger

of historicism coming into play with respect to some of these lines of evidence, because archeologists tend to assume that the links between artifacts and behavior observed in the present (e.g., ochre and body adornment) were also operating in the past. As for timing, some researchers argue that modern human behavior emerged abruptly *c.*50,000 years ago, creating a temporal lag between the origins of anatomically modern humans and the origin of behavioral modernity. Others suggest the origin of modern human behavior is the result of the gradual accumulation of behavioral patterns associated with the appearance of the Middle Stone Age in Africa beginning *c.*250 ka, roughly coincident with fossil evidence for the appearance of anatomically modern humans, or *H. sapiens*.

Modjokerto The old Indonesian spelling for the site now known as **Mojokerto**. Hence the fossils recovered from the site when the old spelling was in use retain that spelling (e.g., **Modjokerto 1**), as does the taxon *Homo modjokertensis*, now a junior synonym of *Homo erectus*. See **Mojokerto**.

Modjokerto 1 Site Mojokerto. Locality "The exact find spot remains unknown" (Anton 1997, p. 501). Surface/in situ Surface. Date of discovery 1936. Finder Tjokrohandoyo. Unit N/A. Horizon "Tuffaceous conglomeratic sandstone" (Anton 1997, p. 500). Bed/member Djertis Beds. Formation Sangiran Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age "From a pumice-bearing level in the region of Modjokerto" and the "youngest of these levels known from that section is 1.81 mya" (Anton 1997, p. 501). Developmental age 4–6 years (Anton 1997), *c.*1 year (Coqueugniot et al. 2004), and <4 years of age (Balzeau et al. 2005). Presumed sex Unknown. Brief anatomical description Partial calvaria that includes most of the vault and part of the floors of the middle and anterior cranial fossae. Announcement von Koenigswald 1936. Initial description von Koenigswald 1940. Photographs/line drawings and metrical data von Koenigswald 1940, Anton 1997, Coqueugniot et al. 2004, Balzeau et al. 2005. Detailed anatomical description Anton 1997. Initial taxonomic allocation *Homo modjokertensis*. Taxonomic revisions *Homo soloensis* (Dubois 1936), *Pithecanthropus modjokertensis* (Jacob 1975), *Homo erectus* (Clark 1978). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category

Pre-modern *Homo*. Significance **Holotype** of *H. modjokertensis* and the specimen used to argue for a relatively primitive pattern of growth in endocranial volume in *H. erectus* (Coqueugniot et al. 2004). Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany.

modularity (L. *modulus*=a measure in music) Modules in biology are entities within a system that have a greater density of internal than external connections (Gass and Bolker 2003). Some regard modules as abstract entities that reflect processes, or sets of connections within networks, while others regard them as spatially contiguous physical entities within organisms. In the **phenotype** of complex organisms such as primates, there are typically many sets of integrated **traits** and such organisms are said to be modular. Modularization can act to release evolutionary constraints, allowing different parts of the phenotype to evolve independently. Thus, modularity is a determinant of **evolvability**. Modular organization also means that changes to one part of an organism or developmental system are less likely to produce deleterious effects elsewhere. An example of the application of the modularity concept in biological anthropology is the work on integration and modularity in primate limbs (e.g., Hallgrímsson et al. 2002, Young and Hallgrímsson 2005, Rolian 2009). This work shows that the modular organization of the limb is evident in the structure of limb and that **covariation** within the limb may have influenced or constrained evolutionary changes in limb proportions. *See also* **morphological integration**.

module An internally integrated unit, such as a complex biological structure or pathway, that is comparatively independent from other surrounding modules with which it may interact. In addition to modularity another way in which the term module is used in paleoanthropology is in dental metrics. *See also* **crown module**; **modularity**.

Mohui *See* **Bubing Basin**.

MOI Abbreviation of the Moiti Tuff in the Koobi Fora Formation, West Turkana, Kenya.

Mojokerto (Location 7°22'S, 112°38'E, Indonesia; syn. Perning, Modjokerto; etym. the modern Indonesian spelling for a nearby village) History

and general description An exposed river-bed deposit, 3 km/1.8 miles north of Perning, 10 km/6 miles northeast of Mojokerto, and 35 km/22 miles west of Surabaya in East Java. On February 13, 1936 a juvenile fossil hominin calvaria was discovered *in situ* 1 m below the surface. The hominin fossil is derived from a conglomeratic sandstone stratum of the **Sangiran** (formerly Pucangan) **Formation**. Temporal span and how dated? There is debate concerning the radiometric age of the site. In 1994, **argon-argon dating** of volcanic hornblende from the deposit provided an age of 1.81 ± 0.04 Ma. In 2003, **fission track dating** of primary zircon grains suggested a maximum age for the hominin at 1.49 ± 0.13 Ma. Recent attempts to more reliably pinpoint the actual find site at Mojokerto have resulted in published interpretations favoring the more ancient date for the hominin partial cranium. Hominin found at site **Modjokerto 1** is the holotype of *Homo modjokertensis*, named by Ralph von Koenigswald in 1936. More recent interpretations place this fossil within the hypodigm of *Homo erectus*, based on its possession of a metopic eminence and an occipital torus, characters many researchers regard as synapomorphic for this hominin species. Chronological age estimates suggest that the Modjokerto child was between 4 and 6 years old at death. **Computed tomography** of the fossil's endocranial features indicates that *H. erectus*' brain growth differed from that observed in modern humans. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Swisher et al. 1994, Huffman 2001, Morwood et al. 2003, Huffman et al. 2005; Hominins Antón 1997, Coqueugniot et al. 2004, Balzeau et al. 2005.

mokondo A term used at the southern African cave sites for a sinkhole. This is an area of **breccia** that has been decalcified and then subsequently washed out, thus providing a cavity into which more recent breccia can accumulate. It is this type of sinkhole and new breccia accumulation that complicates the geology of sites such as **Swartkrans**. The cranium **Stw 53** from Sterkfontein was said to have been recovered from breccia that was in a mokondo/sinkhole (Hughes and Tobias 1977).

molar (L. *mola*=mill stone) A type of tooth. The name refers to the teeth distal to (i.e., behind) the **premolars** in the tooth row. Upper molars

consist of a mesial **trigon** and a distal **talon**; the lower molar equivalents are **trigonid** and **talonid**. There are two **deciduous** and three **permanent** molars. The upper deciduous molars are referred to as dm^1 and dm^2 (or dp^1 and dp^2) and the upper permanent molars as M^1 , M^2 , and M^3 . The lower deciduous molars are referred to as dm_1 and dm_2 (or dp_1 and dp_2) and the lower permanent molars as M_1 , M_2 , and M_3 . Primarily used for chewing, crushing, and grinding food.

Molare Shelter (Location 40°02'21"N, 15°28'32"E, Italy; etym. local name of the area, called "Molara," near Scario) History and general description Rock-shelter containing a large **Middle Paleolithic** deposit with at least seven successive hearth levels. An immature hominin mandible was found at the bottom of these levels in 1985. Temporal span and how dated? **Technostratigraphic** correlation to other sites suggested a date of Würm I (*c.*50–70 ka), but a re-examination of the evidence suggests a "pre-Wurmian" age (*c.*Oxygen Isotope Stage 5b). Hominins found at site The mandible belonged to an immature individual, probably 3–4 years old. The preserved dentition of includes only the right and left dm_1 and dm_2 . Whereas the mandible is usually considered to belong to *Homo neanderthalensis*, Mallegni and Ronchitelli (1989) note that many of the mandibular and dental traits are primitive. Archeological evidence found at site **Mousterian** artifacts with some evidence of artifacts made using the **Levallois** technique. Key references: Geology, dating, and paleoenvironment Mallegni and Ronchitelli 1987, 1989; Hominins Mallegni and Ronchitelli 1987, 1989; Archeology Mallegni and Ronchitelli 1987, 1989.

molarized A term introduced by John Robinson (1956) to describe mandibular premolars with such a well-developed **talonid** that they come to resemble mandibular molars.

molecular anthropology Developments in biochemistry and immunology during the first half of the 20thC allowed the focus of the search for better evidence about the nature of the relationships between modern humans and the great apes to be shifted from traditional, macroscopic, morphology to the morphology of molecules. Sufficient information was known about the differences in organic molecules between organisms as early as 1944 for Marcel Florkin to assemble this

knowledge in a book entitled *Biochemical Evolution*. The earliest attempts to use the proteins of primates to determine the relationships among taxa were made just after the turn of the century, but the results of the first of a new generation of analyses were reported in the early 1960s, and Linus Pauling claimed he coined the name molecular anthropology for this area of research. Zuckerkandl et al. (1960) used enzymes to break up the hemoglobin (Hb) protein into its peptide components, and showed that when the peptides were separated (using starch gel electrophoresis) the patterns of the peptides in the gel for modern humans, gorilla, and chimpanzee were indistinguishable. Morris Goodman (1963) used what was then the new technology of immunology, specifically a process called immunodiffusion, to study the affinities of the serum proteins of the apes, monkeys, and modern humans. He came to the conclusion that because the patterns produced by the albumins of modern humans and the chimpanzee in the immunodiffusion gels were effectively identical, then it is likely that the structures of the albumins were also likely to be, to all intents and purposes, identical. Proteins are made up of a string of amino acids. In many instances one amino acid may be substituted for another without changing the function of the protein. In the 1970s Vince Sarich and Allan Wilson exploited these minor variations in protein structure to determine the evolutionary history of protein molecules, and therefore, presumably, the evolutionary history of the taxa whose proteins had been sampled. They, too, concluded that modern humans and the African apes, in particular the chimpanzee, were very closely related. In a later paper Mary-Claire King and Allan Wilson (1975) suggested that 99% of the amino acid sequences of chimps and modern humans were identical. The discovery, by James Watson and Francis Crick, of the structure of DNA, and the subsequent discovery by Crick and others of the genetic code, showed that it was the sequence of bases in the DNA molecule that determined the nature of the proteins manufactured within a cell. This meant that the affinities between organisms could be pursued at the level of the genome, thus potentially eliminating the need to rely on morphological proxies, be they traditional anatomy, or the morphology of proteins, for information about evolutionary relatedness. The DNA within the cell is located either within the nucleus as nuclear DNA, or within the mitochondria as mitochondrial DNA (mtDNA). Comparisons between the DNA of organisms were

initially made using a method called DNA hybridization. In the early stages of DNA research, DNA hybridization told researchers "relatively little about a lot of DNA," whereas the sequencing method told them "a lot about a little piece" of DNA. Nowadays technological advances mean that whole genomes can be sequenced. Sequencing is favored because the knowledge about the type of differences between the base sequences provides some clues about the steps that are needed to produce the observed differences. This is because the base changes called transitions (A to G and T to C) readily switch back and forth, whereas transversions (A to C and T to G), which are less common, are more stable, and thus are more reliable indicators of genetic distance. These methods, hybridization (e.g., Caccone and Powell 1989) and sequencing (e.g., Bailey et al. 1992; Horai et al. 1992), have been applied to the living great apes, and the number of sequence studies increases each year (for a review see Bradley 2008). Information from both nuclear and mtDNA suggested that modern humans and chimpanzees are more closely related to each other than either is to the gorilla (Ruvolo 1997, Li and Saunders 2005), and when these differences are calibrated using paleontological evidence for the split between the apes and the Old World monkeys, and if one assumes that the DNA differences are neutral, then this predicts that the hypothetical ancestor of modern humans and the chimpanzees and bonobos lived between about 5 and 8 Ma, and probably closer to 5 than to 8 Ma (Bradley 2008). However, when other ways of calibration are used the predicted date for the split is somewhat older (e.g., Arnason and Janke 2002 suggest >10 Ma).

molecular basis of brain size evolution

See brain size evolution, molecular basis of.

molecular biology The study of the molecules involved with the maintenance of life. Although the term suggests it should involve the biology of all molecules, in practice molecular biologists are mainly concerned with complex molecules such as proteins, and in particular with the roles of another class of complex proteins, nucleic acids (e.g., **nuclear DNA**, **mitochondrial DNA**, **RNA**) involved in the maintenance of life.

molecular clock A term introduced by Emile Zuckerkandl and Linus Pauling in 1962 to refer to

the use of differences between molecules to generate a tree of their relationships in which branch lengths are proportional to time. Such proportional trees can then be calibrated using the fossil record and then used to estimate otherwise non-calibrated divergence times. Genetic differences between species can be estimated, among other approaches, using nucleotide sequence differences, DNA/DNA hybridization distances, amino acid sequence differences, restriction-enzyme pattern differences, and immunological distances. According to the **neutral theory of molecular evolution** some classes of mutations accumulate in a sufficiently clock-like manner over relevant time intervals as judged by the relative rate test (Sarich and Wilson 1967b), albeit in a manner that is modulated over longer time periods by factors such as generation time and effective population size. Thus, knowing the genetic distance between two species allows the estimation of the average time since the two genomes diverged. This time is calibrated using known divergence times based on the fossil record. So if D is, say, the amount of DNA sequence divergence per site and u is the mutation rate (estimated from the taxa used to calibrate the clock) then the equation $T=D/(2u)$ can be used to calculate T , the divergence time between the species of interest. For example, paleontological evidence about the timing of the divergence between Old World and New World monkeys can be used to calibrate the molecular clock in primates and from this the divergence time of hominoids from Old World monkeys, or that of modern humans from chimpanzees, can be estimated (e.g., Kumar et al. 2005). However, these times will always be older than the time of population separation, and it is the latter that the fossil record can be used to estimate. Given that population separation is recognized using derived features of one or both lineages, and that these features may not be present at the precise time of population separation, the fossil record will always underestimate the actual population separation time by some unknown amount. The molecular clock is invalid if the locus does not evolve neutrally (i.e., if it is under selection). To use a molecular clock to estimate times of divergence, sufficient external data to calibrate the clock reliably (i.e., a well-dated fossil record) as well as relative rate tests to demonstrate rate constancy at the locus or loci being used are necessary. Recently, the analysis of both the genetic data and the fossil record has

frequently followed a Bayesian approach in which prior probabilities can be assigned both to a range of plausible fossil-based calibration times and to plausible variation in “local” rates of genetic change, such approaches generating best-fit, most probable hypotheses given the data. It is now clear that rates of genetic change vary between and within tree branches and it is also rarely the case that the fossil record is dense enough to demonstrate with confidence that a divergence has not occurred, even though it can show that a divergence has occurred; hence caution needs to be used in interpreting any molecular clock estimates. Neither the primate fossil record nor our understanding of the long-term fluctuations in rates of genetic evolution are currently complete enough to settle unambiguously questions such as the divergence age of crown primates, cercopithecoids, and hominoids, or *Pan* and *Homo*. See also **neutral theory of molecular evolution**.

molecular evolution Evolution involving changes in either **DNA** (due to one or more **bases** being substituted for another, or added, or deleted) or **proteins** (due to one or more **amino acids** being substituted for another).

molecule (L. *moles*=mass) Two, or more, atoms held together by chemical bonds, or the smallest physical unit of a substance that demonstrates the properties of that substance (e.g., a single H₂O molecule has all the properties of a larger volume of water). The term **molecular biology** suggests it should involve the biology of all molecules, in practice molecular biologists are mainly concerned with complex molecules such as proteins and nucleic acids involved in the maintenance of life.

moments of area See **cross-sectional geometry**.

monogenic trait (Gk *monos*=alone) A trait caused by alleles at a single gene locus, following simple patterns of inheritance from the Mendelian laws of genetics. In modern humans monogenic traits include wet or dry earwax and attached or unattached earlobes. Such phenotypic traits are easy to measure and thus have been intensively studied; the single nucleotide polymorphism (or SNP) responsible for the variation in earwax phenotype was discovered in the *ABCC11* gene (Yoshiura et al. 2006) (NB: despite being cited as

such in many textbooks, tongue rolling is *not* a monogenetic trait).

monophyletic See **clade**.

monophyletic group (Gk *monos*=alone and *phylon*=race) See **clade**.

monophyletic species concept See **species**.

monosomy The condition where only one of a pair of chromosomes is present in a diploid organism. In modern humans the only monosomy that is viable is that of the X chromosome.

monozygotic twins When the two offspring produced in the same pregnancy are derived from a single zygote (i.e., a single egg fertilized by a single sperm) that then divides into two separate embryos. Monozygotic twins are generally referred to as identical twins. See also **dizygotic twins**.

monsoon (Ar. *mawsim*=seasonal, referring to the seasonal reversal of the winds) Monsoonal climates are characterized by summer-season precipitation. The West African monsoon is dominated by summer monsoonal precipitation associated with the northward migration of the **intertropical convergence zone**. Tropical Atlantic sea-surface temperatures are the primary variable controlling the strength of West African monsoon and Sahelian precipitation at inter-annual to inter-decadal time scales (Giannini et al. 2003). Variations in continental heating driven by **precession** also influence the land/sea temperature contrast and the strength of the monsoon on multi-millennial time scales (deMenocal et al. 2000, Liu et al. 2003). The Indian monsoon indirectly affects climate in northeast Africa, causing drying. Prior to the uplift of the Himalayas and the Ethiopian highlands, northeast Africa would also have had a substantial monsoon. Summer-season precipitation in monsoonal **tropical climates** creates favorable conditions for C₄ tropical grasses.

Monte Carlo (Fr. *Monte-Carlo* is one of the administrative areas of the state of Monaco, and the Monte Carlo quarter of Monaco is where Le Grand Casino is located) The term “Monte Carlo” is used for a family of methods that allow for statistical tests using randomly drawn samples from a larger set of possible outcomes. The term

comes from the use of random-number generation in gambling. Monte Carlo methods are a subset of resampling analyses (as opposed to exact resampling analyses). *See also* [resampling](#).

Monte Christo Formation (etym. Named after the local town near the type section) [General description](#) The second oldest of the five geological formations recognized in the Malmani Subgroup of the dolomite uplands near to modern-day Krugersdorp in South Africa. [Cave sites within this formation](#) [Sterkfontein](#), [Swartkrans](#). *See also* [Australopithecus africanus](#); [Paranthropus robustus](#); [Sterkfontein](#); [Swartkrans](#).

Monte Circeo (Location 41°14'N, 13°05'E, Italy; etym. from *Circe*, a sorceress from Homer's *Odyssey* who was said to dwell there) A limestone promontory along the Tyrrhenian coast of Italy about 85 km/53 km southeast of Rome that includes a number of caves known to contain **Pleistocene** deposits. There are over 30 caves within the mountain, but only three have produced hominin remains; from west to east they are **Grotta Breuil**, **Grotta del Fossellone**, and **Grotta Guattari**. In the past, the fossils found in the caves were named after the mountain itself (e.g., Circeo I, Circeo II), but more recently workers have taken to naming the remains after the individual cave (see Bietti and Manzi 1991). Hence, Circeo I would now be known as Guattari I. *See also* [Grotta Breuil](#); [Grotta del Fossellone](#); [Grotta Guattari](#).

Monte Fenera (Location 45°42'40"N, 8°18'35"E, Italy; etym. named after the mountain on which the sites are located) [History and general description](#) Two caves, Ciota Ciara and Ciutarun, lie on the western side of Monte Fenera in north-west Italy. Excavations were carried about by C. Conti in 1955–6, but the fragments were not identified as hominin until much later. [Temporal span and how dated?](#) There does not appear to be a published chronology for the site, but the **Mousterian** artifacts and the affinities of the hominin remains with *Homo neanderthalensis* suggest a Middle Paleolithic date. [Hominins found at site](#) The hominin remains consist of two teeth and a fragmentary parietal from Ciota Ciara (known as Ciota Ciara 1–3 or Fenera 1–3), and a single tooth from Ciutarun (known as Ciutarun 1 or Fenera 4). [Archeological evidence found at site](#) The lithic assemblage in both caves is Mousterian.

Key references: [Hominins](#) Mottura 1980, Villa and Giacobini 1996.

Montgaudier (Location 45°40'N, 0°29'E, France; etym. named after a nearby village) [History and general description](#) This series of interconnected but collapsed caves in the Charente region was discovered in the late 19thC and has been excavated by a series of researchers since then. It contains both Middle and Upper Paleolithic deposits, and is known for its **Magdalenian** bone artifacts (which are of uncertain provenance) and for the discovery in 1974 of a juvenile mandible that has been attributed to *Homo neanderthalensis*. [Temporal span and how dated?](#) Radiometric dating has not been attempted; the site is dated based on technostratigraphy, faunal analysis, and geostatigraphy. The layer in which the Neanderthal fossil was found is the oldest in the cave, and could date to *c.*150 ka, but this is an extremely tentative date. [Hominins found at site](#) Several cranial and postcranial remains have been recovered, mostly from the Magdalenian levels. One juvenile Neanderthal mandible was found in the oldest levels of the cave. [Archeological evidence found at site](#) Many artifacts, predominantly from the Magdalenian and **Mousterian**. Some researchers have reported **Solutrean** and **Aurignacian** items, but this has been challenged. The complex geology of the site makes it difficult to reconstruct the archeology. Key references: [Geology, dating, and paleoenvironment](#) Duport 1967; [Hominins](#) Mann and Vandermeersch 1997; [Archeology](#) Duport 1967, Debénath and Duport 1972.

Montmaurin (Location 43°13'N, 0°36'E, France; etym. Fr. after the nearby town) [History and general description](#) This site comprises a series of caves and chimneys in a limestone cliff overlooking the Seygouade River in the Pyrenees region of southern France. The caves were long known to contain archeological materials and were first explored near the beginning of the 20thC by Marcellin Boule and others, but the majority of information comes from the excavations by Louis Méroc and colleagues in the late 1940s. The site is one of the oldest known in France. [Temporal span and how dated?](#) [Biostratigraphy](#) and palynology suggest that the earliest layers (those containing the well-preserved mandible) date to the **Mindel-Riss** interglacial (*c.*400 ka). Most of the site ranges between **Riss I** (*c.*390 ka) and **Würm I** (*c.*100 ka),

although the youngest levels are from the Roman era. Hominins found at site Several hominin dental remains were recovered, including a well-preserved mandible that has been variously interpreted as belonging to a **pre-Neanderthal** or *Homo heidelbergensis*, portions of a maxilla of uncertain taxonomic status, a juvenile mandibular fragment likely *Homo neanderthalensis*, and a few isolated teeth. Archeological evidence found at site The site contains several levels, including late **Acheulean** assemblages associated with the earlier hominin, a typical **Mousterian** layer, and a **Châtelperronian** layer. Key references: Geology, dating, and paleoenvironment Méroc 1963, Girard 1973; Hominins Billy 1982, 1985, Billy and Vallois 1977a, 1977b; Archeology Méroc 1963.

morphocline (Gk *morph*=form and *klinein*=to lean or a gradient) The order of character states from the most primitive to the most derived. Morphoclines are usually established by two criteria: **ontogenetic** and **outgroup**. In the former, the earlier stages in the ontogeny of a character are assumed to be more primitive than the later stages, and in the latter closely related taxa are used as outgroups on the assumption that they are likely to display the primitive character state. For example, the ontogenetic criterion would suggest that the primitive condition for any tooth root is a single root, because all teeth with multiple roots start out as single-rooted. But the outgroup criterion suggests that the primitive condition for the root system of anterior mandibular premolar teeth within the hominin clade is the same as the most common root morphology for *Pan* (2R: MB+D; i.e., a mesiobuccal root and a plate-like distal root). Within the hominin clade there appear to be two derived morphoclines. One that trends towards root simplification, with a single root (1R) at the derived end of one morphocline, and one that trends towards complexity, with teeth with two molar-like roots (2R: M+D) at the derived end of the other morphocline.

morphogenesis (Gk *morphe*=form, shape, plus *genesis*=origin, generation) Morphogenesis is the development of morphology or form during the embryonic stage. Along with pattern formation, which is the formation of discrete tissues along a spatiotemporal pattern, and growth, morphogenesis is one of the three major classes of developmental processes. Morphogenesis is technically about more

than just shape, which is defined as the geometric features of an object that are left once location, orientation, and size have been removed. Morphogenesis, rather, is about form, which is the combination of size and shape and it is thus not sharply distinguishable from growth. The reason is that the developmental processes that produce morphology do not allow for a clear distinction between growth and change in shape. During embryological development, the key developmental processes involved in morphogenesis are cell proliferation, cell polarity, cell adhesion, cell migration, cell hypertrophy, production of extracellular matrix, and cell death. Cell proliferation, cell hypertrophy, and the production of extracellular matrix are also primary drivers of growth. The combined activity of these processes produces changes in the form of embryos as they grow and thus results in morphology. The combination of cell proliferation and cell polarity, for example, is sufficient to produce a change in shape because cell polarity will produce preferential directions of cell division. Cell adhesion is critical for morphogenesis, particularly in early embryonic development. As has been shown in computer simulations, cells that have no properties other than proliferation and a tendency to adhere to each other on only part of their surface cell membrane will spontaneously develop into morphological structures. Cell migration can profoundly influence form by altering the location of centers of cell proliferation. The migration of neural crest cells into the branchial arches, for example, is required for morphogenesis of the face. Physical interactions between tissues and between the organism and its surroundings also play an important role in morphogenesis. During embryological development, as one region of cells grows it will displace neighboring regions. This phenomenon results in a complex interplay of physical interactions during development that is only now beginning to be understood. As the embryonic brain (neural tube) grows, for example, it will expand and stretch out the developing face. The face, which forms from prominences that grow forward from the brain around the primitive mouth (stomodeum), needs to grow at a rate that is sufficient to overcome the fact that it is being stretched out by the growing brain. Physical interactions between muscles and bones and between the musculoskeletal system and the physical environment also exert profound influences on the form of bones; these are also morphogenetic processes. Experiments that deprive bones of mechanical stimuli demonstrate the critical role that such

physical factors play in the development of skeletal morphology. Evolution, which has been neatly summarized as the influence of ecology on development, mainly involves minor adjustments to morphogenesis and to growth, which between them determine the shape and size of the bones and teeth that comprise the hominin fossil record. Genes that affect morphology do so via effects on the complex developmental processes and pathways subsumed within the term morphogenesis.

morphogenetic fields (Gk *morphe*=form or shape, plus *genesis*=origin or generation) The concept of the morphogenetic field originated in the early part of the 20thC. Experiments conducted using dissection, transplantation, and grafting allowed researchers to ascertain that there were some areas (fields of cells) in the developing embryo that were under the influence of self-directed, self-contained regulation, that would eventually lead to the development of an organ, or structure (e.g., heart, limb). It was further shown that these regions had the potential to influence other cells that they were brought into contact with, by exerting an influence over the fate of these cells so that they developed according to the rest of the field. This led to the idea that it was the field itself, rather than the individual cells composing it, which was responsible for the pattern of development leading to the eventual organ or structure. After the middle part of the 20thC the concept lost popularity; there were no direct tests of the concept and the burgeoning field of studying gene expression in embryos took hold. However, from the latter part of last century to today, more sophisticated techniques have been able to demonstrate the molecular basis for the observations that led to the morphogenetic fields concept. These are, first, that there are spatially defined regions of gene expression that are related to important patterning events in diverse developmental contexts and, second, that secreted factors can produce spatial patterns of gene expression that can determine the morphogenetic fate of transplanted tissues.

morpholino *See* knockout.

morphological integration (L. *integrare*=to make complete) The tendency for development to produce **covariation** among morphological **traits**. Under this definition, morphological inte-

gration is a property of the architecture of **development** and it is distinct from correlation or covariation observed in the **phenotype**. Patterns of phenotypic covariation or correlation result from integration when combined with genetic variation in particular populations (Hallgrímsson et al. 2009). The term was originally coined by Olson and Miller (1958) who also laid the foundation for the modern study of integration. The concept appears in Darwin's *On the Origin of Species*. In the following quotation in which he refers to "correlated variation," Darwin presages both the concepts of integration and also **modularity**. Darwin wrote, "I mean by this expression that the whole organisation is so tied together during its growth and development, that when slight variations in any one part occur, and are accumulated through natural selection, other parts become modified. . . . The several parts of the body which are homologous, and which, at an early embryonic period, are identical in structure, and which are necessarily exposed to similar conditions, seem eminently liable to vary in a like manner." (*On the Origin of Species*, 6th edition, 1872). The first formal study of correlated variation, however, is probably that of Sewall Wright (1932), who performed a quantitative analysis of covariation in fowl limb lengths. The population genetics framework for the study of morphological integration was developed principally by James Cheverud and Gunter Wagner in various publications in the 1980s and 1990s (e.g., Cheverud 1982, 1988, 1996, Wagner 1984, 1989, 1996). In this framework, functional integration, or shared functions among traits, leads to genetic and developmental integration through natural selection. This, in turn, produces evolutionary integration, or the tendency for structures to exhibit coordinated evolutionary changes. Much of the pioneering work on morphological integration in primates was done by James Cheverud and colleagues (e.g., Cheverud 1982, 1995, 1996, Ackermann and Cheverud 2000, Marriog and Cheverud 2001). Recent years have seen a surge in studies of integration in the literature on human evolution, where morphological integration is measured primarily via patterns of **phenotypic correlation** or covariation. For paleoanthropologists, understanding morphological integration is an important concern both at practical and theoretical levels. Practically, it is necessary for structuring cladistic studies to avoid highly correlated (integrated) phenotypic traits

(Strait 2001), or for choosing extant models that share similar patterns of integration (and thereby presumably have evolved similarly) to a fossil group being studied (Ackermann 2003, 2009). Theoretically, it provides important insights into evolutionary process, as the degree and pattern of integration can either constrain or facilitate the evolution of complex phenotypes, thereby having a profound impact on the manner in which morphological evolution proceeds. A simple way to think about this is through the following analogy: imagine three objects on your computer screen. You can "grab" each object with your cursor and move each independently; this is like selection acting independently on traits that are not integrated. But imagine using a grouping function to link the objects to each other, so that they only move as a unit (i.e., they are now integrated). In grouping the objects, you have constrained the movement of each object, as they cannot move independently. So if one object becomes fixed, the others do as well. This would be like **stabilizing selection** acting on one trait, which would as a result constrain the evolution of the other, correlated traits. But at the same time, by selecting and moving just one of the three objects, you can move the entire group. In other words, directional selection acting to change a trait would facilitate the evolution of correlated traits, even though those traits are not themselves being selected for. This is very different from the target and amount of selection necessary to move these three traits independently, if they were not integrated, although the end product might appear the same. Obviously in a complex phenotype there are many sets of integrated traits, and in such a case an organism is said to be modular. Modularization can act to release evolutionary constraints, allowing different parts of the phenotype to evolve independently. Williams (2010) provides an example of how the principles of morphological integration can be used to help answer questions related to **evolvability**. See **modularity**.

morphology (Gk *morph*=form and *ology*=study of) The morphology of an animal, structure, or fossil is the combination of its external and internal appearance. It subsumes both gross (i.e., what you can see with the naked eye, also called **macrostructure**) and microscopic (what you need a microscope to see, also called **microstructure**) morphology. To be useful for identification, clas-

sification, and phylogenetic analysis, morphology has to be captured in some systematic way. There are two main systems for capturing and recording morphology. One uses measurements, the other records morphology by using presence/absence criteria, or by comparing the fossil's morphology with a series of standards. The former is referred to as **metrical analysis**, **morphometrics**, or just morphometry. The latter system is called **non-metrical analysis** because it relies on categorical methods for assessing the presence/absence or the degree of development of structures whose morphology needs to be compared. Examples of non-metrical traits include the numbers of cusps or roots a tooth has, or the presence or absence of a structure such as a foramen in the cranium, or a bony tubercle on a limb bone. In the case of morphometric methods, measurements are traditionally made between homologous, standardized locations called **landmarks**. The measurements taken are usually the shortest distance between the landmarks; these are known as chord distances. If the surface between the landmarks is curved, a tape laid between the two points will record the arc distance, and the difference between the chord and arc summarizes the degree of curvature; this can also be captured by the chord distance and the subtense. It is also possible to use angles to record the orientation of a structure relative to the sagittal or coronal planes, or to a reference plane such as the Frankfurt Horizontal or the orbital plane. A family of three-dimensional morphometric techniques, also called three-dimensional morphometrics, can be used to record the shape of an object in three dimensions. The position of each reference point is recorded using a three-dimensional coordinate system, and the distances between pairs of recorded points can be recovered if needed. These are the type of three-dimensional data that are used in a family of methods called **geometric morphometrics**, and these methods of data analysis are being used with increasing frequency. Three-dimensional data can be captured using machines called "digitizers," or they can be captured from laser- or CT-generated images. Digitizers usually have a mobile arm with a fine, needle-like point at the end. The tip of the needle is placed on the reference point and then the machine automatically records the location of the reference point in three dimensions. These three-dimensional coordinate data can be manipulated using specialized software programs

(e.g., Morphologika), and then converted it into a "virtual" solid object whose shape can be visualized and compared. These virtual surfaces are compared using a variety of analytical methods, some of which (e.g., thin-plate spline analysis) were developed by engineers for measuring and comparing the complex three-dimensional shapes of machinery components. Morphology is also used to refer to the scientific study of form as in "the morphological sciences" (syn. anatomy, phenotype).

morphometrics (Gk *morph*=form and *metron*=measurement) Morphometrics is literally the study of **form**, and although form comprises **size** and **shape**, most use of morphometric methods in paleoanthropology focuses on the effective capture and comparison of the shape of complex objects (e.g., teeth, cranium, pelvic bone, proximal end of the femur, carpal, and tarsal bones). Morphometric methods can be divided into traditional morphometrics (i.e., non-geometric) and **geometric morphometrics**. Traditional morphometric methods typically apply bi- and multivariate analytical statistical techniques to a range of measurements, such as distances and distance ratios, angles, areas, and volumes. These methods were and still are valuable, but a common disadvantage is that distance measurements do not preserve the geometric properties of the object, they do not allow those geometric relationships to be reconstructed, nor can such data be subjected to statistical analysis before separating shape information from overall size. In the 1980s several innovations (e.g., coordinate-based analytical methods, the introduction of more sophisticated shape statistics, and the computational power to manipulate deformation grids) meant that researchers could explore and visualize large high-dimensional data sets and take advantage of exact statistical tests based on **resampling**. This new approach to morphometry is referred to as geometric morphometrics because it preserves the original geometry of the measured objects during all phases of the analyses. Geometric approaches used in paleoanthropology include **Procrustes analysis** (Bookstein 1996, Dryden and Mardia 1998), **Euclidean distance matrix analysis** (Lele and Richtsmeier 1991, 2001), and elliptic Fourier analysis (Lestrel 1982). See Rohlf (2000a, 2000b, 2003) for a review and for comparisons of these methods.

morphospecies Cain (1954) defines a morphospecies as a species group defined on the basis

of morphology, and suggests that "all (or very nearly all) species founded upon fossils will of necessity be morphospecies" (*ibid*, p. 51). It is, in effect, the type of species most paleoanthropologists try to recognize, but nevertheless it still leaves moot how much variation can be subsumed within a single morphospecies before a researcher should contemplate establishing another morphospecies to accommodate the "overflow" variation. *See also species*.

mortality The number of deaths per unit of time in a population, scaled to the size of that population. Mortality rate is calculated as number of deaths per 1000 individuals in a given year. Mortality rates, and the pressures that produce these figures, are of central importance in theories that attempt to explain life history strategies in modern humans and nonhuman primates. For example, low mortality rates relax the pressure on reaching reproductive age early and allow for ontogenies to move more slowly, especially during the juvenile period. Juvenile mortality and adult mortality each exert their own influence on fitness across a wide range of life history strategies.

mortality rate doubling time The mortality rate doubling time is the amount of time (usually measured in years) for the hazard of death to double from its initial value in a **Gompertz hazard model**. Starting from the hazard function, we have $h(0)=\alpha$ and $h(a)=\alpha e^{\beta a}$, so that $h(a)/h(0)=2=e^{\beta a}$. Taking the natural logarithms of both sides and solving for t gives $\ln(2)/\beta$ as the mortality rate doubling time. As an example, we can use $\alpha=0.001$ and $\beta=0.08666434$, so that mortality rate doubling time is $\ln(2)/0.08666434=8$ years. This value of a mortality rate doubling time of 8 years has been noted as a general pattern for modern humans (Finch et al. 1990).

mosaic The presence of cells with two different **genotypes** in the same individual. For example, this can occur because of a mutation during development that is then found in only a subset of the cells in the body, or when more than one fertilized zygote fused early in embryonal development (chimerism). In primates, marmoset chimerism occurs as a result of frequent twinning. Twins *in utero* can exchange stem cell lines by an interconnected lattice of blood vessels attached to the same placenta (Benirshke et al. 1962). The term

mosaic evolution is also applied to morphological changes that occur in stages as opposed to a synchronic package (e.g., different rates of brain, locomotor, or dental evolution).

mosaic evolution (L. *mosaicus*=of the Muses. A term applied to a decoration made of many small pieces) The term introduced by Gavin de Beer (1954) to describe what William King Gregory and Robert Broom had earlier described as “palimpsest evolution.” Based on his study of *Archaeopteryx* and the origin of birds, de Beer pointed out that organisms typically combine a mix of evolutionarily older and more recent traits that have evolved at varying rates at different times. They thus present a combination, or mosaic, of “primitive” (plesiomorphic) and “advanced” or “derived” (apomorphic) characters. The mosaic contrasts often correspond to functionally distinct systems (masticatory, locomotor, nervous system, etc.), with those reflecting recent or current major adaptive shifts displaying the fastest rates of change and being the most derived conditions at any given time. However, the need to maintain the overall integrity of the entire phenotype constrains the pace and magnitude of change in any given trait or character complex. The hominin fossil record has been cited as a particularly clear case of mosaic evolution. *See also* **palimpsest evolution**.

mosaic habitat (Gk *mouseion*=a picture or design made up of small components, and L. *habitare*=to inhabit) A mosaic habitat (or habitat mosaic) is one in which a range of different habitat types are scattered across, and interspersed within, a given area. The paleohabitats of many Miocene, Pliocene, and Pleistocene hominin sites have been reconstructed as mosaics. In some, if not all, cases these could be accurate representations of regional habitats, since a great deal of variation in habitat can be present in a relatively small geographic area (Andrews 2006). Examples of the latter include modern Maputaland (Van Wyk 1994) and the Okavango Delta (Ramberg et al. 2006) in southern Africa. However, taphonomic processes are likely to have altered the assemblages upon which the reconstructions are based, resulting in “time-averaged” and “space-averaged” reconstructions that result in a mosaic habitat signal in the absence of a true mosaic habitat. The possibility of time and space averaging should always be considered when faced with paleohabitat reconstructions indicating mosaics. In these cases, statistical tech-

niques such as **ordination** and **rarefaction** may yield valuable information about assemblage biases (Andrews 2006). Modern evidence also shows that although habitats can be highly variable in a small area, they can also vary over even a short period of time, as has been seen for example at Amboseli in Kenya (Altmann et al. 2002). *See also* **time-averaging**.

Moschida (Gk *moskhos*=mouse, testicle, musk) The family name of the musk deer, genus *Moschus*. The musk deer, which has no antlers but has a musk gland of economic importance, resembles a chevrotain, and they live in mountainous forest of southern Asia.

Mossgiel (Location 33°15'S, 144°28'E, Australia; etym. named after a nearby town) History and general description A clay pan on Turmbridge Station, near Mossgiel in New South Wales, that yielded a partial hominin skeleton in 1960. Temporal span and how dated? **Radiocarbon dating** of bone carbonate indicates a **Holocene** age *c.*6050 years before present. Hominins found at site The hominin remains were interred at the site in a sitting position and include a robust partial modern human cranium (including a mandible) and fragmentary postcrania. Archeological evidence found at site Abundant **cores**, **scrapers**, and semi-lunar **microliths** were recovered from the surface of the clay pan. Key references: Geology, dating, and paleoenvironment Macintosh 1965; Hominins Macintosh 1965, Freedman 1985; Archeology Macintosh 1965.

most parsimonious tree The most parsimonious tree, also referred as the most parsimonious **cladogram**, is the tree that requires the fewest number of evolutionary events (as recorded by **character state** changes, or steps) to account for the distribution of similarities among a group of taxa. The recovery of the most parsimonious tree (or trees) is the primary goal of **cladistic analysis**. *See* **cladistic analysis**.

most recent common ancestor The ancestor of a group of species that emerged closest to the present. Because evolution involves species splitting and then their descendents splitting in turn, any group of species will share multiple ancestors that will have emerged at different times. The most recent common ancestor is the one whose emergence date is latest in time. As an

example, consider modern humans and orangutans. Even if we go no further back than the origin of the primates, modern humans and orangutans have at least three ancestors in common: the ancestor of all the haplorhine primates, that of all the hominoid primates, and that of all the great apes. Of these ancestors, the most recent was the ancestor of all the great apes. Thus, the most recent common ancestor of modern humans and orangutans is the ancestor of all the great apes. *See also* cladistic analysis; coalescent time.

motion analysis The capture and analysis of quantitative information about movement, usually undertaken with the goal of studying functional morphology. *See also* kinematics.

motor imitation *See* imitation.

motor speech areas *See* Broca's area.

Moula-Guercy *See* Abri Moula-Guercy.

Mount Carmel A mountainous region on the Mediterranean coast of modern-day Israel contains several historic and prehistoric sites. One valley on its southwestern slope, called **Wadi el-Mughara** in Arabic and *Nahal Me'arot* in Hebrew (meaning "stream of caves" in both cases), is the location of the Middle and Late Pleistocene sites of **el-Wad**, **Tabun**, and **Skhul**, all of which were originally explored by Dorothy **Garrod** and her team in the 1930s and 1940s. Tabun and Skhul, which are, respectively, *Homo neanderthalensis* and anatomically modern human sites, are close both geographically (no more than 100 m apart on the same outcrop) and temporally (both estimated to be between 100 and 130 ka). Another site on Mount Carmel, **Kebara**, has yielded an exceptionally complete postcranial skeleton of *H. neanderthalensis*. *See also* Garrod, Dorothy Annie Elizabeth (1892–1968).

Mousterian (etym. After the site of **Le Moustier**) A technocomplex found in the European and Near Eastern record from sites dating to the **Middle Paleolithic**, which is characterized by the use of the **Levallois** technique and a high proportion of scrapers. It is associated with *Homo neanderthalensis* in Europe, but in the Near East it is found in association with both Neanderthals (e.g., **Tabun**) and with anatomically modern

human fossils (e.g., **Skhul**). French archeologist François Bordes (1961a, 1961b) defined 63 different types of Mousterian stone tool and suggested that different layers within sites had different percentages of each type. He noted four distinctive variants, or facies, of the Mousterian: the Mousterian of Acheulean Tradition, which included small handaxes or backed knives; the Typical Mousterian, which was dominated by sidescrapers; the Denticulate Mousterian, which had a high proportion of notched or toothed flakes; and the Quina-Ferrassie (Charentian) Mousterian, which had steep retouch or was made predominantly on **Levallois** flakes. He argued that each of these facies represented different tribes or cultural groups, who made stone tools based on a cultural tradition. Lewis and Sally Binford (1966) agreed broadly with Bordes' tool typological distinctions, but argued that each tool type had a specific function, so that the different facies represented differences in behavioral demands at the various sites, not cultural differences. Harold Dibble and Nicholas Rolland (1992) have argued that Bordes' 63 tool types do not represent the final intent of the maker, and instead represent different points along the reduction sequence of tool making, from a raw flake to a heavily reused and retouched flake. They reject any explanation based on cultural traditions or function, and argue that the differences among the facies reflect only differences in raw material and intensity of reduction.

Movius' Line The term was apparently introduced by Swartz (1980), but it refers to an observation set out by Hallam Movius in a seminal review entitled *The Lower Paleolithic Cultures of Southern and Eastern Asia* (Movius 1948). At the end of that review Movius points to the demarcation between the "Hand-Axe Culture" seen in Africa, the Near East and much of India, and the "Chopping-Tool Culture" seen in mainland and Southeast Asia (a region he refers to as Southern and Eastern Asia). The absence of **handaxes** in the latter culture struck Movius as significant enough to cause him to write that in "Southern and Eastern Asia...the tools consist for the most part of relatively monotonous and unimaginative assemblages of choppers, chopping-tools, and hand-adze" (*ibid*, p. 411), and he went on to suggest "that as early as Lower Palaeolithic times Southern and Eastern Asia as a whole was a region

of cultural retardation” (*ibid.*, p. 411). The line of demarcation can be clearly seen in Map 4 (*ibid.*, p. 409). Evidence recovered since Movius’ time has shown that hominins in eastern Asia could and occasionally did manufacture bifacially flaked, handaxe-like tools, with well-documented examples from the Bose Basin (Schick and Dong 1993, Hou et al. 2000) in China and from the Imjin/Hantan River Basins in Korea (Norton et al. 2006), but their rarity is consistent with the pattern of geographic distribution noted by Movius.

MPFT *See* Mission Paléoanthropologique Franco-Tchadienne.

MPT Acronym for the Mid-Pleistocene transition (*which see*).

MQ *See* megadont.

MRCA Acronym for the most recent common ancestor of a group (e.g., molecules, taxa). *See* coalescent; most recent common ancestor; phylogeny.

MRI Acronym for magnetic resonance imaging. *See* functional magnetic resonance imaging.

MSA Acronym for the Middle Stone Age (*which see*).

MSD Prefix for fossils recovered from the Mesgid Dora collection area, Woranso-Mille study area, Afar, Ethiopia.

μCT *See* micro-computed tomography.

mudstone A sedimentary rock composed of fine particles of clay and silt size. The term is used to indicate a lithology finer than sandstone but of generally indeterminate composition.

Mugharet el ‘Aliya (Location 35°45’N, 5°56’W, Morocco; etym. the name means “cave of ascent”). This cave site has also been referred to as Dar el ‘Aliya, The High Cave, and Tangier) History and general description Carleton Coon began the first detailed excavations at the cave in the 1930s, and detailed stratigraphic investigations were directed by B. Howe in 1947. Mugharet el ‘Aliya, one of the “Caves of Hercules,” is located at

Cap (Cape) Ashakar, 11 km/7 miles southwest of Tangier. The cave initially formed as a solution cavity within Upper Pliocene conglomeratic limestone, and during a subsequent high-sea-level phase it was breached by wave action. The Pleistocene sediments consist of five beds of well-sorted wind-blown fine-to-medium sand derived from beaches formed beneath the cave. The site is notable for possessing stratified Aterian assemblages that date to beyond the limits of radiocarbon dating. Temporal span and how dated? Electron spin resonance spectroscopy dates on mammalian teeth suggest that the basal Layer 10 dates to 81±9 ka using a linear-uptake model, and 62±6 ka using an early-uptake model, and teeth from Layers 5, 6, and 9 have provided ESR dates ranging from 39±4 to 56±5 ka. These results suggest an age range of 60–35 ka for the archeological sequence, including the Aterian levels in Layers 5 and 6. Hominins found at site Tangier 1, a juvenile maxilla, was recovered by Carleton Coon in 1939 and has been assigned to *Homo sapiens*. Although not recovered *in situ*, it is attributed to the Aterian Layer 5 on the basis of a similar fluorine/phosphate ratio to other fauna from that level. Two isolated teeth (an upper canine and third premolar) are attributed to the maxilla. A third tooth (a worn upper second molar) belongs to a second individual. Archeological evidence found at site The densest artifact accumulations derive from Layers 6 and 5, and are attributed to the Aterian on the basis of abundant bifacial leaf-shaped points, endscrapers, rare pieces with tangs, Levallois cores and flakes, and rare blades removed from opposed platform cores. The faunal remains are incompletely published, but include gazelle, zebra, wild cattle, *Pelorovis*, hartebeest, warthog, golden jackal, and the spotted hyena. The latter likely denned in the cave and may have contributed to the faunal accumulation. Muierii 1 Site Baia de Fier, Romania. Locality Galeria Musteriană. Surface/in situ Surface. Date of discovery 1952. Geological age Direct AMS radiocarbon date $30,150 \pm 800$ years BP (on a combined sample from tibia and scapula) and AMS ^{14}C ultrafiltration $29,930 \pm 170$ years BP (on the cranium); both dates are uncalibrated. Developmental age Adult. Presumed sex Female. Brief anatomical description Partial cranium, preserving the face, most of the neurocranium, and part of the basicranium; partial mandible, preserving the right ramus and corpus, broken anteriorly at the level of the canine; partial scapula, preserving glenoid fossa, lateral spine and axillary border up to the cranial end of the teres major attachment, and a tibial fragment. Announcement Gheorghiu and Haas 1954. Initial description Gheorghiu and Haas 1954. Photographs/line drawings and metrical data Soficaru et al. 2006, Trinkaus 2008a. Detailed anatomical description Soficaru et al. 2006, Trinkaus 2008. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Among the earliest reliably dated anatomically modern human individuals in Europe. Location of original Museum of Ethnography and Folk Art, Craiova and Speological Institut, Bucharest, Romania.

Muierii 2 Site Baia de Fier, Romania. Locality Unknown. Surface/in situ Presumed surface. Date of discovery Unknown. Geological age Ultrafiltration AMS radiocarbon date $29,110 \pm 190$ years BP (uncalibrated). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Partial temporal bone, missing the squamous portion. Photographs/line drawings and metrical data Soficaru et al. 2006. Detailed anatomical description Soficaru et al. 2006. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Among the earliest reliably dated anatomically modern human individuals in Europe. Location of original Museum of Ethnography and Folk Art, Craiova and Speological Institut, Bucharest, Romania.

Muierii 3 Site Baia de Fier, Romania. Locality Unknown. Surface/in situ Presumed surface. Date of discovery Unknown. Geological age Presumed to be contemporaneous with Muierii 1 and 2. Developmental age Adult. Presumed sex Unknown. Brief

anatomical description Fibular diaphysis. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Possibly among the earliest reliably dated anatomically modern humans in Europe. Location of original Museum of Ethnography and Folk Art, Craiova and Speological Institut, Bucharest, Romania.

multiple regression A regression in which there are multiple independent variables, as opposed to simple regression in which there is a single independent variable. In multiple regression, the coefficient associated with any single independent variable is the change expected in the dependent variable associated with a unit change in the independent variable (i.e., the slope) when all other independent variables are held constant. The *P* value associated with each independent variable is the significance associated with adding that variable to a regression model which already contains all of the other independent variables. This can create interpretation problems when two independent variables are highly correlated (e.g., endocranial volume and brain volume). Both variables may be significantly associated with the dependent variable when analyzed by themselves, but in a multiple regression neither variable may have a significant *P* value because adding, for example, brain volume to a regression which already includes endocranial volume improves the fit of the data very little, as is also true for adding endocranial volume to a regression which already includes brain volume. It is useful to check correlations between independent variables before including them in a multiple regression analysis. *See also* regression.

multipoint mapping *See* linkage analysis.

multiregional hypothesis The multiregional hypothesis was formulated by Milford Wolpoff of the University of Michigan and Alan Thorne of the Australian National University during the early 1980s and elaborated subsequently (Wolpoff, Wu, and Thorne 1984, Wolpoff 1989). It is an interpretation of the human fossil record that emphasized a phenomenon known as “regional continuity,” namely what appeared to be morphological continuities in the fossil record of *Homo erectus* and *Homo sapiens*. Specifically, Thorne and Wolpoff (1981) presented evidence that for much of the past million years a distinct

morphological signature could be traced through the hominin fossil record in Australasia. Thorne and Wolpoff later expanded their theory to argue that a similar morphological continuity within geographical regions could be observed in the hominin fossil record over much of the Old World. The multiregional hypothesis of Thorne and Wolpoff argued that *H. erectus* was the first hominin to leave Africa, and that a million years ago these migrants dispersed to populate much of Asia and parts of Europe. It stressed that these regional populations of *H. erectus* encountered and adapted to quite different environments, and because of their relative geographic isolation, regional differences began to appear, yet there was sufficient gene exchange between adjacent groups to ensure that the populations continued to remain as one species. Thorne and Wolpoff pointed to several lines of evidence that suggested to them that the distinctive regional morphology seen in *H. erectus* remains from China could be traced via early *H. sapiens* to distinctive features visible in at least some Asian populations of modern humans. The multiregional hypothesis was similar in some ways to other models of human evolution that had emerged earlier in the 20thC. A few researchers, best represented by the German physical anthropologist Hermann Klaatsch, had argued at the turn of the century that the different modern human races had evolved from different hominin ancestors, and that they in turn had evolved from entirely different species of early anthropoid apes. These theories were shaped by the racial anthropology that was prominent during the early 20thC and they were influenced by the 19thC polygenist theories of anthropologists that considered the different modern human races to be distinct biological species with separate origins. Klaatsch's theory, and others like it that derived the different modern human races from distinct hominin ancestors, attracted few supporters. Aleš Hrdlička (1927, 1930) proposed that all humans had evolved from a "Neanderthal phase" and considered Neanderthals and other forms of *Homo* then known to be ancestors of living humans. Other key scientists including Sir Arthur Keith and Marcellin Boule rejected Hrdlička's hypothesis and argued for a recent common ancestor of living humans. The idea that the various modern human races emerged very early in human evolutionary history re-emerged during the 1960s in a model of human evolution proposed by the

American physical anthropologist Carleton Coon. In 1962 Coon published *The Origin of Races* which examined the question of human evolution and drew upon evidence from the hominin fossil record to argue that the five major modern human races (Caucasoid, Negroid, Capoid, Mongoloid, and Australoid) have existed for more than half a million years. According to Coon, modern human racial diversity was already present in *H. erectus*. Coon's model of human evolution differs from the multiregional model of Thorne and Wolpoff in that Coon believed the various geographical "races" evolved independently from one another, while the multiregional model argues that the distinct geographical populations evolved into modern humans in only relative isolation. In this way Thorne and Wolpoff's theory is similar to a theory proposed in the 1940s by the German physical anthropologist Franz Weidenreich. Weidenreich's polycentric theory of human evolution argued that modern humans had evolved from populations of an early representative of the genus *Homo* that lived in various regions of the Old World. According to Weidenreich, populations of early hominins living in relative geographical separation from other populations evolved into modern humans and because these populations were separated geographically racial variations emerged. Thus, there is a morphological continuity through time in any given geographical region, but Weidenreich was adamant that these populations did not evolve in complete isolation from one another because there was always an important amount of interbreeding between these populations that ensured all these geographical "races" still belonged to the same species. Thorne and Wolpoff explicitly acknowledged the similarities between their own theory and the earlier theory of Weidenreich, although they had invoked more recent biological thinking to explain how this process had occurred. In 1997 Wolpoff and Rachel Caspari published a lengthy explication of the multiregional hypothesis in *Race and Human Evolution*, a text in which they explored the connections between this model of human evolution and Weidenreich's polycentric theory. The original "strong" version of the out-of-Africa hypothesis, which argued that modern *H. sapiens* evolved in Africa and that this population migrated out of Africa and replaced *Homo erectus* in Asia and other archaic hominins throughout Eurasia, is incompatible with the multiregional hypothesis. Adherents to the multiregional hypothesis expressed

doubts about the genetic research conducted by Allan Wilson, Rebecca Cann, and Mark Stoneking on **mitochondrial DNA** from different human populations this and much other genetic work in the 1990s suggested that the evidence is consistent with all modern humans being descended from a small population of *H. sapiens* less than 200 ka. By the late 1990s most paleoanthropologists were interpreting the fossil and genetic evidence as incompatible with a “strong” version of the multiregional hypothesis. However, the results of recent analyses of the draft Neanderthal nuclear genome suggests that whereas modern humans from sub-Saharan Africa showed no evidence of any Neanderthal DNA, three modern humans from outside of Africa showed similar amounts (between 1 and 4%) of shared DNA with Neanderthals. These results are compatible with either a deep split within Africa between the population that gave rise to modern humans and a second one that gave rise to present-day non-Africans plus Neanderthals, or with the hypothesis that there was hybridization between Neanderthals and modern humans soon after the latter left Africa.

multivariate analysis *See* multivariate statistics.

multivariate analysis of variance (or MANOVA) A statistical test that extends **analysis of variance** (or ANOVA) to the multivariate case. MANOVA is used to determine whether there is a significant difference in **vectors** containing the means of two or more continuous variables for two or more groups. For example, if humerus length and radius length are known for skeletal samples belonging to three different species, MANOVA can be used to identify whether a significant difference exists between the three species in mean humerus and radius length. A non-significant result indicates that the vectors of means cannot be said to differ from each other significantly across all groups. A significant result indicates that the null hypothesis that all mean vectors are equal is incorrect; however, it does not indicate which particular variables differ in their means (e.g., humerus length or radius length in the example above) and when more than two groups are included in the analysis, a significant result does not indicate which group or groups differ from the others. As with ANOVA, pairwise tests can be used to identify where the differences

arise from. There are four widely accepted versions of the MANOVA test statistic (Wilks’ lambda, Pillai–Bartlett trace, Lawley–Hotelling trace, Roy’s largest root), all of which give similar results. When MANOVA is performed on two groups (as opposed to three or more) all four versions provide the same result which is equivalent to the result of a **Hotelling T^2 test**.

multivariate size Regardless of whether it is the size of a whole organism, or the size of a smaller subregion of an organism, size can be measured univariately or multivariately. Univariate measures of size are single measurements (e.g., the mass of an animal, the volume of the cranial cavity, the surface area of an articular surface, or the height of a canine). Multivariate measures of size typically reduce multiple size measurements to a single value. The four most common methods of doing so use (a) a **geometric mean**, (b) an equation for the size of a known geometric shape, (c) the first principal component of a **principal component analysis** (or PCA), or (d) centroid size. In the first case, the geometric mean of a set of measurements (usually linear) is calculated to generate a single measure of overall size (e.g., proximal femur size as in Richmond and Jungers 1995, Lockwood et al. 1996, Harmon 2006; forelimb and hindlimb size as in Green et al. 2007; overall skeletal size as in Gordon et al. 2008; and overall cranial size as in Coleman 2008). In the second case, a perfect geometric solid is used to approximate the region of interest (e.g., an articular surface is usually represented as the surface of a partial sphere) or limb segment (often represented as a cylinder or other solid of revolution). Equations for the size of interest, often surface area or volume, are used to approximate size from multiple linear measurements (e.g., femoral and humeral head size as in Ruff 1988, 1990, limb segment size as in Crompton et al. 1996 and Raichlen 2004). In the third case, multiple measurements are included in a PCA without any previous size correction, and scores on the first principal component are interpreted as representing size. It should be noted that multivariate measures of size generated through PCA are dependent on the specimens included in a sample and will change for a particular specimen depending on the other specimens that are included in the analysis. In contrast, measures of size using geometric means or size equations for known

geometric shapes are sample independent (i.e., the value for a particular specimen does not change, regardless of what other specimens are included in an analysis). Furthermore, the first principal component is almost always a mix of size *and* shape information (Jungers et al. 1995). In **geometric morphometrics** analyses, size is usually calculated as centroid size (i.e., the square root of the sum of squared distances of a set of landmarks from their centroid).

multivariate statistics A term which can be broadly applied to a wide range of statistical test as long as the test involves three or more **variables**. Multivariate statistics typically consider the interaction of multiple variables together as opposed to individual analyses of each variable. Commonly used multivariate statistical methods include **multiple regression**, **principal components analysis**, and **discriminant function analysis**.

Mumba Shelter (Location 3°32'S, 35°19'E, northern Tanzania; etym. originally designated as Mumba-Höhle by Margit Kohl-Larsen) History and general description This rock-shelter underlies portions of a gneiss inselberg on the eastern margin of the alkaline and saline Lake Natron. Major excavations were by **Kohl-Larsen** in the 1930s and by Mehlman in the 1970s–1980s. The site remains a key regional sequence because of its c.11 m-thick sedimentary sequence and preserved **Middle and Later Stone Age** artifacts and hominin remains. Temporal span and how dated? The sequence at Mumba Shelter spans the **Late Pleistocene** to **Holocene**. Basal Middle Stone Age deposits and hominin teeth are associated with mean **uranium-series dating** age estimates of c.130 ka and c.110 ka. Overlying strata are dated by additional uranium-series analyses of bone, as well as **radiocarbon dating** assays on shell, charcoal, and ostrich eggshell; the latter material is also dated by **amino acid racemization dating**. The pre-ceramic Later Stone Age levels of Bed III are associated with a 29.96 ± 0.76 ka radiocarbon age estimate; even later deposits date to 2.01 ± 0.01 ka. Hominins found at site Three small morphologically modern human molars occur in Bed VI-B at 7.1 m depth, associated with Middle Stone Age artifacts. Archeological evidence found at site The geological sequence is divided into six beds (numbered from bottom to top), with the basal layer (Bed VI-B) overlying bedrock. Bed VI

is characterized by Middle Stone Age artifacts including rare scrapers and points, and flakes, as well as radial and **Levallois** cores. Locally available quartz and chert are the dominant raw materials throughout the sequence, but obsidian flakes and tools from Bed VI apparently derive from sources in the central Kenya Rift, more than 300 km/185 miles away. Bed V, with an estimated age of between 31 and 67 ka, contains large **backed** pieces (crescents or knives), bifacially and unifacially worked retouched points, small scrapers, and bipolar and Levallois cores, as well as **ochre** and ostrich eggshell beads. These beads have been considered intrusive from Bed III, a hypothesis supported by direct **AMS radiocarbon** age estimates of between 22 and 33 ka and one of two direct amino acid racemization assays. However, a second amino acid racemization result suggests an age of 52 ka for these artifacts, consistent with other age estimates for Bed V. Overlying deposits from the lower portion of Bed III include stone artifacts produced by **bipolar percussion** with rare radial or Levallois core types, and retouched pieces are scarce. Fauna is well preserved in Beds III and V, and include diverse **suids**, **bovids**, hippopotamus, and crocodile, as well as a fish and birds, and other taxa. Above and beneath Bed IV are dense **midden** deposits of land snail (*Achatina* sp.) shells and shell fragments. Key references: Geology, dating, and paleoenvironment Mehlman 1991, McBrearty and Brooks 2000, Conard 2007; Hominins Bräuer and Mehlman 1988; Archeology Mehlman 1979, 1991, McBrearty and Brooks 2000, Prendergast et al. 2007, Diez-Martin et al. 2009.

Mumbwa Caves (Location 15°01'S, 26°59'E in eastern Zambia; etym. named after local village) History and general description Mumbwa Caves consists of multiple sediment-filled entrances formed in a freestanding dolomite outcrop. The site has been excavated a number of times, in the 1920s–1930s by F.B. Macrae, N del Grande, Raymond **Dart**, and Desmond **Clark**; Lawrence Barham renewed fieldwork there in the 1990s. Excavation of what in places is more than 7 m of sediment overlying bedrock has exposed an archeological sequence spanning **Holocene Later Stone Age** strata to **Later and Middle Pleistocene** ones including an example of a windbreak, one of the earliest evidence for hominin habitation structures. Possible **Acheulean** handaxes were

reported from earlier excavations but their presence has not been confirmed by more recent work. Temporal span and how dated? The Mumbwa Caves' sedimentary and archeological sequence spans from more than 170 ka to the present, based primarily on numerous **thermoluminescence dating** estimates on burnt quartz and calcite, more limited **electron spin resonance spectroscopy dating** of teeth, and **radio-carbon dating** assays of charcoal. Hominins found at site Middle and Later Stone Age strata produced six isolated teeth or tooth fragments, and fragments of two femoral shafts, two radii, and a proximal pedal phalanx. Archeological evidence found at site The more than 200,000 stone artifacts show flake production from primarily single and multiple platform cores as well as radial cores (including **Levallois** examples); most made from stone sources less than 10 km/6 miles from the site. Retouched pieces include unifacially and bifacially flaked points as well as some of the earliest backed pieces (segments), and there are also multiple examples of polished and pointed **bone tools**. Several hundred pieces of modified specularite and hematite possibly used as a colorant were imported into the caves. Other features include multiple hearths and a roughly circular area interpreted as the remains of a windbreak. The nonhominin faunal evidence from Mumbwa Caves is sparse, highly fragmented, and bovid-dominated. Taxonomic diversity is comparable to modern or historic fauna in the region, and varies little throughout the sequence, although complementary phytolith analyses suggest some fluctuation between grasslands and wooded grasslands. The majority of the macromammal fauna was hominin- (and to a much lesser extent, hyena-) accumulated; barn owls likely contributed most of the **micro-mammals**. Key references: Geology, dating, and paleoenvironment Barham 2000; Hominins Barham 2000; Archeology Barham 2000.

Mursi Formation (etym. Named after the tribe occupying the area) General description The oldest of the four formations comprised in the **Omo Group**, **Lower Omo Valley**, Ethiopia. It was explored in the late 1960s and early 1970s by the **International Omo Research Expedition**. The exposed sedimentary sequence of the formation is located on the western side of the southern half the Nkalabong range, on the eastern side of the Omo River. The Mursi Formation is

generally divided in three sedimentary members topped by the Mursi basalt; the latter is likely part of the larger Gombe Group basalts found in southern Ethiopia and northern Kenya. The sedimentary sequence, which consists of deltaic and fluvio-littoral deposits, was slightly tilted towards the west and faulted after deposition. No hominins have been found in the formation. The mammalian and non-mammalian fossils found include suids, bovids, elephantids, hippopotamids, deinotheriids, rhinocerotids, equids, turtles, crocodiles, fishes, and molluscs, with suids making more than 50% of the mammalian assemblage. Sites where this formation is exposed Yellow Sands, Cholo (discovered in 2009). Geological age **Potassium-argon dating** of the Mursi basalt that caps the sedimentary members suggests an age of *c.*4 Ma. Key references: Geology, dating, and paleoenvironment Butzer 1976a, de Heinzelin 1983, Brown 1994.

Musée de l'Homme Founded in 1937 by Paul Rivet for the Exposition Internationale des Arts et Techniques dans la Vie Modern (International Exhibition of Arts and Techniques of Modern Life) this museum in central Paris, France, was designed to bring together all the aspects that define humanity, including evolution, present-day unity and variety, and cultural and social expression. It is part of the Muséum national d'histoire naturelle (National Museum of Natural History). In 2006, the ethnographic collection was moved to the newly created Musée du quai Branly, leaving only the physical anthropology and evolutionary history collections at the Muséum national d'histoire naturelle. This move that has garnered considerable debate, with the detractors claiming that the Musée du quai Branly is designed to display only those artifacts that are esthetically pleasing regardless of their scientific value. The Musée de l'Homme was closed for renovations in March 2009 and is expected to reopen in 2012. Hominin fossils and related collections Many of the fossils recovered from French excavations during the 19thC and 20thC including many (but not all) of the remains from **Abri Pataud**, **Arcy-sur-Cure**, **Aurignac**, **La Chapelle-aux-Saints**, **Cro-Magnon**, **La Ferrassie**, **Fontéchevade**, **La Madeleine**, **Malarnaud**, **Montmaurin**, and **La Quina**.

Musée Royal de l'Afrique Centrale *See* Royal Museum for Central Africa.

Museum für Naturkunde Formerly known as the Museum Alexander Humboldt, the Museum für Naturkunde in Berlin, Germany, was established in 1814 when the Humboldt University of Berlin acquired the mineralogy collections of the Berlin Mining Academy collections in 1814. During the 19thC new departments of paleontology and zoology were added, and in 1889 a new building on Invalidenstraße was constructed for the collections. The first Curator of Mammals was Paul Matschie, and his tenure coincided with the time when large collections of animals (and plants, minerals, and cultural items) were coming in from German colonies in Africa and elsewhere. The Museum für Naturkunde has large collections of skulls of gorillas and chimpanzees (100 or more of each), all of them from precisely known localities. Matschie described a large number of new species and subspecies, most of which are without substance, but the collections do include the **type specimens** of *Gorilla beringei*, *Gorilla graueri*, and *Gorilla diehli*. Contrary to rumor, the collections at the Museum für Naturkunde were not destroyed during WWII, although one wing of the museum was partly destroyed, but the museum did become part of the Eastern sector of Berlin, just to the east of the Berlin Wall. At the beginning of 2009, the museum separated from the university and is now known as the Leibniz Institute for Evolution and Biodiversity Research. Contact person Professor Frieder Mayer (e-mail frieder.mayer@mfn-berlin.de). Postal address Museum für Naturkunde, Invalidenstrasse 43, 10115 Berlin, Germany. Tel +49 30 2093-8591. Website www.naturkundemuseum-berlin.de.

mustelid The informal name for the **Mustelidae** (weasels and otters), one of the **caniform** families whose members are found at some hominin sites. *See also* **Carnivora**.

Mustelidae The family that includes weasels, otters, and their close relatives, and one of the **caniform** families whose members are found at some hominin sites. *See also* **Carnivora**.

mutation A change in the sequence of **nucleotides** in a **DNA** molecule. Mutation is one of the four forces of evolution and the only force that creates new variation. Mutations are caused by an error in DNA replication or through damage to the DNA. There are various types of mutation: (a) **point mutations** involve a change from one nucleotide to another, (b) **inversions** occur where a sequence is inverted by 180°, (c) **translocations** or **transpositions** are the terms used when a sequence of nucleotides is moved to another location, and (d) **insertion/deletion** (or **indel**) mutations are where one or more nucleotides are deleted or added to a DNA sequence. In coding regions, the latter may cause a frameshift in the reading of the nucleotide sequence and frameshift mutations are typically highly deleterious. Point mutations can be transitions, where one purine (adenine or guanine) is replaced by another purine or where one pyrimidine (cytosine or thymine) is replaced by another pyrimidine. They can also be transversions, where a purine is replaced by a pyrimidine (or vice versa); in modern humans transitions are more common than transversions. Point mutations in coding regions may be synonymous (also called silent) when they do not cause a change in the protein sequence or nonsynonymous. Nonsynonymous point mutations are called nonsense mutations when they involve a change to a stop codon, or missense mutations when a different amino acid is coded for. Another class of mutations involves the number of **chromosomes**. Mutations that result in changes in the numbers of the whole complement of chromosomes are not viable in humans, but other changes in chromosome number are. Aneuploidy, an abnormal number of chromosomes, can result from **monosomy** (e.g., monosomy X, known as Turner syndrome) or **trisomy** (e.g., trisomy 21, known as Down syndrome). Chromosomal aberrations such as centric fusion can lead to the evolution of chromosome number and organization. For instance, sometime during hominin evolution, the chromosomes 2a and 2b found in the other great apes fused to form the single modern human chromosome 2. *See also* **diploid**; **haploid**; **karyotype**.

mutation accumulation hypothesis One of several theories put forward to explain the evolution of **senescence**. The mutation accumulation hypothesis (Medawar 1952) suggests that

senescence is due to a relaxation of the effects of selection in post-prime reproductive years. Since selection is expected to improve function in the young and in early adult life more than in the later phases of life, Medawar hypothesized that **alleles** with deleterious effects that are manifest only in the later stages of life will be balanced (between an increase in frequency due to mutation and a decrease in frequency due to selection) at higher frequencies than harmful alleles that are manifest earlier in life.

mutation rate The occurrence of a **mutation** per generation or unit of time. Mutations are stochastic events but over longer periods of time they occur at a measurable rate. This rate differs among regions of the **genome** (for example, the mutation rate is faster in **mitochondrial DNA** than in **nuclear DNA**) and among species. Reasons for differences in rate can include the guanine/cytosine content of the DNA, differences in editing capability of the polymerase that replicates the DNA, and secondary structure of DNA in a specific region.

m.y. *See* **myr**.

myelin (Gk *muelos*=marrow) A fatty substance that surrounds and insulates the axons of some

neurons. Myelin is arranged in concentric layers around the axon of the neuron and it is essential for the high-speed conduction of electrical currents across the cellular membrane. The myelin sheath is formed by the glia cells that are adjacent to the axon. In the central nervous system a single oligodendrocyte can myelinate several axons, whereas in the peripheral nervous system a single Schwann cell myelinates only one axon. The myelin sheath is interrupted at regular intervals by nodes of Ranvier (named after the neuroanatomist Louis Antoine Ranvier who first described them in the 19thC). These gaps are characterized by clusters of voltage-gated sodium and potassium ion channels, which enable the electrical signal to propagate by depolarization of the axon's plasma membrane. Nodes of Ranvier significantly increase the rate of conduction along an axon.

mylohyoid line *See* **mandible**.

myr The abbreviation for a period of time expressed in millions of years, as in "2 myr have elapsed since hominins first appeared in Africa." The result of an age determination, or **age estimate**, should be expressed differently, as in "the approximate age of KNM-ER 3733 is 1.8 **Ma**." *See also* **age estimate**.

N

$^{15}\text{N}/^{14}\text{N}$ Two stable isotopes of nitrogen. The relative ratio of $^{15}\text{N}/^{14}\text{N}$ (commonly represented as $\delta^{15}\text{N}$ values in per mil, or ‰, notation) in an animal's bone collagen or fur keratin reflects the foods it consumed and where it consumed them. In most terrestrial ecosystems, plants obtain their nitrogen directly from soil nitrate and ammonium, resulting in nitrogen isotope ratios over 0‰ (e.g., Schmidt and Stewart 2003), but some plants, in particular many legumes, have symbiotic bacteria that fix nitrogen directly from the atmosphere. As a result, these plants have $\delta^{15}\text{N}$ values that resemble air (0‰) (e.g., Ambrose 1991, Schmidt and Stewart 2003). Among C_3 plants, factors such as rainfall, temperature, topography, plant part, rooting depth, mycorrhizal associations, soil age, grain size, mineral content, chemical composition, moisture, and the available form of nitrogen can influence plant $\delta^{15}\text{N}$ values (e.g., Heaton 1987, Ambrose 1991, Schmidt and Stewart 2003). Nitrogen isotope ratios in animal tissues reflect those in the plants that they consume, with some trophic enrichment. Trophic enrichment values can vary considerably. Nevertheless, $\delta^{15}\text{N}$ values in herbivores are generally thought to be approximately 3‰ higher than those in the plants that they consume, and $\delta^{15}\text{N}$ values in secondary carnivores are about 3‰ higher than those in herbivores (6‰ higher than those in plants) (DeNiro and Epstein 1981). In addition to trophic enrichment, consumer $\delta^{15}\text{N}$ values increase with water and nutritional stress (Ambrose 1991). Thus while elevated $\delta^{15}\text{N}$ values tend to indicate higher trophic levels, they can also reflect nutrition or moisture stress (Heaton 1987, Ambrose 1991). It is less clear how accurately omnivory (i.e., some meat in the diet) is recorded although because meat contains relatively more nitrogen per unit weight than does the majority of plant material, meat intake should be reflected in higher values of bone collagen $\delta^{15}\text{N}$ than those found in plants (Phillips and Koch 2002, Schoeninger 1985). Marine animals exhibit higher $\delta^{15}\text{N}$ values in their bone collagen and other tissues than do

terrestrial ones (Schoeninger and DeNiro 1984), and modern human diets that include marine foods have higher $\delta^{15}\text{N}$ values than those with only terrestrial foods. Further, marine diets high in secondary carnivores (e.g., carnivorous mammals and fish) have higher $\delta^{15}\text{N}$ values than do diets with marine invertebrates due to trophic level effects (e.g., Schoeninger et al. 1983, Little and Schoeninger 1995). In regions where prehistoric modern human populations had access to both marine and maize, which confound the use of $\delta^{13}\text{C}$ values, bone collagen $\delta^{15}\text{N}$ values identify dependence on marine foods (Schoeninger et al. 1990). Fuller et al. (2006) show how to use the $^{15}\text{N}/^{14}\text{N}$ (and the $^{13}\text{C}/^{12}\text{C}$ system) systems to investigate the timing of **weaning**. Richards et al. (2000) suggest the enriched levels of ^{15}N in *Homo neanderthalensis* indicate a diet that included a significant component of carnivory, even though some of the energy needs of *H. neanderthalensis* may have been met by low-protein foods.

Nachukui (or NC) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) Refers to a complex of fossil localities in the Nariokotome Member of the Nachukui Formation within the Nachukui drainage in **West Turkana**, Kenya. An early hominin proximal femur, KNM-WT 19700, attributed to *Homo erectus*, was recovered from locality NC1. *See also West Turkana.*

Nacurrie (Location 35°10'S, 143°38'E, Australia; etym. named after a local railway siding near the find site) History and general description A site near Merran Creek about 19 km/12 miles north of Swan Hill in southern New South Wales where George Murray Black collected a series of hominin skeletal remains in 1949. The better-preserved specimens were added to the G.M. Black Collection in the Department of Anatomy, Melbourne University. In 1971 the most complete skeleton was sent for cleaning, restoration, and analysis to Professor

N.W.G. Macintosh (“Black Mac”) at Sydney University; Macintosh and Larnach refer to it as the “Murrabit skull.” After Macintosh’s death the skeleton was returned to Melbourne (now referred to as the “Nacurrie skeleton”) but it was finally analyzed at the University of New England by Peter Brown. In 1984 the Nacurrie skeleton along with the rest of the G.M. Black Collection was repatriated for reburial. Temporal span and how dated? AMS radiocarbon dating on collagen from the skeleton provides a **Late Pleistocene** age of *c.*11.4 ka. Hominins found at site The “Nacurrie skeleton” was a tall and robust adult modern human male with evidence of artificial cranial deformation similar to that seen in individuals from other terminal Pleistocene sites including **Kow Swamp**, **Cohuna**, and **Coobool Crossing**. The Nacurrie skeleton had healed fractures affecting both forearms the right distal fibula and the right parietal, which have been interpreted as ancient evidence of the Aboriginal practice of dispute settlement with the striking of sticks. The shape of the cranial vault is consistent with manual molding. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Brown 1994; Hominins Brown 1994, 2010.

Nadung’a (Location 4°08’N, 35°50’E, Kenya; etym. named for the major river system (laga) near which it is located) History and general description Complex of localities within the Nariokotome Member of the Nachukui Formation in the vicinity of the Nadung’a drainage in **West Turkana**, Kenya. Initial exploration in 1988 was conducted by the West Turkana Archaeological Project (or WTAP), with more extensive excavations undertaken in 2002–4. Temporal span and how dated? The archeological sites are located within the middle of the Nariokotome Member, 17–20 m above the 1.33 Ma Lower Nariokotome Tuff. Stratigraphic correlation with the **Shungura Formation** suggests the youngest site within the Nadung’a complex is slightly above a tuff correlated with the 0.74 Ma Silbo Tuff of the Shungura Formation. Thus, an age range of 1.33–0.7 Ma has been proposed for Nadung’a. Hominins found at site None. Archeological evidence found at site It is debated whether the lithic artifacts recovered from Nadung’a 4 (NAD 4) are an atypical example of the Acheulian industrial complex, or a sample of a different technocomplex contemporaneous with the **Acheulean**. Key references: Geology, dating, and paleoenvironment Delagnes

et al. 2006; Hominins N/A; Archeology Kibunjia et al. 1992, Delagnes et al. 2006.

Nahal Ein Gev *See* Ein Gev.

Naiyena Engol (or NY) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) Refers to a complex of fossil localities in the Kaitio Member of the Nachukui Formation within the Nanyangakipi drainage in **West Turkana**, Kenya. *See also* **West Turkana**.

Nanjing Man *See* Tangshan Huludong.

Nanyangakipi (or NN) (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) (or NN) Refers to a complex of fossil localities in the Kaitio and Natio Members of the Nachukui Formation within the Nanyangakipi drainage in **West Turkana**, Kenya. *See also* **West Turkana**.

Napier, John Russell (1917–87) John Napier was born in Old Windsor near London, England, and attended Canford School. He studied medicine at the Medical College of St Bartholomew’s Hospital, graduating in 1943. He specialized in orthopedic surgery, but his clinical and research interests soon focused on peripheral nerve injuries. He moved to the Anatomy Department at what was then called the London School of Medicine for Women (later known as the Royal Free Hospital School of Medicine) in 1946 and apart from a year as a Visiting Professor at Iowa State University and an interlude at the **National Museum of Natural History, Smithsonian Institution**, in Washington DC, USA, Napier spent the rest of his career within the University of London, latterly at Queen Elizabeth College, and immediately prior to his retirement as a Visiting Professor at Birkbeck College. His interest in the way neurological disorders impaired the function of the hands and feet of modern humans was soon translated into an interest in primate functional morphology, especially gait and dexterity. This interest in the hand led to Napier being invited by Sir Wilfrid **Le Gros Clark** to describe and analyze the *Proconsul africanus* forelimb remains that had been recovered by Louis and Mary **Leakey** on Rusinga Island; this he did with the help of Peter Davis (Napier and Davis 1959). It was natural therefore that when the Leakeys recovered early hominin limb bones from **Olduvai Gorge** in the 1960s they and Phillip **Tobias**

turned to John Napier for help with the analysis of the fossils. Napier focused on the hand (OH 7; Leakey et al. 1964) and he recruited two colleagues at the Royal Free, Michael Day and Peter Davis, to tackle the foot (OH 8; Day and Napier 1964) and the leg bones (OH 35; Davis 1964). John Napier was one of the first people to review the fossil evidence for the evolution of bipedal walking in early hominins (Napier 1964), and his joint authorship of the proceedings of a symposium devoted to primates (Napier and Barnicot 1963), and later the publication of *A Handbook of Living Primates* (1967), which he jointly wrote with his wife Prue Napier, were landmarks in development of primatology. *See also* SK 82.

Nariokotome (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) (or NK) Refers to a complex of fossil localities in the Kaitio and Natoo Members of the Nachukui Formation within the Nanyangakipi drainage in West Turkana, Kenya. An early hominin associated skeleton, KNM-WT 15000, attributed to *Homo erectus*, was recovered from locality Nariokotome III. *See also* West Turkana.

“Nariokotome boy” *See* KNM-WT 15000.

Narmada *See* Hathnora.

Narmada Basin The Narmada Basin is the central part of the Narmada Valley. The sedimentary rocks exposed in the Narmada Basin are from oldest to youngest the Pilikarar, Dhansi, Surajkund, and the Baneta Formations (see Patnaik et al. 2009 for a review of the geology). There are several paleontological and archeological localities at Hathnora: four are in the Surajkund Formation (Surajkund 1, 2, and 3, and Hathnora 1) and one is in the Baneta Formation (Hathnora 2). *See also* GSI-Narmada; Hathnora 1.

Narmada Valley The Narmada River rises in Central India at Amarkantak and then flows westward for 1300 km/806 miles to the Arabian Sea at the Gulf of Cambay. The central part of the Narmada Valley, the Narmada Basin, is the location of several localities (e.g., Hathnora) that have yielded fossil hominin and archeological evidence (see Patnaik et al. 2009 for a review of the history of exploration in this region) *See also* Hathnora.

narrow-sense heritability Narrow-sense heritability (h or h^2) is defined as the additive

genetic variance divided by the phenotypic variance where the additive genetic variance is the weighted average of the squared values of the additive effects. In other words, the additive variance is variance caused by differences among alleles only. Thus, narrow-sense heritability only refers to the portion of the phenotypic variation that is additive (or allelic) and does not take into account variation due to epistatic, dominance, or parental effects. However, the additive effects are important because this variation is the only variation that natural selection can act on. Narrow-sense heritability estimates are typically used in agricultural genetics to estimate how the mean of a trait of interest (such as milk production or size) will change in the next generation given how much the mean of the selected parents differs from the mean of the population. *See also* heritability.

Nasechebun (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) (or NS) A complex of fossil localities in the Kataboi Member of the Nachukui Formation within the Nasechebun drainage in West Turkana, Kenya. *See also* West Turkana.

nasoalveolar clivus The bone between the inferior margin of the nasal, or piriform, aperture and the alveolar process in the region of the upper incisors. The clivus can be flat, concave, or convex, and vertical or inclined. The amount of demarcation between the floor of the nose and the nasoalveolar clivus varies within and among the great apes, whereas in modern humans and most pre-modern *Homo* a distinct sill separates the nasal floor from the nasoalveolar clivus. Among extinct hominins the distinctiveness of the nasal sill varies both within and between taxa. In *Australopithecus africanus* the nasoalveolar clivus and the inferior part of the anterior pillars are in the same plane, and they form a unitary structure, the nasoalveolar triangular frame, that stands out from the rest of the face.

nasoalveolar gutter Term used by Rak (1983) for the depressed upper part of the nasoalveolar clivus in *Paranthropus robustus* and *Paranthropus boisei*. In *P. robustus* the nasoalveolar clivus is scooped out as it passes up to the inferior margin of the anterior nasal or piriform aperture, which is set below the surface of the face between the inferior ends of the anterior pillars. In *P. boisei* a similar appearance is due to the plate-like infraorbital

region (*see* **maxillary visor**) extending anteriorly ahead of the plane of the anterior nasal aperture.

nasoalveolar triangular frame Term used by Rak (1983) for the combination of the **anterior pillars** and the flat **nasoalveolar clivus** in *Australopithecus africanus*. Because these structures are in the same plane they form a unitary structure that stands out from the rest of the face. In *Au. africanus* the lateral margins of the nasoalveolar triangular frame are separated from the rest of the face by the **maxillary furrows**.

nasomaxillary basin Term used by Rak (1983) for the hollowed area between the lateral edge of the nasal bones and the medial end of the inferior margin of the orbit. It is well seen in **OH 5**.

nasopharynx *See* **pharynx**.

NAT Abbreviation of the Natoo Member in the Nachukui Formation, West Turkana, Kenya.

natal group *See* **philopatry**.

National Geological Survey of China (or NGS) In effect beginning in 1913 with the creation of the Geological School of Peking, but founded officially in 1916 by the Ministry of Agriculture and Mines at Peiping. Its purpose was to promote knowledge of mineral resources, carry out a general geologic survey of the country using a uniform scale, and undertake scientific geological research. It was in the process of the survey that the caves at Choukoutien were discovered. The NGS was responsible for the publication of *Palaontologia Sinica*, the *Bulletin of the Geological Survey of China*, and the *Memoirs of the Geological Society of China*, which contain descriptions of the fossil hominins recovered from what was then called Choukoutien and which is now called **Zhoukoudian**.

National Museum and House of Culture, Dar es Salaam One of the constituent museums of the National Museum of Tanzania system. Formerly known as the National Museum – Dar es Salaam, the National Museum and House of Culture is the largest museum in Tanzania with collections and exhibitions covering archeology,

arts, biology, ethnography, and history. The original building was constructed in 1938–9 when it was known as the King George V Memorial Museum. After Tanganyika's independence in 1961 it became known as the National Museum of Tanzania, and it was extended following the presentation of **OH 5** to President Julius Nyerere by Louis **Leakey**, on January 26, 1965. The collections relevant to human evolution include some of the hominins from **Olduvai Gorge**, the hominins from **Ndutu** and **Peninj**, the non-hominin fossils collected by Mary **Leakey** and Terry Harrison at **Laetoli** and by the Wembere Manonga Paleontological Expedition (or WMPE), and the archeological evidence collected by Neville Chittick, Felix Chami, Amandus Kweka, and others. There are plans to provide suitable facilities that will allow the remaining Olduvai Gorge and the Laetoli hominins to be transferred from the **National Museums of Kenya**, as well as other collections from Tanzanian sites that are in museums outside of Tanzania. Hominin fossil collections Olduvai Gorge: **OH 5**, **7**, **8**, **9**, **24**, **62**, and **63**, plus isolated teeth, **Peninj 1**; Laetoli: EP 2400/00 (mandible), EP 1500/01 (face), EP 1000/98 (proximal tibia), and isolated teeth. Contact person Dr Paul Msemwa, Director, or Achilles M. Bufure, Senior Curator and Head of Ethnography Department (e-mail achiles11@yahoo.co.uk). Street address National Museum and House of Culture of Tanzania, Shabaan Robert Street, Dar es Salaam, Tanzania. Postal address National Museum and House of Culture - Dar es Salaam, PO Box 511, Dar Es Salaam, Tanzania. Website N/A. Tel +255 22 2122030/+255 22 2117508. Fax N/A.

National Museum of Natural History, Smithsonian Institution The Smithsonian Institution was founded in 1846 by the Congress of the United States of America through a bequest by James Smithson, a British chemist, for the purpose of creating “an establishment for the increase and diffusion of knowledge” in Washington DC. The Smithsonian's National Museum of Natural History (or NMNH), formerly the US National Museum, opened to the public March 17, 1910, and contains biological and anthropological collections, including stone artifacts, fossils, and casts related to human and primate evolution. The Smithsonian's first secretaries (executive directors) initiated the development of extensive collections of Paleolithic artifacts. These collections include approximately 22,000 objects from 332 locations in 30 countries in Europe, Asia, and

Africa (Petraglia and Potts 2004). The first NMNH curator of physical anthropology, Aleš Hrdlička, founded the American Association of Physical Anthropologists. Although Hrdlička's research focused on North American modern human skeletal biology, he also conducted exchanges with European researchers that initiated the NMNH's fossil human cast collection. Through the work of curator T. Dale Stewart, the Smithsonian's participation in excavations at **Shanidar Cave**, northern Iraq, from 1953 to 1960, led to the housing in NMNH of the Shanidar 3 *Homo neanderthalensis* skeleton, one of 10 fragmentary Neanderthal skeletons uncovered at the site. The Shanidar 3 skeleton and the NMNH's Old World Paleolithic and hominin cast collections are under the care of the Smithsonian's Human Origins Program (or HOP). The HOP was founded in 1985, when the NMNH began its formal research program in human evolutionary studies. The HOP has conducted cooperative research with scientific organizations in Kenya, Tanzania, China, Indonesia, and India. Long-term collaboration with the **National Museums of Kenya** has added extensively to the NMK's fossil and archeological collections from the sites of Olorgesailie, Kanjera, and Kanam, and associated tephra and other geological collections from these sites in the NMNH. The NMNH's National Anthropological Archives holds the research documents of Glynn Isaac and Richard Hay, who were influential in East African archeological and geological research, respectively. The NMNH also maintains physical anthropology collections of nearly 33,000 specimens, primarily modern human skeletal collections (http://anthropology.si.edu/cm/phys_intro.htm). The NMNH's permanent exhibition hall on human evolution opened to the public on the museum's 100th anniversary in 2010. Contact department Human Origins Program (<http://humanorigins.si.edu/contact>). Contact persons Rick Potts (Human Origins Program; e-mail pottsr@si.edu) and David Hunt (Human Skeletal collections; e-mail huntd@si.edu). Postal address Human Origins Program, National Museum of Natural History, PO Box 37012, Washington DC 20013-7012, USA. There are approximately 5000 nonhuman primate individuals, including skin, skeleton, skull, or fluid preparations of select species of cebids, cercopithecids, and hominoids. The NMNH currently holds skeletal remains of 25 *Pongo abelii* from Aru Bay in Sumatra, and 94 *Pongo pygmaeus* from the Sakaiam, Kendawangan, Sempang, Semandong, and Mambulah Rivers in Borneo. Most of the 50 *Gorilla beringei* skeletal specimens are from Rwanda, with a

few from the Democratic Republic of the Congo. Most of the 57 *Gorilla gorilla* skeletal specimens come from Cameroon or Gabon, several from Republic of the Congo, and several are marked as "locality unknown." (<http://collections.nmnh.si.edu/search/mammals>). Contact persons Kristofer Helgen (Curator of Mammals; e-mail helgenk@si.edu) and Darrin Lunde (for use of the primate collections; e-mail lunded@si.edu). Postal address As above. *See also* **Bose Basin; Kanjera; Liang Bua; Nihewan Basin; Olorgesailie**.

National Museums of Kenya Grew out of a desire by European colonial leaders in East Africa to establish a scientific institution devoted to the natural history of the colony. The first natural history museum in Kenya was established in Nairobi in 1910 by the East Africa and Uganda Natural History Society to house the collections generated by local naturalists, but the museum's collections quickly outgrew the original buildings and the Society began construction of a new museum in 1929. The new Coryndon Museum, named in honor of Sir Robert Coryndon, a former governor of Kenya and supporter of the East Africa and Uganda Natural History Society, opened in 1930 and housed the Society's natural history collections as well as its substantial library. The East Africa and Uganda Natural History Society ran the museum until 1939 when it became an independent institution funded by the colonial government. The Coryndon Museum became an important center of paleoanthropological research after 1941 when Louis Leakey accepted a position at the museum. Leakey served as the curator of the Coryndon Museum from 1945 to 1961 and he greatly expanded the museum's collections while he was conducting paleoanthropological research at **Olduvai Gorge**. During his final year as curator Leakey established the **Centre for Prehistory and Palaeontology** at the museum, which served as an important focus of research into human prehistory. The Coryndon Museum was renamed the National Museums of Kenya in 1964 and beginning in 1969 the museum grew to include institutions and sites outside of Nairobi, including the prehistoric site of **Olorgesailie**. Louis Leakey's son, Richard Leakey, served as director of the National Museums of Kenya from 1969 to 1989 and through his efforts the National Museums of Kenya became a major center of paleoanthropological research with a large staff of scientists and a substantial collection of hominin fossils and

archeological artifacts. In 1976 the museum opened the Leakey Memorial Building named in honor of Louis Leakey, which houses research and educational facilities. The fossil collections are dominated by Kenyan sites, but there are still some hominins in the National Museums of Museum from sites in Tanzania. The National Museums of Kenya has grown from a small repository of natural history specimens into a multidisciplinary research institute housing over 20 departments and divisions including archeology and paleontology. There are also 15 regional museums and eight sites open to the public. Hominin fossil and related collections Amboseli, Chemeron, **Chesowanja**, Eliye Springs, Esho Kakurongori, Fort Ternan, Harrar, Hindmarsh Moshi, Homa shell mound, Hyrax Hill, Jawuoyo, Kana shell mound, **Kanam West**, Kanam East, **Kanapoi**, Kanjera, Kapthurin, Karungu, Kijabe flats, Kisese, **Kokiselei**, **Koobi Fora**, Korongo Farm, **Laetoli** (LH 1–8, 10–17, 19–22, 29), **Lainyamok**, Lobo, **Lomekwi**, **Lothagam**, **Lukeino**, Lukenya, Naivasha, Nakoret, **Nariokotome**, Narok, Ngira, Ngorora, Njoro River Cave, Ntuka river, Nyarindi rock-shelter, **Olduvai Gorge** (OH 3–4, 6, some fragments of 8, 9–17, 19–46, 48–60), Ol Kalau, Pickford's site, Sotik, **South Turkwel**, and Tugen Hills. Contact department Department of Earth Sciences, Paleontology Division. Contact person Emma Mbua. Postal address National Museums of Kenya, Museum Hill, PO Box 40658. Website www.museums.or.ke. Tel +254 20 3742131/+254 20 3742161. Fax +254 20 3741424. E-mail nmk@museums.or.ke.

National Natural History Museum, Arusha Established to house and curate the Tanzanian components of the paleontological, paleoanthropological, and archeological collections from the countries in the East African Community that had been housed in the Coryndon Museum (now the **National Museums of Kenya**) in Nairobi. Since the collapse of the East African Community in 1977, the goal was to relocate the **Olduvai Gorge**, **Laetoli**, and other collections from Tanzanian sites to one place. Arusha, near Mount Kilimanjaro, was identified as the best location for the new museum because of its proximity to Olduvai Gorge and Laetoli, and Lakes Natron, Manyara, and Eyasi, all important sources of evidence about human evolution in Tanzania. In the early 1980s the Tanzanian Government donated the old German Fort along Boma Road in Arusha as the site of the new museum. Dating back to 1880s, the

Boma Fort, the oldest colonial building in Arusha, served initially as a military base for the German East Africa Company, and subsequently it was the headquarters of the first provincial administration in the region. This small but fine historical building was transformed into a museum and opened in 1987, but at that time there were no adequate facilities to curate and store the fossil collections, nor were funds available to hire trained curatorial personnel. In addition, due to political tension between Tanzania and Kenya in the 1980s, it was not possible to repatriate the Tanzanian collections from Kenya. Thus, the first hominin fossils from Tanzanian sites to be housed in the National Natural History Museum in Arusha were those collected by the **Olduvai Landscape Paleoanthropology Project** (or OLAPP). The OLAPP project raised the resources needed to convert one of the buildings at the Boma Fort into a facility that was suitable for the preparation and secure storage of hominin fossils. Hominin fossil collection OH 64–74 (including the **OH 65** maxilla). In addition to the hominin fossils the museum houses a large collection of stone artifacts (>4000) and non-hominin faunal specimens (>8000 identified specimens), and a number of fossilized wood fragments from Bed I and Lower Bed II, Olduvai Gorge. Natoo (etym. Named for an ephemeral river system, or laga, in whose drainage the localities are located) (or NT) A complex of fossil localities in the Natoo Member of the Nachukui Formation within the Nanyangakipi drainage in **West Turkana**, Kenya. *See also* **West Turkana**.

natural selection The process of differential survival and reproduction of **genotypes**. Natural selection acts on the **phenotype** and in doing so affects the inherited **alleles** such that it maintains favorable alleles and genotypes in the population and removes deleterious alleles and genotypes. It promotes increased frequency of the most advantageous alleles and genotypes in that environment, and in doing will inevitably reduce the frequencies of other alleles and genotypes. It is one of the four forces of evolution (along with **mutation**, **genetic drift**, and **gene flow**). There are several different types of natural selection. These include **directional**

selection (which can be positive or negative), **balancing selection**, diversifying selection, **purifying selection**, **sexual selection**, and **stabilizing selection**. Ultimately, all forms of natural selection result in differential birth rates (and some differential death rates) for individuals with different fitness levels.

Naturalis See Rijksmuseum van Natuurlijke Historie.

Nazlet Khater (Location 26°47'N, 31°21'E, Egypt; etym. named after the nearby village) History and general description Located on a remnant of a Nile terrace, the site was excavated by the Belgian Middle Egypt Prehistoric Project between 1980 and 1982. It is an underground **chert**-mining site characterized by three types of excavated structure: ditches, vertical shafts, and underground galleries. Temporal span and how dated? A combination of **AMS radiocarbon dating** on charcoal and optically stimulated **luminescence dating** on the **aeolian** sand that fills the excavations suggests the exploitation period of Nazlet Khater 4 is dated from 40 to 35 ka. Hominins associated with site Two burials found on a nearby locality known as Boulder Hill: **Nazlet Khater 1** and **Nazlet Khater 2**. Archaeological evidence found at site **Upper Paleolithic** industry characterized by handaxes in association with a fully developed blade-production system. This assemblage may represent the incursion into the Nile Valley of a transformed Nubian Complex. Key references: Geology, dating, and paleoenvironment Vermeersch et al. 1984, Vermeersch 2002; Archaeology Vermeersch 2002; Hominins Vermeersch et al. 1984, Thoma 1984, Pinhasi and Semal 2000, Crevecoeur 2008a.

Nazlet Khater 1 Site Nazlet Khater, Egypt. Locality Boulder Hill. Surface/in situ *In situ*. Date of discovery 1980. Finders Vermeersch and colleagues. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 37,570+350/-310 years BP (GrA-20145), an AMS radiocarbon age on charcoal associated with the burial. Developmental age Adult. Presumed sex Female. Brief anatomical description Poorly preserved adult skeleton plus the remains of a fetus. Announcement Vermeersch 2002. Initial description Vermeersch 2002. Photographs/line drawings and metrical data Vermeersch 2002.

Detailed anatomical description N/A. Significance One of the very few modern human skeletons from this time period in this region of Africa. Location of original Bordeaux 1 University, France.

Nazlet Khater 2 Site Nazlet Khater, Egypt. Locality Boulder Hill. Surface/in situ *In situ*. Date of discovery 1980. Finders Vermeersch and colleagues. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 38±6 ka (based on an **electron spin resonance spectroscopy dating** age on an enamel fragment). Developmental age Adult. Presumed sex Male. Brief anatomical description The skeleton is complete with the exception of the distal part of the lower limb. Morphological and biometrical comparative analyses of this specimen underline the complex morphology of modern humans from this time period. Nazlet Khater 2 exhibits several retained archaic features, notably on the face and the mandible. The morphology of the bony labyrinth of Nazlet Khater 2 can be distinguished from that of contemporary modern humans. The limb bones show strongly marked muscle insertions and the cross-sectional geometric properties of the long bones suggest they were adapted to substantial loading. Furthermore, Nazlet Khater 2 vertebrae show pathological changes that are unusual for a relatively young adult and it has been suggested these lesions may be related to involvement in the intensive physical activity involved in mining. Initial taxonomic allocation *Homo sapiens*. Announcement Vermeersch et al. 1984. Initial description Thoma 1984. Photographs/line drawings and metrical data Vermeersch et al. 1984, Vermeersch 2002, Crevecoeur 2008a. Detailed anatomical description Crevecoeur 2008a. Significance One of the very well-preserved modern human skeletons from this time period in this region of Africa. Location of original Bordeaux 1 University, France.

NC Abbreviation for Nachukui, one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. See **Nachukui**.

Ndutu (Location 3°00'S, 35°00'E, Tanzania; etym. the site is on the north shore of Lake Ndutu, a seasonal soda-lake at the western end of the Olduvai Main Gorge) History and general description The site was first visited in 1972; surface collections

were made at seven locations and a test trench established the stratigraphy. Formal excavations carried out at the site in September–October 1973 exposed “occupational floors with *in situ* lithic and faunal material” and “a hominid skull” (Mturi 1976, p. 484). Temporal span and how dated? “Later Middle Pleistocene” (Rightmire 1983, p. 246) or less than 400 ka according to tephrostratigraphy. Hominins found at site Ndutu 1. Archeological evidence found at site “270 plotted lithic and faunal materials,” “94 out of the 270 plotted *in situ* materials”...“are splinters and sizeable bone pieces”...“seems to suggest that the area was probably a butchery site” (Mturi 1976, p. 485). Only 20 out of the 126 lithic pieces “are definitive tools”...“among the tools spheroids and hammerstones predominate” (*ibid*). Key references: Geology, dating, and paleoenvironment Mturi 1976; Hominins Clarke 1976, Rightmire 1983; Archeology Mturi 1976.

Ndutu 1 Site Ndutu, Tanzania. Locality Shoreline of Lake Ndutu. Surface/in situ *In situ*. Date of discovery 1973 Finder Amini Mturi. Unit N/A. Horizon Upper, sandy horizon of two, the second without much sand, in greenish clay near the shore of the lake. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon A re-worked tuff that has mineralogical similarities to the Norikilili Member, Upper Masek beds, **Olduvai Gorge**. Nearest underlying dated horizon Underlain by a sand-free unit of green clay. Geological age **Middle Pleistocene**, probably around 200–400 ka on the basis of tuff correlation with Olduvai Gorge (see above). Developmental age Adult. Presumed sex Unknown, but possibly female based on its small size. Brief anatomical description A small, fragmentary cranium that preserves the occipital, much of both parietals and temporals, some of the frontal and facial bones and the sphenoid. The occipital has a marked angulation between its upper and lower scales. The bone of the cranial vault is thick. The face is neither large nor strongly projecting. The vertically thin but projecting brow ridge is separated from the frontal squama by a sulcus. The temporal bone has an ossified styloid process. Endocranial volume Approximately 1100 cm³. Announcement Mturi 1976. Initial description Clarke 1976. Photographs/line drawings and metrical data Clarke 1976, 1990. Detailed anatomical description Rightmire 1983, Clarke 1990, Schwartz and Tattersall 2003. Initial taxonomic allocation *Homo erectus* (Clarke 1976).

Taxonomic revisions *Homo sapiens* (Rightmire 1983, Bräuer 1984), *Homo leakeyi* (Clark 1990). Current conventional taxonomic allocation *Homo heidelbergensis* or *Homo rhodesiensis*. Informal taxonomic category Pre-modern *Homo*. Significance The Ndutu cranium provides a key morphological link between *Homo erectus* and *Homo heidelbergensis* in Africa. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

N_e *See* effective population size.

Neander, Joachim *See* *Homo neanderthalensis*.

Neandertal *See* *Homo neanderthalensis*; **Kleine Feldhofer Grotte**; **Neanderthal**.

Neanderthal In this encyclopedia the taxon *Homo neanderthalensis*, and any specimens belonging to that taxon, are referred to informally as “Neanderthals.” In other publications this group is sometimes referred to as “Neandertals.” The authors who use Neandertal presumably do so because in “new German” (German orthography following 1901) the silent “h” was dropped, so that “thal” became “tal.” However, despite these changes to the German language, according to the International Code for Zoological Nomenclature the Linnaean binomial *Homo neanderthalensis* remains unchanged. This is why we use the old spelling. *See also* *Homo neanderthalensis*; **Kleine Feldhofer Grotte**.

Neanderthal 1 The holotype of *Homo neanderthalensis*. *See* **Kleine Feldhofer Grotte**.

Neanderthal phase hypothesis This hypothesis, also called the Neanderthal phase model, influenced interpretations of human evolution for much of the 20thC. It suggested that modern humans had evolved from an ape-like ancestor through several evolutionary stages, the most recent of which was represented by *Homo neanderthalensis*. Thus, supporters of a **Neanderthal** phase of human evolution believed that at least some Neanderthal populations evolved into modern *Homo sapiens*. After the discovery of *Pithecanthropus erectus* (now *Homo erectus*) by the Dutch anatomist Eugène Dubois in the 1890s,

the German anatomist Gustav **Schwalbe**, in *Studien zur Vorgeschichte des Menschen* [*Studies on Human Prehistory*] published in 1906, suggested that modern humans had either evolved from an ape-like ancestor directly through *Pithecanthropus* and Neanderthal stages, or from other ancestors that must have been very similar to these. However, after French paleontologist Marcellin **Boule** had published his influential study of the **La Chapelle-aux-Saints** Neanderthal, Schwalbe was more willing to view Neanderthals as a side line rather than the ancestors of modern humans. The first comprehensive exposition of what we now call the Neanderthal phase hypothesis of human evolution published in English was by the Czech/American physical anthropologist Aleš Hrdlička in his 1927 Huxley Memorial Lecture of the Royal Anthropological Institution entitled “The Neanderthal phase of man.” Hrdlička opposed the **pre-sapiens hypothesis** and instead interpreted the evolution of modern humans as proceeding in a unilinear fashion from an ape-like ancestor through successive stages that possessed gradually smaller numbers of primitive traits and gradually larger numbers of modern human traits. While he recognized that most of the Neanderthals of western Europe demonstrated a distinctive morphology that was interpreted to be the result of adaptation to a cold climate, he noted that the Neanderthals from **Krapina** collected by the Croatian paleontologist Dragutin **Gorjanović-Kramberger** included a surprising amount of variation with some individuals approaching much more closely the morphology of *H. sapiens*, factors noted by Gorjanović-Kramberger in his seminal 1906 monograph. Hrdlička also argued that the archeological record, rather than supporting the notion that *H. sapiens* with their **Aurignacian** industry had displaced the Neanderthals with their **Mousterian** industry, indicated instead that the Aurignacian industry may have developed from the Mousterian. Hrdlička further noted that for the Neanderthals to be replaced by a more advanced immigrant population there should be evidence of the source of such a group somewhere outside Europe, and at that time no such evidence existed. Given the widespread impact of Boule’s interpretation of the Neanderthals as an extinct side branch of human evolution, as well as the acceptance of the pre-sapiens hypothesis by a large number of influential anthropologists such as Sir Arthur **Keith**, relatively few scientists accepted Hrdlička’s new views about the Neanderthals. However, he did attract several important

advocates including German anatomist Franz **Weidenreich** who studied with Gustav Schwalbe and later oversaw the continuation of the excavations at Choukoutien (now **Zhoukoudian**) that ultimately produced the collection of fossils initially assigned to *Sinanthropus*. For Weidenreich different hominin groups spread throughout the Old World had evolved from an ape-like ancestor through successive *Sinanthropus*/*Pithecanthropus* and Neanderthal stages. While he considered it possible that the western European “classic” Neanderthals could have evolved into modern humans, he believed it more likely that European *Homo sapiens* had evolved from the Neanderthals from the Near East. The German anthropologist Hans Weinert was another strong supporter of the Neanderthal phase hypothesis during the 1940s, but his impact was limited. The excavations conducted at **Mount Carmel** in Palestine during the early 1930s by Dorothy **Garrod** and Theodore McCown had unearthed what were interpreted as Neanderthal remains that were morphologically more similar to modern humans than were the classic Neanderthals of western Europe. This prompted a number of researchers to suggest that these so-called “progressive” Neanderthals had evolved into modern humans, whereas the European classic Neanderthals had been replaced by immigrant populations of modern humans. In the 1950s, the Italian paleontologist Sergio **Sergi** suggested that a Neanderthal population like that found at Mount Carmel had evolved into both modern *Homo sapiens* and the classic Neanderthals. Similarly, Clark **Howell** argued that progressive Neanderthals (like those found at Mount Carmel and Krapina) had evolved into both modern humans and classic Neanderthals. Versions of the so-called pre-Neanderthal hypothesis proliferated during the 1950s and 1960s, but the strongest advocate of the Neanderthal phase theory during the 1960s and 1970s was the American physical anthropologist C. Loring **Brace**. Brace supported what has now become known as the **single-species hypothesis**, which was that at any one time all hominins belong to the same, morphologically diverse, species. According to Brace, in the course of their evolution modern humans had successively passed through **australopithecine**, **pithecanthropine**, and Neanderthal stages of evolution before becoming fully modern humans. Brace accepted Hrdlička’s model of human evolution, but in addition he adopted the new biological thinking of the **modern evolutionary synthesis** to explain how Neanderthals could have evolved into *H. sapiens*. Brace

suggested that stone-tool use made it less necessary for early hominins to use their teeth as a tool, thus leading to consequential morphological changes in the skull. Brace cited evidence of morphological and archeological continuity between Neanderthals and early *H. sapiens*, to support the idea that Neanderthals evolved into the immediate ancestors of modern humans. The Neanderthal phase hypothesis received several setbacks in the 1980s and 1990s as a result of new fossil discoveries, the development of radiometric dating techniques for the time span between approximately 30 and 250 ka, and molecular evidence suggesting that anatomically modern humans had evolved in Africa between 200 and 100 ka. This led to the view that members of this latter group migrated out of Africa to replace the Neanderthals in Western Asia and Europe. While at least one study (Krause et al. 2010) has demonstrated gene exchange between the Neanderthals and anatomically modern humans, the primary ancestral contribution to modern humans in Eurasia clearly derived from the out-of-Africa migrations of early modern people (*see out-of-Africa hypothesis*).

Neanderthaloid (Ge. *Neanderthal*=the valley of the river Neander and Gk *oeides*=resembling, as in having the shape or form of Neanderthals) Originally coined as an adjective meaning simply “Neanderthal-like” (e.g., Burkitt and Hunter 1922) this informal term subsequently came to be used in two distinct senses. A minority of workers applied it to some **Middle Pleistocene** European specimens (e.g., Mauer, Steinheim, Montmaurin, Fontéchevade) displaying one, or more, of the features characteristic of *Homo neanderthalensis*, and because of this they were considered potential Neanderthal ancestors (i.e., “fossils resembling Neanderthals”). Used in this sense it is broadly equivalent to the term “pre-Neanderthal” or “AnteNeanderthal” as used by some French workers. The second sense in which Neanderthaloid has been used is in connection with African and Asian fossil specimens dating from the later Middle or early Upper Pleistocene that resembled, but were distinct from, *H. neanderthalensis* known from Europe and the Near East. Specimens considered to be Neanderthaloid in this sense include fossils from **Jebel Irhoud**, **Kabwe**, **Elandsfontein**, and **Maba**. In both of the senses in which it has been used, Neanderthaloid refers to hominin remains that were considered to resemble *H. neanderthalensis* at a time when the latter represented the largest and best-known group of fossil hominins, so it was natural

to compare new discoveries with *H. neanderthalensis*. For example, Morant (1928) concluded that the Kabwe and Neanderthal crania resembled each other more closely (i.e., were big-faced and strongly constructed) than either did modern humans, and in the monographs about *Sinanthropus pekinensis* Franz Weidenreich devotes substantial effort to showing how those remains differed from *H. neanderthalensis*. However, under the influence of the **Neanderthal phase hypothesis** “Neanderthaloid” subsequently acquired a phyletic connotation, implying that specimens so described represented the African and Asian *evolutionary* equivalents of European and Near-Eastern Neanderthals. “Neanderthaloid” was in common usage from the 1940s to the 1970s. However, since then increasing awareness and adoption of **cladistic** methods, and recognition of the importance of focusing on shared, **derived**, characters when trying to delimit taxonomic groups, has led to the realization that the term “Neanderthaloid” is nothing more than an ill-defined **grade** of fossil hominins and its use has now been largely abandoned.

nearly neutral theory of molecular evolution A modification by Ohta (1992) of Kimura’s **neutral theory of molecular evolution** suggesting that slightly disadvantageous and slightly advantageous mutations often evolve in a similar way as strictly neutral mutations, but that their evolution is dependent on population size. In small populations, the effects of selection are limited such that the fates of nearly neutral mutations, like those of strictly neutral mutations, are determined by random **genetic drift**. In large populations, the effects of selection are significant for nearly neutral mutations and thus it has more influence on their fates. In nearly neutral systems, the rate of substitution generally decreases as population size increases.

negative allometry (Gk *allo*=other and *metron*=measure) This term refers to a relative size relationship in which part of an organism, or a variable that functions as a proxy for part of an organism, increases in size at a slower rate than the overall size of the organism, or a variable that functions as a proxy for the whole of an organism (i.e., the variable becomes proportionally smaller as overall body size increases). *See also allometry; scaling*.

negative assortment This mating pattern, also known as negative assortative mating, occurs when individuals mate with individuals that are

different from themselves at a higher frequency than would be expected by chance (i.e., when “like” mates with “unlike”). An example of negative assortative mating in modern humans is thought to be human leukocyte antigen (or HLA) type (as sensed via pheromones or body odor) (e.g., Ober et al. 1997, Lie et al. 2010, Chaix et al. 2008), although this has not been demonstrated in all populations of modern humans (e.g., Hedrick and Black 1997, Chaix et al. 2008). Red hair in modern humans also shows moderate negative assortative mating (Mascie Taylor and Boldsen 1988).

negative Gompertz hazard model The negative Gompertz hazard model is used as part of the **Siler hazard model** to represent premature (i.e., pre-senescent) mortality. Although it is related to the Gompertz model, the negative Gompertz hazard model was not proposed by Benjamin Gompertz and it is usually only used within the Siler model; immature mortality on its own is more typically represented with a **Weibull hazard model**. The negative Gompertz hazard model gives the hazard of death at exact age a as $h(a) = \alpha e^{-\beta a}$ and the survivorship to exact age a as $S(a) = \exp(-\alpha/\beta(1-\exp(-\beta a)))$, where α is the initial hazard of death at age zero and β is the decrease in the hazard of death (on a logarithmic scale) with advancing age. As noted by Siler (1979), at very old ages the survivorship from the negative Gompertz model is $S(a) = \exp(\alpha/\beta)$, which is not equal to zero. This is an undesirable property of the negative Gompertz, although within the Siler model this problem does not matter as the survivorship from the (positive) Gompertz model does decrease to zero at advanced ages. As the survivorships are multiplicative across the Siler components, ultimately the survivorship for the entire model does reach zero at advanced ages. Survivorship in a Weibull model does reach zero at very old ages, which is why this mortality pattern cannot be used within the Siler model. If it were used then adult survivorship would be forced to equal zero because of the multiplicative nature of the survivorships from the immature and senescent (and residual) components.

negative selection Equivalent to **purifying selection** (*which see*).

neo-Lamarckism *See* Lamarckism.

neoanthropic man *See* Archanthropinae.

Neoanthropinae *See* Archanthropinae.

neocortex (Gk *neos*=new and L. *cortex*=bark; i.e., outer covering) Refers to the phylogenetically newest part of the **cerebral cortex** [i.e., all of the cerebral cortex apart from certain cortical areas that are linked with olfaction (the piriform cortex) and memory and spatial navigation (hippocampus), which are also referred to as the archi- and paleocortex, respectively]. The neocortex, which forms the external shell of the **cerebral hemispheres**, is made up primarily of **neurons** and **glial cells**. It is the largest component of the **forebrain** in mammals and it is the only part of the forebrain that is visible when viewing the whole brain. The neocortex is only present in mammals, although homologous structures, which share certain features of molecular expression and connectivity with the neocortex, have been proposed to exist in reptiles and birds. The most striking and distinguishing architectural trait of the neocortex is that its **neurons** are arranged in several well-defined layers, numbered sequentially from the surface beneath the innermost of the three meningeal layers, the pia mater (layer I) to the layer adjacent to the underlying white matter (layer VI). Although this six-layer structure is characteristic of the entire neocortex, the thickness of individual layers, and the types of neuron within them, varies in different functional regions of the cortex. The characteristic pattern of layering in different cortical areas was shown by Korbinian Brodmann, who used evidence about **cytoarchitecture** to organize the modern human cerebral cortex into about 50 areas. The modern human neocortex is approximately four times larger than the neocortex of the living **great apes** and it is larger than would be predicted using the observed **allometry** relationships within living hominoids (Rilling 2006).

neocortex ratio The ratio of the volume of the **neocortex** to the volume of the rest of the **brain**. Robin Dunbar and colleagues have proposed that this metric is correlated across primate species with variables such as social group size and grooming clique size, which might reflect the complexity of social cognition. Aiello and Dunbar (1993) have argued that the large neocortex ratio of modern humans can be used as a proxy for the size of the groups that individual modern humans are comfortable with. They also suggest that a major force driving the evolution of language was the need to track the status of the individuals in a relatively large social network. In this scenario, spoken language evolved as a replacement for grooming as a more efficient

mechanism for maintaining social connections and exchanging information among a large numbers of individuals. *See also* **language, evolution of**.

Neogene (Gk *neo*=new and *genos*=race, kind) The middle of the three periods that comprise the **Cenozoic** era. Neogene refers to a unit of geological time (i.e., a **geochronological unit**) that spans the interval from *c.*23.5 to 2.58 Ma (Gelasian) or 1.8 Ma (Calabrian). The Neogene comprises two **epochs**, the **Miocene** and **Pliocene**. Some geologists disagree with the decision to elevate the **Quaternary** to period status and thus they still include the **Pleistocene** and the **Holocene** epochs in the Neogene. In this case, the Neogene would span the interval of time from *c.*23 Ma to the present. *See also* **Plio-Pleistocene boundary**; **Tertiary**.

neonatal line (L. *neo*=new and *natus*=to be borne) An **accentuated line** in the **enamel** and **dentine** of deciduous teeth and in the first permanent molars in higher primates caused by the stress of birth interfering with enamel and dentine development. *See also* **enamel development**.

neonate (Gk *neos*=new and L. *natus*=to be born) Literally the “newborn,” but in pediatrics the term is used for infants from birth to 4 weeks old.

neontological species (Gk *neos*=new, *onto*=being, and *ology*=the study of, thus a “new,” or contemporary, species) One of the many terms used to describe a contemporary species defined on the basis of criteria such as evidence of interbreeding, and lack of any evidence of interbreeding between individuals belonging to that species and individuals belonging to any other species. *See also* **species** (syn. **biological species**; **extant species**).

neoteny (Gk *neos*=young plus *teinein*=to extend) Neoteny is a **heterochronic** process that involves the dissociation of ancestral ontogenetic trajectories to produce **paedomorphosis**. In neoteny, shape change is retarded for a given size in the descendant relative to the ancestor and does not proceed as far, resulting in a juvenilized morphology. Importantly, and to distinguish this process from either form of **hypomorphosis**, neoteny does not require associated shifts in adult size or duration of growth. Neoteny has a history of being invoked as a particularly important heterochronic

process for human evolution. Features including large brains, short and flat faces, and hairlessness have been attributed as results of juvenilization via uncoupling of ancestral ontogenetic trajectories. However, instead of providing an understanding of *all* of the key human adaptations as the result of a single, relatively simple, change in development, the invoking of a theory of global neoteny has resulted in other important processes being overlooked. For example, the morphology of modern human lower limbs can probably best be described in terms of **peramorphosis**. Further, modern human development is prolonged relative to that of apes, counter to the requirements of neoteny. For other comparisons, however, neoteny provides a viable explanation (e.g., juvenilized skull and face in bonobos relative to common chimpanzees, who reach similar adult sizes and grow for comparable durations of time).

neotype (L. *neo*=new and *typus*=image) If the **type specimen** of a **taxon** is destroyed for some reason, researchers can apply to the **International Commission on Zoological Nomenclature** to have another specimen, called the neotype, designated in its place.

Nerja *See* Cueva de Nerja.

net reproductive rate (or **NRR**) The integral across age of the product of the **age-specific fertility rate** and the **survivorship** in a hazards analysis. The **NRR** must be lower than the **total fertility rate** because the latter does not include the effect of **mortality** (measured by survivorship). For example, in the (unlikely) event that survivorship to age 13 was zero, the **NRR** would also be zero, regardless of the age-specific fertility rates. As **NRR** includes the effects of both fertility and mortality it can be used to project population size into the future. Another interpretation for **NRR** is as the ratio of the number of daughters in the next generation to the number of mothers in the current generation. For example, a population with a **NRR** equal to 1.0 is simply replacing itself but is neither growing nor declining in size over time. If *T* is the number of years (**generation length**), then under an **exponential population growth** model $NRR=e^{rT}$ and solving for the intrinsic growth rate gives $r=\ln(NRR)/T$. In a **life table** analysis the **NRR** is the average of age-interval midpoints where the averaging is weighted by the product of age-specific fertility rate and survivorship.

neurocranium (Gk *neuron*=nerve and *kranion* = brain case) The cranium is divided into the neurocranium and the **viscerocranium**. The neurocranium is the part of the cranium that surrounds all but the anterior aspect of the **brain** (this is in contact with the viscerocranium) and it contains the **inner ear** and **middle ear**. It comprises the cranial vault, or **calvaria**, which covers the top, back, and sides of the brain, and the **basicranium**, which lies beneath the brain.

neuron (Gk *neuron*=a nerve cell with an appendage) The name for a class of cells in the nervous system. Neurons are specialized for conducting electrical signals that transmit information to other cells. Neurons have long processes called **axons** that only branch close to their termination and shorter-branching projections called **dendrites**. Neurons vary widely in size, shape, and electrochemical properties. Some classes of neurons in the cerebral cortex, such as the **pyramidal cells** of the prefrontal cortex and the **von Economo neurons** of the anterior cingulate and frontoinsular cortex, display morphologies that may serve as a neuroanatomical substrate for the behavioral and cognitive specializations that are seen in the great apes and modern humans.

neuropil The portion of brain tissue that *does not* take up **Nissl stain**. It comprises mainly **dendrites**, **axons**, and **synapses**.

neurotransmitter (Gk *neuro*=nerve) A chemical substance secreted at a synaptic terminal by one **neuron** for the purpose of conveying information via receptors to other neurons or to organs. Neurotransmitters may be either neuroactive peptides or low-molecular-weight molecules. To be a neurotransmitter, a substance must (a) be synthesized in the neuron, (b) be present in the presynaptic terminal and released in quantities sufficient to exert an influence upon the post-synaptic body, (c) mimic endogenously released transmitter when applied exogenously (e.g., as a drug), and (d) be removable from the synaptic cleft by a specific mechanism. There is no evidence that modern human brains have any neurotransmitters that are not also found in the brains of chimpanzees.

neutral allele An allele that has a **selection coefficient** of zero ($s=0$). Any change in the frequency of such alleles is due to random **genetic drift**, **gene flow**, or **mutation**.

neutral mutation A mutation that has a **selection coefficient** of zero ($s=0$). Any change in the frequency of such mutations is due to random **genetic drift** or **gene flow**.

neutral polymorphism *See* **neutral allele**.

neutral theory of molecular evolution A theory developed by Kimura (1968) suggesting that the vast majority of **molecular evolution** involves the replacement of one **neutral mutation** by another neutral mutation.

New Archeology *See* **Binford, Lewis (1930–)**.

NG Abbreviation of Ngrejeng and the prefix for fossils recovered from that site. *See* **Ngrejeng**.

NG 8503 Site **Ngrejeng, Indonesia**. Locality Near the village of Ngrejeng. Surface/*in situ* Surface. Date of discovery 1985. Finder A local villager. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Bapang Formation**. Group N/A. Nearest overlying dated horizon Middle Tuff. Nearest underlying dated horizon Lower Tuff. Geological age *c.*1.02–1.51 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Part of the right side of the mandibular corpus with M₁ and M₂ (still in its crypt); both molars preserve their occlusal morphology. Announcement Aziz et al. 1994. Initial description Aziz et al. 1994. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description Kaifu et al. 2005a. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance This specimen documents dental-size reduction in later *H. erectus* specimens from Java (Kaifu et al. 2005b). Location of original Geological Research and Development Center, Bandung, Indonesia (syn. Sangiran 38).

Ngaloba cranium *See* **LH 18**.

Ngamapa One of the Early and Middle **Pleistocene** sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Ngandong (Location 7°18'S, 111°39'E, Java, Indonesia; etym. named after a local village)

History and general description An open-air, river terrace site on the north bank of the Solo River, about 10 km/6 miles north of Ngawi in East Java. C. ter Haar directed excavations at Ngandong from September 1931 through the end of November 1933. The initial finds consisted of “two fragments, one fine specimen of an adult hominid calvaria” (Oppenoorth 1932a, p. 62). The latter is referred to as **Ngandong 1** and the former as Ngandong 2 and 3; Ngandong 4 and 5 were found in 1932 (Oppenoorth 1932b). Oppenoorth suggested that the calvaria “may represent a stage in the development of man equivalent to that of the neandertaler” (*ibid*, p. 63) and he suggested it be referred to a new species and subgenus of *Homo*, as *Homo (Javanthropus) soloensis* Oppenoorth, 1932. The ter Haar field project produced over 25,000 mammalian fossils, including at least 11 hominin crania and two hominin tibiae. During the dry season, the fossiliferous deposits at Ngandong known as the High Terrace are 20 m above the Solo River. The High Terrace deposits are 3 m thick and have been divided variably, depending on the researcher, into three to five separate strata. Most of the vertebrate fossils were recovered from the lowermost half meter of the High Terrace. The deposit itself is mostly composed of sand and gravel with a large proportion of volcanic material included. **Temporal span and how dated?** The age of Ngandong has been, and still is, controversial. Using faunal correlation, the Ngandong hominins were initially attributed to the Upper Pleistocene. **Uranium-series dating** of bone samples excavated from Ngandong in the late 1980s ranged from 31 to 101 ka, thus supporting these Upper Pleistocene age estimates. In 1997, an international team analyzed additional fossil mammal teeth recovered from Ngandong and using both uranium-series dating and **electron spin resonance spectroscopy dating** techniques they determined that the fossil hominins date from 46.4–27.3 ka. These startlingly recent ages have met with considerable resistance from other scholars who have claimed that the fossil hominins were re-worked from older deposits and are therefore not contemporary with the recently dated mammal teeth, or that the very young ages of the deposit do not correspond with the well-established faunal biostratigraphy of the region. **Hominins found at site** Three different numbering systems have been employed in cataloguing the Ngandong hominins. Originally, the cranial specimens were referred to as “Solo I” through “Solo XI” while the

tibia were referred to as “Tibia A” and “Tibia B.” The modern system refers to the crania as “Ngandong 1” through “Ngandong 12” and retains the original names of the tibiae. The third system (employed by Teuku Jacob) names all of the specimens “Ngandong 1” through “Ngandong 14” with the tibiae included as “Ngandong 9” and “Ngandong 10.” **Ngandong 1** is the **holotype** of *H. soloensis*. All of the Ngandong crania are without faces and most lack the base of the cranium. The crania have thick vaults, bar-like supraorbital tori that are thickest laterally, and an average endocranial volume of 1135 cm³. **Archeological evidence found at site** The High Terrace at Ngandong has yielded crude, small (generally <5 cm in length) stone implements, including cores and flakes. They are mostly water-worn, many are made from chalcedony, with a few being made from chert and jasper. **Key references:** Geology, dating, and paleoenvironment Orchiston and Siesser 1982, Bartstra et al. 1988, Swisher et al. 1996, Grün et al. 1997b; Hominins Weidenreich 1951, von Koenigswald 1975, Jacob 1981, Antón 1999, Durband 2004, Kaifu et al. 2008; Archeology Bartstra et al. 1988 (syn. Solo).

Ngandong 1 Site Ngandong, Indonesia. **Locality** N/A. **Surface/in situ** Surface. **Date of discovery** 1931. **Finder** Unknown. **Unit** N/A. **Horizon** N/A. **Bed/member** High Terrace. **Formation** **Bapang Formation**. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** c.100–27 ka. **Developmental age** Juvenile. **Presumed sex** Unknown. **Brief anatomical description** A thick-walled cranial vault. **Announcement** Oppenoorth 1932a. **Initial description** Oppenoorth 1932a. **Photographs/line drawings and metrical data** Oppenoorth 1932a, Weidenreich 1951. **Detailed anatomical description** Weidenreich 1951. **Initial taxonomic allocation** *Homo soloensis*. **Taxonomic revisions** *Homo erectus* (Santa Luca 1980). **Current conventional taxonomic allocation** *H. erectus*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** The holotype of *H. soloensis*. **Location of original** **Geological Research and Development Center**, Bandung, Indonesia (syn. Solo I).

Ngandong hominins In the introduction to his unfinished monograph the “Morphology of Solo man” Weidenreich (1951) suggests that the paleontological significance of the Ngandong site was first recognized by G. Elbert, a member of the

1907–8 German Selenka Expedition to Trinil, but Elbert referred to it as “Bangoen,” not Ngandong. The site was “rediscovered” in August 1931 by C. ter Haar, who was mapping the area for the Geological Survey. The initial finds were made in September of that year and consisted of “two fragments, one fine specimen of an adult hominid calvaria” (Oppenoorth 1932a, p. 62). The latter is referred to as **Ngandong 1**, or Ngandong Skull 1 and the former as Ngandong Skull 2. Oppenoorth, who was the Acting Director of the Geological Survey, went to Ngandong in October 1931 and during his visit a third skull was found, Ngandong Skull III. Four more skulls and a tibia were found in 1932 (Ngandong Skulls IV–VII and Tibia A) and more in 1933 (Ngandong Skulls VIII–XI and Tibia B). Oppenoorth suggested that the calvaria “may represent a stage in the development of man equivalent to that of the neandertaler” (*ibid.*, p. 63) and he suggested it be referred to a new species and subgenus of *Homo*, as *Homo (Javanthropus) soloensis*. He later withdrew his support for *Javanthropus* (Oppenoorth 1937). The most detailed studies of the Solo crania have been carried out by Weidenreich (1951) and Santa Luca (1980). Although Weidenreich died before his analysis could be completed, he made his taxonomic philosophy clear, stating that “I believe that all the hominids now known belong morphologically to a single species” (Weidenreich 1951, p. 226). Later in the Solo monograph he writes that his earlier studies of the Solo material that were presented in his monograph on the skull of *Sinanthropus pekinensis* (Weidenreich 1943) had convinced him that “Ngandong man was not a true Neanderthal type but distinctly more primitive and very close to *Pithecanthropus* and *Sinanthropus*. For this reason I ranked Solo man with the same group of early hominids as the two latter forms and called the whole group Archanthropines” (Weidenreich 1951, p. 227). Santa Luca (1980) came to much the same conclusion. He also rejected any special affinity with *Homo neanderthalensis* and suggested that the Ngandong hominins be referred to as “the Ngandong group of *Homo erectus erectus*” Santa Luca (1980, p. 133). In a recent careful study Kaifu et al. (2008) make a good case that the cranial evidence suggests (a) there is continuity between the Bapang-AG hominins and the Ngandong hominins, (b) that despite the evidence for continuity there are consistent morphological differences between the two samples (e.g., larger braincase, longer basioccipi-

put, more marked expression of the angular torus, and reduction in the length of the attachment of the temporal muscle, etc. in Ngandong hominins compared to the Bapang-AG sample), and (c) that the Ngandong sample displays more apparently derived features than does the collection of crania from the Bapang-AG levels. *See also Homo (Javanthropus) soloensis; Javanthropus.*

Ngawi (Location 7°23'S, 111°39'E, Indonesia; etym. named after a local village) History and general description This is the site of a 1987 surface find of a hominin calvaria found eroded out of the bank of the Solo River near the village of Ngawi, 10 km/6 miles south of Ngandong. Temporal span and how dated? Unknown, but the morphology of Ngawi matches that of the fossil hominins found at Ngandong and **Sambungmacan**. The most recent radiometric estimates of the ages of these sites range between 27 and 53 ka. Hominin found at site Ngawi 1 is a presumed adult female calvaria that has been attributed to *Homo erectus* and to *Homo (Javanthropus) soloensis*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Swisher et al. 1996. Hominins Widiyanto and Grimaud-Hervé 1993, Widiyanto and Zeitoun 2003.

Ngawi 1 Site Ngawi, Indonesia. Locality Near the village of Ngawi. Surface/in situ Surface. Date of discovery 1987. Finder A local villager. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.27–53 ka based on morphological similarities to the Ngandong and **Sambungmacan** crania. Developmental age Adult. Presumed sex Female. Brief anatomical description Ngawi 1 is an adult calvaria and, based on its relatively low estimated cranial capacity of about 1000 cm³, presumptively female. In its preservation and morphology it is most similar to the Ngandong and Sambungmacan crania. Announcement Sartono 1991. Initial description Sartono 1991. Photographs/line drawings and metrical data Widiyanto and Grimaud-Hervé 1993, Widiyanto and Zeitoun 2003. Detailed anatomical description Widiyanto and Zeitoun 2003. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions cf. *Homo (Javanthropus) soloensis* (Widiyanto and Zeitoun 2003). Current conventional taxonomic

allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Evidence from another east Javan site of a hominin calvaria similar to those from Ngandong and Sambungmacan. Location of original **Balai Arkeologi**, Yogyakarta, Indonesia.

Ngebung (Location 7°20'S, 110°58'E, Indonesia; etym. named after a local village) A locality in the northwestern part of the Sangiran Dome where the Bapang Formation is exposed and from where stone tools, including utilized large flakes and bolas stones, have been recovered. Key references: Archeology Sémah et al. 1992. *See also Sangiran*.

Ngrejeng (Location 7°20'S, 110°58'E, Indonesia; etym. named after a local village) History and general description Within the **Sangiran Dome**, this is the site of a 1985 surface find of a hominin mandibular fragment. The specimen was most likely derived from a stratum between the Lower and Middle Tuffs of the **Bapang Formation**. Temporal span and how dated? Trace element analysis of a bone sample drilled from the corpus, and the mineralization and color of the specimen are consistent with its stratigraphic assignment. The most recent radiometric estimates of the age of this deposit range between 1.24 and 1.51 Ma. Hominin found at site **NG 8503** is a juvenile, consisting of the right side of the mandibular corpus with M₁ and an unerupted M₂. It has been referred to *Homo erectus*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Matsu'ura et al. 1995a, 1995b, Larick et al. 2001; Hominins Aziz et al. 1994, Kaifu et al. 2005a.

NHG Acronym for **Northern Hemisphere Glaciation** (*which see*).

Niah cave (Location 3°49'09"N, 113°46'42"E, Sarawak, Borneo Island, Malaysia) History and general description The Niah cave (or the Great Cave of Niah) is located on the coastal plain of Sarawak (northern Borneo), about 15 km/9.3 miles from the South China Sea. The paucity of marine plants and animals in the Niah sediments suggests the cave was always too far away from the coast for the foraging groups to transport such food-stuffs back to the cave. The cave was excavated extensively in the 1950s and 1960s by Tom and

Barbara Harrisson, and it came to the attention of the international scientific community in 1958 following the discovery of a skull of an anatomically modern human, nicknamed the "Deep Skull." The Deep Skull was excavated from an area nicknamed "Hell Trench" because the mid-day sun beats directly down in that area making it a very difficult area to work continuously. Niah cave contains Late Paleolithic and Neolithic deposits, the latter including as many as 1000 human burials that have been dated to between 6 and 2 ka. Temporal span and how dated? Uranium-series dating provides ages of 35.2±2.6 ka, ages from radiocarbon dating are between 41 and 39 ka, and AMS radiocarbon dating provides ages between 46 and 34 ka; the Neolithic remains have been radiocarbon dated to between 6 and 2 ka. One of the main questions related to the Deep Skull is the possibility that it originated from one of the overlying Neolithic burials. However, the combination of dates from charcoal samples found in close proximity to the skull, together with excavation records, supports the argument that it is Late Pleistocene and dates to between 45 and 39 ka. Hominins found at site The Deep Skull is actually a partial cranium comprising occipital, frontal and upper face, maxilla with four teeth, and part of the basicranium; no mandibular fragments or mandibular teeth were identified. The cranium is gracile in appearance, has a partially erupted M³, and noticeable wear on the M¹; these features suggest that the cranium belongs to a young adult female, possibly between 20 and 30 years of age. Its morphology is most similar to that of modern day Tasmanian and Negroid populations. The maturity of an almost complete left femur and a right proximal tibia fragment found near the Deep Skull is consistent with those bones belonging to the same individual as the cranium. A modern human-looking talus was identified in the "nonhominin" fauna originally sent to Leiden, The Netherlands, for further study. Archeological evidence found at site Taphonomic analysis indicates that clusters of excavated burnt bone are suggestive of hearths or individual depositional events of the calcined bones. Twelve cutmarked bones identified in Hell Trench, in the area of the Deep Skull, include the bones of suids, leaf monkey/macaque, and monitor lizards. Charcoal is present in many different areas of the excavation area. Several thousand stone artifacts best described as simple core and flake tools produced

on locally available raw materials were recovered from the site. The original excavator, Tom Harrison, referred to these core tools as “choppers,” which was a standard description for the time. In addition 146 bone artifacts were identified at Niah, most of them from deposits dating to the Pleistocene/Holocene transition. At least three bone tools have been identified in deposits that may be coeval with the Deep Skull. There are also suggestions that some of the pig incisors may have been used to fashion wooden implements. Repository Sarawak Museum, Borneo, has most of the materials. Some of the materials are also stored in the Natural History Museum, London, England, the University of Bradford, England, the University of Las Vegas, USA, and the University of Leiden, The Netherlands. niche (*L. nidus*=nest) The physically distinctive space, or habitat, occupied by a species. It can also mean the ecological role of a species.

niche construction A term introduced by John Odling-Smee (1988) to describe **biotic** environmental modification. Organisms adapt to their environment, but they are also capable of modifying the environment to better suit their needs (e.g., beavers). This organism-driven environmental modification is seldom as dramatic or substantial as the environmental modification that is brought about by tectonism or climate change, but it is nonetheless significant. Modern humans are capable of significant environmental modification; it is unclear at what stage in their evolution they shifted from adapting to existing environments to being substantial modifiers of the environment. The principles of niche construction are set out by Odling-Smee et al. (2003) in a book of the same name.

Nihewan Basin (Location approximately 41°13'N, 114°40'E, Shanxi and Hubei Provinces and Inner Mongolia Autonomous Region, northern China) History and general description The Nihewan Basin is an area of some 150–200 km²/58–77 square miles comprised of Cenozoic fluvial-lacustrine deposits.

The basin contains a paleolake and a series of tributary stream deposits. The primary river that cuts through the basin is the Sanggan. The Nihewan Basin came to the attention of geologists and paleontologists beginning in the 1920s because of the presence of thick sedimentary deposits (more than 90 m thick in some areas) and the discovery of heavily fossilized animal bones eroding out of these deposits. Beginning in the 1920s, Licent, Barbour, and Teilhard de Chardin provided much of the early geological and paleontological descriptions of the sediments and materials from the Nihewan Basin. The Nihewan Basin sites are among the oldest evidence of hominins in northern China, and currently more than 12 Early and Middle Pleistocene sites have been identified in the eastern part of the Nihewan Basin; **Xujiayao** is a major Middle–Late Pleistocene open-air site located in the western Nihewan Basin. The best-known early Pleistocene sites are Goudi/Majuangou III (they are the same site), Xiaochangliang, and Donggutuo; there are also terminal Pleistocene sites (e.g., Hutouliang). Temporal span and how dated? The thick sedimentary deposits have been dated to the Pliocene and Pleistocene. Traditionally, the Plio-Pleistocene vertebrate remains, referred to as the Nihewan Fauna, corresponds with the European Villafranchian Fauna. An unusual aspect of the Nihewan Fauna is the apparent co-occurrence of *Hipparion* and *Equus* at a number of sites, some of which may be *c.*1 Ma. The earliest faunas from the Nihewan Basin include *Postschizotherium*, *Hipparion*, *Zygodon*, and *Proboscoidipparion*; what appear to be later faunas include *Palaeoloxodon*, *Equus*, *Bison*, and *Dicerorhinus*. Interpretations of the **magnetostratigraphy** have suggested Goudi/Majuangou III may date to *c.*1.66 Ma, Xiaochangliang may date to *c.*1.36 Ma, and Donggutuo to *c.*1.1 Ma; **electron spin resonance spectroscopy dating** dates are much younger and range between 0.87 and 0.21 Ma. Hominins found at site None reported. Archeological evidence found at site More than 20,000 artifacts and vertebrate fossils have been found on the surface or collected from excavations in fine-grained silt, sand, and clay fluvial deposits in the Nihewan Basin. The artifacts are primarily small core and flake tools produced on locally abundant, diverse rock types, including fine-grained silicified quartzite. One of the defining characteristics of the Nihewan Basin is the overall poor-flaking quality of the stone raw materials. While many of the Nihewan core and flake tools indicate similar flaking techniques and capabilities as Oldowan assemblages in Africa, some Nihewan lithic assemblages lack evidence of deliberate stone

knapping (e.g., platform-preparation techniques, retouch, etc.), while others (e.g., Donggutuo) show careful core-reduction techniques. Some use-wear analyses indicate possible evidence of meat and/or hide processing but these studies have only been done on a small subset of the overall artifact collection. Initial taphonomic observations on the fauna from Majuanguo III have reported percussion marks, but another taphonomic analysis of a small subset of the Xiaochangliang faunal assemblage failed to identify any unequivocal evidence of hominin modification. Repository Institute of Vertebrate Paleontology and Paleoanthropology, Institute of Cultural Relics of Hebei Province, China, Donggutuo Field Research Station, China. NISP An acronym for **number of identified specimens** (*which see*).

Nissl stain A histological staining technique developed by the German neurologist Franz Nissl (1860–1919), used to show the **cytoarchitecture** of the nervous system. This method stains large cytoplasmic granular bodies of rough endoplasmic reticulum that are found predominantly in the cell bodies of **neurons**; some light staining of the cell bodies of **glial** cells is also seen. The Nissl stain has been used in comparative studies of the organization of the brains of modern humans and great apes to investigate species differences in the distribution of neuronal morphology, and in neocortical area **parcellation** and organization. For example, the Nissl staining method was used to identify **von Economo neurons** in hominid primates and to examine asymmetry in the nicotinic columns of **Wernicke's area** of modern humans and common chimpanzees.

nitrogen An element commonly used in **stable isotope biogeochemistry**. There are two common isotopes in nitrogen, ^{15}N and ^{14}N ; both are stable and do not decay. *See also* $^{15}\text{N}/^{14}\text{N}$; **stable isotopes**.

NK Abbreviation of Nariokotome, one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* **Nariokotome**.

NMK Acronym for the **National Museums of Kenya** (*which see*).

NN Abbreviation of Nanyanakipi one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* **Nanyanakipi**.

nocturnal (L. *nocturnus*=belonging to the night) The term used for animals that are active at night (i.e., between dusk and dawn). Many strepsirrhine primates (lorises, galagos, and some lemurs) are nocturnal, tending to forage on their own in darkness, and they have a reflective "cat's eye" (a *tapetum lucidum*) that facilitates night-time activity. Since visual cues for things such as conspecificity are less helpful in low light, many nocturnal primates rely more on olfaction (for example, scent marking), or on calls, to distinguish species, groups, and territories. There are many fewer nocturnal haplorhines; the tarsiers and neotropical owl monkeys are the only taxa to be routinely active at night. They do not have a *tapetum lucidum*, but instead they have relatively bigger eyes to facilitate nocturnal activity. No catarrhines are nocturnal, and activity after dusk and before dawn tends to be minimal. Baboons, for example, have preferred group sleeping sites and will settle there before sundown. Most modern human activity at night is made possible because of the cultural innovation of artificial light, and is likely therefore that until fire could be controlled to provide illumination, nocturnal activity would have been severely limited for much of hominin evolutionary history.

Nojiriko *See* Tategahana.

nomen (L. *nomen*=name; pl. *nomina*) Commonly used in the field of biological nomenclature to refer to any scientific name, at any level (e.g., Primates, Hominidae, Hominini, *Australopithecus*, *Australopithecus africanus*). It refers to the name itself, not to any taxon that may be designated by the name. A new taxon is often published together with the phrase "*nomen novum*", meaning "new name." There are other types of nomina. A *nomen nudum* is a name that is

unavailable in nomenclature (i.e., it cannot be used) because it was published without a description or definition of the taxon it denotes. A *nomen oblitum* ("forgotten name") is one which has not been used since 1899, and need not be revived as long as a younger name (a *nomen protectum*) has in the meantime become more familiar. A *nomen dubium* is a name which is of doubtful application, and therefore left in limbo.

nomenclature (L. *nomenclatura*=calling by name; e.g., calling the role) The principles and practice of providing names for taxa. The process of naming a new group is controlled by rules and recommendations set out in the **International Code of Zoological Nomenclature**, otherwise known as the "Code." The stipulations in the Code are designed to ensure that everyone who takes part in discussions about issues involving classification and nomenclature does so with a common understanding of the taxonomic categories and of the taxa in each of the categories. The purpose of the rules and recommendations set out in the Code is to make sure the names given to new taxa do not duplicate those of existing taxa (i.e., **homonymy**), and to prevent two or more names being given to the same taxon (i.e., **synonymy**). It also describes procedures that are designed to avoid new taxa being given inappropriate names.

Nomina Anatomica *See* anatomical terminology.

nondisjunction During meiosis a pair of chromosomes aligned at the equator of the cell may not separate properly, resulting in either no or two copies of that chromosome in all (if it occurs in meiosis I) or some (if it occurs during meiosis II) of the resulting haploid gametes. If such gametes join with a normal gamete and become part of a zygote, then the zygote will be aneuploid (it will have an abnormal number of chromosomes) and it will either have a **monosomy** or **trisomy** of that particular chromosome.

nonindependence *See* independent contrasts.

non-metrical traits Most morphology can be satisfactorily recorded using measurements. Analyses based on measurements are examples of **metrical analysis**. But some morphology is diffi-

cult to measure and is more amenable to **non-metrical analysis** based on non-metrical traits. Most skeletal non-metrical traits are craniodental (like many of the examples given below), but they can also be postcranial. Non-metrical skeletal traits include additional bones called ossicles (e.g., bregmatic, asterionic), bony tubercles (e.g., marginal, pharyngeal), bony ridges or tori (e.g., angular torus, mandibular torus, palatine torus), bony processes (e.g., paracondylar process, third trochanter), bony connections called "bridges" (e.g., divided hypoglossal canal, mylohyoid bridge), fissures (e.g., squamotympanic, mastoid), sutures (e.g., infraorbital, metopic), foramina (e.g., mastoid, supraorbital), and additional cusps, ridges and fissures on the enamel of tooth crowns. Some can be recorded (also called scoring) as either present or absent – these are also called discrete variables – or they are given a nominal value by comparing the morphology observed with predefined categories of expression of that feature (e.g., small/medium/large or well-expressed, expressed, weakly expressed, absent, etc.). Bony non-metrical traits are also divided into hyperostotic and hypostotic, literally meaning traits that are the result of "more bone than usual" and traits that are due to "less bone than usual," respectively. Non-metrical traits are usually regarded as examples of the interaction between genetic information and the developmental environment, and so they are also called epigenetic traits. Hauser and De Stefano (1989), Buikstra and Ubelaker (1994), Manzi (2003), and Hallgrimson et al. (2005) provide excellent reviews of the utility of commonly used non-metric traits. *See also* **epigenetic**.

nonparametric statistics Statistical tests that do not assume that data follow any particular distribution. The most commonly used tests are of **parametric statistics** which assume particular probability distributions (e.g., the **normal distribution**). If data do not meet the assumptions of parametric tests, it is more appropriate to use nonparametric tests such as the **Mann-Whitney U test** or **Wilcoxon signed rank test**, or **resampling techniques** such as the **bootstrap** and **randomization**.

nonrandom mating When mating is affected by physical, genetic, or social preference or by a barrier (e.g., a geographic barrier such as a

large river). Within a population, nonrandom mating results in increased inbreeding and random **genetic drift**. Nonrandom mating can include positive and negative assortative mating. In modern humans cultural factors (e.g., language, education, and religion) and physical characteristics (e.g., height and skin color) are known to affect mating patterns (Spuhler 1972, Lie et al. 2010).

nonrandom sampling *See* bias; ascertainment bias.

nonsense mutation A mutation that changes a codon sequence from one that encodes an amino acid to one that encodes a stop codon. This results in a truncated protein sequence and such mutations are typically deleterious. *See* genetic code; mutation.

nonsynonymous mutation A point mutation (i.e., change in one nucleotide) in a coding sequence that results in a change in the amino acid sequence of a protein. Most changes of this sort are deleterious and are subject to purifying selection, but a small fraction are adaptive and are subject to positive selection. For example, in the modern human lineage there have been two nonsynonymous mutations in the *FOXP2* gene, which encodes FOXP2, a **transcription factor**. This new amino acid sequence is highly conserved in evolution and in modern humans changes in the *FOXP2* gene have been linked to problems with speech and grammar. Enard et al. (2002) demonstrated that this gene has been subject to recent positive selection. *See also* FOXP2; FOXP2; mutation.

nonsynonymous substitution *See* nonsynonymous mutation.

norm of reaction *See* reaction norm.

norma basalis *See* norma basilaris.

norma basilaris (L. *normal*=made according to a pattern, or standard, and basilar is a neologism introduced by translators, that presumably comes from *basis*=base, or pedestal) One of the standard views of the cranium. It is the inferior view, the view that looks at the cranium from its underside, or base. In modern humans it mainly comprises the inferior surface of the hard palate and the undersides of the sphenoid, temporal, and occipital bones.

norma frontalis (L. *normal*=made according to a pattern, or standard, and *frons*=brow, or forehead) One of the standard views of the cranium. It is the anterior view, the view that looks at the forehead and face. In modern humans it comprises the anterior surface of the face, and the anterior surfaces of the squamous part of the frontal bone and the parietal bones.

norma lateralis (L. *normal*=made according to a pattern, or standard, and *latus*=side, or flank) One of the standard views of the cranium. It is the view from the side. In modern humans it comprises the lateral surfaces of the frontal, temporal, parietal, and occipital bones.

norma occipitalis (L. *normal*=made according to a pattern, or standard, and *occipio*=to begin or commence: the part of the head that usually appears first during a normal birth; or *ob*=against and *caput*=head: the part of the head that rests on the ground when you sleep on your back) One of the standard views of the cranium. It is the posterior view. In modern humans it mostly comprises the posterior surfaces of the parietal and occipital bones.

norma verticalis (L. *normal*=made according to a pattern, or standard, and *vertex*=highest point) One of the standard views of the cranium. It is the view from above (i.e., looking down onto the vertex, or the highest point, of the cranium). In modern humans it mostly comprises the superior surfaces of the frontal, parietal, and occipital bones.

normal The state of the Earth's magnetic field when the needle of a magnet points to the North Pole. *See also* geomagnetic dating.

normal distribution A particular probability distribution characterized by data falling symmetrically about the mean and with most data falling relatively close to the mean with observations becoming less frequent as distance from the mean increases. Most traditional statistical tests assume that data are normally distributed; these tests are referred to as **parametric statistics**. Many data sets are not normally distributed, however, and parametric tests should not be applied in these cases. For example, data sets containing counts of specimens or species at a site in which many sites have an observed value of zero are unlikely to be

symmetrically distributed and thus not normally distributed. When data are not normally distributed, parametric tests are at a greater risk of **Type I error** and **nonparametric statistics** should be used instead (syn. Gaussian distribution).

normal fault In structural geology a normal fault is a fault or fracture with an extensional geometry. This type of fault is sometimes referred to as a dip-slip fault and as this term implies the dominant component of the displacement is down the **dip** of the affected strata such that the hanging wall (i.e., the rocks above the fault plane) is displaced downwards relative to the rocks of the footwall (i.e., the rocks below the fault plane)

normal views (L. *normal*=made according to a pattern, or standard) Standard views of the cranium (i.e., *norma verticalis*, superior view; *norma frontalis*, anterior view; *norma lateralis*, right or left lateral view; *norma occipitalis*, posterior view; *norma basalis*, inferior view).

normalizing selection *See* stabilizing selection.

Northern blotting A technique used in molecular biology to study gene expression. In a Northern blot **electrophoresis** is used to separate RNA by size on a gel. The RNA in the gel is transferred to a membrane that is then washed with probes that hybridize to the RNA segments of interest.

Northern Hemisphere Glaciation Refers to the occurrence of major ice sheets over many northern landmasses including North America, Greenland, and much of Asia. The onset of the northern hemisphere glaciation (sometimes referred to as NHG or the **Late Pliocene transition**) is defined by the oxygen isotope record and it takes place in the late Pliocene between 3.2 and 2.7 Ma.

Notanthropus *See* Sergi, Giuseppe (1841–1936).

NRR Acronym for **net reproductive rate** (*which see*).

NS Abbreviation of Nasechibun, one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* Nasechibun.

NT Abbreviation of Natoo one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* Natoo.

nuchal [ME *nucha*=nape (or back) of the neck] The area at the back of the neck where you can feel the nuchal muscles. Used also for the nuchal area on the underside of the basicranium posterior to the foramen magnum where the nuchal muscles are attached.

nuchal area height index [ME *nucha*=nape (or back) of the neck] The index introduced by Wilfrid Le Gros Clark (1950b) to describe the relationship between the height of the cranial vault and the uppermost limit of the nuchal area. It is the ratio between the height of the highest point of the nuchal area above the Frankfurt Horizontal (AG in the index) and the total height of the calvaria above the Frankfurt Horizontal, times 100. The higher the nuchal area the higher the value (e.g., in modern humans the average is approximately 0 to +5 and in chimpanzees it is about 50).

nuchal crest [ME *nucha*=nape (or back) of the neck] A bony crest that takes the place of the superior nuchal line, a roughened line on the squamous part of the occipital bone. It is produced by the attachment of the fascia that covers one of the biggest nuchal muscles, the semispinalis capitis, and when the muscle and the fascia are well developed the superior nuchal line takes the form of a bony crest. Such crests are common in large male gorillas, but they are also seen in some hominin taxa (e.g., *Australopithecus afarensis* and large, presumed male, megadont archaic hominins such as OH 5).

nuchal muscles The muscles (e.g., trapezius and sternocleidomastoid covering the semispinalis and splenius capitis) you can see and feel at the back of the neck. *See also* **nuchal**; **nuchal crest**.

nuchal plane [ME *nucha*=nape (or back) of the neck] Refers to the surface of lower or inferior part of the squamous occipital bone. The inion is the dividing point in the midline between the nuchal plane and the upper part of the squamous occipital bone that forms the occipital plane (syn. lower scale of the occipital bone).

nuclear DNA The DNA that is found within the **nucleus** of eukaryotic cells (i.e., it is intra-nuclear).

In most eukaryotes nuclear DNA, which in a modern human diploid cell consists of roughly 6.4 billion base pairs, forms the majority of the **genome**. The other part of the genome of eukaryotes is the **mitochondrial DNA** found within mitochondria, which are organelles in the cytoplasm (i.e., mitochondrial DNA is “extra-nuclear”). *See also* DNA.

nucleotide Molecules that form the basis of both DNA and RNA. They are also involved in metabolism (e.g., adenosine triphosphate is a nucleotide). Nucleotides are composed of a nitrogenous base (either a purine or a pyrimidine), a five-carbon sugar (ribose or deoxyribose), and one or more phosphate groups.

nucleus (L. *nux*=nut) The term nucleus is used in two ways relevant to human evolution. In cell biology it refers to the membrane-bound organelle in a nucleated, or eukaryotic, cell that contains DNA (known as nuclear DNA). The transcription of DNA occurs *inside* the nucleus, whereas the process of translation occurs *outside* the nucleus in the cytoplasm. In neuroscience nucleus refers to a geographically localized group of neurons that share the same morphology and/or function (e.g., the caudate nucleus, or nuclei of the cranial nerves), or to a group of nuclei (e.g., the basal ganglia, or basal nuclei at the base of the forebrain).

null hypothesis In statistics, a statement to be tested which is typically framed as the absence of a difference between groups or absence of a relationship between variables. The *P* value is the probability that the observed pattern in the data could occur if the null hypothesis were true; if the *P* value is below some threshold (usually 0.05) then the test is said to show a statistically significant result and the null hypothesis is rejected.

number of identified specimens (or NISP) A measure that reflects the number of identified specimens (i.e., a skeletal element, or portion thereof) of any taxon represented in a bone assemblage. The NISP serves as the baseline from which all other related quantitative units (e.g., **minimum number of elements**, **mini-**

mal animal units, and **minimum number of individuals**) are derived. NISP counts are used to compare taxonomic abundances through time or across fossil localities.

numerical-age methods *See* geochronology.

NY Abbreviation of Naiyena Engol one of several groups of localities within the site of **West Turkana** named after ephemeral river drainages. *See* Naiyena Engol.

NY 75'86 *See* Nyabusosi.

Nyabusosi (Location approximately 1°02'N, 30°21'E, Uganda; etym. unknown) History and general description Nyabusosi is a Plio-Pleistocene site in a long series of sediments in the Western Rift about 25 km/15.5 miles southwest of Lake Albert, Uganda. The approximately 1450 m-thick sequence preserves sediments dating from the early Miocene through the Quaternary. W.W. ('Bill') **Bishop** initially explored and mapped the geology in 1963 and reported several localities with Plio-Pleistocene mammal faunas. Some sediments from Nyabusosi have yielded suids that are **Pliocene** (e.g., "Behanga-type" suids that correlate with **Omo Shungura Member G**, i.e., 1.8–2.0 Ma) and others **Middle Pleistocene** suids (e.g., *Meschoerus majus*). Re-study of the sequence by Senut et al. yielded a badly crushed and fragmentary hominin cranium (NY 75'86) from locality NY 15. Associated fauna suggests a Lower Pleistocene date. Temporal span and how dated? Associated fauna [e.g., *Elephas recki*, *Hippopotamus imagunculus* (or *Hippopotamus aethiopicus*), and *Meschoerus limnetes*] suggests a **Late Pliocene** to Lower Pleistocene age. Hominins found at site NY 75'86, a badly crushed and fragmentary cranium attributed to *Homo* sp. that is embedded in ferruginous sandstone matrix. Archeological evidence found at site Site NY 15 yielded several **Oldowan**-like small flakes and polyhedrons made of **quartz** and **quartzite**. Key references: Geology, dating, and paleoenvironment Bishop 1965, Gautier 1970, Harris and White 1979, Senut et al. 1987; Hominins Senut et al. 1987; Archeology Senut et al. 1987.

O

O. Prefix used by the French contingent of the **International Omo Research Expedition** for localities in the **Shungura Formation** (e.g., O. 18). The prefix is also used for fossils found within those localities (e.g., O. 18-1967-18 for **Omo 18-1967-18**).

$^{18}\text{O}/^{16}\text{O}$ ratio Oxygen isotopes can be measured in animal proteins, such as collagen, and in the carbonate or phosphate molecules present in shell, bone, or enamel apatite. The ratio of these stable oxygen isotopes reflects the isotopic ratio of the water ingested by an animal either as drinking water or as part of their diet (see review by Koch 1998). Oxygen isotope ratios in plants reflect their water source and the relative humidity of the environment in which they are growing. Plants growing in drier environments (and animals consuming these plants) have higher $^{18}\text{O}/^{16}\text{O}$ ratios (commonly represented as $\delta^{18}\text{O}$ values in per mil, or ‰, notation) than those growing in wetter, more humid environments. Among **C₃ plants**, $\delta^{18}\text{O}$ values tend to differ among plant parts. Leaves, which are subject to evapotranspiration, tend to have higher $\delta^{18}\text{O}$ values than fruits (transpiration leads to the preferential loss of ^{16}O over ^{18}O from leaf surfaces). As a result, $\delta^{18}\text{O}$ values in consumers may be able to distinguish frugivores and folivores (Cerling et al. 2004). Recent research suggests that $\delta^{18}\text{O}$ values can also be used to distinguish large herbivores that drink frequently from those that drink infrequently (Levin et al. 2006). Animals that drink infrequently (called drought-tolerant) tend to have higher $\delta^{18}\text{O}$ values than those that drink frequently (drought-intolerant). Oxygen isotope ratios can be used to interpret **paleoclimates**, for ^{16}O evaporates more readily than ^{18}O from large bodies of water. Thus rain and rain-derived terrestrial water sources tend to be ^{18}O -depleted (lower $\delta^{18}\text{O}$ values) compared to ocean water. During colder periods, water evaporated from oceans tends to be trapped on land

as ice. This leaves relatively more ^{18}O in liquid water reservoirs such as oceans and lakes. Animals ingesting water during cooler glacial periods thus have higher $\delta^{18}\text{O}$ values than animals living during warmer interglacial periods. Global shifts in $\delta^{18}\text{O}$ values associated with periodic glacial/interglacial cycling have been used to create **Oxygen Isotope Stages**, which are used to calibrate sites in higher latitudes. *See also* **stable isotopes**; **Oxygen Isotope Stages**.

O/M Abbreviation for the **occipito-marginal system** of intracranial venous sinuses. Individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., **OH 5**) are said to show occipito-marginal system dominance. *See also* **cranial venous drainage**.

Oakley, Kenneth Page (1911–81) Kenneth Oakley was born in Amersham, England, and entered University College London in 1930 to study geology and anthropology. After completing his BSc in 1933, Oakley joined the Geological Survey (in 1934) and in 1935 he was appointed Assistant Keeper of Paleontology at the British Museum (Natural History). He completed his PhD at University College London in 1938 with a thesis on Silurian bryozoa. Oakley's work at the British Museum was interrupted by the onset of WWII when he was attached to the Geological Survey and began work on the use of phosphate for fertilizer. This introduced Oakley to the work of Adolphe Carnot, a French mineralogist who had noted in 1893 that the absorption of fluorine in groundwater by bones might be used to determine the age of archeological or paleontological material. Prehistoric archeology had long been plagued by an inability to provide absolute dates for the artifacts or bones excavated, and at the time stratigraphy only gave a relative date. Oakley determined that the absorption of fluorine by bone increased the longer the bone had been buried, but the

amount of fluorine varied widely depending upon other factors such as the concentration of the fluorine in the groundwater and other conditions. This meant fluorine content could not be used to calculate an absolute date, but it could be used to test the relative age of objects found in the same deposit. An early opportunity to test the usefulness of this technique occurred in 1947 when Oakley attended the first **Pan-African Congress on Prehistory** organized by Louis **Leakey** in Nairobi, Kenya. In the early 1930s Leakey had unearthed portions of a cranium and jaw from two adjacent sites called **Kanam** and **Kanjera** that he considered to be from an early form of anatomically modern human, and the geological evidence suggested the fossils were extremely old. This was consistent with Leakey's belief that the australopiths were not human ancestors, and that another more modern human-like line stretched far back in time. Oakley convinced Leakey to allow a **fluorine dating** test of the bones to determine their general age, but the test was inconclusive due to the high fluorine content of the groundwater where the fossils were found. However, the fluorine dating technique proved its worth a year later when he tested the controversial Galley Hill specimen, a morphologically modern-looking skeleton found in a geologically old deposit in 1888. Galley Hill Man was used by Sir Arthur **Keith** to support his own theory that modern humans were of great antiquity, but many doubted that the skeleton was as old as had been claimed. Oakley announced at the 1948 meeting of the British Association for the Advancement of Science that the fluorine test indicated that the Galley Hill remains were quite recent when compared to the results obtained from other fossils from the same area that were known to be old. This suggested that the Galley Hill skeleton was a much later intrusive burial. The success of this test indicated that the fluorine dating method might be used to resolve doubts about the relative age of other controversial fossils. Oakley was released from his wartime duties in 1947, and he returned to the British Museum as a principal scientific officer. In addition to working on fluorine dating methods, Oakley also began work on the collection of prehistoric artifacts housed in the Museum's Department of Geology. In 1949 Oakley published *Man the Tool-Maker*, a book that examined the evidence for human antiquity, the origins and importance of tool-making, the chron-

ology of tool types during the Paleolithic, and the significance of tool use and tool-making to the evolutionary and cultural development of hominids, and contributed to debates over the role of tool use in human evolution. Oakley is perhaps best known for his contributions to exposing the Piltdown hoax. Between 1908 and 1915 Charles Dawson, a solicitor and amateur paleontologist, unearthed fragments of a cranium and mandible from a gravel pit in Sussex, England. The fossils seemed to represent a hitherto unknown hominin that possessed a large brain, but an ape-like jaw. Several prominent English anthropologists, notably Sir Arthur Smith Woodward and Sir Arthur Keith, quickly claimed **Piltdown Man** (*Eoanthropus dawsoni*) was either a direct ancestor of modern humans or on its own branch, but some researchers were uneasy about the specimen. One frequent objection was that the cranial fragments and the mandible belonged to two separate creatures. Debate over Piltdown continued over the next few decades but many anthropologists accepted the specimen at face value. As time passed, however, no more seemingly Piltdown-like hominins were discovered, while in Africa and Asia numerous specimens of *Homo erectus* and *Australopithecus* were making the Piltdown specimen look increasingly aberrant. By 1950 Piltdown Man had been pushed to the periphery of scientific discussion and critics of the fossil felt strengthened in their doubts about the validity of the specimen. The demise of Piltdown began in 1949 when Joseph Sidney Weiner, Reader in Physical Anthropology in the Department of Anatomy at Oxford University, was encouraged by Wilfrid **Le Gros Clark**, Dr Lee's Professor of Anatomy at Oxford University, to initiate an extensive investigation of the Piltdown remains. Weiner later collaborated with Oakley, whose contribution was to subject the cranium and jaw to fluorine testing. This showed conclusively that the fossils were much younger than had previously been thought. They concluded from their investigation that the Piltdown fossils were a forgery: a relatively recent cranium had been planted along with a fresh orangutan jaw that had been chemically stained and the teeth filed down to resemble human teeth. Weiner, Oakley and Le Gros Clark were the joint authors of an article entitled "The solution to the Piltdown problem," published in 1953 in the *Geological Bulletin of the British Museum (Natural History)*, the publication that finally settled the debate over Piltdown Man. Oakley continued to work on the

problem of establishing reliable relative and absolute dating methods, which culminated in his publication of *Frameworks for Dating Fossil Man* in 1964. He also collaborated with Bernard Campbell and Theya Molleson in compiling the three-volume *Catalogue of Fossil Hominids* (1967, 1971, 1977). Oakley retired from his position at the British Museum (Natural History) in 1969. *See also* **fluorine dating**; **Pitldown**.

Oase 1 Site Peștera cu Oase. Locality Panta Strămoșilor. Surface/in situ Surface, recovered amid *Ursus spelaeus* and other large-mammal fossil bone remains. Date of discovery 2002. Finders S. Milota, A. Bilgăr, and L. Sarcina. Nearest underlying dated horizon Stalagmite dated by **TIMS uranium-series dating** to $41,620 \pm c.2400$ cal. years BP. Geological age $34,950 \pm 900$ years BP, an uncalibrated **AMS radiocarbon date**. Developmental age Adult. Presumed sex Male. Brief anatomical description Large and robust modern human mandible with large teeth showing modern human crown morphology. Announcement Trinkaus et al. 2003a. Initial description Trinkaus et al. 2003a. Photographs/line drawings and metrical data Trinkaus et al. 2003a. Detailed anatomical description Trinkaus et al. 2003a, 2006, Trinkaus 2007. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Presently the oldest reliably dated modern human remains in Europe. Location of original Institutul de Speologie “Emil Racoviță,” Cluj-Napoka, Romania.

Oase 2 Site Peștera cu Oase. Locality Panta Strămoșilor. Surface/in situ Surface, recovered amid *Ursus spelaeus* and other large-mammal fossil bone remains. Date of discovery 2003, during mapping of the site. Nearest underlying dated horizon Stalagmite dated by **TIMS uranium-series dating** to $41,620 \pm c.2400$ cal. years BP. Geological age $28,890 \pm 170$ years BP uncalibrated **AMS radiocarbon date**. Developmental age Adolescent. Presumed sex Unknown. Brief anatomical description Modern human cranium, nearly complete. Announcement Trinkaus et al. 2003b. Initial description Trinkaus et al. 2003b. Photographs/line drawings and metrical data Trinkaus et al. 2003b, Rougier et al. 2007. Detailed anatomical description Trinkaus et al. 2003b, 2006, Rougier et al. 2007. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic cate-

gory Anatomically modern human. Significance Presently the oldest reliably dated modern human remains in Europe. Location of original Institutul de Speologie “Emil Racoviță,” Cluj-Napoka, Romania.

Oberkassel (Location $50^{\circ}43'N$, $7^{\circ}10'E$, Germany; etym. named after a nearby town). History and general description This open-air site in a suburb of Bonn was discovered by workers in 1914. Two hominins were found associated with several artifacts, including decorated bone objects and a dog skeleton. Temporal span and how dated? Direct **AMS radiocarbon dating** on the hominin skeleton and associated artifacts suggests an age of *c.*12 ka. Hominins found at site Two nearly complete *Homo sapiens* skeletons found buried next to each other: Oberkassel 1, associated skeleton, adult male; Oberkassel 2, associated skeleton, young adult female. Archeological evidence found at site Bone artifacts attributed to the **Magdalenian** and an associated dog skeleton. Key references: Geology, dating, and paleoenvironment Baales and Street 1998, Street et al. 2006; Archeology Bosinski 1982; Hominins Henke 1986.

objective synonym *See* synonym.

obligate biped *See* bipedal.

obligate bipedalism *See* biped.

oblique crest *See* distal trigon crest.

oblique furrow The term used by Weidenreich (1937) for a feature on a maxillary postcanine tooth crown that others call the fovea posterior. *See also* fovea posterior (maxillary).

oblique ridge *See* distal trigon crest.

obliquity Earth science The Earth's orbital geometry is affected by three “rhythms” or “cycles.” Obliquity is the *c.*41 ka cycle that relates to the tilt of the Earth's axis (i.e., the angle between the Earth's axis and the equator). It interacts with the *c.*23 ka precessional cycle to take the poles of the Earth either closer to or further away from the sun. It was the dominant signal affecting cyclic changes in the global climate between 3 and 1 Ma. *See also* **precession**. Morphology Obliquity is also used to refer to a methodological problem

that can occur when teeth are sectioned for analysis. If the plane of section deviates from an “ideal plane” passing through enamel cusps and/or dentine horn tips, it can result in inflated, and thus erroneous, measures of **enamel thickness** and cuspal, or **crown formation time**. *See also* **precession**.

observational learning *See* **social enhancement**.

obsidian (etym. Pliny suggests it was given its name because obsidian is said to resemble a stone found in Ethiopia by Obsius) A typically black, or dark-colored, silica-rich volcanic glass. When it is subjected to percussion it fractures in a conchoidal fashion (percussion results in a so-called **conchoidal fracture**) and when it is available it is often selected for artifact manufacture at (e.g., **Enkapune ya Muto**). There is evidence from some sites that hominins traveled long distances to fetch obsidian (e.g., **Mumba Shelter**).

obsidian hydration dating Principles and method (or OHD) A chronometric dating method based on the fact that **obsidian** (volcanic glass) weathers, or hydrates, and that the amount of this hydration increases with time. In principle, accurate measurement of the hydrated area (‘the hydration rim’) and the rate of hydration allow calculation of the time since the obsidian surface was first exposed. In the case of stone artifacts, this exposure time is initiated during the process of flake removal, so the hydration present should be a measure of the time that has elapsed since the flake was made. Suitable materials Obsidian. Time range 200–100 ka. Problems Comparison of results obtained from obsidian hydration dating with those obtained by other methods has revealed that there is substantial variability in hydration rates due to compositional variability within obsidian sources and individual artifacts, the latter in part a consequence of substantial variation within local depositional settings (e.g., ground-water composition and past temperatures). Further difficulties arise from the precise measurement of the extent of hydration, which is typically on the scale of a few micrometers. Obsidian hydration dating remains accurate for coarse chronologies, although some advocate its use primarily as a **relative dating** tool (Hull 2001, Rogers 2008). Obsidian hydration dating, along with other

methods, has been used to provide age estimates at **Enkapune ya Muto** and other sites in East Africa.

Occam’s razor William of Occam (or Ockham) was a 13th/14thC English philosopher who promulgated the rule (or “razor”) that all things being equal researchers should favor the simplest hypothesis. In paleoanthropology, Occam’s razor is most frequently applied to **phylogenetic** reconstruction, where the preference for the least complex explanation (i.e., the most parsimonious explanation) is a guiding principle.

occipital (L. *occipio* = to begin or commence, thus the part of the head that usually appears first during a normal birth; or from *ob* = against and *caput* = head, the occiput is the part of the head that rests on the ground when you sleep on your back) One of the unpaired cranial bones. It is a compound bone, which means that it develops from several components. They are, from front to back, a single basilar (or basioccipital) part, paired lateral (or condylar) parts, and posteriorly a single, large, flat, or squamous part. The occipital bone forms the posterior part of the basicranium and contributes to the posterior part of the cranial vault. All four components of the occipital contribute to the border of the foramen magnum. The squamous part of the occipital bone is divided in the midline by the inion into a lower part that forms the nuchal plane and an upper part that forms the occipital plane. The two parts of the occipital squame are also called the lower and the upper scales, respectively.

occipital foramen (L. *occipio* = to begin or commence, thus the part of the head that usually appears first during a normal birth; or *ob* = against and *caput* = head, the occiput is the part of the head that rests on the ground when you sleep on your back) Refers in modern anatomical terminology to a small bilateral foramen, or hole, in the occipital bone that transmits one of the venous channels that allows blood to flow back and forth between the intra- and extracranial venous systems. In times gone by (e.g., in T.H. Huxley’s *Evidence as to Man’s Place in Nature*, p. 76) the term occipital foramen was used for what in modern anatomical terminology is called the **foramen magnum**.

occipital index The ratio introduced by Karl Pearson to describe the curvature of the squamous

part of the occipital bone in the sagittal plane. It is the ratio of the length of the radius of curvature of the occipital bone between lambda and opisthion to the chord distance between lambda and opisthion. Tobias (1967) suggested that it should be replaced by a simple chord-arc index.

occipital length index I An index introduced by Weidenreich (1943, p. 131) to express the projected distance between opisthion and opisthocranion relative to overall cranial length. Both opisthion and opisthocranion are projected onto the **Frankfurt Horizontal** and the horizontal distance between them is divided by maximum cranial length, times 100. Its value is low (approximately 10–15%) in *Pan* and *Gorilla*, and higher (about 25–35%) in modern humans.

occipital length index II An index introduced by Weidenreich (1943, p. 131) to express the distance between opisthion and opisthocranion relative to the distance between nasion and opisthion. The line between nasion and opisthion is projected posteriorly and the locations of opisthion and opisthocranion are projected onto it. The horizontal distance between them is divided by the nasion–opisthion distance, times 100. Its value is close to zero in *Pan* and *Gorilla*, and more negative (c. –25%) in modern humans.

occipital lobe (L. *occipio* = to begin or commence, thus the part of the head that usually appears first during a normal birth; or *ob* = against and *caput* = head, the occiput is the part of the head that rests on the ground when you sleep on your back) One of the four main subdivisions of the cerebral cortex of each cerebral hemisphere; it forms the posterior part of each cerebral hemisphere. The occipital lobe is primarily devoted to visual processing. The primary visual cortex, Brodmann's area 17 (also known as V1 and the striate cortex) is located within the calcarine sulcus, toward the rear of the occipital lobe. The most posterior point on the cerebral hemisphere, called the posterior pole, is formed by the occipital lobe.

occipital sinus (L. *occipio* = to begin or commence, thus the part of the head that usually appears first during a normal birth; or *ob* = against and *caput* = head, the occiput is the part of the head that rests on the ground when you sleep on your back) One of the dural venous sinuses that

make up the external component of the intracranial venous system. The occipital sinus, when present, runs down from the cruciate eminence towards the foramen magnum in a midline groove. In most modern humans the superior sagittal sinus and the straight sinus (the latter drains venous blood from the deep cerebral veins) drain into the transverse sinuses. But in the majority of the crania belonging to *Australopithecus afarensis*, *Paranthropus boisei*, and *Paranthropus robustus*, the venous blood from the same sources drains into occipital sinus, which in turn drains into the marginal sinuses. This pattern of intracranial venous drainage is known as the **occipito-marginal system** of venous sinuses and individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., **OH 5**) are said to show occipito-marginal system dominance. *See also* **cranial venous drainage; occipito-marginal system.**

occipito-marginal system A variant of the internal component of the intracranial venous system. In most modern humans the veins draining the deep structures of the brain drain as the deep cerebral veins into the left transverse sinus, and the superior sagittal sinus drains into the right transverse sinus. Each transverse sinus drains into a sigmoid sinus, which runs inferiorly in a sigmoid-shaped groove from the lateral end of the transverse sinus to the superior jugular bulb, which marks the beginning of the internal jugular vein. This pattern of dural venous sinuses is known as the transverse-sigmoid system. However, in just a few percent of modern humans the venous blood from the brain takes a different route (Kimbel 1984). Instead of draining into the transverse sinuses, the deep cerebral veins and the superior sagittal sinus drain into an enlarged midline occipital sinus, which runs down from the cruciate eminence towards the foramen magnum in a midline groove. The occipital sinus drains into uni- or bilateral marginal sinuses, which run(s) around the margin(s) of the posterior quadrants of the foramen magnum to drain into the superior jugular bulb and/or the vertebral venous plexuses. This is known as the occipito-marginal system of venous sinuses, and individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., **OH 5**) are said to show occipito-marginal system dominance. *See also* **cranial venous drainage.**

occipitomastoid crest [L. *occipio* = to begin or commence, thus the part of the head that usually appears first during a normal birth; or *ob* = against and *caput* = head, the occiput is the part of the head that rests on the ground when you sleep on your back; *mastos* = breast and *oeides* = shape and L. *crista* = crest, literally “a crest along the junction (suture) between the occipital bone and the mastoid part of the temporal bone”] The term *crista occipitomastoidea* was coined by Franz Weidenreich (1943, p. 64) for a crest that in the Zhoukoudian calvaria runs along the suture between the occipital bone and the mastoid part of the temporal bone. It may, or may not, follow the course of the occipitomastoid suture. It forms the bony lateral edge of the cranial attachment of the superior oblique (Kimbel et al. 1985), one of the short muscles of the base of the cranium. When the superior oblique muscle is confined to the occipital bone then the occipitomastoid crest and the occipitomastoid suture are likely to coincide. However, when that muscle is relatively large, or if its location is displaced laterally, then the occipitomastoid crest may run on the temporal bone instead of along the occipitomastoid suture. When the course of the occipital artery coincides with that of the occipitomastoid crest the latter may appear as a compound structure, but in effect it is a single crest divided by a groove for the occipital artery. The occipitomastoid crest is especially prominent and pneumatized in *Australopithecus afarensis*, and in that taxon it forms the lateral face of the occipitomastoid suture. In *Homo neanderthalensis* the occipitomastoid crest region is located in a relatively inferior position, resulting in the impression of a less-projecting and less-robust mastoid process and the distinctive appearance of this anatomical region in Neanderthals.

occlusal (L. *occludere* = to close) Refers to the superiorly facing surfaces of the enamel cap of the mandibular teeth and the inferiorly facing surfaces of the enamel cap of the maxillary teeth that come together in occlusion when the mandible is elevated during the chewing cycle.

occlusal morphology (L. *occludere* = to close) Refers to the size and shape of the superiorly facing surfaces of the enamel cap of the mandibular teeth and the inferiorly facing surfaces of the enamel cap of the maxillary teeth. Occlusal

morphology is usually described in terms of the number and relative size of main and accessory cusps, the pattern of primary and secondary fissures, and the presence/absence of fovea (syn. cusp morphology).

occlusal wear (L. *occludere* = to close) Loss of the volume of a tooth that occurs on the functional or occlusal surface of a tooth (i.e., the surfaces of the upper and lower teeth that meet when the jaws are brought together as the mouth closes). Occlusal wear that can be seen with the naked eye is called gross wear, dental macrowear, or dental mesowear, whereas occlusal wear that can only be seen with a microscope is called **dental microwear**. See also **tooth wear**.

Oceania (L. *oceanus* = sea) The islands, large and small, in the central, western, and southern Pacific. The large islands are Australia and New Zealand; the three major divisions of small islands that make up Oceania are **Melanesia**, **Micronesia**, and **Polynesia**. See also **Sahul**.

Oceania, peopling of Past theories on the human settlement of the Pacific Islands collectively known as **Oceania** have suggested that the immigrants originated in Island Melanesia, Southeast Asia, Japan, Micronesia, or even South America. Evidence from contemporary archeology, linguistics, and genetics now points to several major migrations into Oceania over a remarkably long time period, all of them coming from the west. The initial settlement by modern humans of **Sahul** (the ancient Australia/New Guinea continent) as well as neighboring islands to the east in the Bismarck Archipelago, occurred *c.*50 ka from areas immediately to the west, mostly now submerged (as the **Sunda shelf**) (Summerhayes et al. 2010). This was most likely an extension of an early modern human expansion out of Africa that followed the shorelines of South Asia. As sea levels subsequently rose, the inhabitants of Sahul and the nearby islands were isolated for the following 20–30 ka, a unique occurrence in modern human prehistory, but by the end of the Pleistocene there is evidence of increasing interaction with peoples to the west. At *c.*3300 years BP a small number of seafaring peoples with clear linguistic roots in Taiwan some 1500 years earlier (Gray et al. 2009) entered the Bismarck Archipelago from the west. Within the following 500 years, these people developed remarkable seafaring abilities in the region of the

Bismarcks, but their impact was more linguistic and cultural than genetic (Friedlaender et al. 2008). Then it seems that they spread back along the north shore of New Guinea, along then through the off-shore islands and coastal regions of the Bismarck and Solomon Islands. By *c.*2800 years BP they had settled previously unoccupied islands as far east as Tonga and Samoa (i.e., the Lapita Expansion). It is in the Tonga/Samoa region during the following few hundred years that the basic elements of Polynesian language and culture developed. After a pause of a few more hundred or perhaps even 1000 years, voyagers from this area began colonizing islands far to the east, north, and south (Kirch 2000). Initial settlement dates for various Pacific archipelagos remain controversial, but the Marquesas, the Society Islands (Tahiti), Easter Island, and Hawai'i were settled by at least 1200 years BP, and New Zealand somewhat later, by about 1000–800 years BP. The Polynesians even sailed to South America, bringing back the sweet potato and bottle gourd, rather than the reverse, as had been famously proposed by Thor Heyerdahl. Because of this pattern of ancient settlement, Polynesians form a genetic, linguistic, and cultural phylogenetic entity. Micronesians are more diverse because of influences from Melanesia, Polynesia, and directly from East Asia. The inhabitants of Melanesia are the most diverse of all in genes, language, and culture, with some very ancient mitochondrial DNA genetic relationships with Australian Aborigines, as well as some relatively minor genetic similarities in particular regions with Polynesian and Micronesian groups. Some geneticists have recently even suggested that there are indications of genetic affinities of Australo-Melanesians with pre-modern human groups. *See also Helicobacter pylori.*

Ochtendung (Location 50°21'N, 7°23'E, Germany; etym. named after a nearby town) History and general description Hominin remains were discovered at the foot of an exposure of late **Middle Pleistocene** volcanic and loess deposits during quarrying operations in 1997. The finds were made near a known Middle Paleolithic site. Temporal span and how dated? Stratigraphic correlation suggests a date of **Oxygen Isotope Stage 6** (*c.*128–186 ka). Hominins found at site A few cranial fragments, assigned to *Homo neanderthalensis*. Archeological evidence found at site Three **Middle Paleolithic** stone tools were found associated with the hominin

remains. Key references: Geology, dating, and paleoenvironment von Berg 1997, 2002, Street et al. 2006; Archeology von Berg 1997, 2002; Hominins von Berg 1997, 2002, von Berg et al. 2000.

Ochoz (Location 49°20'N, 16°45'E, Czech Republic; etym. after a nearby village) History and general description This cave, also known as Švédův stůl (the Swedish cave) is southwest of Ochoz village, north of Brno. A hominin partial mandible was found in 1905. Subsequent excavations were conducted in 1953–5 and in 1964, with the latter yielding some hominin cranial fragments and an isolated molar. Temporal span and how dated? **Biostratigraphy** suggests last interglacial to last glacial. Hominins found at site An adult partial mandible, cranial fragments, and isolated molar, attributed to *Homo neanderthalensis*. Archeological evidence found at site **Mousterian and Upper Paleolithic** industries. Key references: Geology, dating, and paleoenvironment Vlček 1969; Archeology Klima et al. 1962, Vlček 1969; Hominins Jelinek 1969, Smith 1982.

ochre (Gk *okhros* = pale yellow) A family of minerals identified by the colored streak they produce and the compounds from which those colors derive: hematite (Fe₂O₃) and goethite [α -Fe³⁺O(OH)]. Ochres can, when pulverized into powder or shaped into "crayon" form, be used as pigment to decorate the body and other surfaces (Watts 2002). Other known applications include but are not limited to animal hide tanning aid (Audouin and Plisson 1982), medicine, vegetable preservative, and component of mastic used for hafting tools (Wadley 2005). Some notable archeological examples include the *c.*40 ka Mungo III burial from Lake Mungo in Australia which was discovered covered in powdered ochre (Bowler et al. 2003), the *c.*77 ka specimens of symbolically incised ochre from **Blombos Cave**, South Africa (Henshilwood et al. 2002), and the assemblage containing multiple types of ochre from between 270 and 170 ka at **Twin Rivers**, Zambia (Barham 2002b).

Ockham's razor *See Occam's razor.*

odontoblasts (Gk *odonto* = pertaining to dentine and *blastos* = bud or immature cell) Dentine-forming cells derived from the mesenchyme of the dental papilla that interact with the inner enamel epithelium to induce hard-tissue matrix secretion.

The cells become elongated during differentiation, with their long axis at approximate right angles to the **enamel-dentine junction** (EDJ) (see images in Nanci 2003). As they lay down matrix they move away from the EDJ and towards the future pulp chamber, leaving behind a long cell process that extends from the secretory end of the cell and into the dentine for a variable distance. This cell process is encased in a dentine tubule approximately 2 µm in diameter. The fluid-filled dentine tubule runs from the EDJ to the pulp, but the odontoblast process (that only extends a variable way along it from the pulpal aspect) responds to changes in osmotic pressure and temperature as the fluid is drawn up and down the tubule. Over a long period of time peritubular dentine, which is harder than intertubular dentine and which contains no collagen, is formed by the odontoblast cell process. This peritubular dentine slowly fills in the tubules resulting in sclerosed or transparent dentine. The extent of transparent dentine formation in roots can be used as an indicator of chronological age (see Aiello and Dean 1990). *See also dentine development; enamel development.*

odontogenesis (Gk *odonto* = tooth and *gena* = to give birth to) *See dentine development.*

OES Acronym for **ostrich egg shell dating** (*which see*).

OH Abbreviation of Olduvai Hominid and the prefix for fossil hominins recovered from **Olduvai Gorge**, Tanzania.

OH 1 Site Olduvai Gorge. Locality RK. Surface/in situ *In situ*. Date of discovery 1913. Finder Hans Reck. Unit N/A. Horizon Near the top of Bed II. Bed/member Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon **Holocene**. Nearest underlying dated horizon Bed II, *c.*1.15–1.70 Ma. Geological age Initially inferred to be contemporaneous with Bed II, now thought to be intrusive and likely Holocene or terminal **Pleistocene** in age. Developmental age Adult. Presumed sex Male. Brief anatomical description An anatomically modern human skeleton found in a strongly contracted position. The cranium is long, narrow and tall and the face is orthognathic. The mandible has a deep body and a strong chin. Announcement Reck 1914. Initial description Reck 1914. Photographs/line drawings and metrical data

Reck 1914, Mollison and Gieseler 1929, Protsch 1974. Detailed anatomical description Mollison 1929, Gieseler 1929. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance The erroneous association of OH 1, a clearly anatomically modern human skeleton, with the Plio-Pleistocene fauna at Olduvai Gorge, along with a similarly mistaken association at **Kanjera**, led Louis **Leakey** in the 1930s–1970s to champion the then-unorthodox idea that modern humans had probably evolved in Africa and had a very ancient evolutionary history on the continent. OH 1 remains important for studies of modern population history and microevolution in East Africa (e.g., Rightmire 1975, 1981, Bräuer 1978, Angel et al. 1980). Location of original Staatssammlung für Anthropologie und Palaeoanatomie München, Munich, Germany.

OH 3 See OH 5.

OH 4 See OH 5.

OH 5 Site Olduvai Gorge. Locality FLK, 45, Archeology Site no. 41a. Surface/in situ *In situ* “in the process of being eroded out on the slopes” (Leakey 1959, p. 491). Date of discovery July 17, 1959. Finder Mary **Leakey**. Unit A paleosol between Tuff IB and IC. Horizon Level 22. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IC. Nearest underlying dated horizon Tuff IB. Geological age Between 1.845 and 1.839 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description This well-preserved cranium is the result of painstaking assembly by Louis **Leakey**, Mary **Leakey**, and Alun Hughes. It preserves all of the upper dentition, much of the face, cranial base, and cranial vault. It is undistorted and the surfaces of the bones and teeth are remarkably well preserved. Endocranial volume 530 cm³. Announcement Leakey 1959. Initial description Leakey 1959. Photographs/line drawings and metrical data Tobias 1967a. Detailed anatomical description Tobias 1967a. Initial taxonomic allocation *Zinjanthropus boisei*. Taxonomic revisions Leakey et al. (1964) proposed that *Zinjanthropus* be reduced to a subgenus within *Australopithecus*, as *Australopithecus (Zinjanthropus) boisei*. Subsequently, Tobias (1967a) recommended that the

subgenus *Zinjanthropus* be sunk into *Australopithecus*, so the taxon became *Australopithecus boisei*. Researchers who support the revival of *Paranthropus* as the genus name for a megadont australopith clade refer to the same species taxon as *Paranthropus boisei*. Current conventional taxonomic allocation *Au.* or *P. boisei*. Informal taxonomic category Megadont archaic hominin. Significance OH 5 is the **holotype** of *Au.* or *P. boisei*. Apart from two deciduous teeth (OH 3) recovered from BK in 1955 and a mandible fragment and a few isolated teeth (OH 4) recovered from MK, also in 1959, the OH 5 cranium was the first well-preserved archaic hominin to be recovered from Olduvai Gorge. Louis Leakey was initially convinced that OH 5 was the maker of the stone tools found in Bed I, but when what he judged to be more *Homo*-like specimens, such as OH 7, OH 8, and then OH 13, came to light they were judged to be more advanced and thus were more likely to have made the Oldowan artifacts. The discovery of such an iconic fossil transformed the availability of funds for research at Olduvai Gorge. In the days before televisions were ubiquitous, the *National Geographic* magazine was the main source of information about the natural world, and via that magazine the Leakey's research at Olduvai became known across the world. The discovery of OH 5 and the discovery of new sites at **Peninj**, on the shores of Lake Natron, together with the relative academic isolation of South Africa because of its apartheid policy, marked the beginning of East Africa as the major focus of activity for paleoanthropologists searching for fossil evidence of early hominins. OH 5 was also the first significant fossil hominin to be dated using the then-novel method of **potassium-argon dating**. The Leakeys used the epithet "Dear Boy" for what is still one of the most impressive and dramatic of all early hominin fossils. Location of original **National Museum and House of Culture, Dar es Salaam, Tanzania.**

OH 7 Site Olduvai Gorge. Locality FLKNN, 45b, Archeology Site no. 38b. Surface/in situ Some of fossils comprising this individual were found on the surface, others during the course of excavations. Date of discovery Leakey (1960, p. 1051) reported in the December 17 issue of *Nature* the recovery (presumably in October or November 1960) of "fragments of a skull and some

teeth, two clavicles, a large part of a left foot, six finger bones and two ribs" at a site FLKNN I that he described as being "not far away, at what appears to be a slightly lower level of Bed I" than the FLK locality where OH 5 was discovered. The juvenile skull and the juvenile hand bones became OH 7, the foot bones OH 8, and the clavicle OH 48. In the February 25, 1961 issue of *Nature* Leakey (1961a) reported that at the same site, FLKNN I, on November 2, 1960 Jonathan Leakey had recovered a hominin mandible, and subsequently "parts of two hominid parietals" were recovered. Finders Jonathan Leakey found the mandible and F. Masao found the right M₂ in 2006. Unit Clay overlying Tuff IB. Horizon Level 3. Bed/member Bed I. Formation Olduvai. Group N/A. Nearest overlying dated horizon Tuff IC. Nearest underlying dated horizon Tuff IB. Geological age *c.*1.84 Ma. Developmental age Juvenile. Presumed sex Male. Brief anatomical description OH 7 presently comprises a juvenile mandible, most of two juvenile parietals, and the balance of the 21 original hand bones that were neither non-hominin, nor obviously adult. An additional mandibular tooth (right M₂) was found in 2006; it was a surface find on an outcrop of Bed I, some 10 m from the FLKNN site. The mandibular corpus is broken at the symphysis, but all the teeth are present in the corpus except the separate right M₂ (see above), and the right and left M₃s. The left parietal is more complete than the right; both are thin. The 13 hand bones come from at least two hands. Announcement Leakey 1960, 1961a. Initial description Leakey 1960, 1961. Photographs/line drawings and metrical data Tobias 1991. Detailed anatomical description Tobias 1991, Susman and Creel 1979. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions. None specific to this specimen. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The specimen is the **holotype** of *H. habilis*. Most researchers regard *H. habilis* as the earliest representative of the genus *Homo*, but some are less convinced that the morphology *H. habilis* shares enough features of the *Homo* clade and grade to justify its inclusion in *Homo*. Functional morphological interpretations of the hand fossils vary from those that emphasize their similarity to modern humans, to those that stress their similarities to *Australopithecus*, including *Australopithecus afarensis*. Location of original **National**

Museum and House of Culture, Dar es Salaam, Tanzania.

OH 8 Site Olduvai Gorge. Locality FLKNN, 45b, Archeology Site no. 38b. Surface/in situ Found *in situ* during the course of an excavation. Date of discovery Leakey (1960, p. 1051) reported in the December 17 issue of *Nature* the recovery (presumably in October or November 1960) of “fragments of a skull and some teeth, two clavicles, a large part of a left foot, six finger bones and two ribs” at a site FLKNN I that he described as being “not far away, at what appears to be a slightly lower level of Bed I” than the FLK site where **OH 5** was discovered. The juvenile skull and the juvenile hand bones became part of **OH 7** and the adult bones **OH 8**. Finder Mary Leakey. Unit/horizon Clay overlying Tuff IB. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IC. Nearest underlying dated horizon Tuff IB. Geological age *c.*1.76 Ma. Developmental age Leakey initially assumed the **OH 8** foot was part of the same juvenile skeleton as **OH 7**, but Day and Napier (1964) and Leakey et al. (1964) later judged them to be adult, and thus evidence of second individual at FLKNN I, but Susman and Stern (1982) and Susman (2008) claim that the distal ends of the **OH 8** metatarsals 2 and 3 are not jagged because they were damaged by predators, but because **OH 8** is a subadult and that the distal epiphyses have been lost. However, a recent careful reassessment of the specimen (De Silva et al. 2010) provides compelling evidence that the **OH 8** foot belongs to an adult individual. Presumed sex Unknown. Brief anatomical description A left foot except for the phalanges, the distal ends of the metatarsals, and the calcaneal tuberosity. There are also some dental fragments. Two hand bones (both proximal phalanges) found with the foot are nonhominin. Announcement Leakey 1960. Initial description Day and Napier 1964. Photographs/line drawings and metrical data No systematic analysis of the whole foot has been undertaken, but measurements of individual tarsal bones are available in Day and Wood (1968), Kidd et al. (1996), Deloison (2004), and Gebo and Schwartz (2006). Detailed anatomical description There is no detailed description of the whole foot. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance The specimen is one of the

paratypes of *H. habilis*. Most researchers regard *H. habilis* as the first representative of the genus *Homo*, but others are less convinced that the morphology *H. habilis* shares enough features of the *Homo* clade and grade to justify its inclusion in *Homo*. The conclusions of functional morphological interpretations of the whole foot and of the component bones vary from those that emphasize similarities to modern humans to those that stress similarities to *Australopithecus*, but most of these assessments are based on the morphology of the talus, which Day and Napier (1964) suggested was the most primitive element in the foot. Some researchers claim that the **OH 8** foot and the **OH 35** distal tibia and fibula belong to the same individual (these reasons are reviewed in Susman 2008 and Susman et al. 2011, but see de Silva et al. 2010 for a counter argument) and it has been claimed that crocodile tooth marks on both sets of bones match up. But questions remain over whether they can be associated geologically (the **OH 8** foot and the **OH 35** distal tibia come from different levels in the Olduvai sequence) and an investigation of the extent of the congruence between the reciprocal joint surfaces on **OH 8** and **OH 35** showed that they were unlikely to belong to the same individual (Wood et al. 1998). Although **OH 8** was allocated to *H. habilis* there are no taxonomically diagnostic cranial remains associated with it, so it could equally well belong to *Paranthropus boisei*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 9 Site Olduvai Gorge. Locality LLK, 46, Archeology Site no. 64. Surface/in situ Surface. Date of discovery December 12, 1960. Finder Louis Leakey. Unit/horizon Tuff in Bed II 3–3.6 m below the base of Bed III. Bed/member Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Tuff IIA. Geological age *c.*1.7–1.2 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Calvaria lacking much of the vault, but preserving the supraorbital region. Announcement Leakey 1961a. Initial description Rightmire 1979b, pp. 101–106. Photographs/line drawings and metrical data Leakey 1961a, Heberer 1963, Rightmire 1979b, Wood 1991. Detailed anatomical description The most complete systematic descriptions are by Rightmire (1979b, pp. 101–6; 1990, pp. 59–70). In one of the early applications of **computed tomography** to fossil hominins, Maier and Nkini (1984) provide information about the sagittal morphology of **OH 9**. Initial taxonomic allocation *Homo leakeyi*. Taxonomic revisions

Homo erectus. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The OH 9 calvaria is seen by many as an early example of *H. erectus sensu stricto* in Africa and it exemplifies the proposition that the distinctive features of *H. erectus* are best expressed in larger specimens. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 10 Site Olduvai Gorge. Locality FLKN, 45a, Archeology Site no. 40b. Surface/*in situ* Surface. Date of discovery 1960. Finders Unknown. Unit Clay horizon approximately 0.9–1.2 m below Tuff IF. Horizon Level 5. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IF. Nearest underlying dated horizon Tuff IE. Geological age *c.*1.79 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Distal-hallucial phalanx from a right foot. Announcement It is included in a figure illustrating the approximate stratigraphic locations of hominins at Olduvai (Tobias 1965c, Fig. 1, p. 24), but it was not referred to in the text, thus its formal announcement was by Day and Napier (1966). Initial description Day and Napier 1966. Photographs/line drawings and metrical data Day and Napier 1966. Detailed anatomical description Day and Napier 1966. Initial taxonomic allocation Hominidae *gen. et sp. indet.* (Tobias 1965c). Taxonomic revisions *Homo habilis* (Day and Napier 1966). Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo*. Significance Although just a single toe bone, OH 10 has been a critical part of the evidence used by those who suggest the postcranial skeleton of *H. habilis* is consistent with that taxon being an obligate biped. However, the results of Day's (1967) multivariate analysis showed that although OH 10 was closer to three modern human samples than to gorillas and chimpanzees, it was significantly different from *all* of the extant comparative samples. Although the OH 10 hallucial phalanx was allocated to *H. habilis* there are no taxonomically diagnostic cranial remains associated with it, so it could equally well belong to *Paranthropus boisei*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 11 Site Olduvai Gorge. Locality DK. Surface/*in situ* Surface. Date of discovery 1962. Finders Mary Leakey and coworkers. Unit Surface of lower Ndotu Beds. Horizon N/A.

Bed/member Lower Ndotu Beds. Formation N/A. Group N/A. Nearest overlying dated horizon Upper Ndotu Beds. Nearest underlying dated horizon Masek Beds. Geological age Middle or Upper Pleistocene (400–32 ka, but probably closer to the earlier end of the age range). Developmental age Adult. Presumed sex Unknown. Brief anatomical description A weathered and abraded fragmentary left maxilla with roots of C–M². Announcement Day 1977. Initial description Rightmire 1980. Photographs/line drawings and metrical data Rightmire 1980. Detailed anatomical description Rightmire 1980. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Homo heidelbergensis* or archaic *Homo sapiens*. Current conventional taxonomic allocation *H. heidelbergensis* or archaic *H. sapiens*. Informal taxonomic category Pre-modern *Homo*. Significance One of the few hominin specimens from this time period in sub-Saharan Africa. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 12 Site Olduvai Gorge. Locality VEK, 86, Archeology Site no. 45b. Surface/*in situ* Surface. Date of discovery 1962. Finder Margaret Leakey. Unit Above Tuff IVA. Horizon N/A. Bed/member Bed IV. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Tuff IVA. Geological age *c.*>0.78 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A skull consisting of posterior vault, parietal, and facial fragments plus a few fragments belonging to the coronoid process of the mandible. There is enough preserved to attempt an endocast reconstruction, and thus generate an estimate of its cranial capacity, but because of the fragmentary nature of all but the posterior part of the cranial vault, this must be regarded as a relatively crude estimate. Endocranial volume 727 cm³ (Holloway 1983). Announcement Leakey and Leakey 1964. Initial description Rightmire 1979b, pp. 106–7. Photographs/line drawings and metrical data As above and Antón 2004. Detailed anatomical description The first systematic descriptions were by Rightmire 1979b (pp. 106–7; 1990, pp. 70–3), but the most complete is that of Antón 2004. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance OH 12 is one of the youngest African fossils attributed to *H. erectus*, yet its estimated endocranial volume is small. It was

the first evidence that *H. erectus*-like hominins subsumed a substantial range of absolute size and endocranial volume. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 13 Site Olduvai Gorge. Locality MNK, 88, Archeology Site no. 71a. Surface/in situ Two fragments of the skull were found *in situ*. Date of discovery October 22, 1963. Finder N. Mbuika. Unit Clayey tuff horizon 1.8 m thick, approximately 3 m above Tuff IIA. Horizon See above. Bed/member Lower Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Tuff IIA. Geological age *c.*1.7 Ma. Developmental age Subadult. Presumed sex Unknown. Brief anatomical description The specimen is the skull of a subadult hominin. It comprises much of the vault, the greater part of the mandible and both maxillae, all of the mandibular teeth, and some of the maxillary cheek teeth. Announcement Leakey and Leakey 1964. Initial description Leakey et al. 1964. Photographs/line drawings and metrical data Tobias 1991a. Detailed anatomical description Tobias 1991a. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions There have been no formal taxonomic revisions, but Tobias and von Koenigswald (1964) pointed out many gnathic and dental similarities between OH 13, *Pithecanthropus* IV, and Sangiran B, both now assigned to *Homo erectus*, and Robinson (1965) considered OH 13 to be conspecific with *H. erectus*. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance OH 13 was designated a paratype of *Homo habilis* and it provides some of the best dental and mandibular evidence for that taxon. Although its postcanine teeth are absolutely small, when they are related to its relatively small body mass it is still megadont. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 16 Site Olduvai Gorge. Locality Maiko Gully, FLK, 45, Archeology Site no. 43. Surface/in situ Surface. Date of discovery November 1963. Finder Maiko Mutumbo. Unit The specimen was found in small fragments on a slope. It is inferred to have come from a horizon in the base of Bed II, approximately 0.9–1.2 m above Tuff IF. Horizon See above. Bed/member Lower

Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IIA. Nearest underlying dated horizon Tuff IF. Geological age *c.*>1.74 Ma. Developmental age Subadult. Presumed sex Unknown. Brief anatomical description This is a very fragmented skull. The cranial vault has been reconstructed from about 107 fragments and it is evident that the reconstruction featured in most illustrations and the one used by Tobias (1991a) is in need of revision. The best-preserved part of the calvaria is the supraorbital region and the region of the mandibular fossa. Fifteen maxillary and 13 mandibular permanent teeth are preserved; the M_{3s} were erupted, but the M_{2s} were not. Announcement Leakey and Leakey 1964. Initial description Leakey et al. 1964. Photographs/line drawings and metrical data Tobias 1991a. Detailed anatomical description Tobias 1991a. Initial taxonomic allocation OH 16 was not included in the list of paratypes of *Homo habilis*, but it was “provisionally referred” to that taxon (Leakey et al. 1964, p. 9). Taxonomic revisions There have been no formal taxonomic revisions. Tobias (1965c, p. 392) considered that the teeth of OH 16 “are compatible with those of an *Australopithecus*,” but later formed the opinion that it belonged to *H. habilis*. Robinson (1965) considered OH 13 to be conspecific with *Homo erectus*, and some researchers have suggested OH 16 samples a second *Homo* taxon at Olduvai Gorge. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance OH 16 was not designated as a paratype of *H. habilis*, but has since been added to the *H. habilis* hypodigms. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 20 Site Olduvai Gorge. Locality HWK, 44a, Archeology Site no. 46c. Surface/in situ Surface. Date of discovery 1959 (it was not initially identified as a hominin but it was recognized as such by Mary Leakey in 1968 when she was sorting through the fauna from the site). Finders Unknown. Unit Surface find but “its degree of mineralization and colour agree closely with those of other bones from the same area known to be from lower Bed II” (Day 1969, p. 230). Horizon Lower augitic sandstone overlying Tuff IF, cutting out Tuff IIA. Bed/member Lower Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon

None. Nearest underlying dated horizon Tuff IF. Geological age *c.*>1.725 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The proximal end of a left femur preserving the greater and lesser trochanters and most of the neck. Announcement Day 1969. Initial description Day 1969. Photographs/line drawings and metrical data Day 1969. Detailed anatomical description Day 1969. Initial taxonomic allocation *Australopithecus cf. boisei*. Taxonomic revisions No formal revisions. Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Michael Day drew attention to the several ways (e.g., long and anteroposteriorly flattened neck, no femoral tubercle) in which OH 20 resembles two proximal femora, SK 82 and SK 97, from Swartkrans that are attributed to *Paranthropus robustus*. Thus, he attributed OH 20 to *Australopithecus cf. boisei*, but there are no taxonomically diagnostic cranial remains associated with OH 20, so it could equally well belong to *Homo habilis*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 22 Site Olduvai. Locality Unnamed location on the surface of the Beds III and IV. Surface/in situ Surface. Date of discovery 1968. Finders Mary Leakey and coworkers. Unit N/A. Horizon N/A. Bed/member Beds III/IV. Formation N/A. Group N/A. Nearest overlying dated horizon Masek Beds. Nearest underlying dated horizon Bed II. Geological age Early or Middle Pleistocene (*c.*1.15–0.6 Ma). Developmental age Adult. Presumed sex Unknown. Brief anatomical description A large right side of the mandible with roots of I₁–M₃ and crowns of P₃–M₂ and most of the ramus. The symphysis is receding, the upper and lower borders of the corpus are parallel, and the corpus is robust. Announcement Leakey 1969. Initial description Rightmire 1980. Photographs/line drawings and metrical data Rightmire 1980. Detailed anatomical description Rightmire 1980. Initial taxonomic allocation cf. *Homo erectus*. Taxonomic revisions *Homo heidelbergensis* (Rightmire 1996, 1998) or early archaic *Homo sapiens* (Bräuer 1984). Current conventional taxonomic allocation *H. heidelbergensis* or early archaic *H. sapiens*. Informal taxonomic category Pre-modern *Homo*. Significance Well-preserved post-*Homo erectus* mandibles from sub-Saharan Africa are rare. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 23 Site Olduvai. Locality FLK. Surface/in situ *In situ*. Date of discovery 1968. Finders Mary Leakey and coworkers. Unit N/A. Horizon N/A. Bed/member Lower Masek Beds. Formation N/A. Group N/A. Nearest overlying dated horizon Nduku Beds. Nearest underlying dated horizon Bed IV. Geological age Middle Pleistocene (*c.*0.6–0.4 Ma). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragmentary left side of the mandibular corpus with P₄–M₂ and roots or alveoli of C, P₃, and M₃. Announcement Leakey 1969. Initial description Rightmire 1980. Photographs/line drawings and metrical data Rightmire 1980. Detailed anatomical description Rightmire 1980. Initial taxonomic allocation cf. *Homo erectus* (Day 1977). Taxonomic revisions Early or archaic *Homo sapiens* (Rightmire 1980, Bräuer 1984), *Homo heidelbergensis* (Rightmire 1996, 1998). Current conventional taxonomic allocation Archaic *H. sapiens* or *H. heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance One of the few sub-Saharan African Middle Pleistocene hominins. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 24 Site Olduvai Gorge. Locality DK East, Archeology Site no. N/A. Surface/in situ The cranium was found embedded in a “mass of calcareous matrix” with only the “right supra-orbital region and the posterior part of the palate exposed” (Leakey et al. 1971, p. 308); the four teeth were found during sieving. Date of discovery October 1968. Finder Peter Nzube. Unit/horizon Tuffaceous clay between the Bed I basalt and Tuff IB. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IB. Nearest underlying dated horizon Bed I basalt. Geological age Between 1.845 and 1.865 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Although this cranium is distorted and very fragmented, it does preserve substantial parts of the vault, face, palate, and base. No anterior teeth are preserved, but both upper premolars and the M¹ and M³ are preserved; its reconstruction was undertaken by Ron Clarke. Announcement Leakey et al. 1971. Initial description Leakey et al. 1971. Photographs/line drawings and metrical data Leakey et al. 1971. Detailed anatomical description Tobias 1991a. Initial taxonomic allocation *Homo aff. habilis*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *Homo habilis*. Informal taxonomic

category Pre-modern *Homo* or transitional hominin. Significance The OH 24 cranium is one of the temporally oldest specimens attributed to *H. habilis* yet it has some of the more “advanced” features noted in OH 13. Because OH 13 is one of the youngest specimens in the *H. habilis* hypodigm it had been suggested that there was a temporal trend in *H. habilis* morphology, but the antiquity of OH 24 casts doubt on that hypothesis. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 28 Site Olduvai Gorge. Locality WK, 36, Archeology Site no. 52. Surface/in situ *In situ*. Date of discovery 1970. Finder Mary Leakey. Unit OH 28 was found “at the base of a sandstone with fragments of the (Tuff IVB) tuff” (Leakey 1971, p. 381). Horizon See above. Bed/member Bed IV. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff in the base of the Masek Beds (spelled “Mesak” in Leakey 1971). Nearest underlying dated horizon Leakey (1971) suggests that the sediments that contain OH 28 postdate Tuff IVB. Geological age *c.*<780 ka. Developmental age Adult. Presumed sex Probably female. Brief anatomical description Left femur lacking the head, greater trochanter, and the condyles; much of the ischium and the ilium (the crest and the anterior superior iliac spines are lacking) of a left pelvic bone. Announcement Leakey 1971. Initial description Day 1971. Photographs/line drawings and metrical data Day 1971. Detailed anatomical description Day 1971. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The apparently derived features shared among the femora recovered from Zhoukoudian and the OH 28 femur (e.g., anteroposterior flattening of the shaft, the convex medial profile, and the low position of the minimum breadth of the shaft, which have been related to high bending moments) link OH 28 with *H. erectus*, and provide support for the hypothesis that while *H. erectus* lower limb morphology (e.g., iliac pillars and the impressions for the ilio-femoral ligament) is consistent with that taxon being a habitual, or obligate biped, it shows consistent departures from the lower limb morphology of modern humans. Prior to the discovery of OH 28 there was no reliable information about the pelvis of *H. erectus*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 34 Site Olduvai Gorge. Locality JK2 West. Surface/in situ *In situ*. Date of discovery 1962. Finder Maxine Kleindienst. Unit “Channel formation” (Day and Molleson 1976, p. 455). Horizon See above. Bed/member Bed III. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A left femur lacking the distal end and part of the shaft of a left tibia. Like all the mammal bones from the same excavation, these hominin bones are so highly abraded that all trace of taxonomically or functionally useful surface morphology has been lost. Announcement Day and Molleson 1976. Initial description Day and Molleson 1976. Photographs/line drawings and metrical data Day and Molleson 1976. Detailed anatomical description Day and Molleson 1976. Initial taxonomic allocation *Hominini gen. et sp. indet.* Taxonomic revisions None. Current conventional taxonomic allocation *Homo erectus* or *Homo heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance The preserved morphology of the femur is consistent with these associated lower limb bones belonging to either *H. erectus* or *H. heidelbergensis*, but the significance of OH 34 is that at the time of its recovery it was the *only* hominin recovered from Bed III. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 36 Site Olduvai Gorge. Locality SC, 90a, Archeology Site no. 60. Surface/in situ *In situ*. Date of discovery 1970. Finder M. Mutala. Unit N/A. Horizon As above. Bed/member Upper Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IVB. Nearest underlying dated horizon Tuff IID. Geological age Extrapolation based on the thickness of strata suggests an approximate age of 1.5–1.2 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Nearly complete right ulna, missing only the distal end. The distal fracture surface is just distal to the pronator crest and is close to the neck. Announcement Leakey 1978. Initial description Aiello et al. 1999. Photographs/line drawings and metrical data Aiello et al. 1999. Detailed anatomical description Aiello et al. 1999. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Paranthropus boisei* (Walker and Leakey 1993). Current conventional taxonomic allocation *Hominini gen. et sp. indet.*, or *P. boisei*. Informal taxonomic category Archaic hominin. Significance

The OH 36 ulna is one of several isolated postcranial fossils (e.g., OH 8, OH 10) from Beds I and II of Olduvai Gorge. It comes from Upper Bed II, which has produced evidence of both *H. erectus* and *P. boisei*. Aiello et al. (1999) carried out a multivariate analysis in which they compared OH 36 to the ulnae of extant apes and modern humans and with fossil hominin ulnae from Omo Shungura (L. 40–19), Baringo (KNM-BK 66), and from southern African fossil sites. When OH 36 was paired with, respectively, KNM-BK 66 and L. 40–19, the variation between these specimens is not consistent with their coming from the same taxon. An analysis of trochlear keel shape also came to the conclusion that OH 36 and L. 40–19 most likely represent different taxa (Drapeau 2008). Thus, given it is most unlikely that KNM-BK 66 ulna belongs to *P. boisei* (it is several hundred thousand years younger than the most recent fossil evidence for *P. boisei*), Aiello et al. (1999) suggested that it is probable that OH 36 belongs to *P. boisei*. If so, it would join OH 3 and OH 38 as evidence for a *c.*1.15 Ma last appearance datum for *P. boisei*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 51 Site Olduvai. Locality GTC. Surface/in situ Surface. Date of discovery 1974. Finders Mary Leakey and coworkers. Unit N/A. Horizon N/A. Bed/member Beds III/IV. Formation N/A. Group N/A. Nearest overlying dated horizon Masek Beds. Nearest underlying dated horizon Bed II. Geological age Early to Middle Pleistocene (*c.*1.15–0.6 Ma). Developmental age Adult. Presumed sex Unknown. Brief anatomical description A fragmentary left side of the mandibular corpus with P₄–M₁ and roots of P₃. Announcement Day 1977. Initial description Rightmire 1980. Photographs/line drawings and metrical data Rightmire 1980. Detailed anatomical description Rightmire 1980. Initial taxonomic allocation cf. *Homo erectus* (Day 1977). Taxonomic revisions *Homo heidelbergensis*. Current conventional taxonomic allocation *H. heidelbergensis* or archaic *Homo sapiens*. Informal taxonomic category Pre-modern *Homo*. Significance One of very few sub-Saharan African hominins from this time period. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 62 Site Olduvai Gorge. Locality FLK, Dik Dik Hill, adjacent to 45c. Surface/in situ Sur-

face. Date of discovery July 21, 1986. Finder Tim White recognized the initial ulna fragment, and the subsequent search and screening of the deposits recovered the many fragments that comprise OH 62. Unit/horizon Most likely eroded from a sand lens below Tuff IC on Dik Dik Hill. This would make it the lateral equivalent of the horizon from which OH 5 was recovered at FLK. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IC. Nearest underlying dated horizon Tuff IB. Geological age Between 1.845 and 1.839 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The skull and all of the major long bones are represented in the OH 62 associated skeleton, but the specimen is *very* fragmentary (there are about 302 fragments). The palate is the most complete part of the skull, followed by the face and the mandible. The tooth crowns that are preserved are very worn. The long bones of the upper limb are better preserved than those of the lower limb, but even the relatively well-preserved humerus cannot provide a thoroughly reliable estimate of its undamaged length. Announcement Johanson et al. 1987. Initial description Johanson et al. 1987. Photographs/line drawings and metrical data Johanson et al. 1987, Johanson 1989. Detailed anatomical description N/A. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo* or transitional hominin. Significance In spite of its very fragmentary condition, OH 62 is a significant specimen for at least two reasons. First, it provides the only unambiguous evidence about the postcranial skeleton of *H. habilis*, for none of the other postcranial elements linked with *H. habilis* have associated taxonomically diagnostic cranial elements. Second, despite the fact that the shafts of the long bones are incomplete, most researchers consider enough is preserved to suggest the limb-length proportions of the OH 62 *H. habilis* individual are not significantly different from those of *Australopithecus afarensis*, but they are significantly different from those of modern humans. This inference is supported by an analysis of the cross-sectional geometry, demonstrating that OH 62 has a degree of humeral strength relative to femoral strength comparable to that of *Au. afarensis*, but unlike those of *Homo erectus* and modern humans (Ruff 2008). Reno et al. (2005) claim there is not enough evidence to support the conclusion that the limb-length

proportions of OH 62 are *more* ape-like than those of *Au. afarensis*. Location of original National Museum and House of Culture, Dar es Salaam, Tanzania.

OH 65 Site Olduvai Gorge, Western lake margin. Locality 64. Surface/in situ *In situ*. Date of discovery August 10, 1995 Finders Amy Cushing and Agustino Venance. Unit The upper part of Bed I in Trench 57 from within “a zone 20 to 50 cm above the base of a 2.5-m-thick tuffaceous silty sandstone infilling” (Blumenschine et al. 2003, p. 1217) incised into Tuffs IB and IC. Horizon See above. Bed/member Bed I. Formation N/A. Group N/A. Nearest overlying dated horizon Tuff IF. Nearest underlying dated horizon Tuff IC. Geological age Between 1.839 and 1.79 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A complete upper dentition in a well-preserved palate and lower face. Announcement Blumenschine et al. 2003. Initial description Blumenschine et al. 2003. Photographs/line drawings and metrical data Blumenschine et al. 2003. Detailed anatomical description N/A. Initial taxonomic allocation *Homo habilis*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo*. Significance Blumenschine et al. (2003) stressed what they interpreted as similarities between OH 65 and KNM-ER 1470. They went on to argue that this supported the hypothesis that variation within the “early *Homo*” fossils from East Africa was best explained as sexual dimorphism within a single species, thus undermining the case for a second species such as *Homo rudolfensis*. Other observers accept that OH 65 strengthens the case for sexual dimorphism within the Olduvai hypodigm of *H. habilis*, but they do not necessarily accept that OH 65 and KNM-ER 1470 are conspecific. Location of original National Natural History Museum, Arusha, Tanzania.

Ohaba Ponor (Location 45°31'N, 23°07'E, Romania) History and general description Cave in the Streiu valley, south of Hunedoara in the Southern Carpathian mountains. Temporal span and how dated? Biostratigraphy and conventional radiocarbon dates on wood charcoal and unburnt bone suggest the following ages: Middle Paleolithic (dated to 43,600±2100–2800 years BP, Level IIIb >41,000 years BP, Level IIIa 39,200±2900–4500 years BP) and

an early Upper Paleolithic horizon. Hominins found at site Right second pedal phalanx (**Ohaba Ponor 1**). Archeological evidence found at site Mousterian (Eastern Charentian), Upper Paleolithic. Key references: Geology, dating, and paleoenvironment Gaál 1928, Mertens 1996; Hominins Gaál 1928, Necrasov and Cristescu 1965, Necrasov 1971; Archeology Mertens 1996, Păunescu 2000.

Ohaba Ponor 1 Site Ohaba Ponor. Surface/in situ *In situ*. Date of discovery 1923. Finder J. Mallász. Horizon Level III. Geological age *c.* 40 ka based on conventional radiocarbon dates from Levels IIIa and IIIb. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right second pedal phalanx. Announcement Gaál 1928. Initial description Gaál 1928. Photographs/line drawings and metrical data Gaál 1931. Detailed anatomical description Gaál 1931. Initial taxonomic allocation *Homo primigenius*. Taxonomic revisions *Homo neanderthalensis*. Current informal taxonomic category *H. neanderthalensis*. Significance The only hominin remains associated with Middle Paleolithic context in Romania Location of original Reported as the Museum of Deva, Muzeul Regional Hunedoara, Deva, Romania, but currently its whereabouts is uncertain.

Ohalo II (Location 32°43'N, 5°34'E, Israel; etym. the name of the local village) History and general description The site of Ohalo II was first surveyed in 1989 by a team led by Dani Nadel during an unprecedented drought that lowered the water level of the Sea of Galilee by 3 m. It was excavated until 1993 when heavy rains re-submerged the site; a second series of excavations were undertaken in 1999–2001 when another drought re-exposed the site. The unique geological setting caused by shallow/calm water flooding has preserved a remarkable number of materials. Temporal span and how dated? Radiocarbon dating on associated charcoal suggests an age of 23–19 ka. Hominins found at site The complete skeleton of an adult male was found in late 1991, apparently intentionally buried with its knees tightly flexed and its hands crossed over its chest. The skeleton is typical of other Epipaleolithic *Homo sapiens* (e.g., relatively robust jaws, rugose muscle markings, and marked asymmetry in the upper limb bones). Archeological evidence found at site The skeleton was found in direct association with a Kebaran assemblage. Apart from the fauna (Belmaker et al. 2001) the waterlogged nature of

the site preserved many organic remains, including evidence of brush huts (Nadel and Werker 1999), plant foods, plant food processing and plant food preparation areas (Weiss et al. 2008, Piperno et al. 2004), and wooden implements (Nadel et al. 2006). Key references: Geology and dating Nadel et al. 1995, Carmi and Segal 1992; Hominins Hershkovitz et al. 1995; Archeology Nadel 2002, Nadel et al. 2002.

OHD See obsidian hydration dating.

OIS Acronym for **Oxygen Isotope Stages** (*which see*).

Okazaki fragment A short fragment of DNA that is created during replication on the lagging strand of DNA (i.e., the strand of DNA that is oriented in the 5' to 3' direction and which is complementary to the leading strand). Since DNA replication always occurs in the 5' to 3' direction, it is continuous on the leading strand, but occurs in sections on the lagging strand. These fragments are then linked by DNA ligase to create a continuous strand.

Okladnik'ov Cave (Location 54°45'50"N, 84°02'34"E, Altai Mountains, Siberia, Russia; etym. named after Alexey Okladnikov, a famous Soviet archeologist) History and general description This cave site in Siberia is best known for being the being the most easterly of the sites containing evidence of *Homo neanderthalensis*. Several hominin fossils have been recovered, but their taxonomic status is much debated, with some arguing they are *H. neanderthalensis*, others saying they evolved from Neanderthals, and still others suggesting similarities between these fossils and Asian *Homo sapiens* and *Homo erectus*. Recent studies of mitochondrial DNA from one adult and a juvenile suggest that the juvenile is a Neanderthal, while the adult is likely not to be. Temporal span and how dated? The remains were directly dating by radiocarbon dating; the juvenile has ages that range from *c.*30 to 38 ka (uncalibrated), while the adult remains are dated to *c.*24 ka (uncalibrated). Hominins found at site Several teeth and a few isolated postcranial bones were recovered, representing one or two adults and one juvenile. Archeological evidence found at site Three layers were identified, all with **Mousterian** stone tools. Key references: Geology, dating, and paleoenvironment Krause et al. 2007b; Hominins Krause et al. 2007; Archeology Kuzmin 2004.

Okote Tuff Tuff exposed in the **Koobi Fora Formation** that defines the base of the Okote Member. Age 1.56±0.05 Ma (McDougall et al. 2005). Lateral equivalent H-2 in the **Shungura Formation**.

Okote Tuff Complex Name given to the tuffs and sediments exposed along the Karari Ridge at **Koobi Fora** that occupy the interval between the KBS and the Chari Tuffs of the **Koobi Fora Formation**. The equivalent interval at Ileret is called the Ileret Tuff Complex or the Lower-Middle Tuffs, and at the western end of the Koobi Fora Ridge it is called the Koobi Fora Tuff Complex (Brown et al. 2006).

OKT Abbreviation for the Okote Member in the **Koobi Fora Formation** (*which see*).

Ola Bula One of the Early and Middle **Pleistocene** sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Ola Bula Formation (etym. Named after a site where the formation is exposed) General description The <80 m-thick Ola Bula Formation is exposed in the Soa Basin, which is the drainage of the Ae Sissa River in central Flores, Indonesia. It is described as comprising "white tuffs and interbedded tuffaceous sediments underlying fluvial deposits" (Morwood et al. 1998, p. 174). Sites or localities where the formation is exposed Boa Lesa, Deko Weko, Dozu Dhalu, Kobatuwa, Kopwatu, Lembahmenge, Malahuma, **Mata Menge**, Ngamapa, Ola Bula, Pauphadhi, Sagala, Tangi Talo, Wolo Milo, Woloceo. Temporal span Early and Middle Pleistocene. How dated? Biostratigraphy, geomagnetic dating, and fission track dating (for details *see* **Mata Menge**). Hominins recovered from the formation None. Archeological evidence recovered from the formation Some 500 artifacts, mostly *in situ*, the majority of which are **flakes and cores**. Key references: Geology, dating, and paleoenvironment Morwood et al. 1998, O'Sullivan et al. 2001; Hominins N/A; Archeology Morwood et al. 1997, 1998, 1999, Brumm et al. 2006.

OLAPP Acronym for the **Olduvai Landscape Paleoanthropology Project** (*which see*).

"Old man of Cro-Magnon" See **Cro-Magnon 1**.

Old World monkeys Old World monkeys (sometimes abbreviated as OWM) is the informal name for the superfamily *Cercopithecoidea*. See *Cercopithecoidea*.

older to younger adults See OY ratio.

Oldowan (etym. Named after the site of **Olduvai Gorge**; Olduvai is Maasai for “the place of the wild sisal”) The Oldowan, which is the oldest recognized stone tool **industry**, is known from sites that date from *c.*2.6 to 1.6 Ma, primarily in Africa. The term was first applied by Louis **Leakey** (Leakey 1935) to artifacts from Olduvai Gorge (the type site), as well as those from **Kanjera** and **Kanam** West on the Homa Peninsula in Kenya. The term Oldowan is not only used for this ancient technology, but also for the suite of artifacts produced by these technological practices, as well as for the sites where these artifacts are found. Mary **Leakey** published the first formal description of Oldowan tools from Bed I and lower Bed II Olduvai Gorge, Tanzania (Leakey 1966a, 1971) and her typology is still widely employed. **Flakes** were produced by using one stone (called a **hammerstone**) to knock flakes off of another (a **core**) in a technique termed hard-hammer percussion. Cores were sometimes set on an **anvil** and struck from above (**bipolar percussion**), others were likely fractured by being thrown against a hard substrate (Plummer 2004). Leakey (1971) classified hominin-modified Oldowan stone artifacts into three groups: **tools**, utilized pieces, and **debitage**. An artifact was only considered a “tool” if it had been intentionally **retouched** or flaked. Tools were further subdivided into light-duty (e.g., small, retouched flakes) and heavy-duty (e.g., **choppers**, **discoids**, polyhedrons) categories based on a mean diameter of less than 50 mm (light duty), or greater than 50 mm (heavy duty), respectively. Hammerstones, anvils, or flakes damaged through use were termed utilized pieces. Mary Leakey’s debitage category included unmodified flakes, flake fragments, and other knapping debris. The term **manuport** was used for natural stones that had been transported and discarded without being modified. Leakey believed that heavy-duty tools were the most significant component of the Oldowan toolkit, that hominins shaped their tools with a clear idea of the desired end product, and that different tool forms were used for different tasks (Leakey 1971). More recently, it has been argued that the Oldowan was a simple but effective method of producing sharp

flakes from stones, and that the flakes, not the cores, were the desired end product (Potts 1991, Toth 1985). Others claim that rather than following a mental template, the hominins responsible for the Oldowan industry relied on simple spatial concepts to coordinate flake production (Wynn and McGrew 1989), and that the different forms of cores were strongly influenced by the size and shape of the raw material, its flaking characteristics, and the extent to which a stone had been flaked (Toth 1985). Recent analyses (e.g., Stout et al. 2005, Braun et al. 2009, Harmand 2009) emphasize that the hominins responsible for Oldowan artifacts displayed a keen understanding of the physical properties of different raw materials and preferentially chose good-quality rock (i.e., tractable and not readily prone to shattering) to flake. Oldowan occurrences are best known from East Africa and sites in the 2.0–2.6 Ma range are found exclusively in this region. Important late Pliocene localities include those in the Omo **Shungura Formation**, the **Gona study area**, and the **Hadar study area** in Ethiopia, and **West Turkana** and **Kanjera** in Kenya. Whether the earliest usage of Oldowan tools was restricted to East Africa, or whether behaviors forming Oldowan sites were more broadly distributed across Africa, is at this point unclear. More recent (i.e., between 1.6 and 2.0 Ma) Oldowan sites have been found in North (e.g., **Ain Hanech**), southern (e.g., **Sterkfontein**), and East (e.g., **Koobi Fora**, **Olduvai Gorge**) Africa. The recovery of a comparable technology to the Oldowan at **Dmanisi**, Georgia, at approximately 1.7 Ma and from **Majuangou** and **Yuanmou**, China, at about the same time suggests that the earliest travelers out of Africa took with them the capacity to make the Oldowan toolkit (Gabunia et al. 2001, Zhu et al. 2004, 2008). The uses that Oldowan tools were put to, the adaptive significance of the earliest lithic technology, and the behaviors that led to archeological site formation have been controversial topics (Plummer 2004). One demonstrable use of these artifacts was animal butchery, but Oldowan artifacts may have been used to work wood and process plant foods as well. Behavioral models of Oldowan site formation include the **home base hypothesis**, **routed foraging**, stone caching, the **favored place hypothesis**, the **resource defense model**, the **dual-unit foraging model**, **refuging**, near-kill accumulation, and male display.

Olduvai See Olduvai Gorge.

Olduvai event *See Olduvai subchron.*

Olduvai Gorge (Location 2°56–59'S, 35°15–22'E, Tanzania; etym. Maasai for “the place of the wild sisal”) History and general description Olduvai Gorge is an approximately 40 km/25 mile-long dry river valley that has been incised at the western margin of the eastern limb of the East African Rift System and which has eroded through sediments dating from *c.*2 Ma to the recent past. The first nonhominin fossils were recovered from Olduvai Gorge by Wilhelm Kattwinkel in 1911 and more were located by Hans Reck in 1913. Reck also recovered a hominin skeleton (OH 1), but this proved to belong to a recently buried modern human. Louis Leakey took over research at Olduvai from Reck in 1931 and for the next 40 years Louis and Mary Leakey, and latterly just Mary Leakey, undertook fieldwork at Olduvai. Since Mary Leakey stopped fieldwork at Olduvai Gorge several other groups have conducted research there (e.g., *see* OH 62, **Olduvai Landscape Paleanthropology Project**); more on the 20thC history of research at Olduvai Gorge can be found in Leakey (1965, p. xi–xiv) and Hay (1976, p. 1–6). The hominin fossil and archeological localities at Olduvai Gorge are located in sedimentary rocks in either the Main Gorge or in a branch called the Side Gorge. The sediments exposed in Olduvai Gorge all lie above the basement lavas and they are divided into seven beds, collectively referred to as the Olduvai Beds, and Hay (1976) makes the point that “in modern stratigraphic usage, the various beds would be considered formations” (*ibid.*, p.6). The four beds immediately above the basalt are identified using roman numerals (Beds I–IV, with Bed I at the bottom), whereas the three beds above them were given local names, the Masek immediately above Bed IV, then the Ndotu, with the Naisiusiu Bed the most recent; what used to be Bed VI of Reck and Leakey (1951) is now known as the Namarod Ash Formation. Beds I and II are readily distinguished wherever they are exposed, but there are places in the gorge where Beds III and IV cannot be readily distinguished and Hay (1976) proposed they be merged into a single unit called Beds III–IV. The sediments of Beds I and II contain several tuff layers (Bed I, Tuffs IA–IF; Bed II, Tuffs IIA–IID) and Olduvai was the first fossil hominin site to be dated using **potassium-argon dating** methods. Within Bed II, just above the Lemuta Member, there is an abrupt change in the

fauna, which is referred to as the “faunal break.” The sediments exposed in the gorges at Olduvai were laid down in and around a paleolake, called Lake Olduvai. The paleolake varied in size, sometimes being small and highly saline and at other times larger with fresher water. The localities at Olduvai are identified using a letter and number code. The letters refer to the names used by the Leakeys for the small valleys, or korongos (Mary Leakey uses that spelling, but Hay 1976 uses “karonga”), made by the streams that drained into the Main and Side Gorges, and to the situation of the locality within that small stream valley. The roman numeral numbers refer to the bed the locality is in. Most of the korongos were named after the Leakey’s relatives and colleagues, with additional letters to denote how adjacent sites are geographically related to each other. So FLKN I is a fossil locality in Bed I in the Frida Leakey korongo that is north of locality FLK I, and FLKNN I is a fossil locality in Bed I in the Frida Leakey korongo that is north of locality FLKN I. Each locality has two other numbers associated with it, a geological locality number and an archeological number. Thus, FLKNN I is geological locality 45 and archeological site no. 31. There is even more terminological complexity for a few localities such as TK, MLK, FLK, FLKN, and FLKNN. At FLK, for example, 10 separate levels are recognized, each of which has a lower-case letter after the site number, so FLK Level 12 is archeological site no. 41g (but all the different levels have the same geological locality number). Three other sites have the FLK designation followed by some qualifier [e.g., “FLK (west of 40),” “FLK, Maiko Gully,” and “FLK South”]. Just to make it even more complicated, these “extra” FLK sites all have the same geological locality number (45), but different archeological site numbers (42, 43, and 44, respectively). Temporal span and how dated? **Argon-argon dating, geomagnetic dating, and potassium-argon dating** suggest the sediments at Olduvai Gorge span the period between *c.*2 Ma to *c.*1300 years BP. Hominins found at site More than 60 fossil hominins have been recovered from Olduvai Gorge including OH 5, the type specimen of *Paranthropus boisei*, OH 7, the type specimen of *Homo habilis*, OH 9, a *Homo erectus* cranium, and OH 62, a partial skeleton of *H. habilis*. Olduvai Landscape Paleanthropology Project

Multidisciplinary field and laboratory project established in 1989 to investigate the paleoecological context of the hominin activities at **Olduvai Gorge**. It is co-directed by Robert Blumenschine (who heads the archeology subgroup) and Charles Peters (who heads the paleobotanical subgroup.); the third, geological, subgroup is headed by Ian Stanistreet. The focus of the fieldwork has been lowermost Bed II and Middle-Upper Bed I. The early field seasons focused on the margin of the paleolake, **Lake Olduvai**, and on the regions of Olduvai Gorge that had not been explored in detail by Louis and Mary Leakey. Its first major field season was in 2000. The project has built and maintains a field laboratory at Olduvai Gorge, where it carries out much of the analysis of the stone tools and faunal remains it has recovered from the excavations conducted, and it has helped train Tanzanian students.

Olduvai subchron One of the first events (now called **subchrons**) to be recognized in the **geomagnetic polarity time scale** (GPTS). It is an episode of normal magnetic direction within the Matuyama reversed epoch (now called the **Matuyama chron**) from *c.*1.9 to *c.*1.785 Ma that was recognized in the sediments of **Olduvai Gorge** (Grommé and Hay 1963). The lower boundary (i.e., between the R1 and N1 magnetozones) is 6 m below Tuff IA, and the upper boundary (i.e., between the N1 and R2 magnetozones) is just above Tuff IF, between it and Tuff IIA.

olfactory bulb The olfactory bulb is the part of the vertebrate forebrain involved in the detection and discrimination of odors. The olfactory bulb is the most rostral (i.e., anterior) structure of the brain in most vertebrates, but in haplorhine primates (i.e., apes, monkeys, and tarsiers) in which the olfactory bulbs are relatively small compared to the **cerebral hemispheres** they are mostly hidden beneath the overlying **frontal lobe**. The olfactory bulbs sit either side of the midline crista galli in the floor of the anterior cranial fossa

above the cribriform plate of the ethmoid, which separates it from the olfactory epithelium of the nasal cavity. Olfactory receptor neurons in the olfactory epithelium project their axon fibers through perforations in the cribriform plate to the main olfactory bulb. The main olfactory bulb in haplorhine primates is small relative to overall brain size, which may reflect a reduction in olfactory sensitivity. In addition, as judged by the accumulation of **pseudogenes**, apes have lost many olfactory receptors and modern humans have approximately twice as many olfactory receptor pseudogenes as other apes, suggesting there has been further relaxation of selection on olfactory capacity in the hominin clade. In most vertebrates, an additional structure, an accessory olfactory bulb, is located dorsal and posterior to the main olfactory bulb. The accessory olfactory bulb is part of an independent system for the processing of pheromones and other chemical substances that are important in sociosexual behavior. It receives inputs from the vomeronasal organ and sends outputs to the amygdala and hypothalamus to influence aggression and other aspects of social behavior. The vomeronasal organ and accessory olfactory bulb are highly variable among catarrhine primates (i.e., Old World monkeys and apes) and they appear to regress during fetal development in many species, including modern humans. The extent to which the accessory olfactory system is functional in modern humans is unclear.

oligonucleotide (Gk *oligos* = few or little, so literally “a few nucleotides”) A short fragment of single-stranded **DNA** that is typically less than 30 **bases**, or **nucleotides**, long and which is used as a **probe** for **DNA hybridization**, or as a **primer** for the **polymerase chain reaction**. It is also possible to make oligonucleotides from RNA.

Ologresailie (Location 1°35'S, 36°37'E, Kenya; etym. Maasai for “the place of the Giselik people,” and applied to the nearby volcano) History and general description A large site complex located in the southern Kenya part of the **East African Rift System** with numerous archeological and paleontological sites in well-dated **tuffaceous** sediments near the margins of a fluctuating lake, best known for locally dense concentrations of **handaxes** and other **Acheulean** implements, but the upper layers contain substantial evidence of the Middle Stone Age. J.W. Gregory first noted stone tools at Ologresailie in 1919 but it was the survey and

excavation undertaken by Louis and Mary Leakey (with the help of Italian prisoners of war) between 1942 and 1945 that led to Ologresailie being gazetted as part of the Coryndon Museum in Nairobi. Further excavations were conducted from 1961 to 1965 by Glynn Isaac and have been ongoing since 1985 under the direction of Richard Potts. Temporal span and how dated? Sediments of the Ologresailie basin are divided into two geological formations. The **Early and Middle Pleistocene-aged Ologresailie Formation** has been studied in detail; the Middle and Later Pleistocene Oltulelei Formation has only been recently defined. The Ologresailie Formation has been divided into 14 numbered members. **Argon-argon dating of anorthoclase feldspars in tephra** and magnetostratigraphic analyses of sediments have provided an age estimate of 992 ± 39 ka for a water-lain ash deposit in the middle of Member 1, and an age estimate of 493 ± 1 ka for pumices within Member 14. The **Brunhes-Matuyama boundary** occurs near the base of Member 8. Formal dates for the overlying Oltulelei Formation have yet to be published. Hominins found at site The diminutive partial cranium **KNM-OG 45500** (but published as KNM-OL 45500) was recovered in 2003 from 970–900 ka sediments. Archeological evidence found at site More than 100 excavations have been undertaken in Ologresailie Formation sediments, primarily in Members 1, 6/7, and 11. The more than 34,000 recovered stone artifacts, predominantly made from local (<5 km/3 miles) Mio-Pliocene lavas, demonstrate substantial technological and typological variability within the Acheulean behavioral system. Reconstructions using **soil carbonate isotopic analysis**, analyses of **diatoms**, and the rich mammalian fauna suggest the paleoenvironment ranged from open grassland settings to shallow floodplains and wetlands on the margin of a variably fresh or alkaline series of lakes. The distribution of archeological traces indicates a relationship between the paleoenvironment and hominin behavior. Key references: Geology, dating, and paleoenvironment Isaac 1977, 1978b, Deino and Potts 1990, Potts et al. 1999, Behrensmeier et al. 2002, Potts 2007, Owen et al. 2008; Hominins Potts et al. 2004; Archeology Isaac 1977, Potts et al. 1999.

OLS Acronym for **ordinary least squares regression** (*which see*).

OMD 1'28 *See* Oranjemund.

omega-3 fatty acids *See* essential fatty acids.

omega-6 fatty acids *See* essential fatty acids.

omnivore *See* omnivory; eclectic feeder.

omnivory (L. *omni*, from *omnis* = all, every, plus *vorous*, from *vorare* = to devour) The ability to eat a wide range of plants and animals. Several primates, including vervets, baboons, chimpanzees, and modern humans, are described as omnivores. However, the ability of modern humans to process foods (e.g., by cooking), means they can incorporate a particularly wide range of items into their diets. Thus, modern humans are the only habitually omnivorous extant primate and among large mammals only pigs and bears are as omnivorous. *See also* eclectic feeder.

Omo Prefix sometimes used in place of the “O.” used by the French contingent of the **International Omo Research Expedition** for localities in the **Shungura Formation** (e.g., Omo 18) and for the fossils found within those localities (e.g., **Omo 18-1967-18**).

Omo 18-1967-18 (or Omo 18-18) Site **Omo-Shungura**. Locality 18. Surface/in situ Surface. Date of discovery 1967. Finder René Houin. Unit N/A. Horizon C-8. Bed/member Member C. Formation **Shungura Formation**. Group Omo Group. Nearest overlying dated horizon Tuff D. Nearest underlying dated horizon Tuff C. Geological age *c.* 2.6 Ma. Developmental age Presumed adult. Presumed sex Unknown. Brief anatomical description An adult mandibular corpus that extends from a fracture through the M_3 alveolus on the right side through to a fracture just mesial to the left M_3 alveolus. There are no tooth crowns preserved, but the broken surfaces of all, or part, of the roots of the left C– M_2 and the right I_2 – M_2 are exposed. Announcement Arambourg and Coppens 1967. Initial description Arambourg and Coppens 1967. Photographs/line drawings and metrical data Arambourg and Coppens 1967. Detailed anatomical description N/A. Initial taxonomic allocation *Paraustralopithecus aethiopicus*. Taxonomic revisions *Australopithecus africanus* (Howell 1978), *Australopithecus boisei* (Coppens 1980). Current conventional taxonomic allocation

Paranthropus aethiopicus. Informal taxonomic category Megadont archaic hominin. Significance The holotype of *Pa. aethiopicus*. Although almost all researchers regard the genus *Paraustralopithecus* as a junior synonym of the genus *Paranthropus*, researchers who want to maintain a distinction between the pre- and post-2.3 Ma parts of the East African hypodigm of *Paranthropus* do this by recognizing the species *Paranthropus aethiopicus*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Omo 323-1976-896 Site Omo-Shungura. Locality Omo-323. Surface/in situ *In situ*. Date of discovery 1976. Discoverer Claude Guillemot. Unit N/A. Horizon G-8. Bed/member Member G. Formation Shungura Formation. Group Omo Group. Nearest overlying dated horizon G-28. Nearest underlying dated horizon Tuff G. Geological age *c.*2.1 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description This partial cranium consists of nine substantial fragments (a–i). They include (a) a frontal fragment that preserves glabella, (b) the non-squamous parts of the left temporal, (c) a fragment that includes the posterior vault and the right mandibular fossa, and (g) part of the right maxilla including the worn crowns of P³–M¹, and a left canine and P⁴. Endocranial volume Approximately 490 cm³ (Brown et al. 1993) [NB: Brown et al. (1993) claim that “with the recovery of KNM-ER 23000, we feel that these new estimates of cranial volume are more accurate” (*ibid*, p. 157), but there is very little of the cranial vault preserved and Alemseged et al. (2002) are more prudent and do not venture an endocranial volume estimate). Announcement Coppens and Sakka 1980. Initial description Coppens and Sakka 1980. Photographs/line drawings and metrical data Alemseged et al. 2002. Detailed anatomical description Alemseged et al. 2002. Initial taxonomic allocation *Australopithecus* sp. Taxonomic revisions *Australopithecus boisei* (Alemseged et al. 2002). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance Omo 323-1976-896 shows affinities with the hypodigms of both *Paranthropus aethiopicus* and *Paranthropus boisei*, but it is closer to the latter than to the former. Any differences between it and the existing *P. boisei* bauplan are consistent with within-species polymorphism, but Alemseged et al.

(2002) claim that the Omo 323-1976-896 calvaria “emphasizes the anagenetic link between *A. aethiopicus* and *A. boisei*” (*ibid*, p. 111). Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Omo I Site Omo-Kibish. Locality KHS (Kamoya’s Hominid Site). Surface/in situ Surface. Date of discovery 1967 and 2001. Finder Kamoya Kimeu. Unit N/A. Horizon N/A. Bed/member Member I. Formation Kibish Formation. Group N/A. Nearest overlying dated horizon Aliyo Tuff at the base of Member III. Nearest underlying dated horizon Nakaa’kire Tuff about 15 m above the base of Member I. Geological age Late Middle Pleistocene *c.*195 ka. Developmental age Young adult. Presumed sex Male, based on the large mastoid process and its overall size. Brief anatomical description An associated skeleton comprising a skull that includes a substantial part of the cranial vault (more complete on the right than the left) and parts of the face and mandible, and parts of the axial skeleton, the shoulder girdle, pelvic girdle, and the upper and lower limbs. The axial skeleton is represented by several well-preserved cervical and thoracic vertebra, and numerous vertebral and rib fragments. The shoulder girdle remains include the left clavicle and both coracoid processes. The right humerus is the only relatively complete upper limb long bone, and although the bones of both forearms are represented, the only carpal, metacarpal, and phalangeal remains belong to the right hand. A large and small fragment of the left pelvic bone and the distal ends of the femur and the tibia are preserved, as is the first ray of the right foot, plus the medial cuneiform and the navicular. Endocranial capacity Probably similar to Omo II (1435 cm³). Announcement Day 1969. Initial description Day 1969. Photographs/line drawings and metrical data Day 1969. Day and Stringer 1991, Day et al. 1991, Pearson et al. 2008a. Detailed anatomical description Day and Stringer 1991. Day et al. 1991, Kennedy 1984, Bartsiakas 2002, Pearson et al. 2008a, Voison 2008. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance The cranial vault of Omo I is high and globular, with a nearly vertical frontal bone, rounded occipital and pronounced parietal bosses that give the

cranium an “*en maison*” form in posterior view; the mandible bears a slight chin. The cranium and postcranium are modern human in overall morphology but retain some primitive features. The original inferred age of *c.*130 ka, as well as the revised age of 195 ka, places this skeleton among the earliest evidence of modern humans. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Omo II Site Omo-Kibish. Locality PHS (Paul’s Hominid Site). Surface/in situ Surface. Date of discovery 1967. Finder Paul Abel. Unit N/A. Horizon N/A. Bed/member Member I. Formation Kibish Formation. Group N/A. Nearest overlying dated horizon Aliyo Tuff at the base of Member III. Nearest underlying dated horizon Nakaa’kire Tuff approximately 15 m above the base of Member I. Geological age Late, Middle, or early Upper Pleistocene, most likely 195 ka. Developmental age Older adult based on suture closure. Presumed sex Male, based on its robusticity. Brief anatomical description A well-preserved calvaria preserving all of the vault bones except portions of the frontal and the posterior and lateral parts of the basicranium. Endocranial volume 1435±20 cm³. Announcement Leakey et al. 1969. Initial description Day 1969. Photographs/line drawings and metrical data Day 1969, Day and Stringer 1982, 1991, Schwartz and Tattersall 2003. Detailed anatomical description Day and Stringer 1982, 1991, Bräuer 1984, Rightmire 1984a; Schwartz and Tattersall 2003. Initial taxonomic allocation *Homo sapiens* or *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation Taxonomic proposals for Omo II have included *H. sapiens*, *Homo helmei*, *Homo heidelbergensis*, *Homo rhodesiensis*, and late archaic *H. sapiens*. Informal taxonomic category Pre-modern *Homo*. Significance The vault is high and the frontal is moderately receding, but closer to vertical than in Kabwe or Saldanha. The lateral segment of the supraorbital torus is small, suggesting affinities with modern humans. However, the occipital bone is strongly angled, maximum vault breadth is across the supramastoid tubercles, the mastoids are mediolaterally thick, and the tympanic is robust, suggesting affinities with *H. erectus* or *H. heidelbergensis*. Whereas Omo I is evidently anatomically modern, the angled occipital and robust temporal bone of Omo II align it with pre-modern *Homo*. Geologic evidence indicates the two

are coeval, raising questions of whether they sample a single, morphologically variable population, two morphologically distinct populations, or whether the Omo II calvaria might have eroded from an older context. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Omo III Site Omo-Kibish. Locality N/A. Surface/in situ Surface. Date of discovery 1967. Finders N/A. Unit N/A. Horizon N/A. Bed/member Uncertain, probably Member I or III. Formation Kibish Formation. Group N/A. Nearest overlying dated horizon If from Member I, the Aliyo Tuff at the base of Member III (but if from Member III it would be Member IV). Nearest underlying dated horizon If from Member I, Nakaa’kire Tuff approximately 15 m above the base of Member I (but if from Member III, the Aliyo Tuff at the base of Member III). Geological age Either *c.*195 ka (Member I) or *c.*104 ka (Member III). Developmental age Presumed adult. Presumed sex Unknown. Brief anatomical description A fragmented cranial vault including a frontal that includes glabella. Announcement Day 1969. Initial description Day (1969) reported “what resemblance it has lies with the more modern of the first two Omo skulls” (*ibid*, p.1138). Photographs/line drawings and metrical data Day 1969. Detailed anatomical description N/A. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance A further example of an Omo I-type cranial vault. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Omo Basin *See* Lower Omo Basin.

Omo Group The older of the two inclusive stratigraphic sequences (the younger one is called the Turkana Group) exposed within the region known as the Lower Omo Basin (also called the Lower Omo Valley) and the Turkana Basin. It consists of the Mursi, Nkalabong, Shungura, and Usno Formations to the north, the Koobi Fora Formation to the east, and the Nachukui Formation to the west. *See also* Omo-Turkana Basin; Turkana Basin.

Omo Group Research Expedition A research team, led by Jean-Renaud Boisserie, that has been conducting fieldwork in the Lower Omo Basin since 2006–7.

Omo-Kibish (Location $c.5^{\circ}23'N$, $35^{\circ}56'E$, Ethiopia; etym. named after the police post at Kibish) History and general description A complex of sites in the **Kibish Formation**, part of the **Turkana Group**, that outcrops along the lower Omo River in Ethiopia. The site complex, which was initially explored by Frank Brown and later by a team headed by Richard Leakey, yielded a series of hominins (**Omo I, II, and III**) in 1967. Geological work by Karl Butzer and colleagues established the basic organization of the sedimentary sequence that is still used today. Doubts expressed by paleoanthropologists in the 1980s over the initial minimum age for Omo I by **uranium-series dating** (U-Th) prompted renewed work on the Kibish Formation in 1999 and 2001–3 by John Fleagle, Frank Brown, Zelalem Assefa, John Shea, and colleagues. The new research discovered additional hominin fossils, including more fragments of Omo I, and help clarified the geochronology (although not to everyone's satisfaction), which indicated that both Omo I and II likely date to $c.195$ ka. Temporal span and how dated? Each member in the Kibish Formation formed during high stands of Lake Turkana that correlate with the deposition of **sapropels** in the Nile's sediment cone in the Mediterranean. Member I correlates with S7 (i.e., sapropel 7) $c.197$ ka, Member III with S4 $c.104$ ka, and Member IV with S1 $c.8$ ka. **Argon-argon dating on tephra** in the Kibish Formation is consistent with those correlations. The Nakaa'kire Tuff low in Member I just below the level of Omo I and II dates to 196 ± 2 ka, the KHS Tuff near the base of Member II chemically correlates with a tuff from **Konso** dated to more than 154 ka, and the Aliyo Tuff in Member III dates to 104 ± 1 ka. A series of ages by **radiocarbon dating** on beds of molluscs from the top half of Member IV range from 3.6 to 13.1 ka. Hominins found at site From Member I, Omo I, an associated skeleton including a skull, Omo II, a calvaria, and Kib-163, the AHS tibia, comprising the distal three-quarters of a left distal tibia. From Members I or III, Omo III, frontal and nasal plus parietal fragments. From Member III or IV, Kib-170-1 and Kib-170-4, two cranial fragments from CHS. From Member IV, from the site of "Pelvic Corner," an unpublished pelvis, cranial fragments, and other bones recovered in 1967, and from JHS, an undescribed frontal, mandible, and tibia recovered in 2001. Archeological evidence found at site Members I–III contain

scattered concentrations of small **Middle Stone Age** artifacts with preferential use of finer-grained raw materials. Most of the tools lack retouch, but some leaf-shaped bifacial points as well as sporadic, larger handaxes, picks, or lanceolates (which resemble Acheulean artifacts) were recovered. Member IV contains **Later Stone Age** artifacts and bone **harpoons**. Key references: Geology, dating, and paleoenvironment Butzer 1969, Butzer and Thurber 1969, Butzer et al. 1969, McDougall et al. 2005, 2008, Brown and Fuller 2008, Feibel 2008; Hominins Day 1969b, Day and Stringer 1982, 1991, Bartsiokas 2002, Pearson et al. 2008a, 2008b, Voison 2008; Archeology Shea 2008, Sisk and Shea 2008, Assefa et al. 2008b, Louchart 2008, Trapani 2008.

Omo Rift Zone Part of the **East African Rift System**, a series of river valleys and basins that extends from the **Afar Rift System** in the northeast, via the **Main Ethiopian Rift System** to the **Omo Rift Zone** in the southwest. Hominin fossil and archeological sites in the Omo Rift Zone include **Fejej**, **Usno Formation**, **Shungura**, and the site complexes around Lake Turkana (e.g., **Koobi Fora**, **West Turkana**, **Lothagam**, and **Kanapoi**).

Omo-Shungura *See* **Omo Basin**; **Shungura Formation**.

Omo-Turkana Basin The **Lower Omo Basin** and the **Turkana Basin** are effectively two components of an area of low country between the Ethiopian and Kenyan domes (north and south) and between the walls of the **East African Rift System** (east and west). The Omo-Turkana Basin extends for about 500 km/310 miles from north to south and up to about 100 km/62 miles from east to west. For the past few million years, or so, the larger southern component of the basin has been occupied by Lake Turkana. The latter has fluctuated in size becoming larger when inflow exceeds any outflow and evaporation and smaller when it does not. The sediments in the Omo-Turkana Basin are divided into the Omo Group and the Turkana Group. The major fossiliferous formations within the Omo-Turkana Basin are the **Koobi Fora**, **Mursi**, **Nachukui**, **Nkalabong**, **Shungura** and **Usno Formations**. The major hominin fossil and archeological site within the Omo-Turkana Basin are **Koobi Fora**, **Lothagam**,

the **Omo region**, and **West Turkana**. *See also* **Omo Group**; **Turkana Group**.

ontogenetic (etym. *See* **ontogeny**) Any criterion, explanation, or test, that involves ontogeny. For example, the **ontogenetic criterion** is the proposal that the morphology of a character early in its ontogeny is likely to be the primitive condition of that character.

ontogenetic allometry *See* **allometry**; **scaling**.

ontogenetic criterion A criterion for deciding which state of a **character** is **primitive** and which is **derived**. When employing the ontogenetic criterion, one examines the distribution of the states of the character in the development of the species being examined, on the grounds that the morphology of a character early in its ontogeny is likely to be the primitive condition of that character. For example, the ontogenetic criterion would suggest that the primitive condition of the root of a tooth is a single root, for this is what all tooth roots, whether they eventually have one or several roots, look like early in their development (syn. the ontogeny character polarization criterion). *See also* **cladistic analysis**.

ontogenetic scaling (Gk *ontos* = being, *geneia* = origin) The process by which an ancestrally retained ontogenetic trajectory is followed to different adult endpoints, producing allometrically scaled adults. The ontogenetic trajectories for large and small animals who are ontogenetically scaled are similar; in descendant animals larger than the ancestors the trajectory is carried to a farther endpoint (**peramorphosis** via **hypermorphosis**) and in smaller descendants the similar ontogenetic trajectory is simply truncated at an earlier point (**paedomorphosis** via **hypomorphosis/progenesis**).

ontogeny (Gk *onto* = being and *gena* = to give birth to) A term that refers to all of the phases of **life history** that precede the cessation of **growth**. It is also used to refer to the unique developmental history of each individual organism.

open reading frame (or ORF) Refers to a DNA coding sequence that is translated into mRNA. Such a sequence runs from an initiation **codon** to a termination codon. It has the potential to encode a

protein and is, for example, unbroken by a premature stop codon (hence the term “open”). If you find an open reading frame it usually indicates you have found a **gene**.

operational taxonomic unit (or OTU) Any taxon used in a **cladistic analysis** or phylogenetic analysis. To avoid circular reasoning hypotheses about the nature of operational taxonomic units must be generated using **phenetic** and not **cladistic** methods. In phylogenetic comparative analysis an operational taxonomic unit refers to an actual extant or fossil taxon for which data have been measured as opposed to an internal branching node within a phylogeny. Measurements from operational taxonomic units are often referred to as tip data. *See also* **hypothetical taxonomic unit**; **phylogenetic comparative analysis**.

opposable thumb An opposable thumb refers to the ability to bring the palmar pulp surface of the first digit squarely into contact with – or opposite to – the palmar pads of one or more of the other digits (i.e., “true” opposition) (Napier 1993). Thus, all digits are involved in true opposition; the thumb abducts and flexes (resulting in conjunct rotation) across the palm while the finger(s) flexes to meet the thumb. Napier (1961) suggested that a truly opposable thumb is found only in Old World monkeys, apes, and modern humans. In modern humans and great apes the joint surface between the trapezium and base of the first metacarpal is saddle-shaped, such that the thumb moves around a flexion/extension axis and an abduction/adduction axis with conjunct motion about these axes, facilitating opposition in the sense of pronation (or rotation) (Cooney et al. 1981, Hollister et al. 1992, Brand and Hollister 1999, Cerveri et al. 2008, Marzke et al. 2010). In modern humans, these joint surfaces are less curved than in African apes, allowing for accommodation of large axial loads on the joint associated with forceful pinch and grasp (Marzke et al. 2010). In modern humans opposition is facilitated by a broad area of contact between the pulps of the finger(s) and thumb making the modern human hand especially able to manipulate objects. In apes, opposability is hampered by the relatively short thumb compared to long fingers. In contrast, terrestrial monkeys, such as baboons and mandrills have more enhanced manipulative skills because the thumb-to-finger length ratio is

more similar to that in modern humans. In modern humans, the opposability and overall grasping function of the thumb is accentuated compared to that of apes. Modern humans have an additional muscle, the flexor pollicis longus, that is either absent or only rudimentary in other primates, in addition to relatively enlarged intrinsic muscles to the thumb, such as the opponens pollicis, that together make the modern human thumb much stronger and more manipulative than that of other primates (Tocheri et al. 2008). In modern humans, the leverage or moment arm of the flexor pollicis longus muscle is enhanced by the presence of a sesamoid bone underneath the tendon. This sesamoid is accommodated by a facet on the proximal palmar surface of the thumb's distal phalanx. However, the facet is proximal to the "hollow" proximal volar fossa. This fossa, the sesamoid facet, and sesamoid bone are found in some nonhuman primates and thus the presence of a sesamoid does not necessarily reflect potential tool-use ability (Shrewsbury et al. 2003). The potential torque of the thumb muscles is estimated to be much higher in modern humans compared to that in chimpanzees (Marzke et al. 1999). Due to the shape of the carpometacarpal joint of the thumb many New World monkeys and strepsirrhines (e.g., capuchin) have a pseudo-opposable thumb. Pseudo-opposability refers to the ability to move the thumb close to the fingers (but not using the type of movement that occurs at the trapezial-first metacarpal in modern humans, the great apes and baboons), thus in pseudo-opposability there is no pulp-to-pulp contact between the thumb and finger(s). Other primates lack an opposable thumb completely (e.g., tarsiers) or the thumb is greatly reduced or absent (e.g., spider monkey).

optically stimulated luminescence dating
See luminescence dating.

optimal foraging theory A subset of evolutionary ecology concerned with the foraging behavior of an organism. MacArthur and Pianka (1966) are credited with developing optimal foraging theory to determine the optimal diet of a predator in terms of the net amount of energy gained from the prey relative to the amount of energy expended in acquiring it (i.e., energetic returns). Their model predicts how a predator's diet breadth, or the number of prey types included in the diet, will respond to changes in its environment. For exam-

ple, a predator foraging in an unproductive environment should have a greater diet breadth than one foraging in a highly productive environment, because it must target a greater number of prey types to maximize its energetic returns and satisfy its energetic requirements. The fundamental assumption of optimal foraging theory is that all foragers behave optimally, with the objective of maximizing energetic returns (i.e., obtaining more calories with minimal effort). Early archaeological applications of optimal foraging theory date to the 1970s and focused largely on changes in subsistence behavior. Today, optimal foraging theory is increasingly used to examine subsistence change through time in response to environmental change, **resource depression**, demographic shifts, or technological innovation. Inferences derived from optimal foraging theory have featured strongly in a variety of issues, including the origin and diffusion of agriculture, the material correlates of social status, early human social organization, and the evolution of human life history.

Oranjemund (Location $c.28^{\circ}36'S$, $16^{\circ}26'E$, Namibia; etym. from the German for "Orange mouth" the name of a nearby diamond-mining town) History and general description The site on the beach between the Orange River and the Atlantic Ocean where, in 1988, Daan Marais found OMD 1'28, a calvaria that most likely eroded from a black clay horizon on the riverbank 100 m from the find-spot. The calvaria is long and narrow, has a thick cranial vault, a fairly low and receding frontal region, and a thin but projecting supraorbital torus. The latter has substantially thinner lateral segments, but no clear sulcus between the medial and lateral segment. Temporal span and how dated? No absolute dates are available, but when the morphology of OMD 1'28 is compared with other better-dated hominin crania from Africa the age of the calvaria is estimated to be $c.50-100$ ka. Hominins found at site OMD 1'28. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Senut et al. 2000; Hominins Senut et al. 2000; Archeology N/A.

orbital geometry Three aspects of the Earth's relationship to the sun, including the tilt of the Earth's axis, the stability of that axis, and the shape of the Earth's orbit around the sun. Changes in orbital geometry are predictable over the **Neogene**, but predictions break down further

back in time (Laskar 1989). Predictable changes in (a) the tilt of the Earth's axis (called **obliquity**) follow a *c.*41 ka cycle, (b) the extent to which the Earth's axis wobbles (called **precession**) follow a *c.*23 ka cycle, and (c) the shape of the Earth's orbit round the sun (called **eccentricity**) follow a *c.*100 ka cycle. These changes in orbital geometry alter the latitudinal and seasonal distribution of **insolation** (i.e., incoming sunlight) as calculated by Laskar et al. (2004) with demonstrated influences on Earth's **climate**. The regularity of these cycles during the Neogene is such that **astrochronology** can be used to calibrate, or "tune" (as in "orbital tuning") **paleoclimate** cycles to the **astronomical time scale**. *See also* **astronomical theory**; **astronomical time scale**.

orbital tuning The process of matching a stratigraphic record to the calculated fluctuations in **insolation** (i.e., incoming sunlight) based upon **astronomical theory**. Orbitally tuned age models are dependent on absolute dating boundaries (e.g., the geomagnetic polarity time scale). Within those age constraints cyclic variations in a paleoclimate proxy may be tied to a dominant orbital frequency. The presence of other orbital frequencies provides independent corroboration of whether or not the "tuning" is valid. This approach has been very powerful for improving the age-model resolution for the Pliocene and Pleistocene using the oxygen isotope stratigraphy of benthic foraminifera as done by the SPECMAP project (Imbrie et al. 1984), and more recently updated and extended by Lisiecki and Raymo (2005). *See* **astronomical theory**; **astronomical time scale**; **Oxygen Isotope Stages**; **stable isotopes**.

Orce region (Location 37°43'N, 2°28'W, Spain; etym. after a nearby town) Located in a geographical depression of exposed Lower Pleistocene sediments (Gibert et al. 1983) in the southeastern Spanish province of Andalucía, this region has been reported to have one of the best Plio-Pleistocene mammalian fossil records in Europe (e.g., Martínez-Navarro 2002). There are three main sites in the Orce region: **Venta Micena**, **Fuentenueva**, and **Barranco León**. **Venta Micena** is the oldest of the sites, and is best known for the debate over whether a cranial bone from the site is from a hominin or from a nonhuman mammal. The two other sites contain mainly faunal remains and some possible stone tools. *See also* **Venta Micena**.

ordinal taxon A taxon in the taxonomic category "order" in the Linnaean system. Orders are relatively inclusive groupings (e.g., the order **Primates**). Other orders include the order **Carnivora**, which includes all the mammalian taxa that principally consume meat, and the order **Artiodactyla**, which includes all the mammalian taxa with an even number of hoofed toes.

ordinary least squares regression A form of **regression** in which model **parameters** are fit by minimizing the sum of the squared differences between observed and predicted values of the dependent variable. Least squares techniques may be applied to **simple regression** or **multiple regression**. Ordinary least squares regression, or OLS, minimizes error about the dependent variable and assumes no error in the independent variable(s) (or ignores error in the independent variables, depending on who you ask). It is a type of **Model I regression**. *See* **regression**.

ordination *See* **seriation**.

ORF Acronym for **open reading frame** (*which see*).

organ of Corti This term refers to a ribbon-like array of hair cells in the cochlea part of the membranous labyrinth of the inner ear. The organ of Corti lies on the basilar membrane within the cochlear duct part of the membranous labyrinth. The hair cells are stimulated in response to relative movement between the endolymph and the hair cells and the stimulation of hair cells is the means by which higher animals detect sound. The hair cells of the inner ear are an example of a highly conserved structure, for they are homologous with the hair cells embedded in the lateral line of fish.

oropharynx *See* **pharynx**.

Orrorin (etym. *Orrorin* = original man in the Tugen language) A genus established in 2001 by Senut et al. (2001) to accommodate a new species they introduced for fossil remains recovered from the *c.*6.0 Ma **Lukeino Formation** at **Aragai**, **Cheboit**, **Kapcheberek**, and **Kapsomin** in Baringo District, Kenya. The authors claimed that the various cranial and postcranial features that distinguished the new fossils from *Pan* could not be accommodated in any of the existing hominin

genera. White et al. (2009a) suggest that the morphological differences between species assigned to *Ardipithecus* and to *Orrorin* do not justify their being assigned to different genera, in which case the former genus would have priority and *Orrorin* would be the junior synonym of *Ardipithecus*. Type species *Orrorin tugenensis* Senut et al., 2001.

Orrorin tugenensis Senut et al., 2001 (etym. *Orrorin* = original man in the Tugen language; *tugen* = Tugen Hills) The genus and species established in 2001 by Senut et al. to accommodate cranial and postcranial remains recovered from the c.6.0 Ma **Lukeino Formation** at **Aragai, Cheboit, Kapcheberek, and Kapsomin**, Baringo District, Kenya. The femoral morphology has been interpreted (Pickford et al. 2002, Richmond and Jungers 2008) as suggesting that *O. tugenensis* is at least a facultative biped, but other researchers interpret the radiographs and computed tomography scans of the femoral neck as indicating a mix of bipedal and nonbipedal locomotion (Galik et al. 2004, Ohman et al. 2005). Otherwise, the discoverers admit that much of the critical dental morphology is “ape-like” (Senut et al. 2001, p. 6). *O. tugenensis* may prove to be a hominin, but it is equally and perhaps more likely that it belongs to another part of the adaptive radiation that included the common ancestor of panins and hominins. White et al. (2009a) suggest that the morphological differences between *Ardipithecus ramidus* and *O. tugenensis* do not justify their being assigned to different genera, in which case the latter taxon would be transferred to the genus with priority (i.e., *Ardipithecus*) as *Ardipithecus tugenensis* (Senut et al., 2001) White et al., 2009. First discovery KNM-LU 335 (1975). Holotype BAR 1000'00 (2000). Paratypes KNM-LU-335, BAR 349'00, BAR 1002'00, BAR 1004'00, BAR 1003'00, BAR 1001'00, BAR 1215'00, BAR 139'00, BAR 1425'00, BAR 1426'00, and BAR 1900'00. Main sites Localities in the Tugen Hills, Kenya, as listed above.

orthogenesis A model of biological evolution popular in the early 20thC. Theodor Eimer, professor of zoology and comparative anatomy at the University of Tübingen, used the term orthogenesis (also called orthogenetic evolution) to refer to a model of evolution that proceeded in straight lines instead of the branching pattern of evolution promoted by Charles Darwin. This may explain why by the end of the 19thC most biologists had

accepted the principle of biological evolution, yet many of them rejected Darwin's mechanism of natural selection in favor of neo-Lamarckian models of evolution consistent with orthogenesis. Supporters of orthogenesis believed that it was an inherent biological property of all organisms to evolve along predetermined lines of development. Thus, selection and adaptation play little, or no, role in orthogenetic models of evolution. A strong early 20thC advocate of orthogenesis was Henry Fairfield Osborn, a paleontologist at the American Museum of Natural History. Osborn's research on the extinct group of mammals called Titanotheres had suggested there were parallel lines of development in these organisms. Osborn did not invoke orthogenesis in his discussions of human evolution, but some paleoanthropologists did, foremost of whom was Arthur Smith Woodward who was deeply involved in the study of the **Pitldown** fossils. Smith Woodward argued that the evolution of the human brain was driven by internal biological factors and was not an adaptive response to environmental conditions or the product of changing human behavior. Arthur Keith also argued that the evolution of large brains in different hominin taxa was likely the result of an inherent and general tendency for brain enlargement in Pliocene hominins. Later, the British anatomist Wilfrid Le Gros Clark also suggested that orthogenesis helped to explain why primates in separate lineages had evolved similar traits and developed along similar evolutionary lines despite the fact they had diverged from a common ancestor at a geologically remote period. Orthogenetic theories of evolution began to wane by the middle of the 20thC as the mammalian fossil record became more complete and many examples of nonlinear evolutionary series in the fossil record were discovered. Orthogenesis finally fell out of favor in the 1950s in response to the rise of the modern evolutionary synthesis and to the general acceptance of models of evolution that were closer to that promulgated by Darwin.

orthognathic (Gk *orthos* = straight and *gnathos* = jaw) A term that literally refers to jaws that do not project, but technically it refers to skulls in which no part of the face or mandible (except the chin) projects forwards. It is usually quantified by measurements of the distance between a landmark on the base of the cranium

(e.g., **basion**, **porion**) and a landmark on the front of the face (e.g., **subnasale**, **alveolare**). *Paranthropus boisei* and *Paranthropus robustus* are examples of fossil hominin taxa that have relatively flat or orthognathic faces (ant. **prognathic**).

orthogonal (Gk *orthogonion* = right-angled) In a direction at right angles to the plane of reference. The axes generated by multivariate analytical methods are usually orthogonal.

orthograde *See posture.*

orthologous genes (Gk *orthos* = straight and *logos* = proportion) **Genes** present in different organisms that are descended from a common ancestor (e.g., the myoglobin genes in chimpanzees/bonobos and modern humans are orthologous).

orthologue Abbreviation of **orthologous genes** (*which see*).

orthoquartzite *See quartzite.*

orthotropy (Gk *orthos* = straight and *tropus* = direction) In materials science, a material whose properties differ among each of three orthogonal axes, but those properties are similar within each of the three axes. Wood is an example of an orthotropic material; the stiffness of a log in its long axis differs from that in the axis perpendicular to its growth rings and from that in the axis tangential to its growth rings. The anthropoid mandible exhibits orthotropy at a histological or supraosteonal level of organization. Bone in other regions, like the shaft of the femur, can also be orthotropic, although the differences in elastic moduli in the tangential (perpendicular to the cortical shaft) and circumferential directions often differ by about 10% and thus the elastic structure is close to **transverse isotropy**. The three-dimensional elastic structure for most bones of vertebrates has not been investigated but is presumed to be orthotropic or transversely isotropic because of regular structural patterns involved in bone growth and remodeling, although this is likely not the case in regions constructed of woven bone.

OS (L. *os* = bone, as in *osseus* = bone or bone-like) The Latin term for bone. In the Latin version of **anatomical terminology** “os” is used as a prefix for many of the bones. Some researchers

still use the Latin form (e.g., “**os coxae**” instead of the official English-language term “hip bone” or “pelvic bone”), but to be consistent those who do so should refer to *all* bones in their Latin form (e.g., the scaphoid as the “**os scaphoideum**” and “**caput ulnae**” instead of the “head of the ulna”). It is more appropriate to use the English-language terms listed in the *Terminologia Anatomica* than to continue to use terminology that is arcane. However, for some bones “os” is still used as a prefix as part of the formal name of some bones (e.g., “**os centrale**” is both the Latin *and* the English-language term for a cartilaginous nodule that in modern humans usually fuses with the scaphoid, but which in the great apes more often persists as a separate carpal bone). *See also anatomical terminology.*

os centrale (L. *os* = bone, as in *osseus* = bone or bone-like) A cartilaginous nodule that in modern humans usually fuses with the scaphoid, but which in the non-African apes more often persists as a separate carpal bone. *See also scaphoid-os centrale fusion.*

os coxae (L. *os* = bone, as in *osseus* = bone or bone-like and *coax* = hip) Some researchers use the Latin terms “**os coxae**” instead of the English-language term “hip bone” or “pelvic bone.” But to be consistent, those who do so should refer to all bones in their Latin form (e.g., the scaphoid as the “**os scaphoideum**” and the head of the ulna as the “**caput ulnae**”). *See also anatomical terminology.*

OSL Acronym for optically stimulated luminescence dating. *See luminescence dating.*

Osmundsen, Lita *See The Wenner-Gren Foundation for Anthropological Research.*

ossification (L. *os* = bone and *facere* = to make) The process of bone formation, or osteogenesis. There are two types of ossification: **intramembranous ossification** and **endochondral ossification**; in both types bone formation begins at a focus called an ossification center. Bone formation by intramembranous ossification (e.g., in the flat bones of the cranial vault) begins at centers of ossification within flat sheets or “membranes” (hence the term intramembranous) of collagen fibers. Bone-forming cells called osteoblasts form a featureless osteoid matrix that first calcifies

(involving calcium phosphate) and then ossifies (involving the formation of hydroxyapatite). As more and more matrix is calcified and then ossified, the distance between individual bone-forming cells increases and thus the cells are gradually isolated from one another in osteocyte lacunae. Most eventually lie quiescent, some die from inadequate nutrition, and some of these mineralize within the lacuna. Groups of osteoclasts cut out microcavities in previously formed bone (this happens during both bone formation and bone remodeling). The space created is then filled in by bone formed first at the periphery and then in circles of ever decreasing size; these are the Haversian lamellae in an osteon system. The central canal in such an osteon system contains a nutrient blood vessel and the osteocytes communicate with each other via minute canaliculi. Most of the bones of a hominin skeleton are formed by the second type of ossification, endochondral ossification. Endochondral ossification is a two-stage process. First, cells called chondroblasts form a hyaline cartilage model of the future bone. Cells in the middle of the cartilage model initially divide and grow by interstitial growth (as distinct from appositional growth). This enables rapid formation of the cartilage model. Chondrocytes then swell (hypertrophy) and die, leaving only a mineralized shell of cartilage matrix. This mineralized cartilage is then resorbed by osteoclasts (strictly speaking, chondroclasts) and at the same time osteoblasts start forming osteoid matrix on the walls of the spaces once occupied by chondroblasts. This happens first at the primary center of ossification, and this primary center is soon surrounded by a sleeve of subperiosteal bone that forms beneath the periosteum. In long bones the bone formed from the primary center of ossification is called the diaphysis. Primary centers usually appear between 7 weeks and 4 months of intrauterine life. Some bones (e.g., auditory ossicles, zygomatic, carpals, and tarsals) usually form from a single primary center; other bones (e.g., sphenoid, temporal) always form from multiple primary centers. Secondary centers of ossification, or epiphyses, form in complex bones (e.g., vertebrae), at the ends of long bones, and at the sites of bony processes (e.g., trochanters of the femur and the tubercles of the humerus). Long bones can continue to grow in length because new cartilage is laid down in epiphyseal plates between the primary center in the shaft of the bone and the epiphyses at either end. Bones stop

growing in length when the epiphyseal plates cease to form new cartilage. When this happens the primary and secondary centers of ossification fuse into a single continuous bone. Epiphyseal plates are sometimes visible in radiographs as a dark line between the diaphysis and the epiphysis. *See also modeling; remodeling.*

ossification center *See ossification.*

Osteichthyes (Gk *ostei* = bony and *ichthys* = fish) The name of the superclass of aquatic vertebrates that subsumes all the bony fish, both freshwater and marine. Bony fish can be divided into two classes: the diverse Actinopterygii (ray-finned fish) with more than 23,000 species, and the smaller and much less common Sarcopterygii (lobe- or fleshy finned fish), which include the ancestors of terrestrial vertebrates. The earliest known ray-finned fish appeared about 395 Ma in freshwater deposits and about 230 Ma in marine deposits. Most of the fish remains found in early hominin sites are freshwater taxa, although some marine taxa are found in late Pleistocene coastal sites. Africa has a diverse freshwater fish fauna, with almost 50% of the families being endemic, including the electrosensing Mormyridae (elephantfish) and the “flying” fish Pantodontidae. Other taxa are remnants from the Gondwanaland fauna, such as the Characiformes (e.g., tigerfish) and Cichlidae (included in the diverse Perciformes). Lungfish (Lepidosireniformes) and bony-tongues (Osteoglossidae) are remnants of more archaic distributions, while catfish (Siluriformes) from Asia and the minnow-like cyprinids (Cypriniformes) are later immigrants. Rifting in the Miocene and the Pleistocene was particularly significant for the evolution and ecology of African fish. It changed much of the topography of Africa from a flat landscape crossed by river systems to one with high relief and many lake basins. These new lacustrine zones were rapidly colonized by previously river-adapted fish and the well-studied cichlids in several African great lakes are examples of “explosive” adaptive radiations (Salzburger and Meyer 2004). Many early *Homo* remains are associated with lacustrine sites (e.g., **Olduvai Gorge** where there is evidence of hominin exploitation of wetland resources including fish; Ashley et al. 2009). *See also catfish; fish.*

osteoblasts (Gk *osteon* = bone and *blastos* = bud or immature cell) The cells that manufacture the

collagen fibers and proteoglycans that comprise the osteoid matrix which eventually becomes bone. The matrix initially becomes calcified with calcium phosphate and then the calcium phosphate is converted into hydroxyapatite crystals. This matrix plus collagen, plus a few dormant osteoblasts (called osteocytes) comprise **bone** tissue. *See* **bone**; **ossification**.

osteoclasts *See* **bone**; **ossification**.

osteocytes *See* **bone**; **ossification**.

osteodontokeratic *See* **Dart, Raymond**; **Makapansgat**.

osteogenesis (Gk *osteon* = bone and *genesis* = origin) Bone formation, or ossification. *See also* **ossification**.

osteon (Gk *osteon* = bone) *See* **ossification**.

ostrich egg shell The fossilized eggs, or more often fragments of eggs, of ostrich-related species are the most common avian fossils in African hominin sites, especially open-air sites. This is doubtless because the egg shell of ostrich-related species is less than 5 mm thick. In Africa, two main lineages of ostrich-related birds run from the Oligo-Miocene to the Pleistocene. One, called *Aepyornithoid* (i.e., “resembling *Aepyornis*”), has erroneously been related to (or even sometimes synonymized with) the elephant birds (i.e., the *Aepyornithidae*) of Madagascar, that have been extinct since the 19thC. But the features used to do this are probably primitive and cannot be used to infer such a relationship. The other main lineage shows marked evolutionary changes in the arrangement of the pores in the shell, together with a global size reduction through time. It is not clear which of the two lineages is ancestral to the extant ostrich genus *Struthio*. These taxa are useful for dating and for paleoenvironmental reconstruction, for ostrich-related birds are indicative of open, dry savanna-like habitats. *See also* **ostrich egg shell dating**.

ostrich egg shell dating Principle Ostrich egg shell and the shells of other large ratites (e.g., emus, moas) constitute some of the best-known materials for the analysis of protein **diagenesis** to determine age, as the proteins are tightly bound

into the crystal structure of the shell and are not affected by humidity variation in the burial environment. As a result, egg shell protein approximates a closed system, unlike bone or mollusc shell. Whereas racemization or epimerization of various amino acids can be detected in egg shell using liquid or gas chromatography, dating of sites in the Middle to Later Pleistocene has most often used the epimerization reaction of L-isoleucine to D-alloisoleucine, since the reaction kinetics have been shown to be linear. Method The reaction that brings about the change is temperature-dependent, but if average temperature can be estimated independently of sample age or if an ostrich egg shell sample from the Later Pleistocene of the site in question can be simultaneously dated by isoleucine epimerization and **AMS radiocarbon dating** then age estimates for at least two to three times the age of the calibration piece can be regarded as reliable. It is also possible to control for pieces that have been heated to higher than ambient temperature through exposure to fire, by measuring the relationship between L-isoleucine/D-alloisoleucine ratios and breakdown resulting from a different chemical decomposition reaction: de-carboxylation. The availability of a proxy for temperature, and lack of response to humidity variation make ostrich egg shell dating more reliable than amino acid racemization studies of bone, and ostrich egg shell dates have generally matched AMS radiocarbon dates made on the same sample. Ostrich egg shell dating can also be corroborated through analysis of stable carbon and oxygen isotopes in the samples to obtain paleoclimate information. Time range The crystal structure of ostrich egg shell is such that amino acids may be retained within it for upwards of 15–17 Ma, although isoleucine epimerization may only be valid for c.100–135 ka in the tropics and up to 1 Ma in China. Problems The influence of temperature and inter-laboratory variation in results. Examples Brooks et al. 1990, Miller et al. 1992, 1999, Johnson et al. 1997. *See also* **amino acid racemization dating**.

OTU Acronym for operational taxonomic unit. *See* **cladistic analysis**; **operational taxonomic unit**; **phylogenetic comparative analysis**.

Oulad Hamida 1 *See* **Thomas Quarry**.

out-of-Africa hypothesis This hypothesis on modern human origins emerged during the

1980s and drew upon paleontological, archeological, and genetic evidence to support the idea that modern humans had evolved within Africa, and then had migrated in one, or very likely more than one event, out of Africa to populate the Old World and later the New World. Thus, according to this hypothesis, all modern humans originate from a group of *Homo sapiens* that left Africa relatively recently. Importantly, the out-of-Africa hypothesis rejects the idea that *Homo erectus* populations existing in Asia and elsewhere had evolved into *H. sapiens*, or had given rise to any current modern human populations, as is argued by the supporters of the **multiregional hypothesis**. The out-of-Africa hypothesis for the origin of modern humans is now sometimes referred to as “Out of Africa 2” in recognition of the fact that the first hominin dispersal out of Africa was undertaken much earlier by *H. erectus*. Some of the basic tenets of the out-of-Africa hypothesis were proposed by William (Bill) Howells in 1976. Howells’ “Noah’s Ark hypothesis” argued that all modern humans originated from a single recent population of *H. sapiens* that was already morphologically modern. He suggested that groups of these early *H. sapiens* spread throughout the world replacing the existing more archaic hominin populations. During the early 1980s Günter Bräuer suggested a slightly different version of the hypothesis. This was initially called the Afro-European sapiens hypothesis, but was later changed to “**replacement with hybridization**,” this latter version allowed for interbreeding between *H. sapiens* and the archaic populations they replaced (Bräuer 1984). The most widely accepted version of the out-of-Africa hypothesis, also called the “**recent African origin**” or “replacement model” was proposed in 1988 by Christopher Stringer and Peter Andrews in an article published in the journal *Science* entitled “Genetic and fossil evidence for the origin of modern humans” (Stringer and Andrews 1988). They argued that modern *H. sapiens* evolved from a *Homo heidelbergensis* ancestor in Africa *c.*200 ka and that the hominin groups existing outside of Africa did not contribute in any significant way to the ancestry of current modern human populations. According to Stringer, some of these early *H. sapiens* migrated out of Africa between *c.*100 ka and spread throughout the Old World where they replaced existing populations such as *Homo neanderthalensis*. Important evidence for this hypoth-

esis came from research conducted by Rebecca Cann, Mark Stoneking, and Allan Wilson at the University of California at Berkeley and published in their influential paper “Mitochondrial DNA and human evolution” in the journal *Nature* in 1987. By studying the accumulation of mutations in the **mitochondrial DNA** of women from different geographical populations and by estimating mutation rates over time these researchers concluded that all living human populations shared a most recent female common ancestor who lived in Africa *c.*200 ka. The out-of-Africa hypothesis also draws upon evidence from the fossil and archeological records. Fossil hominins with a morphology similar to that of anatomically modern humans and dated to *c.* 70–100 ka have been recovered at **Klasies River Mouth** and **Border Cave** in southern Africa. Debates over the role of the *H. neanderthalensis* in human evolution assumed a new significance when it became clear that the *H. sapiens*-like remains found at sites such as **Qafzeh** and **Skhul**, in Israel, were likely to be *c.*100 ka, which meant that the Neanderthal remains found at sites such as **Amud** and **Kebara** almost certainly *postdated* the earliest regional evidence for *H. sapiens*, making it very unlikely that Neanderthals had evolved into modern humans. This latter scenario has also been weakened by the discovery of Neanderthal remains that may be as recent as 32 ka and of *H. sapiens* remains in Africa at Omo-Kibish and Herto that are estimated to be between 160 and 200 ka. The archeological evidence has also been interpreted (e.g., McBrearty and Brooks 2000) as being consistent with the recent African origin or replacement model. Supporters of the out-of-Africa hypothesis reject claims by advocates of the multiregional hypothesis that the China or Southeast Asia fossil record provides evidence of morphological continuity that connects *H. erectus* to *H. sapiens*. While at least one study (Krause et al. 2010) has demonstrated gene exchange between the Neanderthals and anatomically modern humans, the primary ancestral contribution to modern humans in Eurasia clearly derived from the out-of-Africa migrations of early modern people. Thus, whereas the strongest form of the out-of-Africa hypothesis has apparently been falsified, in its weaker form it has survived refutation. However, as some have pointed out (e.g., Relethford 2003), there is little to choose between the weak form of the the out-of-Africa hypothesis and the weak form of the multiregional hypothesis.

outcrop A naturally occurring exposure of rock at the Earth's surface. Geological investigation of outcrops have significant advantages over subsurface studies utilizing core or geophysical properties in the ability to collect large samples, follow lateral facies variations, and directly examine 3D geometry of strata. A significant drawback of outcrops relates to the rapid alteration of some rocks exposed to the atmosphere or to soil formation.

outer table *See* cranial vault.

outgroup The term used for a **taxon** (or taxa if it is a composite outgroup) used to help determine the polarity of the characters used in a cladistic analysis. Outgroups are normally closely related, preferably primitive, taxa. *See* **cladistic analysis**; **phylogenetic comparative analysis**.

outgroup criterion One of the criteria used to determine the **polarity** (i.e., which is the most primitive state and which the most derived) of the states of a character. The principle is that the character states seen in closely related, preferably primitive, sister taxa of the group being studied are likely to manifest the primitive states for that character. *See also* **cladistic analysis**.

overdominance *See* **balancing selection**.

Owen's lines Richard Owen was the first to describe "contour lines" in dentine. He suggested that they correspond to successive positions of the sheet of **odontoblasts** that form the dentine during tooth formation (Owen 1840–1845). Subsequent research suggests that Owen's contour lines occur because dentine tubules simultaneously all make a short bend along a line parallel to the outer contour of the tooth, and researchers have proposed that this phenomenon is due a disturbance to the regular secretion of dentine matrix. Thus clusters, or groups, of irregularly spaced Owen's lines are superimposed onto the regular underlying pattern of long-period **Andresen lines** in dentine; Owen's lines do not always coincide with Andresen lines. The equivalent of Owen's lines in enamel are **Wilson bands**.

owl pellet The regurgitated, indigestible remains of food ingested by owls. Owl pellets, particularly those attributed to *Tyto alba*, are considered to be the main way microfaunal remains

enter the fossil record at archeological and paleontological sites. Owls are specialized predators of microfauna. When the prey is small, microfauna are eaten whole without preparation and the indigestible skin, hair and bone are regurgitated resulting in the deposition of a structure called an owl pellet. This digestive treatment both concentrates micromammal remains and also may protect their bones from other diagenetic processes. Small concentrated lenses of fossil rodents within archeological and paleontological sites are attributed to the repeated use of roosting sites by owls. The activities of owls thus are important for the preservation of an important part of the paleontological and paleoenvironmental record. *See also* **microfauna**.

OWM Acronym for **Old World monkeys** (*which see*).

oxygen An element commonly used in paleoclimate reconstructions and **stable-isotope biogeochemistry**. Oxygen has two common isotopes (^{18}O and ^{16}O) and one rare isotope (^{17}O); all three isotopes are stable and do not decay. *See* $^{18}\text{O}/^{16}\text{O}$; **paleoclimate**; **stable isotopes**.

Oxygen Isotope Stage 1 (or OIS 1) **Time span** *c.*141 ka–present. **Magnetozone** Brunhes Chron, normal polarity. This is the current Holocene stage. We are currently in an interglacial period. The only living *Homo* species during this stage is *Homo sapiens*.

Oxygen Isotope Stage 2 (or OIS 2) **Time span** *c.*29–14 ka. **Magnetozone** Brunhes Chron, normal polarity. **Significant events** The **Last Glacial Maximum** occurs during OIS 2 and it includes three **Heinrich events** (H): H1 (*c.*14.5 ka), H2 (*c.*20.5 ka), and H3 (*c.*23.4 ka). **Examples of sites in OIS 2** Abri Flageolet I, Abri Pataud, and **La Ferrassie** (France).

Oxygen Isotope Stage 3 (or OIS 3) **Time span** *c.*57–29 ka. **Magnetozone** Brunhes Chron, normal polarity. **Significant events** This period is known as the interpleniglacial which is broken up into five rapidly oscillating interstadials: Oerel (*c.*58–54 ka), Glinde (*c.*51–48 ka), Moershoofd (*c.*46–44 ka), Hengelo (*c.*39–36 ka), and Denekamp (*c.*32–28 ka). **Heinrich event** (H) H4 took place at *c.*31.8 ka and H5 transpired at *c.*41.9 ka. The

last appearance date of *Homo neanderthalensis* is during this stage. Examples of sites in OIS 3 Saint-Césaire and Le Moustier (France), Banyoles and Zafarraya (Spain), Shanidar, Amud, Kebara Units III–VI, Boker Tachtit Levels 1–4, and Boker A (Israel), Grotta Breuil (Italy), Pavlov (Czech Republic), Zhoukoudian Upper Cave (China).

Oxygen Isotope Stage 4 (or OIS 4) Time span *c.*71–57 ka. Magnetozone Brunhes Chron, normal polarity. Significant events Heinrich event 6 took place at *c.*64.2 ka. Examples of sites in OIS 4 La Ferrassie (France, the Mousterian levels have been dated to OIS 5 and OIS 4); Regourdou (France) may be either stage 5e or early stage 4.

Oxygen Isotope Stage 5 (or OIS 5) Time span *c.*130–71 ka. Magnetozone Brunhes Chron, normal polarity. Significant events This stage is broken up into five substages, with a series of quick oscillations designated 5a–5e. The last major interglacial correlates to OIS 5e, and this period is also known as the Eemian. The majority of *Homo neanderthalensis* sites are during stage 5. Examples of sites in OIS 5 Regourdou (France, may be either stage 5e or early stage 4), Lazaret (France), La Ferrassie (France, the Mousterian levels have been dated to OIS 5 and OIS 4), Taubach (5e), Tata (Hungary), Saccopastore 1 and 2 (Italy), Krapina (Croatia, may be either 6 or beginning of 5e), Šipka (Czech Republic), Subalyuk (Hungary), Gánovce (5e) (Slovakia). The peaks within this OIS date to approximately: 5.1 peak, *c.*82 ka; 5.2 peak, *c.*87 ka; 5.3 peak, *c.*96 ka; 5.4 peak, *c.*109 ka; 5.5 peak, *c.*123 ka.

Oxygen Isotope Stage 6 (or OIS 6) Time span *c.*191–130 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 6 - Krapina (Croatia) (possible alternative dating OIS 5), Biache Saint-Vaast, Combe Grenal, Fontéchevade, La Chaise-de-Vouthon (l'Abri Suard), Lazaret, and Montmaurin (La Niche) (France), La Cotte de St. Brelade (Jersey), Pinnacle Point (South Africa), Ochtendung (Germany), Krapina (Croatia, either 6 or beginning of 5e).

Oxygen Isotope Stage 7 (or OIS 7) Time span *c.*243–191 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 7 Pontnewydd Cave (Wales), Steinheim (Germany).

Oxygen Isotope Stage 8 (or OIS 8) Time span *c.*300–243 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 8 Mesvin IV (Belgium), Ariendorf 1 (Germany).

Oxygen Isotope Stage 9 (or OIS 9) Time span *c.*337–300 ka. Magnetozone Brunhes Chron, normal polarity. Distinguishing whether a site is from OIS 9 or OIS 11 is often difficult because the intervening stage (OIS 10) was very short. Examples of sites in OIS 9 Hoxne (England), Pradayrol and Terra Amata (France), Steinheim (Germany), Castel di Guido.

Oxygen Isotope Stage 10 (or OIS 10) Time span *c.*374–337 ka. Magnetozone Brunhes Chron, normal polarity.

Oxygen Isotope Stage 11 (or OIS 11) Time span *c.*424–374 ka. Magnetozone Brunhes Chron, normal polarity. Distinguishing whether a site is from OIS 9 or OIS 11 is often difficult because the intervening stage (OIS 10) was very short. Examples of sites in OIS 11 Sidi Abderrahman (Morocco) Beeches Pit (and OIS 12), Boxgrove (or OIS 13), and Swanscombe (England), Bilzingsleben (Germany).

Oxygen Isotope Stage 12 (or OIS 12) Time span *c.*478–424 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 12 Beeches Pit (and OIS 11).

Oxygen Isotope Stage 13 (or OIS 13) Time span *c.*533–478 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 13 Boxgrove (or OIS 11) (England), Mauer (possible alternative dating OIS 15).

Oxygen Isotope Stage 14 (or OIS 14) Time span *c.*563–533 ka. Magnetozone Brunhes Chron, normal polarity. Example of a site in OIS 14 Sima de los Huesos (Spain).

Oxygen Isotope Stage 15 (or OIS 15) Time span *c.*621–563 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 15 Atapuerca (Gran Dolina) (Spain).

Oxygen Isotope Stage 16 (or OIS 16) Time span *c.*676–621 ka. Magnetozone Brunhes Chron, normal polarity. Example of a site in OIS 16 Tangshan Huludong (China).

Oxygen Isotope Stage 17 (or OIS 17)
Time span *c.*712–676 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 17 Pakefield (England) (possible alternative dating OIS 19), Zhoukoudian Lower Cave (China).

Oxygen Isotope Stage 18 (or OIS 18)
Time span *c.*761–712 ka. Magnetozone Brunhes Chron, normal polarity. Examples of sites in OIS 18 Gesher Benot Ya’aqov (could be in OIS 18–20) (Israel).

Oxygen Isotope Stage 19 (or OIS 19)
Time span *c.*790–761 ka. Magnetozone Brunhes Chron (780–760 ka), normal polarity, and Matuyama Chron (787–780 ka), reversed polarity. Examples of sites in OIS 19 Gesher Benot Ya’aqov (could be in OIS 18–20), Pakefield (England) (possible alternative dating OIS 17).

Oxygen Isotope Stage 20 (or OIS 20)
Time span *c.*814–790 ka. Magnetozone Matuyama Chron, reversed polarity. Example of a site in OIS 20 Gesher Benot Ya’aqov (could be in OIS 18–20) (Israel).

Oxygen Isotope Stage 21 (or OIS 21)
Time span *c.*866–814 ka. Magnetozone Matuyama Chron, reversed polarity.

Oxygen Isotope Stages A sequence of periods of relative differences in the ratio of oxygen isotopes used to provide approximate ages for archeological and fossil sites. The initial crucial discovery that led to the use of oxygen isotopes for geochronology was the demonstration by Urey (1947) of variations in the oxygen content of the shells of foraminifera (also called benthic or planktonic foraminifera, or just “forams”) recovered from the sea floor. Foraminifera contain two isotopic forms of oxygen, ^{16}O and ^{18}O , and Urey demonstrated that the relative amounts of the “light” (^{16}O) and “heavy” (^{18}O) isotopes varied according to the temperature of the seawater. When the water is warm evaporation removes more of the lighter isotope, thus increasing the $^{18}\text{O}/^{16}\text{O}$ ratio, and when the water is cool the $^{18}\text{O}/^{16}\text{O}$ ratio declines. Emiliani (1955, 1966) used the link between the $^{18}\text{O}/^{16}\text{O}$ ratio and water temperature, together with information provided by recently devised absolute dating methods, to reconstruct ocean temperatures for the past 400

ka. Shackleton (1967) argued that the $^{18}\text{O}/^{16}\text{O}$ ratio could also be used as a proxy for terrestrial glaciations, suggesting that the $^{18}\text{O}/^{16}\text{O}$ ratio in the oceans would fall when ^{18}O -rich water was locked up in expanded ice caps and enlarged glaciers. Emiliani (1972) used this association to show that the history of temperature fluctuations inferred from oxygen isotope levels in the past million years was more complex than the classical interpretation of four 100 kyr-long glaciations separated by 100–300 ka interglacial periods. Emiliani (1955) was the first to propose that the maxima and minima of the inferred paleotemperature curve be referred to as “stages” (hereafter referred to as Oxygen Isotope Stages or OIS, but also and increasingly referred to as marine isotope stages or MIS) starting with OIS 1 for the most recent maximum. Thereafter odd numbers were used for peaks of maximum temperature and even numbers for troughs of minimum temperature. Shackleton and Opdyke (1973) showed that planktonic and benthic foraminifera have similar isotope records and were able to demonstrate that sea levels predicted from the oxygen isotope record were matched by terrestrial geological evidence in both Barbados and New Guinea. They also extended the 19 stages of Emiliani (1955) to 22, and proposed that these stages should be adopted as a “standard for the latter half of the Pleistocene” (ibid, p. 48). Emiliani and Shackleton (1974) combined data from the shorter deep-sea cores from the Atlantic and the Caribbean with the longer, more densely sampled record, from a new core (V28-238) from the Pacific, and since then additional cores have expanded the temporal span of the record and better sampling methods have improved its precision. An older glacial/interglacial terminology based on continental indicators of cold and warm climate phases has been replaced by the OIS numerical system, allowing more precise estimates of age. Thus the Würm glacial corresponds with OIS 2–4, the Riss with OIS 6, the Mindel with OIS 8, 10, 12, and 14, and Günz with OIS 16 (even-numbered OIS are minima). The recognition of OISs allowed the validation of the so-called astronomical theory of climate. This theory was mathematically formulated early in the 20thC by the Serbian mathematician Milutin Milankovitch, who hypothesized that the Earth’s orbital components (namely, **eccentricity** of the Earth’s orbit, its tilt, or **obliquity**, and the **precession** of the Earth’s axis)

were strongly implicated in geologically recorded climate change. However, it was not until the development of the quasi-continuous deep-sea isotopic record that there was an adequate enough geological record to test theory; Hays et al. (1976) unambiguously showed that fluctuations in the oxygen isotopes in the deep-sea cores contained the periods associated with orbital components. Once it became clear that the orbital "Milankovitch cycles" were significant drivers of climate change it became possible to use the mathematically generated time estimates to fine tune less-precise geological records, so-called "orbital tuning." The OIS (or MIS) system is increasingly being used to indicate the age of fossil sites that cannot be dated precisely using methods that measure time in years. In some cases layers of tephra at fossil sites are also found intercalated in the marine sediments sampled by deep-sea cores. Whereas the latter sediments are deposited more or less continuously, some cycles of deposition may be missing from the nonmarine sections. These correlations between terrestrial and marine sequences have enabled the dates from the terrestrial sections to be orbitally tuned using the marine sequences (deMenocal and Brown 1999). See also **astronomical theory; astronomical time scale; orbital geometry; orbital tuning.**

OY ratio This is defined by Caspari and Lee (2004, p. 10895) as "the ratio of older to younger adults (OY ratio) in the death distribution

over time." They intended the measure to provide a summary of the number of "old" adults relative to "young" adults in a death assemblage. They define adulthood as the age at which the third molars come into occlusion, and they further define "old" adults as those with estimated ages twice that of the age at which the third molars come into occlusion. Although they (Caspari and Lee 2004, p. 10896) argued that "ages were used to allocate specimens to life history categories that are themselves independent of actual ages," it is not possible to have life history categories (such as "old" and "young") that are truly independent of age. To define "twice the age" of attainment of adulthood, it is necessary to specify an age by which adulthood (occlusion of the third molars) is reached. As a consequence, they suggested 15 years as the age at which individuals enter adulthood, and 30 years (2×15 years) as the age at which individuals enter "older" adulthood. Given their definitions, the OY ratio is the number of individuals estimated to have died at or over 30 years of age divided by the number of individuals estimated to have died between 15 and 30 years of age. Ages at death were estimated in Caspari and Lee's analyses by using **Miles' method**. The proportion of "old" adult deaths out of all adult deaths (D_{30+}/D_{15+}) is related to the OY ratio [it is equal to $OY/(1+OY)$] but has simpler properties as well as a more straightforward demographic interpretation. The D_{30+}/D_{15+} death proportion is the **survivorship** to age 30 years (in a **stationary population**) for those who survive to adulthood (age 15 years).

P

P. Prefix used by the French contingent of the **International Omo Research Expedition** for localities in the **Shungura Formation** (e.g., P. 996). The prefix is also used for fossils found within that locality (e.g., P. 996–17).

P. 996–17 A fossil hominin from the **Shungura Formation**. Its original locality was “P. 996,” but in later publications it is referred to as “L. 996.” See L. 996–17.

p arm See **chromosome**.

p-deme See **deme**.

P value Associated with a statistical test, the probability that the observed pattern in a data set could occur if the **null hypothesis** were true. If the *P* value is below some threshold (usually 0.05) then the test is said to show a statistically significant result and the null hypothesis is rejected.

PA Prefix used for hominin fossils recovered from sites in China (e.g., PA 830 from **Hexian**).

PA 830 See **Hexian 1**.

pachymeninx (Gk *pachys*=thick and *meninx*=membrane) Refers to the dura mater, the thick outer layer of the meninges that is formed from mesoderm. See also **meninges**.

Paderborn (Location 51°41′N, 8°44′E, Germany; etym. named after the nearby town) History and general description A hominin cranial fragment was recovered from gravel deposits outside of the city of Paderborn in Westfalia in 1976. Original **radiocarbon dating** by Reiner Protsch, who is alleged to have falsified data, suggested an age of 27.4±0.6 ka, but recent redating has shown it to be post-medieval. Temporal span and how dated? Direct dating of the skull fragment

by **AMS radiocarbon dating** has revealed that this skull is recent (238±39 years). Hominins found at site A relatively robust skull fragment attributed to attributed to *Homo sapiens*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Street and Terberger 2002, Street et al. 2006; Archeology N/A; Hominins Henke and Protsch 1978.

paedomorphosis (Gk *pedo*=child plus *morphe*=form, shape) A category of resultant morphologies that follow from three different kinds of **heterochronic** processes (time **hypomorphosis**, rate **hypomorphosis**, or **neoteny**). All of these processes produce, in various ways, descendants with ancestral juvenile characteristics or shapes retained during later stages of ontogeny. Since the juvenile features are shifted to the adult, there are no “new” paedomorphic morphologies. See also **hypomorphosis**; **neoteny**.

Paglicci (Location, 41°40′N, 13°37′E, Italy; etym. unknown) History and general description The existence of sediments in this cave, near Rignano Garganico in Apulia, was first reported by R. Battaglia in 1955, but excavations did not begin until the early 1960s under F. Zorzi and F. Mezzena. Temporal span and how dated? **Radiocarbon dating** has provided a range from 34,300±800 years BP for layer 24B2 to 11,440±180 years BP for layer 7c-2. The layer containing the two hominin burials has been dated to 24,720±420 years BP. Hominins found at site In addition to at least 30 hominin fragments scattered through the sequence, two burials are known from the bottom of layer 21. These two burials, an adolescent male (Paglicci 12) and an adult female (Paglicci 25), have been referred to as “Cro-Magnon” in character. Fragmentary remains recovered from Paglicci have been submitted to mitochondrial DNA analyses and they appear to differ significantly from *Homo neanderthalensis*. Archeological evidence found at site The sequences

primarily contains **Gravettian** and **Epigravettian** artifacts. Key references: Geology, dating, and paleoenvironment Galiberti 1980; Hominins Corrain 1965, Caramelli et al. 2003, 2008, Mallegni 2005; Archeology Mussi 2001.

pairwise distance matrix See distance matrix.

Pakefield (Location 52°25.9'N, 1°43.8'E, England; etym. name of a nearby village) History and general description Changes in sea level have recently re-exposed sections of the Cromer Forest-bed Formation (CF-bF) between Pakefield and Kessingland on the North Sea coast of eastern England and Pakefield is one of the excavations on that section of the coast. Temporal span and how dated? The artifacts come from sediments that probably belong to Oxygen Isotope Stage 17 (but could be as old as Oxygen Isotope Stage 19) and to the early part of the Brunhes chron. The presence of *Mimomys* suggests that Pakefield is probably older than the type section of the CF-bF. Hominins found at site None. Archeological evidence found at site Thirty-two worked flints, including a simply flaked core and a crudely retouched flake, were found *in situ*. Key references: Geology, dating, and paleoenvironment Parfitt et al. 2005; Hominins N/A; Archeology Parfitt et al. 2005.

Palaeanthropi See Sergi, Sergio (1878–1972).

Palaeo-Anthropology Research Unit (or PARU) The umbrella term for all the paleoanthropology research undertaken within the Witwatersrand University Department of Anatomy during the time Phillip Tobias was the head of that department. In 1999 the responsibility for research at Sterkfontein was transferred from PARU to a new entity, the Sterkfontein Research Unit, with Phillip Tobias as the Director and Ron Clarke the Deputy Director.

Palaeoanthropus A new genus established by Reck and Kohl-Larsen (1936) to accommodate the species *Palaeoanthropus njarasensis*, which they had proposed to accommodate the Eyasi 1 calvaria. Type species *Palaeoanthropus njarasensis* Reck and Kohl-Larsen, 1936.

Palaeoanthropus njarasensis Reck and Kohl-Larsen, 1936 First discovery Eyasi 1. Holotype Eyasi 1. Paratypes N/A. Main sites Eyasi.

Palaeoanthropus palestinus McCown and Keith, 1939 See Skhul I; Skhul IV; Tabun 1; Tabun 2.

palaeoanthropic man See Archanthropinae.

Palaeoanthropinae See Archanthropinae.

Paleoanthropological Inventory of Ethiopia One of the few attempts to locate potential hominin fossil sites on a large, regional, scale. Led by Berhane Asfaw, the inventory was a collaboration between the Ethiopian Ministry of Culture and Sports Affairs, the Laboratory for Human Evolutionary Studies at the University of California, Berkeley, the NASA-Goddard Space Flight Center, the Los Alamos National Laboratory, and the University of Tokyo. It used images from two space-based systems, Landsat thematic mapping (TM) and large-format camera (LFC). The former is a satellite-based system that measures the intensity of reflected sunlight in seven wavebands, and the resulting color images were used to identify vegetation and distinctive tephra. The high-resolution LFC images were taken during the Challenger shuttle mission in 1984. The two sets of data were collected for the main Ethiopian Rift Valley and for the Afar depression, and they were combined to help identify promising sedimentary basins. Thereafter, so-called “ground-truth information” was collected from 1988 onwards by researchers who explored the basins by vehicle and on foot to verify the presence of potential sites. Several sources of hominin fossils in the Ethiopian Rift Valley were identified by the Paleoanthropological Inventory of Ethiopia, one in the north and one in the south. Examples include the site complex within the Kesem-Kebena basin to the north of Lake Koka, in the Awash River system upstream of the Hadar and Middle Awash study areas, and the site of Fejej between the river Omo to the west and Lake Chew Bahir to the east. For more information see Asfaw et al. (1990).

paleoanthropological terminology The terminology used to describe hominin fossils is a mixture of the terminology used by modern human anatomists (i.e., anatomical terminology) and terms introduced by anthropologists and paleoanthropologists when they have encountered structures in nonhuman primates and in the hominin fossil record that are not ordinarily seen in modern humans. Some of these terms were initially described

using the Latin form (e.g., Franz Weidenreich's *crista occipitomastodea* and Gustav Schwalbe's *placum alveolare*) in which case it is conventional to use italics for these terms. However, there is no need to italicize terms that were initially described in English (e.g., Yoel Rak's nasopalveolar gutter and Weidenreich's preglenoidal plane). *See also anatomical terminology.*

paleoanthropology (Gk *palaios*=ancient, *anthropos*=human being, and *ology*=study of; literally the study of ancient humans) In the present day this term is interpreted differently in Europe and North America. In Europe it is synonymous with human, or hominin, paleontology, whereas in North America it is interpreted more inclusively to include archeology as well as hominin paleontology. The meaning of paleoanthropology has changed over the past century and a quarter. The French geologist and paleontologist Louis Lartet may have been the first scientist to use the term. In a paper published in the *Annales des sciences géologiques* in 1872 he divided the science of paleontology into three subdisciplines: paleoanthropology (*paléo-anthropologie*), paleozoology, and paleophytology. However, when he refers to paleoanthropology in that and subsequent papers Lartet primarily discusses prehistoric archeological artifacts and monuments, not prehistoric human skeletal remains. However, when Lartet and his colleague Chaplain Duparc used the term *paléo-anthropologie* in 1874, they did so in the context of a discussion about Stone Age humans and the possible existence of human ancestors in the Miocene. Thus, although by 1874 Lartet was using paleoanthropology to refer to *any* kind of scientific study that addressed prehistoric or Stone Age humans, before long other researchers began to narrow and refine its meaning. One of the first people to use the term paleoanthropology more exclusively was Clémence Royer, a controversial French scholar who wrote on subjects ranging from economics and philosophy to anthropology and biology. It was she who translated Charles Darwin's *On the Origin of Species* into French in 1862 and she was an early member of the Société d'Anthropologie de Paris. In a paper published in the *Journal des économistes* in 1879 she described *paléo-anthropologie* as the study of lost races of humans through their fossil remains. According to this formulation paleoanthropology was distinct from, but connected with, prehistoric archeology, which was the study of the artifacts manufactured by these "lost races." According to Royer, paleoanthropology and prehistoric archeology "reveal to us the successive

phases of the social evolution of human kind, of his customs, of his instincts and of his rudimentary institutions" (1879, p. 408). The person who bears most of the responsibility for defining paleoanthropology as a scientific discipline was the French anthropologist Paul Topinard. In his influential book *Éléments d'anthropologie générale (Elements of General Anthropology)* published in 1885, Topinard noted the recent expansion and the changing nature of research into human prehistory. He acknowledged the contributions of the French prehistorian Gabriel de Mortillet, who since the 1860s had argued that the study of prehistory is an anthropological science, and it was Gabriel de Mortillet who proposed the term *paléoethnologie* (paleoethnology) for the scientific investigation of prehistoric humans. But Topinard was among those who objected to de Mortillet's new term. One reason for Topinard's preference for paleoanthropology was that it emphasized the study of skeletal remains and physical anthropology as distinct from the study of archeological artifacts. Indeed, Topinard was critical of prehistorians who focused on simply amassing collections of flint artifacts. In a paper entitled "La paléo-anthropologie" presented at the 1889 Congrès international d'anthropologie et d'archéologie préhistoriques (the precursor of the International Congress of Prehistoric Anthropology and Archaeology) and published in the congress proceedings in 1891, Topinard distinguished between paleoanthropology, which deals with prehistoric human fossils and the identification of prehistoric human races, and paleoethnography, which deals with prehistoric artifacts and material culture, prehistoric art, and the customs of different prehistoric races. Paleoethnography was the domain of archeologists and ethnologists, whereas paleoanthropology was the domain of zoologists and anatomists. Topinard expanded upon and clarified his point in *L'homme dans la nature (Man in Nature)* published in 1891, where he stated that the scientific study of prehistoric humans can be divided into two separate concerns: (a) the study of the fossil remains of humans and (b) the study of the society of these humans through their artifacts, dwellings, sepulchers, and artistic remains. In essence, Topinard is saying that paleoanthropology is synonymous with human paleontology. In a paper presented to the Société d'Anthropologie de Lyon another French anthropologist, Philippe Salmon, offered a very similar definition of paleoanthropology (Salmon 1888, pp. 208–9). Thus, by 1891 paleoanthropology had emerged as a distinct scientific discipline in France and largely, but not solely through the efforts of Paul Topinard, it was increasingly

understood to be the anthropological study of prehistoric humans via their fossil remains. It was a paper read by Topinard at the Congrès International d'Anthropologie et d'Archéologie Préhistoriques in 1889 that helped promulgate the new discipline of paleoanthropology outside of France. Thomas Wilson, the curator of the Department of Prehistoric Anthropology at the Smithsonian Institution and one of America's prominent archeologists, attended the congress and upon his return to the USA he published a report on it in *The American Naturalist* in 1892. He discussed Topinard's paper and introduced the term "paleoanthropology" to Americans. The same year, in the *Annual Report of the Board of Regents of the Smithsonian Institution*, Wilson listed paleoanthropology (meaning the study of prehistoric skeletal material) as one of the disciplines related to prehistoric anthropology. Similarly, in a paper published in 1892 the influential German anthropologist and biologist Rudolf Virchow followed Topinard in using paleoanthropology to mean *specifically* the study of human fossil remains, as distinct from archeological artifacts. By the end of the century Europe's leading anthropologists and archeologists recognized paleoanthropology as a science that dealt specifically with human paleontology. During the first half of the 20thC few books or articles used paleoanthropology in their titles, but this changed in the 1960s. Wilfrid Le Gros Clark's *The Fossil Evidence for Human Evolution: An Introduction to the Study of Paleoanthropology*, originally published in 1955, was not only one of the first books to use paleoanthropology in its title, but it also helped to redefine the emerging modern science of paleoanthropology. Clark described paleoanthropology as the study of fossil hominids and the comparative anatomy of humans and existing primates. Significantly, Clark noted that in recent years paleoanthropologists, rather than scientists trained in other disciplines, were playing a more critical role in the interpretation of the fossil evidence of human evolution. In the 1970s several books appeared bearing the term paleoanthropology in their titles, including Russell Tuttle's *Paleoanthropology: Morphology and Paleoeecology* (1975), Glynn Isaac's *Perspectives on Human Evolution: East Africa and Paleoanthropology* (1976), and James A Gavan's *Paleoanthropology and Primate Evolution* (1977). It was around this time that William (Bill) Howells and Patricia Jones Tsuchitani offered a more inclusive interpretation of paleoanthropology. In their introduction to *Paleoanthropology in the People's Republic of China* (1977), a report arising from a visit to China by a delegation of US paleoanthropologists, they

defined paleoanthropology as a discipline that encompasses the interdisciplinary study of early humans from the perspective of such disciplines as archeology, physical anthropology, geology, geophysics, paleobotany, and paleontology, thus distinguishing modern paleoanthropology from the way it was interpreted by Topinard et al. Howells and Tsuchitani *emphasized* the connection between the study of human fossils and prehistoric archeology, rather than distinguishing the two activities. However, when in 1980 Gail Kennedy and Milford Wolpoff both published textbooks entitled *Paleoanthropology*, they were not interpreting paleoanthropology in the same way. In his textbook Wolpoff interpreted it more inclusively to include archeology, but Kennedy excluded archeology and suggested that modern paleoanthropology was a synthetic science that relied on developments in "evolutionary biology, population genetics, biochemistry, geochronology, paleontology, ecology, biomechanics, multivariate statistics, and cybernetics," all of which supplement the traditional biometrics and descriptive, functional, and comparative anatomy of earlier studies (1980, p. 2). The most up-to-date interpretation of paleoanthropology used in the North American, more inclusive, sense can be found on the website of the Paleoanthropology Society founded in 1992 (www.paleoanthro.org/thesociety.htm). To quote from its website it suggests that "paleoanthropology is multidisciplinary in nature and the organization's central goal is to bring together physical anthropologists, archeologists, paleontologists, geologists and a range of other researchers whose work has the potential to shed light on hominid behavioral and biological evolution."

Paleoanthropology Society Founded in 1991, the two goals of the Society are to foster an understanding of the processes which underlie the evolution of behaviorally and anatomically modern humans, and to create, largely through face-to-face interaction, a multidisciplinary group of researchers who share this common goal and who will work collaboratively towards it attainment. An underlying premise of the Society is that to understand how modern humans evolved it is necessary to examine the interactions between biology and behavior and to set these within an appropriate environmental and chronological context; thus membership is drawn from a variety of disciplines. The Society, which accepts all applicants for membership regardless of nationality and level of academic attainment, focuses on three activities. The first is a publicly accessible

web site, www.paleoanthro.org, which, in addition to information about the Society, contains a membership directory, a student section, a series of published dissertations, and links to other relevant websites. The second is an electronic journal, *PaleoAnthro*, which may also be accessed, free of charge, through the website. *PaleoAnthro* focuses on the publication of large, data-rich articles, which can take advantage of the less stringent spatial constraints of an electronic format; letters and book reviews are also published. Finally the Society hosts an annual 2-day meeting, the first was held in St Louis, MO, USA, in 1992, which is held in conjunction, in alternate years, with the Society for American Archaeology and the American Association for Physical Anthropology. *See also paleoanthropology*.

paleoclimate (Gk *palaios*=ancient and *klima*=which refers to the slope of the Earth's surface, is the origin of L. *clima*=referring to climate, or latitude) Assessments of climate made for time periods where it is not possible to take direct measurements of four climate variables, namely temperature, precipitation (rainfall, snowfall), and wind speed and direction. Information about past climates must come from proxies for the four climate variables. These proxies can be divided into two main categories: biotic and chemical. The biotic proxies are mainly to do with productivity (e.g., in warmer phases the oceans have a greater biomass and tree rings are wider) and with direct evidence of the types of plants and animals that were living at the time; the chemical proxies include changes in oxygen isotope ratios recorded in foraminifera and in air bubbles in ice. Paleoclimate can be reconstructed on a global or on a regional scale. *See also climate; climate forcing*.

paleoclimate reconstruction *See paleoclimate*.

paleocommunity deme *See deme*.

paleodeme *See deme*.

paleodemography The demography of past populations or samples from which no records of age or sex are available. These populations or samples may be modern humans from the recent past, or they may be from different taxa where the data are derived from paleoanthropological research.

paleoecology (Gk *palaios*=ancient, *oikos*=house, and *logia*=study) Interactions between an organism and its environment in the past. Paleocology is of interest in hominin paleontology because it enables researchers to investigate the factors affecting past human behavior and evolution from a holistic perspective. Studies of paleocology are focused on either the interactions centering on a particular species (paleoautecology) or reconstructions of community ecology at a particular site, or during a well-defined time interval in the past.

paleoenvironment (Gk *palaios*=ancient and OF *environ*=round about) Information about the climate, landscape, and the vegetation of a fossil locality in the remote geological past. It is a more inclusive concept than paleoclimate. *See also environment; paleoenvironment reconstruction*.

paleoenvironmental reconstruction The process of deducing past environmental conditions from the physical and biological evidence left behind in the geological record. Cognate evidence can be abiotic or biotic and it can take many forms (e.g., sedimentology, soil chemistry, paleobotany, and vertebrate and invertebrate paleontology). For example, biotic evidence includes palynology, a subfield of micropaleontology. Fossil pollen and spores in lacustrine or terrestrial sediments can be used to infer the plant species that occurred at the time when the environment existed, and when the means of their dispersal and taphonomy are taken into account the relative abundance of the plants which produced them. Depending on the type of plants and sediments involved, the evidence might represent plants occurring on either a regional or local level. Knowledge of the abiotic environment can be gained either directly from evidence of natural processes in the preserved sediments or indirectly from a study of the biotic components and secondary inference based on their known ecological preferences. For example, the presence of a perennial river in the local paleoenvironment could be inferred primarily from the scale of paleochannels or particular types of cross bedding in the sedimentary deposits, or the biotic evidence such as preserved freshwater oyster reefs and riverine fish, reptiles, and mammals in the associated fossil assemblage. Like much of geology and paleontology, paleoenvironmental reconstruction relies on the principles of **uniformitarianism**; present

processes are the key to the past. Paleoenvironmental reconstruction is by its nature multidisciplinary. Since many of the factors that determine the paleoenvironment interact, the nature of the evidence may require complex analyses and negotiation to arrive at a consensus interpretation. Recently, paleoenvironmental reconstructions of fossil localities have relied on a multiproxy approach, which tries to reconcile different strands of evidence recovered from a site to create a fuller picture of the past. Multidisciplinary paleoanthropological projects now routinely take this approach, since past environments are seen as a key aspect of understanding evolutionary processes.

paleohabitat A past habitat. *See* **habitat**.

Paleolithic The "old stone age," defined by John Lubbock in 1865 as the time when humans coexisted with extinct fossils and stone implements were rough-hewn, in contrast to the Neolithic, or "new stone age," when stone implements were generally polished. The term now refers both to a time period (the sum of human history from the invention of stone tools until *c.* 10 ka) and to a distinct economic, social, and technological complex, usually defined as reliance on flaked stone tools, low population sizes, and foraging. It is customarily divided into three stages (**Lower**, **Middle**, and **Upper Paleolithic**), each having unique features. In Africa, the terms Early, Middle, and Late Stone Age first introduced by A.J.H. Goodwin and C. van Riet Lowe in 1929 are preferred, although they are broadly similar to the Eurasian terms. Prior to the advent of absolute dating, most sites were simply attributed to one of these stages.

paleomagnetic dating (Gk *palaios*=ancient and *magnes*=magnet) *See* **geomagnetic dating**.

paleomagnetic record (Gk *palaios*=ancient and *magnes*=magnet) *See* **geomagnetic polarity time scale**.

paleosol (Gk *palaios*=ancient and L. *solum*=ground) A soil of the geological past, typically recognized by the preservation of characteristic structures, color, mineral segregations, or chemistry that relate to soil-forming processes at the time the paleosol was active at the Earth's surface. The characteristics of paleosols reflect the controlling factors of soil formation (i.e., climate, vegetation, relief, parent material,

and time) and thus can be used to reconstruct some of these variables for the geologic past. Investigation of paleosols at **Kanapoi** (Wynn 2000) was used to characterize the habitats available to *Australopithecus anamensis* there *c.* 4 Ma.

paleotelic (Gk *palaios*=ancient and *telikos*=end, so "towards a purpose") *See* **palimpsest evolution**.

Pálffy barlang *See* **Dzeravá Skála**.

palimpsest (Gk *palimpseston*=scrape again. The term originally referred to a parchment, the surface of which had been scraped in places to allow for reuse, and so by extension the text written on it was likely produced by several authors on different occasions) In paleoanthropology a palimpsest refers to an archeological or fossil assemblage formed of elements deposited at different times and often by different causes or agents. Some cave deposits are evidently palimpsests. The shelter afforded by caves make them attractive to a succession of hominins and various carnivores such as bears, hyenas, and various raptors (e.g., **Die Kelders**). As such the accumulated fauna is often a combination of the dietary leftovers from hominin and nonhominin sources that must be distinguished if the research focus is hominin behavior. It is useful to distinguish between "depositional" and "behavioral" causes. For example, the abraded *Homo erectus* fossils (calotte, femur, molar tooth) recovered some distance apart from a sandbank on a bend of the Solo River at **Trinil**, central Java, very likely comprise a "depositional" palimpsest in the sense that the bones were doubtless redeposited on the sandbank at different times, having been carried down by the river. However, an archeological assemblage can also be a "behavioral" palimpsest. Glynn **Isaac** developed the idea of a behavioral palimpsest in the early 1980s in what he termed the "dynamic flow-through model" for site formation (Isaac 1983, Kroll and Isaac 1984) and the concept has recently been revisited (Domínguez-Rodrigo et al. 2007a). For example, sites such as those at **Olduvai Gorge** (e.g., FLKN) are almost certainly the time-averaged result of many instances of stone tools and butchered bones being deposited at that place by hominins, plus bone deposition at the same location by felids. A similar argument can be advanced for Dmanisi being a behavioral palimpsest. Realistically, any site that has a sample size of artifacts or fauna large

enough to be detected in the archeological or fossil record is likely to be a palimpsest, whether formed over days, months, years, decades, or thousands of years.

palimpsest evolution (Gk *palimpseston* = scrape again. The term originally referred to a parchment, the surface of which had been scraped in places to allow for reuse, and so by extension the text written on it was likely produced by several authors on different occasions) The term used by William King Gregory and Robert Broom to describe what is usually referred to as “**mosaic evolution.**” In 1910 Gregory differentiated between what he then termed caenotelic (later “habitus”) traits and paleotelic (later “heritage”) traits. Caenotelic characters are of direct current adaptive relevance whereas paleotelic characters are phylogenetically older (comparable to symplesiomorphies in cladistic parlance). The latter may have been functionally important, but they do not relate to a specific current niche. For example, in early hominins the form of the hindlimb adapted to bipedal locomotion is a caenotelic trait, but the limb’s elements (femur, tibia and fibula, tarsus, pentadactyl extremity) constitute a paleotelic trait. Gregory made the important point that the terms are relative since paleotelic traits were once caenotelic. In 1947 he described the resulting assemblage of features as a “palimpsest,” but the term had been introduced by Robert Broom in 1924 when in a review of reptilian evolution he referred to “habitus” and “heritage” features. *See also mosaic evolution.*

palynology (A neologism created in 1944 by Hyde and Williams. Its roots are Gk *paluno* = to sprinkle and *pale* = dust, and the suffix *ology* = study of) The study of pollen and other organic microfossils recovered from sedimentary rocks and sediments (other plant microfossils; i.e., **phytoliths** and **starch grains** are usually not included in palynology, the former because they are made of silica and not strictly organic, and the latter because they have not been observed to fossilize). Palynology includes the use of pollen (a) to reconstruct past environments and climates, (b) to investigate of the effects of the activity of modern humans and extinct hominins (e.g., logging and burning) on the flora, and (c) in the creation of plant species lists to assist in reconstructing the diet of extinct hominins. Traverse (2007) provides

a useful primer for researchers contemplating exploring the potential of pollen for any of the types of analysis set out above. *See also pollen.*

Pan A number of different chimpanzee species have been recognized since the 1860s. It was then that Du Chaillu described *Troglodytes koolookamba* and *Troglodytes calvus* from Gabon, in addition to the ordinary chimpanzee which he, in line with the nomenclature most commonly in use at the time, called *Troglodytes niger*. Other supposed species were described throughout the 19thC and early 20thC, until Schwarz in 1932 decided that only one species was necessary, with four subspecies. Subsequently authorities have been almost unanimous in separating out one of these as a distinct species, *Pan paniscus*. It became known as the pygmy chimpanzee but is now more commonly designated the bonobo, leaving the simple name “chimpanzee” for *Pan troglodytes*. In the latter half of the 20thC authorities tended to assume, with very little scrutiny, the existence of three subspecies within *P. troglodytes*: the West African chimpanzee, *Pan troglodytes verus*, the Central African chimpanzee, *Pan troglodytes troglodytes*, and the East African chimpanzee, *Pan troglodytes schweinfurthii*. When re-examined, by both molecular and morphological means, this simple picture has turned out to be unsatisfactory. First, **mitochondrial DNA** (or mtDNA) sequencing in the 1990s showed that West African chimpanzees differ absolutely from others, with many fixed substitutions indicating a considerable time since they separated; it has therefore been proposed that they constitute a different species, *Pan verus*. Secondly, the mtDNA of chimpanzees from between the Sanaga and Niger Rivers (i.e., between *verus* and *troglodytes*) is different yet again, and it is now customary to recognise them as a further subspecies, *Pan troglodytes ellioti* (initially, but incorrectly, called *Pan troglodytes vellerosus*). Thirdly, morphological analysis pointed out that there is as much difference within *P. t. schweinfurthii* as between that and *P. t. troglodytes*, so the former “*schweinfurthii*” is often now divided into a northwestern subspecies (*schweinfurthii*) and a southern and eastern one (*marungensis*). Finally, there is a growing view that there is not much difference between Central and Eastern chimpanzees, and some lump them together.

Pan-African Association of Prehistory and Related Studies The organization that plans and organizes the successors to the **Pan-African**

Congress on Prehistory and Quaternary Studies. It was established at the 1983 Pan-African Congress on Prehistory and Quaternary Studies in Jos, Nigeria.

Pan-African Congress on Prehistory and Quaternary Studies This series of congresses (now called the **Congress of the Pan-African Association of Prehistory and Related Studies**) has played a leading role in promoting research and scholarship in African prehistory. The congresses bring together researchers for sessions of delivered papers, but an important and consistent component of the congresses has been one, or more, excursions to paleontological and archeological sites. Thus far, 13 congresses have been held: Nairobi, Kenya, 1947; Algiers, Algeria, 1952; Livingstone, Zambia, 1955; Leopoldville (now Kinshasa, Democratic Republic of the Congo), 1959; Santa Cruz de Tenerife, Canary Islands, 1963; Dakar, Senegal, 1967; Addis Ababa, Ethiopia, 1971; Nairobi, Kenya, 1977; Jos, Nigeria, 1983; Harare, Zimbabwe, 1995; Bamako, Mali, 2001; and Gaborone, Botswana, 2005; and Dakar, Senegal, 2010. The first Pan-African Congress on Prehistory in Nairobi in 1947 was organized and hosted by Louis Leakey. It brought together scholars of African prehistory with the goal of sharing and disseminating new scientific knowledge and discoveries. During that meeting the Abbé Breuil was elected President and Robert Broom Vice-President. Professor Lionel Balout and the Abbé Breuil organized the second congress, held in Algiers in 1952. Desmond Clark, who was the president of the prehistory section of the Algiers congress organized the third congress in Livingstone. Its president was Louis Leakey, who gave an impromptu demonstration of skinning an antelope with stone tools he had fashioned. It was at this congress that the terms **Early**, **Middle**, and **Later Stone Age** were defined and formally endorsed. Another important proposal was that the stratigraphic/climatic divisions defined for East Africa (Kageran, Kamasian, Gamblian, etc.) should not be applied to other parts of the African continent unless there was firm evidence to support such a correlation. The proposal that the Pleistocene faunal sequence should be divided into four stages has now largely passed out of use, but it provided a tool for regional or even wider correlations, and it was the best chronological tool then available. The fourth congress was held in Leopoldville (now Kinshasa, Democratic Republic of the Congo) in 1959, and it was there that Louis Leakey announced Mary Leakey's discovery of **OH 5**, the holotype of

Zinjanthropus boisei, at **Olduvai Gorge**. Politics threatened the sixth congress scheduled for Dakar in 1967. The Senegalese media and some politicians wanted to exclude scientists from South Africa, but President Senghor intervened and allowed them to attend, and it was at this congress that the new hominin discoveries from the Omo Basin were announced by Clark Howell. The **Pan-African Association for Prehistory and Related Studies** was established at the ninth congress, held in Jos in 1983, and Desmond Clark and Thurstan Shaw were elected to Honorary Membership because of their "outstanding contributions towards the realization of the objectives of the Association." The scope of the twelfth congress held in Gaborone in 2005 was expanded to include cultural heritage management, historical archeology, and post-colonial archeology. The Gaborone congress was important in another way, for it was the first congress at which a native African, the Ethiopian scientist Zeresenay Alemseged, announced a major hominin discovery.

Pan fossils See KNM-TH 45519–45522, KNM-TH 46437–46440.

Pan paniscus A species of extant chimpanzee known as the **bonobo**. It was previously referred to as the "pygmy chimpanzee," but after Schultz (1969) showed there is extensive overlap between the limb dimensions of *Pan paniscus* and *Pan troglodytes*, and given that the mean of the field-recorded body masses of seven *P. paniscus* males exceeded the mean body mass of 15 *P. troglodytes* males (Jungers and Susman 1984), the epithet "pygmy" was inappropriate. The first formal taxonomic consideration of the bonobo suggested it was a subspecies of the chimpanzee (*Pan satyrus paniscus* Schwarz, 1929), but 4 years later Coolidge (1933) raised it to the rank of species. The type specimen, a skull and skin (#9338), is in the collection of the **Royal Museum for Central Africa**. Randall Susman's edited volume is the primary source for historical and for most scientific information about the bonobo (e.g., Coolidge 1984, Van den Audenaerde 1984), but Johanson (1974) and Cramer (1977) also provide important detailed assessments of the dentition and cranial morphology, respectively, of the bonobo. In addition to its importance as one of the living taxa most closely related to modern humans some have taken the view that among the extant *Pan* taxa *P. paniscus* "may approach more closely to the common ancestor of chimpanzees

and man than does any living chimpanzees” (Coolidge 1933, p. 56). Adrienne Zihlman has been a consistent advocate of Coolidge’s proposition and a comparison of the limb proportions of *P. paniscus* and *Australopithecus afarensis* captured simply, but effectively, in a diagram (Zihlman 1984, Fig. 15) has been a powerful promotional icon for this proposal. *See* **hominid**; **Hominidae**.

panin The informal or vernacular term for a specimen that belongs to a taxon within the tribe Panini. For example, *Pan paniscus* is a panin taxon and KNM-TH 45519 is a panin fossil.

Panini The tribe that includes chimpanzees and bonobos and all the fossil taxa more closely related to chimpanzees and bonobos than to any other living taxon.

Panina If the tribe **Hominini** is interpreted to include both the clade that contains modern humans *and* the clade that contains extant chimpanzees/bonobos then some researchers (e.g., Andrews and Harrison 2005) discriminate between the two clades at the level of the subtribe. In this case the clade that contains extant chimpanzees/bonobos would be called the **Panina** and the clade that contains modern humans would be called the **Hominina**.

paninan The informal term for individuals or taxa within the subtribe Panina. *See* **Panina**.

Panthera (*L. panthera* from Gk *panther*, but the word is probably of Oriental origin, cf. Sanskrit *pundarikam* “tiger,” probably literally “the yellowish animal”) The cosmopolitan genus of large cats that includes the extant lion *Panthera leo*, tiger *Panthera tigris*, panther *Panthera onca*, leopard *Panthera pardus*, and their extinct close fossil relatives. The genus *Panthera* appears in the fossil record in the middle **Pliocene** and becomes a relatively speciose taxon; it now has modern representatives on five continents.

Panxian Dadong (Location 25°37'38"N, 104°44'E, Guizhou Province, China; etym. means “Grand Cave”) History and general description Panxian Dadong (sometimes abbreviated to “Dadong”) is a middle-level cave juxtaposed between lower and upper caves within an approximately 230 m hill situated on the western part of the Guizhou Plateau that comprises carboniferous and Permian limestones, cataclas-

tic rocks, basalt, and coal deposits; the hill itself is about 1630 m above sea level. Dadong is a large cave with a roughly 55 m-wide and 50 m-high entrance and it is about 220 m from the entrance to the back wall; the total area of the cave floor is approximately 8000 m². The cave contains an estimated 19.5 m of deposit near the entrance of the cave, but the top 1–2 m has been disturbed by local people mining potassium nitrate for use in the production of gunpowder and it was removed during the initial excavation of the site in 1992. Four excavations were conducted at Dadong between 1996 and 2000 by a joint Sino-American research team led by Sari Miller-Antonio and Lynne Schepartz on the American side and Huang Weiwen and Hou Yamei on the Chinese side. Three primary stratigraphic units were identified – (from top to bottom) Unit 1, Unit 2, and Unit 3 – with Unit 2 divided into two separate stratigraphic layers (Units 2a and 2b). The majority of the vertebrate paleontological (including hominins) and archeological remains were excavated from Unit 2. Temporal span and how dated? Middle to Late Pleistocene based on the presence of the *Ailuropoda-Stegodon* fauna. Unit 2a: uranium series 180–142 ka, electron spin resonance 156–137 ka; Unit 2b: electron spin resonance 294–214 ka. Hominins found at site Five hominin teeth were allocated to “*Homo sapiens*” (Jones et al. 2004, Karkanas et al. 2008), although others suggest they belong to “archaic *H. sapiens*” (Liu and Si 1997), but none of the teeth have been described in detail. If these hominin teeth turn out to be modern human, then it will have significant implications for hypotheses about the origins of modern humans because of their early date. Archeological evidence found at site Core and flake stone implements produced on locally available limestone, basalt, and chert. Analysis of the raw materials and artifact typologies suggests more reliance on basalt and chert and an increase in the number of artifacts though time. It has also been suggested that some of the *Rhinoceros* teeth were flaked and used as tools. Analysis of the faunal remains suggests that hominins were the primary accumulators of the animal bones, with carnivores, birds, and rodents playing minor roles. Repository Dadong Village Research Station, Guizhou, China. papionin The informal name for the tribe **Papionini** (*which see*).

Papionini (L. *papio* = baboon, which gives rise to *Papio*, the name for the genus that contains the baboons) One of two tribes within the subfamily **Cercopithecinae** (the other tribe within the subfamily is the **Cercopithecini**, or guenons), the family **Cercopithecidae**, and the superfamily **Cercopithecoidea**. The papionini comprises baboons and their allies. The extant genera included in the Papionini are *Papio* (common baboons), *Mandrillus* (drills and mandrills), *Theropithecus* (geladas), *Macaca* (macaques), *Cercocebus*, *Rungwecebus*, and *Lophochebus* (mangabey). Fossil genera within the Papionini include *Parapapio*, *Dinopithecus*, and *Gorgopithecus*. Papionins tend to be relatively large-bodied and they are mainly terrestrially adapted (except for several macaque and mangabey species that are arboreal), whereas cercopithecins are smaller and generally more arboreal. Several papionin species have “long” faces, or dog-like muzzles, in comparison to the shorter faces of the guenons. The papionins are the best studied of the groups within the Old World monkeys, and a good deal is known about their evolution and past diversity, in part because their fossils are relatively common at many archeological and hominin paleontological sites. The two cercopithecine tribes, the Papionini (papionins) and Cercopithecini (cercopithecins), radiated in the late Miocene to the Pleistocene. By the late Miocene there is fossil evidence for the modern genus *Macaca* in North Africa (Delson 1974), tallying with X-chromosome data that suggest a divergence of *Macaca* from other papionins at 7.6 ± 1.3 Ma (Tosi et al. 2005). In the terminal Miocene and earliest Pliocene, *Macaca* dispersed around the Mediterranean and radiated into Europe and Asia, reaching latitudes as far north as 53° (UK). It was in the Pliocene and Pleistocene that the major adaptive radiations of the African and Eurasian papionins occurred. Late Miocene *Macaca* probably gave rise to *Paradolichopithecus* and *Procynocephalus*, two Eurasian papionin genera that were successful in the Pliocene, but which became extinct in the Pleistocene (Jablonski 2002). Data from mitochondrial DNA and the Y chromosome suggest substantial speciation within *Macaca* during the late Pliocene and Pleistocene in Asia (Tosi et al. 2003). The Pliocene and Pleistocene papionin radiations in Africa are better documented than those that occurred in Eurasia, but many of the species that thrived in the Plio-Pleistocene did not survive into the late Pleistocene and Holocene.

The very latest Miocene or earliest Pliocene witnessed the divergence of the taxa that gave rise to the *Mandrillus/Cercocebus* and *Papio/Theropithecus/Lophochebus* clades (Tosi et al. 2005), probably from a Central African source (Bohm and Mayhew 2005). *Papio*, *Theropithecus*, and *Lophochebus* then speciated in quick succession *c.* 4 Ma (Harris 2000), although, like *Mandrillus* and *Cercocebus*, the fossil record of *Lophochebus* is poor compared to those of *Theropithecus* and *Papio*. *Parapapio* and *Theropithecus* were the two dominant cercopithecine genera in the Plio-Pleistocene. *Parapapio*, although found in East African deposits, had a stronghold in southern Africa, but it was extinct by the early Pleistocene. *Theropithecus* had a wider geographic distribution than *Parapapio*, and a longer temporal span. It was most diverse in the Turkana Basin, but fossils have been recovered from southern Africa (including Angola), North Africa, and Eurasia (see Hughes et al. 2008 for a review). The genus now has only one surviving member, *Theropithecus*, the gelada, which is confined to the highlands of Ethiopia and Eritrea. The most abundant and widespread modern sub-Saharan African papionin genus, *Papio*, was poorly represented in the East African Plio-Pleistocene record, although it was more prevalent in southern Africa. Its fossil record is relatively poor compared to that of *Theropithecus*. *Papio hamadryas* fossils (in the form of *Papio robinsoni*) have been recovered from Plio-Pleistocene sites in southern Africa, including Swartkrans. The classification of modern baboons has veered from placing them all into a single species, *P. hamadryas*, and new genetic data suggest there may be at least five species with a complicated history. Present-day diversification apparently began when the modern chacma baboon, *Papio ursinus*, diverged in southern Africa *c.* 1.8 Ma and then dispersed out and speciated during the Pleistocene (Newman et al. 2004).

paracone (Gk *para* = beside or by and *konos* = pine cone) One of the terms proposed by Osborn (1888) for the main cusps of mammalian molar teeth. It is the term used for the main cusp beside (i.e., on the buccal aspect of) the **protocone** on a maxillary (upper) molar tooth crown, and it also the term used to refer to the main buccal cusp of a bicuspid upper premolar. It is part of the **trigon** component of an upper molar crown (syn. eocone, mesiobuccal cusp, tuberculum anterium externum).

paraconid (Gk *para* = beside or by and *konos* = pine cone) A term some researchers have used for an

enamel feature on a mandibular molar tooth crown more commonly referred to as a **premetaconulid**. Paraconid is one of the terms proposed by Osborn (1888) for the main cusps of mammalian molar teeth. It was given its name because it is the main cusp beside (i.e., on the lingual aspect of) the **protoconid** on a mandibular molar tooth crown, but in higher primates including hominins this main cusp has been lost. *See also* **premetaconulid**.

paracristid A term used by Schwartz and Tattersall (2002) for an **enamel crest** more commonly referred to as the **mesial marginal ridge** in a mandibular postcanine tooth crown. *See also* **mesial marginal ridge**.

parallel evolution Parallel evolution is the independent origin of similar traits in closely related taxa (e.g., the coronally rotated petrous bones seen in *Homo* and *Paranthropus* may not have been inherited from their most recent common ancestor, in which case coronally rotated petrous bones in *Homo* and *Paranthropus* would be an example of parallel evolution, or if bipedalism evolved independently in *Australopithecus afarensis* and *Australopithecus africanus*, then this, too, would be an example of parallel evolution). **Convergent evolution** is the independent origin of similar traits in distantly related taxa (e.g., the acquisition of thick-enameled teeth in orangutans and cebus monkeys). Simpson (1950) was most likely the originator of these terms, or if not he certainly was among the first to formalize them (Simpson 1961). He suggests “there is no really fundamental difference between” them (*ibid*, p. 181), and inevitably whether a trait in two taxa that are not in the same clade qualifies as an example of parallel or convergent evolution (i.e., whether the taxa are “close” or “distant”) is a subjective decision. Convergent and parallel evolution are examples of **homoplasy**, for both concern the appearance of similar morphology in two taxa that is not seen in the most recent common ancestor of those taxa. *See also* **evolution**; **homoplasy**.

paralogous genes (Gk *para*=beside and *logos*=reason) Genes formed by a **gene-duplication** event. Paralogous genes often have similar functions and they may form a series of related genes known as a **gene family** (e.g., the *HOX* gene family and the **globin** gene family). Any demonstrated **homology** between paralogous genes of the same species can be used to establish gene phylogenies.

paralogue *See* **paralogous genes**.

parameter (Gk *para*=alongside and *meter*=measure) The true, generally unknowable, population values that researchers try to estimate with sample statistics. Most statistical analyses involve collecting data on a sample whose members are part of a larger population. The statistics calculated for the sample, such as the mean, standard deviation, variance, or range, are estimates, determined with some error, of the corresponding population parameters. Paleoanthropologists can sometimes measure every known example of a trait, such as the mesiodistal length of all of the well-preserved mandibular first molars belonging to an early hominin taxon such as *Australopithecus afarensis*. However, even if the sample is large the value determined it is still not a population parameter. It is still a sample statistic for the researcher is using the known specimens as a sample to make an inference about the mean of the trait for the entire species. Many treat the terms parameter and variable as synonyms, but they are not. For example, the mesiodistal length of mandibular first molars is a variable, the mean and standard deviation of the mesiodistal length of mandibular first molars for the population of all members of the species *Pan troglodytes* are parameters, and the mean and standard deviation of the mesiodistal length of mandibular first molars as calculated for the sample of *P. troglodytes* in the **Powell Cotton Collection** are sample statistics (i.e., they are estimates of the parameters of the population of *P. troglodytes* from which the sample in the Powell Cotton Collection is drawn).

parametric statistics Statistical tests which assume that data follow particular probability distributions (e.g., **normal distribution**) to estimate **parameters** of those distributions such as the mean and **variance**. Most common statistical tests (e.g., *t* test, *F* test, **analysis of variance**, etc.) are parametric. Inappropriate use of parametric tests when data do not meet the assumptions of parametric tests will result in outcomes being subject to increased **Type I error**. In such cases one should use **nonparametric statistics**.

paramolar tubercle The anglicization of a term (*tuberculum paramolare*) used by Bolk (1915) for an enamel feature on the buccal face of the **paracone** between the tip of the paracone and the

cemento-enamel junction of a maxillary molar (syn. anticone, buccostyle ectostyle j, paramolar cusp, paramolar tubercle of Bolk, parastyle, tuberculum paramolare). *See* parastyle.

paramolar tubercle of Bolk Anglicization of the *tuberculum paramolare* of Bolk (1915). *See* paramolar tubercle.

Paranthropinae (Gk *para*=beside and *anthropos*=human being) A subfamily formally introduced by Broom (1950) for *Paranthropus crassidens* and *Paranthropus robustus*. Robinson (1972) later added *Gigantopithecus* von Koenigswald, 1935 to the list of taxa, and he widened his interpretation of the Paranthropinae to include “*Zinjanthropus*, *Meganthropus* from Java, and *Paraaustralopithecus*” (*ibid.*, p. 6). *See also* *Paranthropus*.

paranthropoid (Gk *para*=beside, *anthropos*=human being and *oides*=form, literally “*Paranthropus*-like”) A term used to suggest a specimen is *Paranthropus*-like. For example, one of the three mandibles from Tighenif (**Tighenif 1**) is substantially larger than the other two, and Briggs (1968) suggested that it belonged to a “paranthropoid” group, whereas he assigned the two smaller mandibles, Ternifine 1 and 2, to a “telanthropoid” group.

Paranthropus (Gk *para*=beside and *anthropos*=human being) Hominin genus established by Robert Broom in 1938 to accommodate the species *Paranthropus robustus*. Many researchers considered the differences between the hypodigms of *Australopithecus* and *Paranthropus* insufficient to justify a second genus for the southern African archaic hominins, so it became a junior synonym of *Australopithecus*. However, the genus *Paranthropus* has been revived by researchers who consider that *P. robustus*, *Paranthropus boisei*, and *Paranthropus aethiopicus* belong to a separate hominin clade. Species in the genus *Paranthropus* are often informally called robust or “robust” australopiths. They are characterized by postcanine megadontia, thick enamel caps on their molars and premolars, a distinctive occlusal morphology in which the cusp tips of the postcanine teeth are located towards the center of the crown, and a number of highly derived features in the cranium, and especially in the facial skeleton, generally thought to be functionally related to the generation and dissipation of high masticatory loads. Type species *Paranthropus robustus* Broom, 1938.

***Paranthropus aethiopicus* (Arambourg and Coppens, 1967) Wood and Chamberlain, 1987** (Gk *para*=beside, *anthropos*=human being, *L. australis*=southern, Gk *pithekos*=ape and *aethiopicus*=Ethiopia) A new name combination used by researchers who do not recognize *Paraaustralopithecus* as a separate genus, but who do consider pre-2.3 Ma megadont hominins from **Omo-Shungura** to belong to a species within a *Paranthropus* clade that antedates and is distinct from *Paranthropus boisei*. The hypodigm of such a species would include a well-preserved adult cranium from **West Turkana (KNM-WT 17000)** together with mandibles (e.g., KNM-WT 16005) and isolated teeth from the **Shungura Formation**; some also assign **L. 338y-6** to this taxon. The only postcranial fossil that is considered to be part of the hypodigm of *P. aethiopicus* is a proximal tibia from **Laetoli**. The fossil evidence for *P. aethiopicus* is similar to *P. boisei* except that the face of the former taxon is more prognathic, the cranial base is less flexed, the incisors are larger, and the postcanine teeth are not so large or morphologically specialized. But there is only one relatively complete *P. aethiopicus* cranium, thus the warnings of Smith (2005a) about making taxonomic inferences based on small samples are especially relevant. The only source of information about the endocranial volume of this taxon is KNM-ER WT 17000. When the new taxon *P. aethiopicus* was introduced in 1968 it was the only megadont hominin in this time range. With the discovery of *Australopithecus garhi* it is apparent that robust mandibles with long premolar and molar tooth rows are being associated with what are claimed to be two distinct forms of cranial morphology. *See also* **Laetoli**; *Paraaustralopithecus aethiopicus*.

***Paranthropus boisei* (Leakey, 1959) Robinson, 1960** (Gk *para*=beside and *anthropos*=human being, and *boisei* to recognize the help provided to Louis and Mary Leakey by Charles Boise) For researchers who support the hypothesis that *Australopithecus robustus* and *Australopithecus boisei* are sister taxa it makes sense to revive the genus *Paranthropus* as a way of recognizing that clade. In which case *Zinjanthropus boisei* Leakey, 1959 that became *Au. boisei* (Leakey, 1959) Tobias, 1967a would become *Paranthropus boisei* (Leakey, 1959), a combination first used by Robinson (1960). *P. boisei* has a comprehensive craniodental fossil record. There are several skulls (the one from **Konso** being especially complete and well preserved), several well-preserved crania, and many mandibles and

isolated teeth. There is evidence of both large- and small-bodied individuals, and the range of the size difference suggests a substantial degree of body-size sexual dimorphism. *P. boisei* is the only hominin to combine a massive, wide, flat, face, massive premolars and molars, small anterior teeth, and a modest endocranial volume (mean *c.*480 cm³). The face of *P. boisei* is larger and wider than that of *P. robustus*, yet their brain volumes are similar. The mandible of *P. boisei* has a larger and wider body or corpus than any other known hominin, and the tooth crowns apparently grow at a faster rate than has been recorded for any other early hominin. There is, unfortunately, no postcranial evidence that can with certainty be attributed to *P. boisei*, but some of the postcranial fossils from Bed I at Olduvai Gorge currently attributed to *Homo habilis* may belong to *P. boisei*. The fossil record of *P. boisei* extends across about 1 million years of time during which there is little evidence of any substantial change in the size or shape of the components of the cranium, mandible, and dentition (Wood and Constantino 2007). First discovery OH 3 (1955). Holotype OH 5 (1959). Paratypes None. Main sites Chesowanja, Konso, Koobi Fora, Malema, Olduvai Gorge, Peninj (Natron), Shungura Formation, West Turkana. *See also* *Zinjanthropus boisei*.

***Paranthropus crassidens* Broom, 1949** (Gk *para*=beside, *anthropos*=human being, and *L. crassus*=dense) Hominin species introduced by Robert Broom in 1949 to accommodate SK 6, an adult mandible recovered at Swartkrans from breccia now believed to be derived from Member 1. Broom opted for the new species name because he considered the Swartkrans teeth to be similar to those of “the Kromdraai ape-man *Paranthropus*” but he argued that the new finds deserved their own species name because “they are much larger and differ in a number of respects” (Broom 1949, p. 57). He thus assigned it to a new species, *Paranthropus crassidens*. Some researchers have supported the distinction between the Swartkrans and Kromdraai hypodigms (e.g., Grine’s 1984 careful analysis of the morphology of the deciduous teeth), but most researchers do not now make a specific distinction between the hypodigms, thus *P. crassidens* is now regarded as a junior synonym of *Paranthropus robustus*. First discovery SK 2 (1948). Holotype SK 6. Main site Swartkrans (Mbs 1, 2, and 3). *See also* *Paranthropus robustus*; *Paranthropus robustus crassidens*.

***Paranthropus palaeojavanicus* (von Koenigswald, in Weidenreich, 1945)** (Gk *para*=beside, *anthropos*=human being, *palaios*=ancient, and *L. javanicus*=from Java). A new combination first used by Robinson (1954a). He proposed that the taxon *Meganthropus palaeojavanicus* was a “good” species, but he suggested that *Meganthropus* was not a “good” genus. So he (*ibid*, p. 196) formally proposed the species *M. palaeojavanicus* be transferred to the genus *Paranthropus*. *See also* *Meganthropus*; *Meganthropus palaeojavanicus*; *Paranthropus*.

***Paranthropus robustus* Broom, 1938** (Gk *para*=beside, *anthropos*=human being, and *L. robus*=oak or strength) Hominin species established by Robert Broom to accommodate fossil hominins recovered in 1938 from what was then referred to as the “Phase II Breccia” (now called Member 3) at Kromdraai B, in Gauteng, South Africa. The fossil record is less numerous than that of *Australopithecus africanus*. The dentition is well represented, some partial crania are well preserved, but most of the mandibles are crushed or distorted. The postcranial skeleton is not well represented. Research at Drimolen was only initiated in 1992 yet already more than 80 hominin specimens have been recovered and it promises to be a rich source of evidence about *P. robustus*. The brain, face, and chewing teeth of *Paranthropus robustus* are larger than those of *Au. africanus*, yet the incisors and canines are smaller. The crania of *P. robustus* include specimens which have ectocranial crests, whereas there are no *Au. africanus* crania with unambiguous crests. What little is known about the postcranial skeleton of *P. robustus* suggests that the morphology of the pelvis and the hip joint is much like that of *Au. africanus*. It was most likely capable of bipedal walking, but most researchers subscribe to the view that *P. robustus* was not an obligate biped (but see Susman 1988a). It has been suggested that the thumb of *P. robustus* would have been capable of the type of grip necessary for stone tool manufacture, but this claim is not accepted by all researchers. Most researchers subsume *Paranthropus crassidens* Broom, 1949 recovered from Swartkrans into *P. robustus*, but Robinson (1954a, p. 198) suggested that it be regarded as a subspecies of *P. robustus*. First discovery TM 1517 (1938). Holotype As above. Main sites Cooper’s, Drimolen, Gondolin, Kromdraai (Mb 3), Swartkrans (Mbs 1, 2, and 3). *See also* *Paranthropus*; *Paranthropus robustus crassidens*.

***Paranthropus robustus crassidens* Broom, 1949** (Gk *para*=beside, *anthropos*=human being, and L. *robustus*=oak or strength and *crassus*=dense) A new combination first used by Robinson (1954a). Robinson (1954a, p. 198) formally proposed that the Swartkrans part of the *Paranthropus robustus* hypodigm be regarded as a subspecies of that taxon. *See also Paranthropus robustus*.

***Paranthropus robustus robustus* Broom, 1938** (Gk *para*=beside, *anthropos*=human being, and L. *robustus*=oak or strength) A new combination first used by Robinson (1954a). Robinson (1954a, p. 196) formally proposed that the Kromdraai part of the *Paranthropus robustus* hypodigm be regarded as a subspecies of *P. robustus*. *See also Paranthropus; Paranthropus robustus*.

parapatric speciation A mode of speciation in which a new species evolves when part of a species population colonizes a new ecological niche in a geographical zone adjacent to that of the “parent” species. Unlike **allopatric speciation** there is not a physical boundary separating the parent and “daughter” populations, but because these two populations are subject to different selective pressures the hybrid individuals resulting from mating between the populations experience reduced fitness. Over time, this reduces **gene flow** between the populations and favors mating within each population. This effect, in combination with **natural selection** affecting each population in different ways, can lead to the two populations becoming reproductively isolated.

parapatry (Gk *para*=beside and *patris*=fatherland) Two organisms with adjacent but not significantly overlapping geographic ranges (or, if their ranges do overlap, there is only a small contact zone) are described as being parapatric (e.g., most extant baboon species are parapatric). In parapatric speciation, there is usually a physical barrier between populations and new species arise from contiguous (adjacent) populations. It may also occur when a subpopulation of the parent population moves into an area with a different environment and thus different selective pressures, causing a selective advantage for traits that differ from those seen in the majority of the parent population. This can cause **clinal variation** and eventually divergence and speciation. Interbreeding between populations occurs at

hybrid zones where the populations meet, but because there is no significant gene flow between the populations the populations maintain their unique characteristics. Using a baboon analogy, Jolly (2001) has suggested that hybrid zones were important in creating diversity and hence speciation within *Homo*. *See also reticulate evolution; speciation*.

paraphyletic An adjective used to describe a taxon that is part of a **paraphyletic group**. *See paraphyletic group*.

paraphyletic group (Gk *para*=beside and *phulon*=a class) A taxonomic grouping that includes only part of a **clade** or **monophyletic group**. For example, if the term “great apes” is used to refer to a group that includes chimpanzees, gorillas, and orangutans, then the term refers to a paraphyletic group. This is because there is sound evidence that the clade structure of those taxa is (((*Homo, Pan*) *Gorilla*) *Pongo*). Thus, there is no clade made up of *Pan*, *Gorilla*, and *Pongo* that does not include *Homo*.

paraphyly The state of a taxonomic group that is paraphyletic. *See paraphyletic group*.

parasagittal crests (Gk *para*=beside, L. *sagitta*=an arrow and L. *crista*=cock’s comb, or a tuft of feathers, in the midline of a bird’s head) A term usually used for two sharp crests of bone running either side of the inter-parietal, or sagittal, suture. The bony crests form when the medial borders of the fascia covering the temporalis muscles are raised up. In extant hominoids the interval between the crests is occupied by fat and small blood vessels. *See also sagittal crest; sagittal keel*.

parastyle A term introduced by Osborn (1892) for an accessory cusp located mesiolingual to the **paracone** of a maxillary molar. It has been used to describe an equivalent feature on the crowns of fossil hominin teeth (e.g., Robinson 1956); Grine (1984) refers to a similar structure as the **mesiostyle**. Parastyle has also been used by some researchers (e.g., Scott and Turner 1997) for a different enamel feature on the buccal face of the paracone more commonly referred to as the **paramolar tubercle**. *See also mesiostyle, mesial accessory tubercle, paramolar tubercle*.

paratype (Gk *para*=beside and *typus*=image) Specimens other than the **holotype** listed in the original description of a taxon.

Paraustralopithecus Arambourg and Coppens, 1968 (Gk *para*=beside, L. *australis*=southern, and Gk *pithekos*=ape) Hominin genus established by Camille Arambourg and Yves Coppens (1967) to accommodate the type species *Paraustralopithecus aethiopicus*. The genus *Paraustralopithecus* is now regarded as a junior synonym of either *Australopithecus* or *Paranthropus*. Type species *Paraustralopithecus aethiopicus* Arambourg and Coppens, 1967. *See also Paraustralopithecus aethiopicus* Arambourg and Coppens, 1967.

Paraustralopithecus aethiopicus Arambourg and Coppens, 1968 (Gk *para*=beside, L. *australis*=southern, Gk *pithekos*=ape, and *aethiopicus*=Ethiopia) Hominin species established by Camille Arambourg and Yves Coppens to accommodate a mandible Omo 18-1967-18 from the Shungura Formation, Omo region, Ethiopia. Subsequently Howell (1978a) assigned the holotype mandible to *Australopithecus africanus* (thus making *Paraustralopithecus aethiopicus* a junior synonym of *Au. africanus*), and Coppens (1980) implied the species should be sunk into *Australopithecus boisei* (*see Paranthropus boisei*), but others have assigned pre-2.3 Ma megadont fossils from the Shungura Formation and West Turkana (e.g., KNM-WT 17000) to either *Australopithecus aethiopicus* or *Paranthropus aethiopicus*. When *Para. aethiopicus* was introduced in 1967 it was the only megadont hominin in this time range. With the discovery of *Australopithecus garhi* it is apparent that robust mandibles with long premolar and molar tooth rows are being associated with what are claimed to be two distinct forms of cranial morphology. First discovery Omo 18-1967-18 (1967). Holotype As above. Main sites Omo-Shungura, West Turkana. *See also Paranthropus aethiopicus*.

parazone (Gk *para*=beside and *zone*=girdle) The region of a Hunter-Schreger band which, when a tooth is cut longitudinally, shows enamel prisms running parallel to this plane of section. Gustav Preiswerk (1895) was the first to define and name parazones, diazones, and perikymata in his thesis on the microstructure of ungulate enamel (Pickerill 1913, Osborn 1990) (ant. diazone). *See also* decussation.

parcellation A term used in neuroscience to refer to the subdivision of the cerebral cortex into anatomically distinct regions by virtue of cytoarchitecture, chemoarchitecture, or the pattern of connectivity. It was an early version of parcellation that Brodmann used to divide the cerebral cortex into the cytoarchitectonically-distinctive **Brodman's areas**. *See also* Nissl stain.

parent/offspring conflict According to Trivers (1974), since parents share an equal genetic relationship with all of their offspring, they should divide their investment evenly among those offspring. However, it is in the offspring's interest to get the parents to focus investment on them. A branch of parent/offspring conflict theory, called maternal/fetal conflict, examines the conflicting interests of mothers and fetuses during gestation, where the placenta plays a large role in trying to extract more resources from the mother than she would otherwise be willing to give (Haig 1993). This type of conflict can be manifested in ways such as decreasing maternal sensitivity to insulin so that more blood sugar is available to the fetus, and increasing maternal blood pressure so that a greater blood supply is available to the fetus.

parental effects *See* genomic imprinting; heritability.

parental investment Any investment by a parent in an individual offspring that increases the offspring's chance of survival (and hence reproductive success) at the cost of the parent's ability to invest in other offspring (Trivers 1972). Parental investment is usually unbalanced between the sexes, and the sex that invests the most in offspring is thought to be the more discriminating sex when it comes to finding a mate. Aspects of parental investment in modern humans and nonhuman primates include gestation, lactation, carrying of offspring, food provisioning, and protection. In most primates, females are the higher-investing sex, although callitrichines and some modern human populations show significant male parental investment.

parietal art *See* art.

parietal lobe One of the four main subdivisions of the cerebral cortex of each cerebral hemisphere. It is located between the frontal lobe anteriorly and the occipital lobe posteriorly. The

parietal lobe is involved in processing information about somatic sensation, body position, attention, visual and spatial relations, and **language**. The parietal lobe contains the primary somatosensory cortex, which lies on the postcentral gyrus.

parietal-occipital plane In some crania (e.g., OH 5) the external aspect of the squamous part of the occipital bone and the external aspect of the posterior part of the **parietal bones** form a continuous flat surface which is referred to as the parietal-occipital plane, or planum.

pars mastoidea *See* mastoid process.

pars opercularis *See* Broca's area.

pars orbitalis *See* Broca's area.

pars triangularis *See* Broca's area.

parsimony (*L. parsimonia* = frugality) The principle stating that the most economical explanation is the one that should be adopted in the first instance; it is the equivalent of **Occam's razor**. For example, in **phylogenetic systematics** the parsimony principle means that the **cladogram** that involves the fewest evolutionary changes (i.e., the fewest character state changes) is the one that should be preferred.

partial volume averaging One of several technical problems involved in the data-acquisition stage of **computed tomography** (or CT). The problem arises due to the combination of "finite slice collimation" and the different beam widths used in imaging structures that consist of different tissues each of which may have its own **attenuation value**. These different values may contribute to a single measurement made during the scanning process. The effect of mixing different tissues during the scanning measurements is that the resulting CT number is not the average of the attenuation coefficients of the different tissues. The CT reconstruction process is a nonlinear one, which means that mixing tissues before the logarithm is taken will result in a value that is different from the one that would be generated if the tissues were mixed after the logarithm has been taken. Partial volume averaging can result in erroneous CT numbers, and/or streaks (called artifacts) in the CT image. *See also* **computed tomography**.

PARU Acronym for the Palaeo-Anthropology Research Unit within the **Witwatersrand University Department of Anatomy**. *See* **Palaeo-Anthropology Research Unit**.

passive scavenging A carcass transport strategy defined as the culling of small amounts of meat or marrow from animal carcasses heavily ravaged and abandoned by their initial predators. Opportunistic passive scavenging has been documented ethnographically in some hunter-gatherer groups (e.g., the Hadza), although a carcass acquisition strategy characterized by obligate passive scavenging of terrestrial mammals is considered to be outside the range of modern human behavior.

pastoralist (*L. pastor* = a shepherd) Mobile societies that rely on livestock as a food source, which are driven to move seasonally in search of forage and water. Pastoral systems based on the herding of domesticated or partially domesticated animals arose 10,000–12,000 years BP, approximately at the same time as crop domestication. Worldwide, the most common animals herded by pastoralists are sheep, goats, cattle, horses, donkeys, camels, reindeer, and yaks. Economically, pastoralism is viable in regions too arid for the planting of crops, and pastoralists frequently control their ecosystems by using fire to limit the growth of trees and to rejuvenate pasture. The degree of mobility in pastoralist societies varies. In nomadic pastoralist societies, entire households move up to several hundred kilometers with their herds, living in impermanent, easy-to-construct shelters such as tents. Transhumance pastoralists frequently move seasonally between two locations, such as a cool, high-altitude valley in the summer and a warm, lower-altitude valley in the winter. Housing may be more permanent in the case of transhumance pastoralists for only a subset of the household may be actively involved in livestock management. Milk, blood, meat, skin, and dung are common products of pastoral societies, but wool or hair can be important as well. Agriculturalists and pastoralists frequently develop extensive regional trade networks to exchange goods, and historically competition for land has often led to conflict between pastoral and agricultural groups.

pattern *See* mode.

PAUP Acronym for Phylogenetic Analysis Using Parsimony. PAUP is a computer software program written by David Swofford (Swofford 2003) that is

widely used to perform cladistic analysis. Typically, PAUP is used to find the most parsimonious tree or cladogram implied by a given character state data matrix. It also is capable of performing statistical tests designed to assess the stability of cladograms and of the clades contained within them (e.g., the **bootstrap** and the **jackknife**); PAUP* 4.0 includes maximum likelihood and distance methods.

Pauphadhi One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Paviland *See Homo sapiens*; radiocarbon dating.

Pavlov (Location 48°52'N, 16°40'E, Czech Republic; etym. named after a nearby village) History and general description A series of five open-air loess sites on the base of the northern slopes of the Pavlovské Hills above the Dyje River floodplain, that are labeled Pavlov I–VI. These sites are closely associated with the nearby **Dolní Věstonice** sites, which are located about 500 m away; Pavlov I is the largest and most complex. Systematic excavations at Pavlov I and II were conducted from 1952 intermittently until 1972. Pavlov VI was discovered and excavated in 2007. The sites have yielded archeological and hominin skeletal remains, including a ritual burial. Temporal span and how dated? Calibrated radiocarbon dating of charcoal has provided a date of **Oxygen Isotope Stage 3** (c.26–29 ka). Hominins found at site Associated skeleton (Pavlov 1), maxilla (Pavlov 2), two mandibles (Pavlov 3 and 4), and isolated teeth (Pavlov 5–28). Archeological evidence found at site An **Upper Paleolithic** (Gravettian) stone tool assemblage, clay figurines, and remains of dwelling structures. Key references: Geology, dating, and paleoenvironment Joris and Weninger 2004; Hominins Vlček 1971, Trinkaus and Svoboda 2005; Archeology Klima 1954, 1959, Svoboda 1997, 2005. *See also Dolní Věstonice I.*

PCA *See principal components analysis.*

PCR Acronym for **polymerase chain reaction** (*which see*).

PCSA Abbreviation of the physiological cross-sectional area of a muscle. This measure provides an

estimate of the **force** a muscle can generate, and it is used in models that attempt to estimate the efficiency of different modes of locomotion (e.g., Pontzer et al. 2009).

PCSBM Acronym for **portable confocal scanning optical microscope** (*which see*).

pdf Acronym for **probability density function** (*which see*).

PDL Acronym for **periodontal ligament** (*which see*).

peak growth velocity In modern humans, after a period of latency during the childhood and juvenile life history phases, the **adolescent growth spurt** is initiated. Peak growth velocity is the point at which growth velocity reaches its maximum during this period. It occurs approximately 1 year prior to onset of menarche in girls, which is distributed across a wide range of chronological ages. Following peak growth velocity, growth velocity decreases rapidly in mass, and particularly in linear dimensions since increasing levels of sex steroids act to facilitate epiphyseal closure.

Pech de l'Azé (Location 44°51'29"N, 1°15'14"E, France; etym. the name derives from Languedoc, meaning roughly Donkey Hill. Note that the accent on the final e is not pronounced). History and general description The site consists of four adjacent localities, numbered I, II, III, and IV, in a small tributary of the Dordogne River in southwest France. Pech de l'Azé I and II are opposite ends of a tunnel-shaped cave and Pech III is a very small cave 30 m west of Pech II; Pech IV is a collapsed cave 80 m east of Pech I. Pech I was first excavated in the 19thC, but it was in 1909, at the entrance of the cave, that Capitan and Peyrony recovered the remains of a *Homo neanderthalensis* child associated with a Mousterian of Acheulean Tradition (or MTA) assemblage. Bordes excavated the site from 1949 to 1951 and again from 1970 to 1971; Soressi most recently excavated there in 2004–5. Bordes discovered Pech II while working at Pech I, and excavated there at times between 1950 and 1969. Pech IV was also discovered by Bordes, tested by Mortureux between 1953 and 1956, excavated by Bordes between 1970 and 1977, and excavated by Dibble and McPherron between 2000 and 2003. Temporal span

and how dated? Pech I, II, and IV contain Middle Paleolithic industries; Pech III contained a small assemblage that was attributed to the Acheulean and the lower portion of the Pech II sequence is attributed to the Acheulean. **Electron spin resonance spectroscopy (ESR) dates** on Pech II show two periods of deposition: one in **Oxygen Isotope Stage (OIS) 6** and the other starting in late OIS 5 through to *c.*40 ka. The Pech I industries consist only of MTA, and recent ESR and AMS radiocarbon dates on Pech I show the deposits to date to *c.*51–41 ka and a reanalysis of the stratigraphic association of the *H. neanderthalensis* remains places them in this same time range. The Pech IV sequence was thought to overlap with the upper portion of the Pech II sequence and the Pech I sequence. **Thermoluminescence dating** results from the base of Pech IV suggest an age of 100 ka. **Hominins found at site Pech de l'Azé 1** (from Pech I) is a hominin partial cranium and mandible of a young child; an isolated tooth from another young individual has also been published. Isolated teeth are known from Pech IV. **Archeological evidence found at site Pech IV** is the type site for the Asinipodian (Latin Pech de l'Azé), a Middle Paleolithic industry dominated by small flake production. Aside from their stone tool industries, fauna are well preserved at Pech I, II, and IV. Pech I and IV have evidence for the use of fire. Pech I and IV also have abundant pieces of worked manganese dioxide. Key references: Geology, dating, and paleoenvironment Grun and Mellars 1991, Soressi et al. 2007; Hominins Maureille and Soressi 2000; Archeology Bordes 1972, McPherron and Dibble 2000, Soressi et al 2008, Dibble et al. 2009b.

Pech Merle (Location 44°40'27"N, 1°38'40"E, France; etym. Occitan *pech*=hill; *merle* is unknown) **History and general description** This extensive cave site near the village of Cabarets, France, has been known for its paintings since at least 1926. It is one of the few sites with cave paintings that is currently open to the public. **Temporal span and how dated?** Stylistic features of the artwork make it likely from the Gravettian period. **Radiocarbon dating** of the pigments has provided an age of *c.*25 ka. **Hominins found at site** None. **Archeological evidence found at site** Many fragmentary faunal remains, and rare pieces of engraved art on bones. Key references: Geology, dating, and paleoenvironment Lorblanchet et al. 1995; Hominins N/A; Archeology Lemozi 1922, 1929, Lemozi et al. 1969, Faurie 1999.

pectoral girdle (L. *pectoralis* from *pectus*=breast and ME *girdle*=sash) The bones by which the proximal part of the upper limb is attached to the axial skeleton. The pectoral girdle, which comprises the scapula and clavicle, is part of the postcranial skeleton.

pedal digit *See also* digit; foot.

pedal ray *See also* foot; ray.

pedigree A chart showing the relationships among individuals in a family. In genetics, pedigrees are used to show the phenotypes of related individuals. These have been important for identifying the pattern of inheritance of normal traits (i.e., whether a trait is X-linked or autosomal) and genetic diseases.

pedogenic (Gk *pedon*=Earth and *genos*=birth) Refers to the characteristic structure, color, mineralogy, and horizontal zonation characteristics of soils in the process of being formed. Pedogenic carbonate is a mineral precipitate formed in the subsurface (or B) horizon of a soil as the result of the supersaturation of the soil solution with respect to carbonate minerals (generally calcite). The mechanisms that drive precipitation of carbonate minerals (i.e., evaporation and degassing of carbon dioxide produced by respiration) are most pronounced in arid to semi-arid conditions, and thus pedogenic carbonate is most commonly found in such environments. The nodules and rhizoliths it contains preserve the carbon and oxygen stable-isotopic signatures during the time of soil formation and thus in ancient soils they can be used as a proxies to reconstruct paleovegetation, paleoclimate, and paleoenvironment. *See* C₃ and C₄.

pedomorphic (Gk *paid*=child and *morph*=form) *See* pedomorphosis.

pedomorphosis Gk *paedo*=child and *morph*=form) A term introduced by Walter Garstang in 1922, pedomorphosis refers to a category of resultant morphologies that follow from three different kinds of heterochronic processes (time hypomorphosis, rate hypomorphosis, or neoteny). All of these processes produce, in varying ways, descendants with ancestral juvenile characteristics or shapes retained during later stages of ontogeny. Since the juvenile features are shifted to the

adult, there are no “new” pedomorphic morphologies. *See also* **hypomorphosis**; **neoteny**.

Peers Cave *See* **Fish Hoek**.

Pei, Wenzhong [裴文中] (1904–82)

Wenzhong Pei (also spelled Wen-chung P'ei), who was born in Lauxian (now Fangnan) in Hebei Province in northern China, entered Beijing University in 1921, and joined the Geology Department in 1923 where he specialized in paleontology. After completing his degree in 1927 he was offered a position with the **Geological Survey of China** by Wenhao Weng, its director. Weng and the Geological Survey had just completed an agreement with the Canadian anatomist Davidson **Black** of the **Peking Union Medical College** in Beijing on a collaborative effort to study China's Cenozoic deposits. They were focusing their efforts at a particularly rich fossil site called Choukoutien (now called **Zhoukoudian**), where the Austrian paleontologist Otto **Zdansky** had found modern human-like (as opposed to ape-like) teeth as part of a diverse Pleistocene fauna. When Anders Bohlin found yet another tooth in 1927, Black realized its significance and announced the discovery of a hitherto unknown species of hominin he called *Sinanthropus pekinensis* (now *Homo erectus*). Pei joined the excavations at Zhoukoudian in 1928 and in 1929 he was made the field supervisor. In December 1929 Pei discovered the first complete *Sinanthropus* calotte, and in 1930 he began to find quartz artifacts in the same sediments that had yielded the *Sinanthropus* remains. A year later Pei and Black found charred bone and other evidence that was interpreted as evidence that *Sinanthropus* had used fire. Over the next several years more cranial and postcranial fossils were discovered, along with large quantities of animal fossils. After Davidson Black's death in 1934 the German physical anthropologist Franz **Weidenreich** was appointed to direct the **Cenozoic Research Laboratory**, which had been established by Black and Wenhao Weng in 1929 to oversee excavations at Zhoukoudian and other sites. In 1925 Pei had begun to study archeology in Paris with the prominent French prehistorian Henri Breuil, but he did not complete his doctorate until 1937. Little excavating could be done during the war years, so between 1937 and 1948 Pei devoted much of his time to studying the extensive collection of archeological and paleonto-

logical material housed at the Cenozoic Research Laboratory, while also lecturing on prehistoric archeology at Beijing University and Yanjing University. With Weidenreich's departure from China in 1941, Pei became the director of the Cenozoic Research Laboratory. When the People's Republic of China was established in 1949, Pei was named head of the museum's division of the Bureau of Social and Cultural Affairs within the Ministry of Culture. He remained in this post until 1953 and in the following year was appointed a researcher in the Chinese Academy of Sciences' **Institute of Vertebrate Paleontology and Paleoanthropology** (or **IVPP**), the successor institution to the Cenozoic Research Laboratory. At the IVPP Pei organized research programs in human paleontology and paleolithic archeology and directed excavations at a number of Chinese prehistoric sites. Pei's excavations during the mid-1950s at Dingcun and Guanyindong transformed archeologist's understanding of the Paleolithic in China, and he also made the first survey of the Mesolithic in China. In 1963 Pei became the director of the Paleanthropological Research Laboratory, a section of the IVPP, and in 1979 he was appointed chairman of the Beijing Natural History Museum. Pei remained at the IVPP and continued to teach and conduct research until his death in 1982.

Peking Man The informal name given to the taxon represented by the fossil hominin remains recovered from Locality 1 in the Zhoukoudian Lower Cave, a site not far from Peking. The remains were initially assigned to *Sinanthropus pekinensis*, but early in 1940 Wilfrid **Le Gros Clark** transferred them to *Pithecanthropus erectus* and later that year Franz **Weidenreich** formally suggested that taxon be a junior synonym of *Homo erectus*. *See also* *Homo erectus*; **Zhoukoudian**.

Peking Union Medical College (or **PUMC**)

The college that grew out of the activities of the London Missionary Society. The China Medical Board of the **Rockefeller Foundation** began its support of PUMC in 1915 and carried on doing so until 1936. The **Cenozoic Research Laboratory** was established at the PUMC in 1929, and in a joint effort with the **National Geological Survey of China**, it organized the excavations at Choukoutien (now called **Zhoukoudian**). Both Davidson **Black** and after him Franz **Weidenreich** headed the Department of Anatomy at the PUMC

and during their tenures the college became a focus for paleoanthropological research in China. During the Cultural Revolution the PUMC was re-named the “Capital University of Medical Sciences,” but in 1979 it resumed activity under its old name and it is still in operation.

pelvic girdle (L. *pelvis*=basin and ME *girdle*=sash) The pelvic girdle, which is part of the postcranial skeleton, comprises the bones that form the pelvis (i.e., the two pelvic bones and the sacrum).

pelvis The pelvis surrounds the birth canal and provides attachments for the propulsive muscles of the hindlimb, the muscles of the anterior abdominal wall, as well as the muscles that move and support the spine. Its shape reflects the overall shape of the torso. The pelvis is formed by the sacrum and two pelvic, or hip, bones and because it forms a complete bony ring the three components are called the pelvic girdle. The pelvic bone is still sometimes referred to as the innominate bone, but this is obsolete terminology. Each adult pelvic bone is formed from three component bones – the ilium, ischium, and pubis – which fuse during early childhood to form the single pelvic bone. The ilium is the broad, cranial portion, the pubis the ventral portion that meets in the midline, and the ischium the dorsal and caudal portion; all three contribute to the acetabulum, or hip joint socket. All three also border the large obturator foramen, which is covered in life by a fibrous membrane except for a small gap that transmits a nerve and blood vessels. The hip joint is a large, synovial ball-and-socket joint capable of flexion/extension, abduction/adduction, rotation, and circumduction. The articular surface is c-shaped and it is referred to as the lunate surface. The sacroiliac joints are synovial anteriorly but posteriorly each pelvic bone is bound to the sacrum by strong ligaments. There is little movement at these joints, but what slight movement there is (known as nutation) is important for dissipating stresses during bipedal locomotion (Lovejoy 2005). The other joint between the pelvic bones is ventrally between the two pubes. This is a symphyseal joint, with the articulating surfaces covered by hyaline cartilage with interposed fibrocartilage. This joint is normally not mobile, although it may expand slightly due to the influence of hormones during parturition. Locomotor adaptation is the chief determinant of variation in pelvic form among

primate species. Monkeys tend to have narrow pelvises that are short craniocaudally, which is directly related to their long, flexible lumbar spine that they use during pronograde walking and running. Apes, and especially great apes, have craniocaudally elongated pelvises consistent with their shortened lumbar vertebral column and stiff torso, which provides stability for hoisting the body up during arm-hanging and climbing (Waterman 1929). The orientation of the iliac blades of the great apes generally tracks that of the rib cage. Apes have a broad rib cage and shoulder joints facing laterally, and correspondingly reoriented, dorsally-rotated, iliac blades. Monkeys, and basal hominoids such as *Proconsul* (Ward 1993), retain narrow iliac blades that face more laterally, which is consistent with their narrow thoracic cage and ventrally facing shoulder joints. The modern human pelvis is shorter and broader than in any other extant primate. The wide modern human sacrum accommodates the widely set vertebral zygapophyses in the lumbosacral region, which are necessary for upright posture and human lumbar lordosis. The expanded iliac blades of the modern human pelvis are rotated so that the external surface faces partly laterally; it is on this surface that the lesser gluteal musculature (gluteus minimus and medius) originates. These muscles abduct the femur at the hip joint and keep the pelvis level during the single support phase of modern human bipedal gait; only modern humans among the great apes have this abductor mechanism, and it is a critical component of our bipedal adaptation (Lovejoy 1988). This iliac form also places the abdominal oblique muscles in a position to wrap around the abdomen and assist in the lateral pelvic rotation that is part of the bipedal gait of modern humans. The iliac blades of *Australopithecus* tend to be more horizontal and more widely flared than those of *Homo*. With the expansion of the size of the pelvic inlet in *Homo* to accommodate larger-brained neonates, the acetabulae became more widely set and the ilia more vertical. The acetabulocrystal buttress has become more pronounced and the portion of the ilium anterior to this buttress became expanded as well. The part of the ilium dorsal to the sacroiliac joints is expanded in modern humans and provides a large area of attachment for the erector spinae musculature. The large acetabulum of modern humans provides increased an articular area for load transmission through the hip, something not

found in *Australopithecus* and perhaps some early *Homo* individuals probably because of the altered geometry of their pelves (Ruff 1995). However, in all hominins the acetabulum is inclined anteriorly and inferiorly, thus maximizing the articular area for axial load transmission in bipedal posture, but this orientation also limits the range of hip abduction. Hominins all also have short, retroflexed ischia, which allow the hamstring muscles the leverage to assist in extending the thigh in bipedal postures (McHenry 1975). This contrasts with the ischia of great apes and New World monkeys, which are elongated and dorsally directed, thus providing maximum leverage when the thigh is flexed during quadrupedal locomotion and in climbing postures. In modern humans, because of the tight relationship between fetal head size and the pelvic inlet, male and female pelves are sexually dimorphic. As such, the sex of a skeleton can be determined with a fair degree of accuracy from the form of the pelvic bone. Because of the wider set of the hip joints and the wider pelvic inlet in modern human females, the angle between the caudal rami of the pubes is wider than in males, and their internal margins are everted, forming a lip that flares ventrally. Another region that is broader in females than males is the greater sciatic notch along the dorsal margin of the pelvic bone between the sacroiliac joint area and the spine of the ischium. Sometimes, due to stretching of ligaments during pregnancy, small bony scars develop adjacent to the sacroiliac joints anteriorly and caudally. In modern humans, the pelvic inlet is broader mediolaterally than anteroposteriorly (i.e., it is platypelloid), whereas the opposite proportions are found at the outlet. As a consequence, in modern humans the neonatal head rotates during the birth process; *Australopithecus* and early *Homo* pelves appear to be platypelloid at both the inlet and the outlet and would not have had a rotational birth mechanism (Tague and Lovejoy 1986, Simpson et al. 2008). Climate influences pelvic shape in modern humans because body breadth heavily influences surface-area-to-volume ratios, thus affecting a body's capacity for radiating heat. Tropical peoples tend to have narrower pelves than those in more northern latitudes, with members of *Homo neanderthalensis* having the broadest pelves of all (Ruff 1991). Neanderthals also have particularly long, thin pubic rami, which also would have projected further ventrally than those of modern humans; this may be related to the shape of their torso (Rak and Arensburg 1987). *See also lumbar vertebral col-*

umn; scapula, evolution in hominins; sexual dimorphism.

penetrance The proportion of individuals with a specific genotype that express a specific phenotype. For example, people who have a faulty copy of the *Huntington* gene have a 100% chance of being affected by Huntington's disease (i.e., the penetrance is 100%), while those who have faulty copy of the *HMBS* (or hydroxymethylbilane synthase) gene have only a 10–20% chance of being affected by acute intermittent porphyria (i.e., 10–20% penetrance). Penetrance may be affected by the environment or by the effects of other genes.

Peninj (Location 2°50'S, 35°40'E, Tanzania; etym. refers to the Maasai name for the local river, also referred to as Binini or Pinyini) History and general description The site located west of Lake Natron and near the boundary between Kenya and Tanzania was first noticed from the air but it was initially explored on foot in January 1964 by Richard Leakey and then later that year by an expedition jointly led by Leakey and Glynn Isaac. The Peninj sediments were deposited in three different alluvial environments: one was within a delta not far from a lake (the Type section), the second at the beginning of an alluvial fan (the Southern escarpment), and the third was along the course of the Peninj River at the foot of the Sambu volcano (the Northern escarpment). Temporal span and how dated? Several stratigraphic intervals are represented in the Peninj exposures. The basement is made up of the Sambu lavas, overlaid by the Hajaro Formation, which is divided into two members: the Hajaro Beds and the Hajaro lavas. Overlying the Hajaro Formation is the Humbu Formation. This 40 m unit is divided into three members: the Basal Sands with Clays (BSC), the Main Tuff Limestone basaltic unit, and the Upper Sands with Clays (USC). Overlying the Humbu Formation is the Moinik Formation, with the Clay and Trachytic Tuff member and capped by the Upper Tuff member. Potassium-argon dating and argon-argon dating of the sequence suggest the following dates (their uncertainty is due to anagenetic modification of minerals): Sambu lavas (2.5–2 Ma), the base of BSC (1.7 Ma), Main Tuff (1.9–1 Ma, with an intermediate range of 1.6–1.4 Ma), base of Moinik Formation (1.3 Ma). Hominins found at site The only hominin fossil, discovered in 1964, consists of a well-preserved and

fairly complete mandible (**Peninj 1**). Archeological evidence found at site Two Acheulean sites (PEEN1 and PEES2, formerly RHS and MHS, respectively) were initially discovered and excavated by Isaac (Isaac 1967). Some Oldowan localities were later excavated, among which the most important is ST4 (Domínguez-Rodrigo et al. 2009). Key references: Geology, dating, and paleoenvironment Isaac 1967, Curtis 1974, Manega 1993, Domínguez-Rodrigo et al. 2009; Hominins Leakey and Leakey 1964; Archeology Isaac 1967, Domínguez-Rodrigo et al. 2009.

Peninj 1 Site Peninj. Locality Type section (Isaac 1967, Map 2). Surface/in situ *In situ*. Date of discovery January 11, 1964. Finder Kamoya Kimeu. Unit/horizon Initially reported as “clayey sands and sandy grit” layer beneath “ostracod and gastropod limestone” (Isaac 1967, Fig. 1), but now Basal Sands with Clays (BSC). Bed/member N/A. Formation Humbu Formation. Group N/A. Nearest overlying dated horizon Main tuff, 1.6–1.4 Ma (Isaac and Curtis 1964), but recent research suggests this may be *c.*1.3 Ma. Nearest underlying dated horizon TBS-1 basalt from the BSC, 1.7 Ma. Geological age Between *c.*1.5 and 1.3 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Apart from many cracks in the surface bone and the lack of the coronoid process on the right side and the condyle and the coronoid process on the left side the mandible is complete. All of the teeth are in place in the mandible. Announcement Leakey and Leakey 1964. Initial description Tobias 1965a. Photographs/line drawings and metrical data Leakey and Leakey 1964, Tobias 1965a, 1965b, Wood 1991. Detailed anatomical description None available. Initial taxonomic allocation “An unmistakable australopithecine” (Leakey and Leakey 1964, p. 7). Taxonomic revisions “Probably a late member of the Olduvai species, *A. boisei*” (Tobias 1965b, p. 27). Current conventional taxonomic allocation *Paranthropus boisei*. Informal taxonomic category Megadont archaic hominin. Significance This exceptionally complete and mostly well-preserved mandible provides insights into the morphology of the mandible of *P. boisei*. The exceptional degree of wear on the postcanine tooth crowns deprives researchers of the opportunity to study the detailed crown morphology of Peninj 1, but the excessive wear seen in the postcanine tooth row (all of the enamel has been removed from the metaconid and protoconid of the right P₄, from the metaconid, protoconid, and the hypoconid of the right M₁ and much of it from

these cusps on the left M₁, and all of the enamel has been lost from the protoconid and hypoconid of the left M₂) suggests that at least this individual, if not the other members of the taxon, was consuming abrasive preferred foods. It is difficult to imagine that this degree of wear could have been caused by the consumption of **fallback foods**. Location of original National Museums of Kenya, Nairobi, Kenya.

peramorphosis (Skt *para*=beyond plus Gk *morphe*=form, shape) Like **paedomorphosis**, peramorphosis is a category of resultant morphologies that follow from three different kinds of **heterochronic** processes (time **hypermorphosis**, rate hypermorphosis, or **acceleration**). Unlike paedomorphosis, however, peramorphosis includes new shapes since the processes that contribute to these morphologies extend the ancestral ontogenetic trajectory beyond its original endpoint. *See also* **hypermorphosis**; **acceleration**.

percussion The action of one object striking another, used in the study of stone tools to refer to the technique by which rock is fractured. In direct percussion, the stone, bone, antler, or wood **hammer** strikes the rock directly, whereas with indirect percussion an intermediate object, typically a chisel-like piece of bone, wood, or antler is placed on the rock and struck, directing the impact force for the more reliable production of elongated **flakes** and **blades**.

perforator (L. *perforare*=to bore) A flake or blade with one (or rarely multiple) small, pointed tip(s) shaped by finely controlled retouch (see Debénath and Dibble 1994). Sometimes referred to as a “borer,” perforators are inferred to have been used in the scraping or drilling of holes in materials such as wood, bone, shell, and hide.

pericone A term used by Szalay and Delson (1979) for an accessory cusp on the occlusal surface of a maxillary molar that others refer to as a Carabelli(s) trait. *See* **Carabelli(s) trait**.

pericranium *See* **periosteum**.

Perigordian A term that refers to early **Upper Paleolithic** technologies predominantly found at sites in central and southwestern France, and named after the Périgord region. Denis Peyrony introduced the term Perigordian to describe a technology that appeared at the same time as, but was distinctive

from, the **Aurignacian**. The results of more recent excavations suggest that what was originally called the Perigordian I should be subsumed within the **Châtelperronian**, and the Perigordian II and III should be subsumed within the Aurignacian. The Upper Perigordian (Perigordian IV, V, and VI) is still seen as a separate technology, characterized by backed points made on blades, rare bone tools, carved, stylized figurines of women (called Venus figurines), parietal art, and use of shelters, and dated to 28–21 ka. Similar technocomplexes found at sites outside of this area of France are usually called **Gravettian**.

perihelion (Gk *peri*=around and *helios*=sun) The point on the Earth's axis when it is closest to the sun. It is around this time that insolation (i.e., the intensity of the sun's rays on the Earth's surface) is at its maximum.

perikymata (Gk *peri*=around and *kymata*=waves) External ridges that encircle the crown of all permanent teeth; they are especially pronounced on the labial surface of the crowns of the anterior teeth. Perikymata were named by Gustav Preiswerk (1895) in his thesis on ungulate enamel structure. The "troughs" between perikymata are coincident with **striae of Retzius** (reviewed in Risnes 1985). Perikymata counts can be used to estimate the time it takes to form the **imbricational enamel** (or lateral enamel), but it is also necessary to know the **periodicity** of the perikymata. *See also* **enamel development**; **striae of Retzius**.

perilymph (Gk *peri*=around and *lymph*=watery) Watery fluid between the **membranous labyrinth** and the walls of the **bony labyrinth**. It is rich in sodium, resembles **cerebrospinal fluid** (or CSF), and communicates with the CSF via a narrow canal called the cochlear canaliculus.

period A unit of geological time (i.e., a **geochronologic unit**). It is a subdivision of an era, and it is itself subdivided into **epochs**. For example, the **Neogene** period is within the **Cenozoic** era and is itself divided into the **Miocene** and **Pliocene** epochs. The corresponding **chronostratigraphic unit** equivalent of an epoch is a **system**.

periodicity (Gk *periodos*=interval of time) The number of daily **cross-striations** between **striae of Retzius** in **enamel**, and/or the number of

von Ebner's lines between **Andresen lines** in **dentine**. The periodicity of these **long-period incremental lines** is consistent within all teeth belonging to the dentition of an individual (FitzGerald 1996, Smith 2006), but it may vary among individuals of a taxon. The modal value for the periodicity of long-period incremental lines in fossil hominins is 7 days in australopiths and 8 days in *Homo* (Lacruz et al. 2008). The presence of incremental lines in enamel allows researchers to determine the rate and duration of crown formation, and in some cases it is possible to infer the age at death of individual specimens (reviewed in Aiello and Dean 1990, Dean 2000, 2006, Smith et al. 2006). *See* **Andresen lines**; **cross-striations**; **striae of Retzius**; **von Ebner's lines**.

periodontal ligament (or PDL) (Gk *peri*=around *odonto*=pertaining to dentine) A fibrous connective tissue ligament that exists in the 300–500 µm-wide space between the tooth root surface and the inner aspect of the alveolar bone socket. The PDL is rich in blood vessels and proprioceptive nerve endings that relay information about **bite force** to the brain and trigger protective reflexes. The PDL contains bundles of collagen fibers that run between the alveolar bone and the cementum layer covering the tooth root. These fibers suspend the tooth in the socket and cushion the impact of the bite force.

periosteum (Gk *peri*=around and *osteum*=bone) A tough fibrous and cellular covering that tightly adheres to the external surface of bones. It is an important source of blood supply to bone and its undifferentiated (i.e., unspecialized) cells are capable of converting to **osteoblasts**, which can then form new, initially lamellar, bone. On the external surface of the bones of the **cranial vault** the periosteum is called the **pericranium** and on the internal surface of the vault it is called the **endosteum**, which is equivalent to the outer endosteal layer of the **dura mater**. When a bone fractures the cells in the periosteum differentiate into the osteoblasts, which are responsible for the bone formation that eventually heals the fracture. *See also* **ossification**.

peripatric speciation A mode of **speciation** in which a new species evolves as a consequence of a small subpopulation of the original species population colonizing a new geographic area (e.g., animals trapped on a large mat of vegetation that

separates from a much larger island). These peripheral populations are geographically isolated from the parent population, and because their population size is small, **genetic drift** becomes a powerful factor, driving the new populations to become genetically distinct and, eventually, reproductively isolated from the parent population. This process is also known as the **founder effect**. Peripatric speciation can be thought of as a special case of **allopatric speciation** insofar as reproductive isolation (and, hence, a new species) evolves in geographically isolated populations. *See also* *Homo floresiensis*.

Perissodactyla (Gk *perisso*=odd-numbered and *daktulos*=toe) The name of the mammalian order in which the axis of the leg goes through a single-hoofed toe (cf. **Artiodactyla**, in which the axis passes between *two* hoofed toes). Perissodactyls were common and underwent an adaptive radiation earlier in the **Cenozoic**, particularly in North America, but during the **Neogene** times that are relevant for human evolution this order was relatively impoverished, with low species diversity. Nonetheless, perissodactyl fossils are common within some early hominin faunal communities. The perissodactyl taxa found at hominin sites include members of the **Rhinocerotidae** (rhinoceros) and the **Equidae** (zebras, horses, and their allies). Examples of another extant perissodactyl family, the **Tapiridae** (or tapirs), have been recovered from some archeological sites in Asia, particularly in Malaysia.

permanent dentition (L. *per*=throughout, *manere*=to remain, and *dentes*=teeth) In modern humans and other catarrhine primates, the permanent dentition consists of the two **incisors** (I), one **canine** (C), two **premolars** (P), and three **molars** (M) in each quadrant of the jaw, which either replace the **deciduous dentition** [i.e., the permanent incisors (I) replace the deciduous incisors (i), the permanent canines (C) replace the deciduous canines (c), and the premolars (P) replace the deciduous molars (dm)] or are formed in the alveolar process distal to the deciduous dentition (i.e., the permanent molars, M).

permutation test *See* randomization.

Perning *See* Mojokerto.

person-years lived in an age interval The total number of years (based on the **radix**) lived in an age interval, represented in a **life table** as L_x or

${}_nL_x$. For example, consider a life table where there are 250 deaths. In the first age interval (from birth to 1 year of age) there are 10 deaths. Taking the actual number of deaths (250) as the radix, the number of individuals who survive the first year of life was $250-10$, or 240. Each of these individuals lived 1 year, accounting for 240 people-years. Of the 10 individuals who died in the first year of life, we assume that their ages at death were uniformly distributed across the age interval. Consequently, their average age at death would be 0.5 years, and they would on average live for half of the age interval. They consequently contributed 10×0.5 years, or 5 people-years. The total people-years lived during the first year of life was therefore 245. ${}_nL_x$ can be found directly from **survivorship**, such that ${}_nL_x = n \left(\frac{l_x + l_{x+1}}{2} \right) = \frac{n}{2} l_x + \frac{n}{2} l_{x+1}$, where n is the age interval width. Person-years lived in an age interval is consequently equal to the average of the survivorship at the opening of the interval and at the opening of the next interval multiplied by the width of the interval. The assumption of a uniform distribution of deaths within an age interval can be problematic, particularly for the earliest age intervals in a life table. As a consequence, in **Weiss' model life tables**, Weiss used ${}_1L_0 = 0.35l_0 + 0.65l_1$. The concept of "person years lived in an age interval" is not typically used in hazards analysis because there are no defined age intervals.

Peștera Cioclovina Uscata (Location 45°35'N, 23°07'E, Romania; etym. in Romanian literally the "dry Cioclovina cave") **History and general description** The Cioclovina cave is part of a large **karstic** system, known since the 1880s. Several episodes of paleontological research have been conducted, including excavation that produced **Mousterian** and **Aurignacian lithic** material. In the early 1940s the site was used also for phosphate mining, and a **hominin calotte** was discovered during the mining operations. **Temporal span and how dated?** **Typology** of artifacts and **AMS radiocarbon dating** on hominin and faunal remains suggest the hominin activity at the Cioclovina cave was during the Mousterian and during the early **Upper Paleolithic**. **Hominins found at site** The Cioclovina calotte. **Archeological evidence found at site** Evidence of Mousterian and Aurignacian lithic industries. **Key references:** **Geology, dating, and paleoenvironment** Olariu et al. 2003, Soficaru et al. 2007; **Hominins** Rainer and Simionescu 1942, Harvati et al. 2007, Soficaru et al. 2007; **Archeology** Păunescu 2001.

Peștera cu Muierii A karstic cave system in Romania that comprises several galleries. *See* **Baia de Fier**.

Peștera cu Oase (Location 45°01'N, 21°50'E, Romania; etym. Romanian for “cave with bones”) History and general description This site, discovered in 2002, consists of previously sealed galleries that form part of a karstic complex in southwestern Romania. Paleontological fieldwork, including mapping and excavation of the fossil-bearing sediments, was undertaken in 2003–4 and in 2006. Skeletal remains of two hominin individuals were recovered among bones of *Ursus spelaeus* and other large mammals in the surface accumulation of the side gallery (Panta Strămoșilor); no cultural remains were found. Temporal span and how dated? Hominin presence in the Peștera cu Oase seems to have been ephemeral and was possibly limited to one episode. The hominin remains are dated to between 34,950±c.900 years BP (AMS ultrafiltration radiocarbon uncalibrated age for **Oase 1**) and 28,890±c.170 years BP (AMS ultrafiltration radiocarbon uncalibrated age for **Oase 2**), with a suggested oldest calibrated age of c.40.5 ka. Hominins found at site **Oase 1** (mandible) and **Oase 2** (cranium); a temporal bone originally assigned to a third individual (**Oase 3**) is now thought to belong with the **Oase 2** cranium. Archeological evidence found at site None. *See also* **Oase 1; Oase 2**.

PET Acronym for positron emission tomography, a neuroimaging modality. *See* **positron emission tomography**.

petalia (Gk *petalos*=leaf, outspread) A cerebral petalia is a modest relative expansion of part of one **cerebral hemisphere** in relation to its size in the opposite, or contralateral, cerebral hemisphere. Petalias are considered by some to be a manifestation of a more general anatomical asymmetry of the brain. The most typical configuration in modern humans is the combination of a right frontal lobe petalia with a left occipital lobe petalia. Some authors have argued that this petalia torque pattern is unique to modern humans and can be linked to the evolution of language abilities (Crow 2000). Fossil evidence attributed to *Homo erectus*, however, suggests that endocasts of at least some earlier hominin species show similar asymmetrical cerebral petalias (Holloway and De La Coste-

Larymondie et al. 1982) and recent comparative studies, using measurements from magnetic resonance imaging scans, suggest that left-occipital and right-frontal petalias are also seen in chimpanzees (Hopkins and Marino 2000, Hopkins et al. 2008). There is no evidence of the left-right petalia torque in any primate species outside of the great apes.

Petralona (Location 40°22'N, 23°10'E, Chalkidiki peninsula, Northern Greece; etym. Greek for “stone threshing place”) History and general description The Petralona Cave was discovered in 1959 by Philippos Chatzarides, a local villager, and the Petralona fossil hominin cranium was discovered the following year. Excavations were conducted in 1968 and 1974–5 by Aris Poulianos. Temporal span and how dated? **Biostratigraphy, electron spin resonance spectroscopy dating, and uranium-series dating** has been used to date the cranium, with age estimates ranging from the lower **Middle** to the late **Middle Pleistocene**. Hominins found at site **Petralona cranium**. Archeological evidence found at site Proposed lithic evidence from the cave are probably not artifacts. Key references: Geology, dating, and paleoenvironment Hennig et al. 1981, Ikeya 1980, Kurtén and Poulianos 1977, Poulianos 1982; Hominins Breitingner 1964, Kokkoros and Kanellis 1960, Rightmire 2001, Stringer et al. 1979; Archeology none relevant. *See also* **Petralona cranium**.

Petralona cranium Site **Petralona**. Locality Petralona Cave. Surface/*in situ* Surface. Date of discovery 1960. Finder Christos Sarigiannides. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Middle to late Middle Pleistocene. Developmental age Adult. Presumed sex Male. Brief anatomical description Complete cranium, including dentition with the exception of the incisors and canines. Announcement Kokkoros and Kanellis 1960. Initial description Kokkoros and Kanellis 1960. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions *Homo erectus* (e.g., Breitingner 1964), archaic *Homo sapiens* (e.g., Stringer 1974), *Homo heidelbergensis* (e.g., Rightmire 2001). Current conventional taxonomic allocation *H. heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance One of the most complete Middle Pleistocene crania from Europe, this specimen has featured in attempts to

envisage the **pre-Neanderthal** population of Europe. **Location of original** Department of Geology, Aristotle University of Thessaloniki, Greece.

petro-median angle (L. *petrous*=rock-like and *medius*=middle) The term used by Phillip Tobias (1967a) for the angle between long axis of the petrous part of the temporal bone as seen from below (i.e., in norma basilaris), and the median, or sagittal, axis of the cranium. For example, the petromedian angle is more acute (i.e., smaller) in *Pan*, whereas in later *Homo* and in *Paranthropus boisei* it is closer to the coronal plane and is thus more obtuse (i.e., larger). For more detail see Tobias (1967a, pp. 33–4). *See also* **basicranium**.

petrous (L. *petrous*=rock-like; the same root as “petroleum” which is literally “rock oil”) Refers to the hard (hence “rock-like”) wedge-shaped part of the temporal bone.

petrous angle (L. *petrous*=rock-like) The angle between the long axis of the petrous part of the temporal bone and the coronal plane. Equivalent to angle α in Dean and Wood (1981) which is defined as the angle formed by a line from the lowest point in the most lateral part of the tympanic plate to the center of the carotid canal and then drawn on from that point to the medial point on the apex of the petrous pyramid.

PGLS Acronym for **phylogenetic generalized least squares** (*which see*).

Phacochoerus The name of the genus that contains the extant and extinct warthogs. *See* **Suidae**.

phage This term (an abbreviated form of bacteriophage) refers to a virus that infects bacteria. The use of phages during the development of molecular biology enabled researchers to understand the role DNA plays in heredity. In 1952, the Hershey–Chase experiments confirmed that DNA was the genetic material. These experiments used a T2 phage labeled with phosphorus-32 to make its DNA radioactive and sulfur-35 to make its protein component radioactive. After the phages infected bacteria, Hershey and Chase found that it was the DNA, and not the protein, from the phage that entered the bacterial cell and infected it.

Phaneranthropi *See* Sergi, Sergio (1878–1972).

pharyngeal arches *See* **branchial arches**.

pharyngotympanic tube *See* **auditory tube**.

pharynx (Gk *pharunx*=a chasm) The hollow soft-tissue structure that connects the mouth and nose with the esophagus and the larynx. It is in three parts. The superior part, the nasopharynx, connects anteriorly with the nasal cavities via the posterior nares. The middle part, the oropharynx, communicates anteriorly with the mouth via an opening that is bounded superiorly by the soft palate, laterally by the palatoglossal folds and inferiorly by the junction of the anterior two-thirds and the posterior third of the tongue. The inferior part, the laryngopharynx, lies posterior to the larynx and extends laterally around it as far as the attachments of the inferior constrictor muscle. The pharynx is made of soft tissues so there is no direct evidence of it in the fossil record. However, it is one of the structures that differ substantially in shape in chimpanzees and modern humans. The **basicranium** and the pharynx in the modern human **neonate** are much the same as they are in an adult chimpanzee; this configuration allows modern human neonates to suckle and breathe at the same time. However, once the cranial base flexes the soft palate no longer seals off the mouth from the respiratory tract. Instead, in adult modern humans the soft palate seals off the nose and nasopharynx from the mouth and oropharynx.

phase The term refers to combinations of **alleles** at different **loci** linked together on the same **chromosome**. It also refers to cycles of **chewing**.

phase I *See* **chewing**.

phase II *See* **chewing**.

phenetic (Gk *phainen*=to show) A form of analysis that uses information about all of the phenotype. Contrast this with a cladistic analysis that just focuses on shared-derived, or **apomorphic**, aspects of the phenotype. Phenetic methods should be used to identify taxa (also called **alpha taxonomy**), and cladistic methods should be used to investigate the relationships among taxa. *See also* **morphology**; **phenotype**.

phenetic species concept *See* species.

phenogenomics Phenogenomics is the use of large shared databases and data standardization to enable large-scale analyses of phenotypic data in combination with genetic data. Examples of this include the development of large-scale databases for imaging data that can be mined using bioinformatic techniques. Within biological anthropology, the move towards sharing **computed tomography** scans of primate skeletal material combined with genetic data are examples of phenogenomic approaches. Although no genetic material is usually available for fossil specimens, the move towards sharing scans of fossil material is motivated by similar principles and ideals.

phenotype (Gk *phainen*=to show and *typus*=image) All the observable characteristics of a living thing, from its molecular structure up to its overall size and shape. The phenotype is determined by complex interactions between the genotype and the environment. *See also* **epigenetic**; **phenotypic plasticity**.

phenotypic plasticity (Gk *phainen*=to show, *typus*=image, and *plaisen*=to mold) The tendency for the same genotype, or genetic program for development, to generate a range of phenotypes (called **reaction norms**) in response to different environmental settings. Although the study of the relationship between environment and phenotype has a long history (e.g., Wolterek 1909), the concept was developed in its modern form by Schmalhausen (1949). The phenotypic differences may be initiated during development or changes to the phenotype may take place during adulthood. These phenotypic differences and changes can be behavioral as well as morphological. Ultimately, the capacity for plasticity, and the degree to which an organism's phenotype is malleable, is dependent on the fitness benefit of this plasticity. The results of this capacity for flexibility in response to environmental pressures can be described using a reaction norm, but in some cases the direction of plasticity is similar in all organisms. It is often difficult to tease apart whether phenotypic plasticity itself is an adaptation, whether variation in the trait under investigation has been under selective pressure, or whether environmentally related variation in a trait is plastic but not necessarily adaptive. In modern humans, the relationship between age at menarche in girls and the family environment

has been taken as an example of phenotypic plasticity: family instability (as a proxy for environmental instability) is thought to lead to earlier age at menarche and at reproduction. The relationship between body condition and reproductive capacity in women, where very low body fat resulting from undernutrition or extreme physical exercise results in irregularities or cessation in menstrual cycling, is another example of phenotypic plasticity.

phenotypic variance *See* heritability.

philopatry (Gk *philo*=loving and *patris*=fatherland) The term used when an individual remains within their natal group (i.e., the group they were born into). Primate social groups tend to be structured such that once either males or females reach sexual maturity they move away from the group in which they were born, presumably to minimize inbreeding. In Old World monkeys it is common for the males to move away from their natal group, but females stay in theirs; hence this is known as female philopatry. This social structure contrasts with that for chimpanzees, in which it is the males that tend to remain in their natal group (i.e., male philopatry). Joining another group is not always straightforward for emigrants. In species that have female philopatry and a high level of male-male competition, some incoming males may not be able to successfully challenge the resident males for access to mature females. In these cases, nonresident males may form separate "bachelor" groups. Incoming chimpanzee females can face aggression from resident females, as they represent competition. Hominin social groups may have been more similar to those seen in the closest extant great ape than in monkeys, so using a chimpanzee analogy, early hominins may have exhibited male philopatry, with attendant female-female aggression.

phonation (Gk *phone*=sound) Phonation is the use of the respiratory, or vocal, tract to manufacture sounds. Phonations are normally made when the vocal folds vibrate during exhalation. Phonations range from the type of sound units that make up **spoken language** to unspoken exclamations such as a sustained "aaaagr" sound and an aperiodic noise like a hiss.

phoneme *See* spoken language.

phonolite *See* lava.

phonology (Gk *phone*=sound and *ology*=study of) Literally the “sound system” of a language. Phonology is a more inclusive category than phonetics. For in addition to phonetics, which concerns the specific mechanics of sound production, it also encompasses the mechanisms involved in the transmission and the perception of speech sounds. A central feature of spoken languages is the way specific sounds function within a linguistic or communicative system to encode meaning. According to Hauser et al. (2002) the perception and articulation of sounds is a primitive feature of the modern human language faculty, for many animals manipulate speech sounds to communicate various social (e.g., dominance) as well as affective (e.g., fear) states. Pinker and Jackendoff (2005) argue that modern human phonology is qualitatively different from the sound system of other animals, and they suggest the “major characteristics of phonology are specific to language, uniquely human, discretely infinite, and not recursive” (*ibid*, p. 212). In this interpretation, the evolution of modern humans favored two phonological systems, both of which are rule-governed. One system combines meaningless sounds into morphemes and a second system combines morphemes into words and phrases. The first phonological system is present in other animals, such as birds, but it is absent in nonhuman primates. This discontinuity suggests that this more basic sound-combination system evolved independently in modern humans. The second system has no parallel in the animal kingdom yet it is a characteristic of all known modern human languages.

photon starvation See computed tomography; lack-of-signal artifacts.

PHS (Location 5°24.55'N, 35°54.07'E, Ethiopia) Acronym of Paul's hominid site, where Paul Abell found the fragments that were reassembled to form the **Omo II** cranium. The strata exposed at the site are near the top of Member I of the **Kibish Formation** in the **Omo Rift Zone**, Ethiopia. Note that the site is not at the location given in Butzer (1969). A map made by Paul Abell at the time of the discovery and a contemporary photograph by Karl Butzer place PHS locality 3.3 km/1.8 miles west by north of KHS (McDougall et al. 2005).

phyletic gradualism The phenomenon in which an ancestral species is gradually transformed

through many incremental stages into a new descendant species. This mode of evolution, which is typically associated with **anagenesis** (but can also be associated with **cladogenesis**) is the one envisioned by Charles **Darwin** to have been the end result of natural selection. There are a growing number of paleoanthropologists who believe that *Australopithecus anamensis* was transformed into *Australopithecus afarensis* through this process, and many researchers believe that *Homo neanderthalensis* evolved from earlier, even more archaic pre-modern *Homo* populations using the same mode. A taxonomic implication of phyletic gradualism is that the boundaries of species are likely to be difficult to locate and define, and because of this its adherents are likely to recognize a smaller rather than a larger number of species in the fossil record. See also **anagenesis**; **lumper**.

phylogenetic (Gk *phylon*=race, *genesis*=origin, and *etikos*=from) Adjective formed from the noun **phylogeny**. For example, a **phylogenetic tree** is a branching diagram that depicts a hypothesis about the shape of part of the tree of life. A phylogenetic analysis (also known as **cladistic analysis**) is a form of analysis that is designed to recover information about relationships that are the product of phylogeny. Confusingly phylogenetic analysis results in a branching diagram called a **cladogram** and not a phylogeny or a phylogenetic tree. A phylogenetic tree is a more complicated hypothesis than a cladogram, for it includes time and specifies ancestors and descendants whereas a cladogram does not.

phylogenetic analysis See cladistic analysis.

Phylogenetic Analysis Using Parsimony See PAUP.

phylogenetic comparative analysis A type of analysis which recognizes that species data are not statistically independent, and which takes into account phylogenetic information when identifying relationships across multiple taxa. The two most commonly used types of phylogenetic comparative analysis are **phylogenetically independent contrasts** and **phylogenetic generalized least squares** (*which see*).

phylogenetic constraint A cause of **phylogenetic inertia**, which is the persistence of a

trait despite changes in aspects of the environment that can be expected to be selectively important for that trait. The most commonly invoked phylogenetic constraints are limited genetic variation, **pleiotropy**, and functional interdependency. *See also* **phylogenetic inertia**.

phylogenetic generalized least squares

(or PGLS) A type of **phylogenetic comparative analysis** devised by Emilia Martins and Thomas Hansen (1997) that takes into account phylogenetic relatedness when comparing continuous variables among three or more taxa. This technique differs from the earlier-developed technique of **phylogenetically independent contrasts** in that rather than using the branching sequence and **branch lengths** within a phylogeny to calculate standardized differences between continuous variables for various taxa, PGLS uses the same phylogenetic information to adjust the error matrix that is used in a generalized least squares model. For example, regression typically assumes that the error term has equal variance for all data points, and that the covariance between the data points is zero (i.e., data points are independent). Phylogenetic generalized least squares adjusts the error term using a covariance matrix in which more closely related taxa have relatively high covariance, and more distantly related taxa have relatively low covariance. Bivariate regression results are identical for phylogenetically independent contrasts and PGLS under the standard regression model which assumes a Brownian motion model for the evolution of continuous values in which values are expected to diverge randomly from an original state. However, PGLS can be further modified to reflect other models of character evolution. A common variant imposes an Ornstein–Uhlenbeck process, which assumes that continuous values tend to revert to a mean value over time. This process has been likened to stretching a rubber band; the more the rubber band is stretched, the stronger the force attempting to pull the rubber band back to its original state. As with phylogenetically independent contrasts, concerns arise when PGLS slopes differ from traditional regression slopes. *See also* **phylogenetically independent contrasts**.

phylogenetic inertia (Gk *phylon*=race, *genesis*= origin, and L. *inert*=idleness) The persistence of a trait despite changes in aspects of the

environment that can be expected to be selectively important for that trait (syn. phylogenetic effect, phylogenetic lag). Thus, phylogenetic inertia applies to two situations. One is where a trait persists after the selective force that produced and/or maintained it stops operating. The other is where a trait is unaffected by new environmental conditions that there is reason to think should have resulted in selection acting on the trait. A number of potential causes of phylogenetic inertia have been proposed. The most commonly invoked are limited genetic variation, **pleiotropy**, and functional interdependency. These are often referred to as **phylogenetic constraints**. Behavioral plasticity is among the other potential causes of phylogenetic inertia. In paleoanthropology, phylogenetic inertia has played an important role in the debate about the locomotor behavior of the australopiths. A number of those who contend that australopiths were striding bipeds have invoked phylogenetic inertia to explain the australopiths' primitive, chimpanzee-like, traits (e.g., their curved fingers and toes).

phylogenetic lag A synonym for **phylogenetic inertia** (*which see*).

phylogenetic species concept (or PySC)

Introduced by Cracraft (1983). Nixon and Wheeler (1990) describe the PySC as “the smallest aggregation of populations diagnosable by a unique combination of character states.” *See also* **species**.

phylogenetic systematics An integrated approach to phylogeny reconstruction and classification devised by Willi Hennig (1966). The phylogeny reconstruction aspect of phylogenetic systematics is commonly called **cladistic analysis**, or just cladistics, and is discussed in the entry for the former. This entry focuses on Hennig's approach to classification. According to Hennig, classifications should encode only information about phylogeny such that taxonomic groups should include all of the descendants of the most recent common ancestor (or MRCA) of that group. In other words, Hennig argued that taxonomic groups should always be **monophyletic**. This emphasis on monophyly distinguishes phylogenetic systematics from the other major approach to classification, **evolutionary taxonomy**, which allows taxa to be paraphyletic if members of a clade exhibit significant adaptive differences.

phylogenetic tree A phylogenetic tree is a branching diagram that tries to capture as accurately as possible the evolutionary history of a taxon. The evolutionary history of a taxon is the path taken as one traces its ancestors (initially recent, but subsequently increasingly remote) back into the tree of life. It is a more complex hypothesis than a cladogram because it specifies ancestors and descendants. Several different phylogenetic trees may be compatible with a single cladogram. In a phylogenetic tree, time is on the vertical axis and morphology on the horizontal axis.

phylogenetically independent contrasts (or PIC) A type of **phylogenetic comparative analysis**. Devised by Joseph Felsenstein (1985), PIC takes into account phylogenetic relatedness when comparing continuous variables among three or more taxa. Most statistical analyses assume statistical independence of data points, but Felsenstein recognized that in phylogenetic comparative analyses species are *not* statistically independent data points because some taxa share a more recent common ancestry than others, and thus would be expected to be more likely to share similar values for any variable because they have been phylogenetically independent for a shorter period of time (i.e., less time has elapsed since they were a single species). Phylogenetically independent contrasts works by converting species data into differences between pairs of species (contrasts between two operational taxonomic units), between a species and an internal node within the phylogeny (contrasts between an operational taxonomic unit and a hypothetical taxonomic unit), or between pairs of internal nodes (contrasts between two hypothetical taxonomic units). These contrasts are then standardized by a function of the expected covariance between taxa, which is determined by the branching sequence and the branch lengths implied by the phylogeny of the taxa in an analysis. If branch lengths represent time of divergence between taxa, then standardized contrasts are similar to rates of accumulated difference between taxa; these “rates” are independent of each other although the raw data are not. Thus bivariate PIC analyses test whether difference in one variable tends to be associated with difference in another variable throughout the whole phylogeny represented by the sample. This approach differs from analyses of species data that investigate the relationship between species values themselves, rather than values for differences between sister taxa.

Nunn and Barton (2001) provide an accessible discussion of PIC along with worked examples and some variants on the main technique. One early concern regarding PIC regressions was that because there are only $n-1$ contrasts for a data set of n taxa, PIC analyses would have less power than traditional regressions. However, PIC regressions have the same number of degrees of freedom as traditional regressions because PIC regressions must be forced to pass through the origin (i.e., have a Y intercept of zero), and thus only one degree of freedom is lost in PIC regression analyses instead of two. It should be noted, however, that some researchers have suggested that degrees of freedom should be adjusted downward in PIC analyses when soft polytomies are present in the phylogeny (Garland and Díaz-Uriarte 1999). A further criticism leveled against PIC is that the results are not directly comparable to traditional regressions. However, it has been demonstrated that PIC regression slopes can be placed in raw data space (i.e., superimposed on a bivariate plot of operational taxonomic unit data rather than contrast data) by passing the PIC slope through the phylogenetically weighted mean of the X and Y variables (Rohlf 2001). Traditional regression is thus shown to be a special case of PIC in which all taxa inhabit a star phylogeny (i.e., a single clade with a massive polytomy at its base) where all operational taxonomic units are equally closely related to each other. It has been argued that since comparative data sets in most analyses do not conform to star phylogenies, it is incorrect to use traditional regression when phylogenetic information is available. A further issue arises when PIC slopes are compared to traditional regression slopes. PIC slopes are often (although not always) shallower than traditional slopes, and it is not unusual for hypothesis tests for a single data set to produce a significant result using traditional regression and a non-significant result using PIC. Questions of interpretation become more difficult in this scenario. A strictly statistical interpretation would observe that the traditional regression model is flawed because the error variable is incorrectly partitioned; once the error is correctly partitioned using phylogenetic information the significance of the relationship disappears, so the relationship is not significant. A more applied biological interpretation would observe that the traditional regression indicates a real relationship among the operational taxonomic unit data, and that the lack of significance for the PIC regression would suggest that most of that relationship is due to correlated

differences in the two variables between clades, with less patterned covariance between variables within adaptive radiations, implying that the relationship between the operational taxonomic units is driven primarily by differences deep in the phylogeny. A third interpretation may be that the phylogeny is incorrect. This is an important consideration, particularly when incomplete fossil taxa are included in an analysis. There is some work suggesting that phylogenetic comparative analyses are robust to some error in branch lengths, and somewhat less so to errors in branching sequence, although it is unclear how much error in the phylogeny is “acceptable” (Diaz-Uriarte and Garland 1998, Symonds 2002). Finally, even among practitioners of PIC, there is some debate as to how the technique can be extended. For example, Desdevises et al. (2003) present a method that combines traditional and PIC regression to partition the relationship between two variables into a phylogenetic component, an error component, and the component of interest (usually a functional or ecological relationship). Thus researchers can potentially identify how much of a relationship is functional, how much is phylogenetic, and how much is due to phylogenetic niche conservatism. However, Rohlf (2006) has argued that accounting for phylogeny simply allows for a more accurate estimation of the error component, implying that it is not meaningful to discuss a “phylogenetic component” of the regression. The proper name for the method is phylogenetically independent contrasts, but it is often referred to in its shortened form, “independent contrasts.” *See also* **phylogenetic generalized least squares**.

phylogeny (Gk *phulon*=tribe or race and *gena*=to give birth to) The phylogeny of a taxon is the same as its evolutionary history. The evolutionary history of a taxon is the path taken as one traces ancestors (initially recent, but subsequently more remote) back into the tree of life. Evolutionary history is usually represented visually as a branching diagram called a **phylogenetic tree**, also called simply a phylogeny. A phylogeny is a more complex hypothesis than the hypothesis about relationships set out in a **cladogram**; the former includes specific hypotheses about ancestors and descendants, whereas the latter does not. Thus, a single cladogram may be consistent with several different phylogenetic trees. Strictly speaking, only taxa have phylogenies; individual organisms have

an **ontogeny**, but not a phylogeny (syn. genealogy, ancestry).

phylogeny reconstruction The generation of an hypothesis or set of hypotheses concerning the phylogenetic or descent relationships among a group of taxa. Phylogeny reconstruction can be carried out in a number of different ways. In paleoanthropology the main methods are **phenetic** and **cladistic analysis**. See these entries for these methods for further information about how phylogenetic hypotheses are generated with them. *See also* **cladistic analysis**.

phylogram *See* **branch length**.

physical map A map of the whole genome, or a region of the genome, where the relative positions of markers are defined by the number of base pairs between them rather than by the recombinational distance or **linkage**.

phytolith (Gk *phyton*=plant and *lithos*=rock) One of several kinds of plant microfossils, phytoliths are small noncrystalline silica bodies found within the tissues of plants. They function as a form of structural support and/or as a physical defense mechanism against herbivory. They are thought to be one of the major causes of tooth wear. The shapes and sizes of phytoliths are usually unique to the plant taxon (e.g., at the level of the family, tribe, or genus and sometimes even at level of the species) and/or plant organ (e.g., leaf, bark, or fruit) that produced them. They are most commonly produced in the surface organs of plants (e.g., leaves, husks, and rinds of fruits). Phytoliths (unlike pollen) usually remain where the plant died and they are stable in nonalkaline environments, so can be useful markers of ancient plants. They can be recovered from archeological sediments, stone tools, ceramics, and dental calculus, and can provide information on which plants were present in the environment or in the diet of individuals and groups. Piperno (2006) provides a useful primer for those planning to exploit plant microfossils for diet and/or paleoenvironmental reconstruction and Bamford et al. (2006) provide an example of how these methods can be successfully applied. *See also* **use wear**.

PIC Acronym for **phylogenetically independent contrasts** (*which see*).

pig Informal inclusive term to describe the taxa within the family *Suidae* (syn. *suid*, *swine*). *See Suidae*.

pigmentation Colored material in plant or animal cells that is not due to structural color (such as iridescence). Examples of pigmentation variation in modern humans and other primates include the color of the skin, hair, and eyes. In the skin, color is the result of three features: melanin, blood, and keratin. Over 100 genes have been identified as being involved in pigmentation in mammals (e.g., Jackson 1997, Rees 2003, Sturm et al. 2001). Many of these are not involved in normal pigment variation within a species, but were discovered because they are mutated in a genetic disease or condition (e.g., albinism). It was initially estimated that approximately three genes had major effects on normal skin pigmentation variation in modern humans (Harrison and Owen 1964), but more recent analyses have identified close to 20 genes involved in normal skin, hair, and eye color variation in different populations (for a review see Sturm 2009). Among these are the melanocortin 1 receptor gene (or *MC1R*) and *OCA1*, and variants of *MC1R* have been linked to red/fair hair, fair skin, and freckles (e.g., Flanagan et al. 2000, Valverde et al. 1995) while variants of *OCA2* have been linked to lighter iris color in the eyes (Duffy et al. 2007, Frudakis et al. 2003, Sulem et al. 2007). Rogers et al. (2004) studied variation in alleles of *MC1R*, whose protein product affects skin and hair color by modifying production of one of two forms of the pigment melanin, either eumelanin or pheomelanin. Eumelanin is protective against ultraviolet radiation while pheomelanin is not. Earlier research by Harding et al. (2000) had found that the melanocortin gene is variable in non-African population while in Africa all the individuals studied possessed an allele specifying the production of eumelanin. Rogers et al. used silent mutations in an African version of the gene to calculate that a **selective sweep** for that allele occurred approximately 1.2 Ma. Using *Pan troglodytes* as a **proxy** for the earliest human ancestors, Rogers et al. suggest that hominins, like chimpanzees, originally possessed fair skin covered by protective fur. The 1.2 Ma sweep date for *MC1R* has been interpreted by Rogers' team as suggesting that modern human ancestors evolved dark skin around the time that they lost their body hair to reduce damage from solar radiation. Several hypotheses (not necessarily mutually exclusive) exist to explain normal human pigmentation variation.

These include **sexual selection**, **purifying selection** because of ultraviolet intensity and folate photolysis, selection for sufficient vitamin D production, and **genetic drift** (Aoki 2002, Harding et al. 2000, Jablonski and Chaplin 2000, Madrigal and Kelly 2007, Rana et al. 1999).

Pillai-Bartlett trace *See multivariate analysis of variance*.

Piltdown (etym. The name of the closest village to Barkham Manor) The saga of the discovery of the remains of "Piltdown Man," their validation by the British Museum (Natural History) in London, and their later exposure as an elaborate fraud, began before 1908. What follows is extracted from Joe Weiner's fine description of his first-hand work on the Piltdown material (Weiner 1955) and from information painstakingly assembled by Frank Spencer and Ian Langham and presented in book form (Spencer 1990). Charles Dawson, a solicitor (the equivalent of a US attorney) who practiced in Uckfield, Sussex, apparently was aware of the Barkham gravel beds and their exposure in a trench alongside a lane leading to part of Barkham Manor, but it was in 1908 that a laborer reported striking and shattering a hollow object in what later became known as the Piltdown Gravel Pit. A fragment belonging to the "hollow object" was shown to Dawson, who reported that it was "an unusually thick human parietal bone" and he also remarked that "peculiar brown flints" had been recovered from the same gravel pit. Dawson paid periodic visits to the site (he was the steward, or the agent, of Barkham Manor) and sometime in the fall of 1911 he wrote that he had "lighted on a larger piece of the same skull which included a portion of the left supra-orbital border" and not long after he reported finding a piece of a hippopotamus tooth (Spencer 1990, p. 31). Dawson had been an Honorary Collector for the British Museum (Natural History) since 1884, so it was not surprising that he contacted Arthur Smith Woodward at the museum about his finds. Dawson wrote to Smith Woodward in February 1912, but he could not visit the site until June of the same year. On June 2, 1912, Smith Woodward, accompanied by Fr. Pierre Teilhard de Chardin, traveled to Uckfield where they met Dawson who took them to Piltdown, and it was during that visit that Dawson recovered a third cranial fragment. Smith Woodward and Dawson visited the site several times that summer, and near the end

of June Dawson (in Smith Woodward's presence) exposed part of the right side of a mandible, and thereafter they recovered "three pieces of the parietal bone" (*ibid*, p. 33) from a spoil heap, and a further piece of cranium that fitted the broken edge of the occipital fragment found by Dawson on June 2. Someone "leaked" the news of the discoveries and the *Manchester Guardian* ran the story of November 21, 1912, but the first formal presentation of the finds (i.e., the "Pre-Chellean paleoliths," the **eo**liths, fossil mammal bones, and "nine pieces" of the cranium, a mandible with M₁ and M₂, plus a reconstruction of the Piltdown I skull by Smith Woodward) was made by Dawson, Smith Woodward, and Grafton Elliot Smith at the December 18 Meeting of the Geological Society of London held in Burlington House; the December 28 issue of the *Illustrated London News* included a long article about the finds. The specimen was named *Eoanthropus dawsoni* (literally "Dawson's dawn man") and it immediately attracted considerable attention. While many accepted Smith Woodward's interpretation that the cranium and jaw belonged to a single individual, and that while "the skull is essentially human" . . . "the mandible appears to be that of an ape, with nothing human except the molar teeth" (Smith Woodward quoted in Weiner 1955, p. 3), other observers were more skeptical. For example, David Waterston, Professor of Anatomy at King's College, London, thought the cranium, which he considered was "in all essentials human," and the mandible, which was "chimpanzee-like," came from different individuals. In July 1913, Dawson recovered a pair of nasal bones and on August 30, 1913, Fr. Teilhard de Chardin recovered a canine tooth (the two nasal bones and the canine are illustrated in Dawson and Woodward 1914) of Piltdown I. No further evidence of the skull was recovered from the trench at Barkham, but in January 1915, Dawson, who had widened the search to neighboring fields, reported the recovery of a piece of hominin frontal bone at Sheffield Park, and later that year in the same location he recovered a piece of occipital and a molar tooth of what would become Piltdown II; he also found a rhinoceros molar. Dawson became sick towards the end of 1915, and he died on August 10, 1916. Thereafter Smith Woodward visited the sites of Piltdown I and II many times but found nothing, and he even retired to Hayward's Heath to be close to the site, but despite continued searching no more evidence was ever found; no more hominin fossils, no more "worked" flints, and no more bones of

extinct animals. Smith Woodward arranged for a memorial stone to be erected at the Piltdown I site and it was unveiled by Sir Arthur Keith on July 22, 1938. In the foreword of Smith Woodward's 1948 book about Piltdown, *The Earliest Englishman*, Sir Arthur Keith wrote that "the Piltdown enigma is still far from a final solution." Meantime, discoveries in China and southern Africa were forcing researchers to concede that if Piltdown was to be accepted as evidence of a Pliocene hominin, then all the other well-authenticated hominin evidence must belong to one lineage, with the Piltdown evidence for "dawn man" being the only evidence for a second lineage. Two important developments in 1950 helped resolve "the Piltdown enigma." In that year vegetation around the Piltdown I site was cleared by the Nature Conservancy, and despite much excavation and sieving, nothing of any interest was recovered (Toombs 1952). The second development involved the **fluorine dating** method. This method was little used in the early decades of the 20thC, but it attracted the attention of Kenneth Oakley who spoke about its potential at the First **Pan-African Congress on Prehistory** in Nairobi in 1947. When Oakley applied the fluorine method to the Piltdown fossils the large-mammal fossils were found to have fluorine levels that varied between 3 and 1.6%, whereas the levels in the alleged Piltdown I hominin were only about 0.2% (Oakley and Hoskins 1950). These levels were similar to those found in contemporary bones, and the author suggested that the result "requires some explanation" (*ibid*, p. 381). These results were undoubtedly an important element in spurring Joseph Weiner and Wilfrid **Le Gros Clark** to collaborate with Kenneth Oakley to re-examine the alleged fossil hominin evidence from Piltdown. The morphological analyses showed that the nature of the flat occlusal surfaces of the molar teeth in the jaw was inconsistent with the flattening having been caused by natural wear; the edges of the cusps were sharp and not rounded, and the wear was greater on the lingual, or tongue, side of the teeth, rather than on the buccal side as is the case for naturally worn teeth. There was also evidence the teeth had been artificially abraded, for while the teeth on the mandible had been filed on the occlusal surface only, the Piltdown I canine and the Piltdown II molar had also been filed down on the sides. In addition, the dentine was flush with the enamel, and not below the level of the enamel as one would expect in naturally worn teeth. Radiography showed that the roots of the molars in the jaw were much

more ape-like than Underwood had contended, and there was no secondary dentine in the canine. Furthermore, the sand grains in the pulp space were not consolidated, but were loose, consistent with being recently introduced into the cavity. Weiner et al. were convinced the morphology of the mandible was consistent with that seen in modern orangutans, and when they broke a modern orangutan jaw in the same place as the Piltdown I jaw the resemblances between the two were very obvious. As part of the same detailed examination Oakley applied a more sensitive form of fluorine analysis to the Piltdown remains. The results of these analyses showed that the fluorine levels in the cranial bones and the mandible were 0.1 and 0.3%, respectively (Weiner et al. 1953). These fluorine levels implied two things. First, the cranial bones and the mandible were not the same age, and second, the mandible was almost certainly modern. This was consistent with Oakley's observation that when he drilled the teeth to extract dentine for analysis he noticed a smell of burning; this was evidence that there was still a substantial amount of organic material in the dentine. In addition, the three scientists showed that while the brown color of the coliths was natural, the "paleolith" flint found by Teilhard de Chardin was "deliberately stained" with chromium, an element that does not occur naturally in the Piltdown gravels, and when they deliberately chipped the flint it was white beneath the surface. Most likely all of the four or five "paleolith" flints found at the Piltdown I site were Neolithic flints stained to look older. Between 1911 and 1914 18 fossil mammal bones and teeth had been recovered from the Piltdown I site; four were found *in situ*, two on the surface of an adjoining field, and the rest on spoil heaps; *none* were ever found anywhere nearby thereafter. Apart from one very dubious exception, no other evidence of such animals had ever been found in southern England outside of East Anglia; thus an isolated pocket of Villafranchian fossils at Piltdown is literally incredible. Other researchers showed that the level of radioactivity in the stegodon (*Elephas cf. planifrons*) teeth (and it is probable that the four tooth fragments came from two molars) could *only* be matched at a site in Tunisia, and it and a *Hippopotamus* tooth (that could only have come from Malta) had been stained with chromate. The rest of the mammal bones were almost certainly from "the Red Crag of East Anglia" (Weiner and Stringer 2003, p. 66), and as might be surmised from the name of the site, these fossils did not need staining. Finally, Kenneth Oakley showed

that the "club-like bone implement" found at the Piltdown I site was a piece of silicized bone that had been worked with a metal knife. Piltdown II was also highly suspect: the fluorine analyses showed that the tooth does not belong to the cranium, the frontal and occipital were stained with both iron and chromate, the mammal fossils came from Red Crag, and the frontal fragment proved to be part of the same cranium that provided the pieces of Piltdown I. All this was more than sufficient evidence for Weiner, Oakley, and Le Gros Clark to say with confidence that the Piltdown hominin fossils were modern and not ancient, and that their association with the Piltdown site was the result of an elaborate hoax (Weiner et al. 1953). Joe Weiner's excellent book about the Piltdown fraud was reprinted with a new introduction and afterword contributed by Chris Stringer (Weiner and Stringer 2003). In the afterword Stringer reviews the "runners and riders" in the Piltdown fraudster stakes. In addition to the person who Weiner considered the chief suspect, Charles Dawson, the other potential fraudsters can be divided into those who have been proposed as his potential accomplices, those who have been proposed as the sole perpetrator of the fraud, and finally people who might have combined their energies to perpetrate the fraud. The accomplice category is small, and includes just Lewis Abbott (a local jeweler and amateur paleontologist). Those considered as potential sole perpetrators of the fraud include Frank Barlow [a preparator at the British Museum (Natural History)], William Butterfield (the Curator of the Hastings Museum), Sir Arthur Conan Doyle, Venus Hargreaves (the labourer who assisted Dawson), Martin Hinton (a junior colleague of Sir Arthur Smith Woodward's), Sir Arthur Keith, Sir Grafton Elliot Smith, William Johnson Sollas (professor of geology at Oxford), Fr. Teilhard de Chardin, and Sir Arthur Smith Woodward. The only two pairs of people proposed as co-conspirators are Martin Hinton and Fr. Teilhard de Chardin, and Samuel Woodhead (a public analyst) and John Hewitt (a professor of chemistry). References for these accusations are given in Weiner and Stringer (2003). Notwithstanding the suggestions given above, there is both circumstantial and direct evidence in favor of Dawson's involvement. The circumstantial evidence includes several examples of Dawson's dishonesty in connection with other antiquarian curiosities (Russell 2003), and Weiner sets out the direct evidence in his account of the fraud (Weiner 1955). For example, Weiner recounts

that as part of his investigation he had been advised to contact A.P. Pollard, the Assistant Surveyor of the Sussex County Council, to ascertain his views about the Piltdown controversy. Weiner reports that Pollard was forthright and said that “I believe it (Piltdown) is a fraud. At least, that is what my old friend Harry Morris used to say” (*ibid*, p. 154). This refers to an assessment of one of the Piltdown flints by a noted flint expert, Harry Morris, who was an acquaintance of Pollard’s. Weiner managed to track down Morris’ “flint cabinet” and in it was a stained flint (resembling the three “Pre-Chellean paleolith” flints from Piltdown) with two notes. On one was written “Stained by C. Dawson with intent to defraud (all) – H.M.” and on the other “Stained with permanganate of potash and exchanged by D. for my most valuable specimen.” Furthermore, when dilute hydrochloric acid was applied to the three Piltdown “paleoliths,” plus the flint Morris had received in exchange from Dawson, the dark stain on the surface quickly dissolved to expose a white surface. Finally, Stringer is of the opinion that the Piltdown II molar comes from the same individual as the mandible of Piltdown I. If this is the case then this is further evidence that Dawson is linked with *both* Piltdown II and Piltdown I. However, numerous other people besides Dawson were, and continue to be, suspected as the perpetrator(s) and the authorship of the Piltdown fraud has still not definitively been resolved.

Piltdown I *See* Piltdown.

Piltdown II *See* Piltdown.

pink breccia *See* Swartkrans.

Pinnacle Point (Location 34°12’S, 22°05’E, South Africa) History and general description This series of at least 15 caves and rockshelters overlooking the Indian Ocean is exposed in quartzite cliffs near Mossel Bay, South Africa, has been under intensive investigation by Curtis Marean and his colleagues since 2000. Site PP13B, a 30 m×8 m cave, is the most extensively studied and excavated and it is one of the few **Middle Stone Age** (or MSA) archeological sites to sample **Oxygen Isotope Stage** (OIS) 6. Unlike most coastal caves the sediments in PP13B were not scoured by the rising sea levels of the last interglacial. Temporal span and how dated? Published dates for the OIS 6 sediments (the Lightly Consolidated or LC-MSA deposit) have bounding

single-grain optically stimulated **luminescence dating** age estimates of 164±12 and 90±6 ka, with overlying **uranium-series dating** estimates on **speleothems** that formed during cave closure ranging from 39 to 92 ka. Hominins found at site Two hominin fragments were found from disturbed sediments in PP13B, but these likely derive from MSA strata. They include a left parietal fragment of a young adult (specimen 4500) and a central incisor (specimen 4501). Archeological evidence found at site Multiple hearths, abundant shellfish remains, **Levallois** and other flakes, cores, and bladelets made predominantly of quartzite, and more than 50 pieces of red ochre, many of them ground or scraped. Faunal remains from the LC-MSA deposit include tortoise and a variety of bovids, particularly eland and fewer grysbok/steenbok and mountain reedbuck. Key references: Geology, dating, and paleoenvironment Marean et al. 2004, 2007, 2010, Jacobs 2010, Karkanas and Goldberg 2010, Rector and Reed 2010; Hominins Marean et al. 2004, Marean 2010; Archeology Marean et al. 2004, 2007, Jerardino and Marean 2010, Schoville 2010, Thompson et al. 2010, Watts 2010.

Pinza-abu Cave *See* Ryukyuu Islands.

piriform aperture (L. *pirium*=pear) The opening into the nose from the face. The size, shape, and especially the form of the floor of the opening (e.g., smooth or sharp) have been used by paleoanthropologists as taxonomic and functional indicators. *See also* *Homo neanderthalensis*.

piriform cortex (L. *pyrum*=pear, it refers to the “pear-shape” of the nasal aperture) Part of the **allocortex** component of the **cerebral cortex** and concerned with the processing of olfaction (syn. paleocortex). *See also* **cerebral cortex**.

Pisces (L. *piscis*=fish) A discarded taxonomic term for the vertebrate group colloquially referred to as fish. The group of aquatic vertebrates formerly referred to as the Class Pisces is now thought to be **paraphyletic**, which is why in fish circles it has been abandoned. However, the term is still found in the literature and many faunal lists from fossil sites use it to refer to fish. The proper formal taxonomic umbrella term for the types of fish commonly recovered from the hominin fossil and archeological record should be the superclass **Osteichthyes**, which includes all bony fish.

piscivore (L. *piscis*=fish, plus *vorous*, from *vorare*=to devour) Literally, a fish eater. An organism that habitually feeds upon fish is called a piscivore, whereas the practice of eating fish is called piscivory.

Pithecanthropidae A family introduced by Eugène Dubois in 1894 to accommodate the taxon *Pithecanthropus erectus*, which just a year earlier he had introduced as *Anthropopithecus erectus*.

pithecanthropine Informal term for a member of the Pithecanthropidae (*which see*).

Pithecanthropus II *See* Sangiran 2.

Pithecanthropus III *See* Sangiran 3.

Pithecanthropus IV *See* Sangiran 4.

Pithecanthropus B *See* Sangiran 1b.

Pithecanthropus Haeckel, 1868 (Gk *pithekos*=ape and *anthropos*=human being) The genus name *Pithecanthropus* was introduced by Ernst Haeckel in his 1868 *Natürliche Schöpfungsgeschichte* (*The History of Creation*) for *Pithecanthropus alalus*, a taxon that Haeckel predicted would be found to provide a link between *Prohylobates* and modern humans. This, the penultimate and 29th stage in Haeckel's evolutionary scheme, was described in the 1906 English translation of his 1874 *Anthropogenie* (*The Evolution of Man*) as the “speechless primitive men” (*Alali*), which were men as far as their general structure is concerned (especially in the differentiation of the limbs), “but men who lacked one of the chief human characteristics, articulate speech and the higher intelligence that goes with it, and so had a less developed brain” (Haeckel 1906). The first researcher to use the genus *Pithecanthropus* in the conventional way was Eugène Dubois, who in 1894 used it to accommodate the taxon just 1 year earlier he had named *Anthropopithecus erectus*. The genus name was used until relatively recently for new species (e.g., *Pithecanthropus rudolfensis*) but Weidenreich (1940) was the first among many to recommend that *Pithecanthropus* (and *Sinanthropus*) should be transferred to *Homo*, so *Pithecanthropus* is now one of the many junior synonyms of *Homo*. *See also Pithecanthropus rudolfensis*.

Pithecanthropus mandible B *See* Sangiran 1b.

Pithecanthropus dubius von Koenigswald, 1950 (Gk *pithekos*=ape, *anthropos*=human being, and L. *dubiosus*=doubtful) A taxon introduced by von Koenigswald (1950) to accommodate the mandible Sangiran 5. First discovery Sangiran 5 (1939). Holotype As above. Main site Sangiran. *See also Pithecanthropus erectus; Homo erectus*.

Pithecanthropus erectus (Dubois, 1892), Dubois, 1894 (Gk *pithekos*=ape, *anthropos*=human being, and L. *erectus*=upright) A new combination used by Eugène Dubois (Dubois 1894) for the hominin species just a year earlier he had named *Anthropopithecus erectus* to accommodate an upper molar (Trinil 1) and a skullcap (Trinil 2) from Trinil. Wilfrid Le Gros Clark (1940) proposed that the *Sinanthropus* fossil hominins recovered in 1923 and thereafter from Choukoutien (now Zhoukoudian) should be transferred to *Pithecanthropus erectus*. Later in the same year Franz Weidenreich (1940) transferred the *Pithecanthropus erectus* hypodigm to *Homo*, so *Pithecanthropus erectus* is a junior synonym of *Homo erectus*. Howell (1994, Table 1) provides a useful review of how the new taxon was viewed by researchers in the two decades following its announcement. First discovery Trinil 1 (1891). Holotype Trinil 2 (1891). Main sites Trinil, Sangiran. *See also Homo erectus*.

Pithecanthropus modjokertensis (von Koenigswald, 1945) (Gk *pithekos*=ape, *anthropos*=human being, and L. *modjokertensis*=after the name of the village close to where Modjokerto 1 was found) A new combination introduced by Ralph von Koenigswald who was no longer willing to accommodate *Homo modjokertensis* within *Homo*.

Pithecanthropus robustus Weidenreich, 1945 (Gk *pithekos*=ape and L. *robustus*=oak or strength) Taxon introduced by Franz Weidenreich (1945) to accommodate the *Pithecanthropus* IV partial cranium (Sangiran 4) that was recovered from Sangiran in December 1938 and January 1939. von Koenigswald and Weidenreich (1939) attributed the cranium to *Pithecanthropus*, but Weidenreich subsequently argued that differences between the *Pithecanthropus* IV cranium and the *Pithecanthropus* crania I–III, which he accepted as *Pithecanthropus erectus*, justified the new species and that for “this more robust and primitive group I propose the name *Pithecanthropus robustus*”

(Weidenreich 1945, p. 33). First discovery Sangiran 4 (1938–9). Holotype As above. Main site Sangiran. See also *Pithecanthropus erectus*.

***Pithecanthropus rudolfensis* Alexeev, 1986**

(Gk *pithekos*=ape, *anthropos*=human being, and *rudolfensis*=after the old name, Lake Rudolf, for Lake Turkana) Hominin species established by Alexeev in his book *The Origin of the Human Race*. Although Alexeev did not formally designate KNM-ER 1470 as the holotype of the new species, he implied as much. He also complied with the rules if not the recommendations of the International Code for Zoological Nomenclature in the sense that the name *rudolfensis* was both available and valid and he compared the new species with *Pithecanthropus erectus*. Colin Groves (1989) proposed that *Pithecanthropus rudolfensis* be transferred to *Homo* as *Homo rudolfensis*; Wood (1992) provided a more comprehensive differential diagnosis for *H. rudolfensis* and later still it was formally proposed that KNM-ER 1470 be the lectotype of *H. rudolfensis* (Wood 1999). If *Homo habilis sensu lato* does subsume more than one species, then *H. rudolfensis* would be the second species. First discovery KNM-ER 819 (1971). Lectotype KNM-ER 1470 (1972). Main sites **Koobi Fora, Uraha**. See also *Homo rudolfensis*.

-pithecus (Gk *pithekos*=ape) Postfix meaning ape, or “ape-like.”

pixel See computed tomography.

plagioconule See metaconule.

plagiocrista A term introduced by Vanderbroek (1967) for an enamel feature on a maxillary molar tooth crown more commonly referred to as a distal trigon crest. See also distal trigon crest.

plain film radiography Also known as conventional radiography, this is the technology used to take standard radiographs of the chest or fractured bones in a clinical setting. Because the image is made from a single source of X rays, all you see on a conventional radiographic image is an outline of the densest structure between the source and the X ray film. Franz Weidenreich was one of the first paleoanthropologists to make intensive use of plain film radiography in his monographs on the **Zhoukoudian Lower Cave** fossils.

plane of interest See computed tomography; confocal microscopy.

planktonic foraminifera See foraminifera.

plant microfossils (Gk *micros*=small) Plant microfossils are plant remains that cannot be seen with the naked eye. They consist of **phytoliths**, **pollen**, and **starch grains**. All three types of microscopic body have been identified at archeological sites, and all three can be used to reconstruct diet and/or the **paleoenvironment**. See also **phytoliths**; **pollen**; **starch grains**.

plantar aponeurosis See foot function; longitudinal arch; push-off; windlass effect.

planum nuchale See nuchal plane.

planum temporale (L. *planus*=flat and *tempus*=time, thus it is literally “the flat part of the surface of the brain that lies beneath the temple”; NB: the part of the hair that tends to go gray first) A feature of the surface of the superior part of the temporal lobe of the **cerebral hemisphere**. It lies immediately posterior to Heschl’s gyrus (which corresponds to the location of primary auditory cortex) and anterior to the termination of the **Sylvian fissure**. The planum temporale can be defined only in species that possess a clear Heschl’s gyrus (i.e., hominoids). In line with the predominant left-sided language dominance seen in modern humans, the surface area of the planum temporale is greater on the left than on the right side in modern humans. However, the planum temporale also displays left-hemisphere dominance in great ape brains. Because the planum temporale is not evident on the surface of the cerebral hemispheres, and thus its presence and size are not accessible using natural or prepared endocasts, we have no access to evidence about its evolution within the hominin clade.

plasmid (Gk *plassein*=to mold, plus L. *id*=the same) A circular DNA chromosome that is independent of the primary set of chromosomes. Plasmids are typically found in bacterial cells (but they can also be found in Archaea and Eukaryotes) and may carry **genes** for antibiotic resistance or other phenotypic products. In the laboratory, plasmids can be constructed that contain specific genes or DNA fragments of interest and these can be

introduced into a cell. In this way, for example, bacteria (or yeast) can be used to replicate DNA fragments, to investigate expression patterns, or to produce a protein product.

plastic *See* phenotypic plasticity; plastic deformation.

plastic deformation (Gk *plastein*=to mold and L. *deformare*=undo form) Bones can be distorted by pressure either before they are fossilized or before fossilization has substantially hardened and stiffened them. These distortions result in permanent plastic deformation. This is difficult to correct, but researchers have recently used computer software to generate information about the “average” shape of other fossils belonging to the same fossil taxon, or the “average” shape of chimpanzee and modern human crania in order to determine the most likely shape of a deformed possible early hominin cranium (Zollikofer et al. 2005).

plasticity *See* phenotypic plasticity.

Plateau de Ruffet *See* Combe-Capelle.

platform The portion of a flake that includes the part of the **striking platform** removed from the core when a flake is detached (syn. butt).

pleiotropy (Gk *pleiōn*=more and *tropos*=towards) Describes the circumstances under which a single gene has been shown to influence multiple phenotypic traits. These pleiotropic properties may be manifested concurrently, or they may be separated temporally, across the lifetime of an individual. For example, high levels of testosterone in young adult modern human males may contribute to reproductive success, but later in life they are correlated with an increased risk of prostate cancer, and Marfan’s syndrome, a defect in the *FBNI* gene and abnormal production of the protein fibrillin, is characterized by abnormally long and slender fingers, extremely mobile joints, disproportionately long limbs, as well as by heart and eye defects. Pleiotropy may be one of the reasons why phenotypic characters are found to co-vary for reasons other than shared evolutionary history.

Pleistocene (Gk *pleistos*=most and *kainos*=new) This term, introduced by Charles Lyell in 1839, refers first of the two **epochs** that comprise

the **Quaternary** period. Pleistocene refers to a unit of geological time (i.e., a **geochronologic unit**). It spans the interval of time between 2.58 Ma (Gelasian) or 1.8 Ma (Calabrian) and 11.5 ka. In this encyclopedia Pleistocene is used in the sense meant before the 2009 International Union of Geological Sciences decision (*see* **Plio-Pleistocene boundary** for details).

Plesianthropus Broom, 1938 (Gk *plesios*=near to and *anthropos*=human being) A genus established by Robert **Broom** (1938, p. 377) to accommodate the early hominin species previously referred to as *Australopithecus transvaalensis*. *Plesianthropus* was formally sunk into *Australopithecus* by Robinson (1954a, p. 196) and it is now almost universally regarded as a junior synonym of *Australopithecus*. *See also* *Australopithecus*; *Australopithecus africanus*.

Plesianthropus transvaalensis (Broom, 1936) Broom, 1938 [Gk *plesios*=near to and *anthropos*=human being and *transvaal*=refers to the old name for the province (now called Gauteng) where Sterkfontein is located] A new combination employed by Broom (1938). This hominin species was originally established by Robert **Broom** 1936 as *Australopithecus transvaalensis* to accommodate **TM 1511** and similar fossils recovered from **Sterkfontein**. In 1938 Broom transferred the species to *Plesianthropus*. John **Robinson** (1954a, p. 198) formally proposed that the species *Plesianthropus transvaalensis* be relegated to a subspecies of *Australopithecus africanus* as *Au. africanus transvaalensis* suggesting that among the dental differences between *Au. africanus transvaalensis* and *Au. africanus africanus* were that the M_1 of the former lacked a C6 and that the deciduous lower canine of the latter lacked a mesial cusplet. Most researchers consider *Plesianthropus transvaalensis* to be a junior synonym of *Australopithecus africanus*. First discovery **TM 1511** (1936). Holotype As above. Main site Sterkfontein. *See also* *Australopithecus africanus*; *Australopithecus transvaalensis*.

plesioconulid A term sometimes used for an accessory cuspid on the occlusal surface of a mandibular postcanine tooth; it is more commonly referred to as a **mesioconulid**. *See also* **mesioconulid**.

plesiomorphic (Gk *plesio*=near and *morph*=form) The primitive condition, or state, of a

character used in a phylogenetic or **cladistic analysis**. *See also* **cladistic analysis**.

plesiomorphy (Gk *plesio*=near and *morph*=form) The state of a character in the hypothetical most recent common ancestor of a clade, or the state of a character in an outgroup (syn. **sympleiomorphy**). *See also* **cladistic analysis**.

Plio-Pleistocene (Gk *pleion*=more, *pleistos*=most, and *kainos*=new) The period of geological time since *c.*5 Ma (i.e., that includes the Pliocene and Pleistocene epochs). It is most often used because it covers the interval during which most of hominin evolution occurred and it almost certainly includes the origin and subsequent evolution of *Homo*. Some authors use Plio-Pleistocene because it approximates the period of time during which the northern hemisphere has been glaciated. *See also* **Northern Hemisphere Glaciation**; **Plio-Pleistocene boundary**; **Pleistocene**; **Pliocene**.

Plio-Pleistocene boundary In 2009 the International Union of Geological Sciences (or IUGS) ratified a proposal that the boundary between the **Pliocene** and **Pleistocene** epochs be lowered from the Calabrian-Gelasian boundary at 1.8 Ma (near the base of the **Olduvai subchron**) to the Gelasian-Piacenzian at 2.58 Ma (near the base of the **Matuyama chron**). More than a half-century of debate has surrounded this issue and it is unlikely that this decree will fully resolve the question. The International Geological Congress of 1948 made an attempt to define the Plio-Pleistocene boundary under the stipulation that it should be based on changes in marine faunas. They determined it to be at the base of the Calabrian **stage** in Italy, later dated to the end of the Olduvai subchron (i.e., 1.8 Ma). In 1983, the International Commission on Stratigraphy agreed with this decision, and used sediments at Vrica in Calabria dated to the top of the Olduvai subchron to identify the beginning of the Pleistocene. However, as interest in global climate change grew in the ensuing decades, the problem of the **Quaternary** resurfaced. The historical association of the Quaternary with a global cooling event had many workers pushing for its official recognition (*see* **Tertiary**) arguing that the present global climate is distinct from that of the **Neogene**, and that the climate changes involved happened from 2.8 to 2.4 Ma (near the base of the Gelasian). To maintain the geochronological hierarchy, any effort to for-

mally ratify the Quaternary as the third **period** of the **Cenozoic** must necessarily be correlated with an effort to also lower the base of the Pleistocene, and this is what happened in 2009. In this encyclopedia Pleistocene is used in the sense meant before the 2009 IUGS decision. The last major published time scale, in which the base of the Pleistocene is defined by the reference section (i.e., the Global Boundary Stratotype Section and Point, or GSSP) of the Calabrian Stage at 1.806 (*c.*1.8) Ma is Gradstein et al. (2004); the revised time scale approved by IUGS, in which the base of the Pleistocene is defined by the GSSP of the Gelasian Stage at 2.588 (*c.*2.6) Ma is Gibbard et al. (2010). Opponents of the 2009 decision cite the lack of faunal turnover at the Calabrian-Gelasian boundary and stress that the latest glacial episode may not be fundamentally different from the rest of the Neogene. The resulting 44% expansion of the Pleistocene is opposed by a large body of researchers who work on late Cenozoic (post-Miocene) subjects, on the grounds that this radical shift was not adequately justified under chronostratigraphic guidelines and that representatives of the affected disciplines were not consulted; a formal move to reverse the action is being prepared for presentation to the IUGS. For more detail on the debate see Gibbard et al. (2010), Aubry et al. (2009), Head et al. (2008) and McGowran et al. (2009).

Pliocene (Gk *pleion*=more and *kainos*=new) The second and the most recent **epoch** of the **Neogene** period. Pliocene refers to a unit of geological time (i.e., it is a **geochronologic unit**). It previously spanned the interval between *c.*5.3 and 1.8 Ma (Calabrian), but in 2009 the International Union of Geological Sciences allocated the Gelasian stage to the **Pleistocene** so until and unless their recommendation is overturned the Pliocene now spans the interval of time between *c.*5.3 and 2.58 Ma (Gelasian). In this encyclopedia Pliocene is used in the sense meant before the 2009 International Union of Geological Sciences decision (*see* **Plio-Pleistocene boundary** for details). The Pliocene is typically divided into Late and Early subdivisions.

ploidy (Gk *ploos*=fold) A multiple of the basic number of **chromosomes** in a cell. Normal modern human somatic cells are diploid (i.e., two sets), while the gametes are haploid (i.e., a single set). In modern humans, any abnormally polyploid cells produced during reproduction are not viable, but

polyploidy is important for the production of new plant species.

plunge In structural geology, plunge refers to the **dip** and dip direction of linear features such as the axial trace of a fold or the orientation of the long axis of sedimentary **clasts** or fossils. It is usually given as the angle from the horizontal followed by the bearing from north (i.e., 34° to 270°). It can be useful to analyse the plunge directions of fossils to test for evidence of any **reworking** of that fossil assemblage by natural agencies such as stream action or trampling. In this type of analysis, nonrandom plunge values (i.e., orientation) can be taken as evidence of reworking of fossils by the action of streams, rivers, or slope wash.

PM Acronym for the posterior maxillary plane of Enlow. *See* **posterior maxillary plane**.

PM plane *See* **posterior maxillary plane**.

Podbaba (Location approximately 59°06'N, 14°23'E, Czech Republic; etym. named after the neighborhood of Prague in which it is found) History and general description A partial calvaria, discovered in 1883 and thought to derive from an **Aurignacian** layer, was destroyed during blasting in 1921. Temporal span and how dated? Undated. Hominins found at site A partial calvaria attributed to *Homo sapiens*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Churchill and Smith 2000; Hominins Churchill and Smith 2000.

point (OF *pointe*=sharp end) In the analysis of stone artifacts, the term point refers to pieces that are pointed in shape. Typically (but not always), points are inferred to represent the tips of hunting weapons such as spears or arrows. Stone points are characteristic of many **Middle Stone Age** sites in Africa (e.g., **Blombos Cave**), and they also occur at some similarly aged Middle Paleolithic sites in Eurasia. Ethnographic, historic, and archeological data demonstrate that points were also made of other materials such as bone and wood, although for obvious reasons these rarely preserve in the archeological record.

point mutation *See* **single nucleotide polymorphism; mutation**.

Poisson's ratio A material property, denoted by ν , that measures the degree to which a material contracts (or, rarely, expands) in the directions perpendicular to the axis of the direction in which it is being placed under tension. Conversely, it can represent the degree to which a material expands in the directions perpendicular to the direction in which it is being compressed. Mathematically, it is defined as the negative of the ratio of transverse **strain** divided by axial strain. Rubber has a Poisson's ratio of nearly 0.5 (which is the maximum possible value of ν), while cork has a ratio that is nearly 0. Cortical bone is often said to have a Poisson's ratio of 0.3, although this is an oversimplification.

polarity (Gk *polus*=axis) Earth sciences Refers to each end of an axis passing through a sphere and in that sense it is used to refer to the direction, either normal or reversed, of the Earth's magnetic field. *See also* **geomagnetic dating**. Systematics In **cladistic analysis** it is used to refer to the alignment of a sequence of character states, with the most primitive character state at one end and the most derived at the other. *See also* **cladistic analysis; morphocline**.

polarity chronozone *See* **chron**.

polarity reversal *See* **geomagnetic dating**.

polarization Earth sciences In earth science polarization refers to rocks that have magnetized particles so that at the time of deposition of sediments or when a lava cools, the direction of the Earth's magnetic field is preserved. At present the Earth's field is polarized so that the needle of a compass points to the north; this is called the normal direction. This has not always been the case and the Earth's history has seen a series of polarity reversals related to changes in pattern of flow in the fluid Earth core. *See also* **geomagnetic dating**. Systematics In systematics, polarization is the process of deciding which state of a character is primitive and which is derived. Several techniques have been developed to facilitate polarization. These include the stratigraphic criterion, the ontogenetic criterion, and communality analysis, but the most widely used technique is outgroup analysis. *See also* **cladistic analysis**.

pollen (L. *pollen*=fine flour, mill dust) One of several kinds of **plant microfossils** (the others

are **phytoliths** and **starch grains**). Pollen is the male gamete of flowering plants and it is either wind-borne or carried by insects. The shapes and sizes of pollen grains are usually unique to the plant taxon (e.g., at the level of the family, tribe, or genus and sometimes even at the level of the species) that produced it, and can be used to identify the presence of these plants in the archeological record. Pollen is particularly hardy and fossilizes well, but because pollen can travel long distances it is more useful for reconstructing the paleoenvironment rather than for reconstructing diet. The study of pollen is called **palynology** and *Traverse (2007)* provides a useful primer for anyone exploring the use of pollen for reconstructing the paleoenvironment. *See also* **palynology**; **paleoenvironmental reconstruction**.

poly-A tail The term refers to the addition of adenosine monophosphates to the end of a **messenger RNA** sequence after the mRNA has been generated by **transcription**, but before it leaves the nucleus. The addition of adenosine monophosphates (also called polyadenylation) is important for mRNA transport from the nucleus to the cytoplasm and for proper **translation**.

polycentric *See* **Weidenreich, Franz**.

polygenic trait A phenotypic trait that results from the combined effect (action of) alleles at more than one locus and the environment, which does not follow simple Mendelian patterns of inheritance. Because they depend on the simultaneous presence of several alleles as well as an environmental influence, polygenic traits have more complex hereditary patterns than simple monogenic traits (e.g., skin color, hair color, height, weight, and blood pressure). The variation in polygenic traits in a population is often described as continuous, and it can be depicted by a bell curve.

polygenist theories *See* **multiregional hypothesis**.

polymerase An enzyme that catalyzes the synthesis of DNA or RNA using an existing DNA or RNA template. *See also* **polymerase chain reaction**.

polymerase chain reaction (or PCR) This reaction serves to copy, or amplify, a fragment of DNA. The process has three steps: DNA denatura-

tion, primer annealing, and DNA extension. First, the DNA is heated to approximately 94°C to separate (or denature) the double-helix structure into single strands. The temperature is then lowered to enable primers to stick, or anneal, to the DNA. This temperature is dependent on the GC base composition [i.e., the guanine (G) and cytosine (C) content] of the primers and the DNA sequence of interest. Primers, which define the segment of DNA to be amplified, are short single-stranded fragments of DNA (usually 15–25 base pairs long) that are complementary to a portion of the DNA sequence of interest. In the third and last step the temperature is increased again, this time to approximately 72°C, to enhance the activity of the *Taq* polymerase, an enzyme that adds complementary bases to extend the single-stranded DNA molecule. This cycle of denaturation, annealing, and extension is repeated 25–40 times during PCR, so that although initially only a small amount (maybe only a few molecules) of DNA is present; the repeated PCR process increases the amount of the specified fragment of DNA exponentially so that following PCR millions of copies are present. There are several variants of PCR. In reverse transcription PCR (RT-PCR) RNA is first reverse transcribed into DNA and then that DNA is amplified, and in quantitative PCR (qPCR), or real-time PCR, the specified DNA is both amplified and quantified.

polymorphic *See* **polymorphism**.

polymorphism (Gk *poly*=much and *morphe*=form, literally “many forms”) A morphological or genetic feature or character with alternative specifiable states within a biological population. For the genotype, for example, polymorphism includes having more than one type of allele at a locus (e.g., sickle cell). Examples from morphology relevant to human evolution include the several discrete forms the root system of a tooth may take or the sex-specific variation seen in the occurrence of sagittal crests. Not to be confused with **polytypism**, which describes a species with multiple phenotypically and/or genotypically distinct populations that may be classified as subspecies (e.g., chimpanzees, orangutans).

Polynesia (Gk *polus*=much or many and *nesos*=island, literally “many islands”) One of the three major divisions of small islands that make up **Oceania** (the others are **Melanesia** and **Micronesia**). The islands within Polynesia (e.g., Samoa, Tahiti) extend

north from New Zealand to Hawai'i, and east to Easter Island. For obvious reasons these islands were among the last places to be reached by modern humans. *See* Oceania, **peopling of**.

polypeptide (Gk *poly*=much and *peptide*, a compound containing two, or more, amino acids) A string of amino acids forming all, or part of, a **protein**.

polyphyletic An adjective used to describe a taxon that is part of a **polyphyletic group**. *See* **polyphyletic group**.

polyphyletic group (Gk *poly*=many and *phylon*=races) A polyphyletic group is a taxonomic grouping that includes taxa from more than one **clade** or monophyletic group. The "baboon" group, if it includes savanna (*Papio*), forest (*Mandrillus*), and gelada (*Theropithecus*) baboons, is an example of a polyphyletic group because there is sound molecular evidence that mandrills belong in a separate clade. *Papio* and *Theropithecus* form a clade with a group of smaller-bodied monkeys that are assigned to *Lophocebus*, whereas *Mandrillus* forms a clade with a different group of smaller-bodied monkeys. The latter are assigned to the genus *Cercocebus*, which is a different group of smaller-bodied monkeys. Recent analyses suggest that the morphological similarities between mandrills on the one hand, and savanna baboons and gelada baboons on the other, are the result of convergent evolution or parallel evolution and are therefore examples of **homoplasy** rather than **homology**.

polyphyly *See* **polyphyletic group**.

polytypic *See* **polytypism**.

polytypism (Gk *poly*=much and *typos*=impression) A species with multiple phenotypically and/or genotypically distinct populations that may be classified as subspecies (e.g., chimpanzees or orangutans). Not to be confused with **polymorphism**, which refers to a feature or character of the phenotype or genotype with alternative specifiable states (e.g., number of cusps on a molar tooth or the pattern of intracranial venous sinuses) within a biological population.

ponderal index (L. *pondus*=weight) Ratio of body mass relative to stature, calculated as [(body

mass)^{1/3}/stature]×100. Modern humans have a high ponderal index compared to the extant great apes. Archaic hominins such as *Australopithecus afarensis* appear to have had a low, relatively ape-like, ponderal index.

Pongo At first it was thought that the flanged adult male orangutans were a different species from the juveniles that were usually seen in Europe, and they were even placed in a separate genus, *Lophotes*, but gradually it was realized that substantial change occurs during the ontogeny of male orangutans. Until the late 20thC most researchers recognized just one orangutan species, but since then fixed genetic and absolute morphological differences have been elucidated between Bornean and Sumatran orangutans, and they are now universally distinguished as different species: *Pongo pygmaeus* from Borneo and *Pongo abelii* from Sumatra. There are also differences between different populations within Borneo, and three subspecies (*Pongo pygmaeus pygmaeus* from the northwest, *Pongo pygmaeus wurmbii* from the southwest, and *Pongo pygmaeus morio* from the northeast) are recognized, but there is growing evidence that they may be nearly as distinct from one another as each of them is from the Sumatran form.

Pontnewydd (Location 53°13'N, 3°28'W, Wales, UK; etym. named after the nearby town of Bontnewydd) History and general description Known since at least the late 1800s, this cave site was excavated between 1978 and 1995 by the National Museums and Galleries of Wales. Researchers found an Acheulean assemblage and several hominin remains, including a well-dated tooth, which is the second-oldest hominin fossil in Britain, after Swanscombe. Temporal span and how dated? Uranium-series dating and thermoluminescence dating suggest an age of *c.*200 ka for the oldest tooth. Hominins found at site A molar that is similar to the fossils from **Krapina**, and two other hominin fragments that are likely but not necessarily from the Acheulean layers. Several other Holocene hominin remains were also recovered. Archeological evidence found at site An Acheulean stone tool assemblage, as well as later, Middle Paleolithic deposits. Key references: Geology, dating, and paleoenvironment Green et al. 1981, Green 1993; Hominins Green et al. 1981, Green 1993, Aldhouse-Green et al. 1996; Archeology Green et al. 1981, Green 1993.

population Evolution The group of interest for a study. A population may include the entire species, a subset, or a small sample taken from a species. Statistics The full set of possible values from which a smaller set of values known as a **sample** is drawn for use in statistical tests. For example, a sample of cranial capacities can be drawn from the population of all chimpanzee crania which have ever existed. Statistics based on a sample are used to make inferences regarding the population from which the sample is drawn.

population bottleneck *See* bottleneck.

population genetics The study of allele frequencies in populations. Specifically, it focuses on the effects of the four forces of evolution (**natural selection**, **genetic drift**, **gene flow**, and **mutation**).

population size Population size is literally the number of individuals alive at any one time for a given population. Typically, in modern human demography the population size is specified at mid-year, although if the population is stationary the population size is unchanging and could be measured at any time. Population size is used synonymously with census size, as the number of individuals alive at any one time. Population size is usually greater than effective population size, which is the size of an idealized population that would produce the same amount of genetic drift as observed in the actual population. *See* **effective population size** for examples of demographic processes (such as variance in completed family sizes) that lower the effective population size relative to the (census) population size.

population structure A population is described as structured if mating is not random. For example, in modern humans, geography (including distance or barriers), language, and other cultural factors influence mate choice and thus gene flow.

Porc-Épic Cave (Location 9°34'N, 41°53'E, Ethiopia; etym. Fr. for “porcupine,” presumably because porcupines frequented the cave, but the reason the name was attached to the cave is obscure) History and general description The investigation of the cave, which was formed in Mesozoic limestone in the Ethiopian highlands, has a complex history. It was first excavated by a French team in the 1920s and 1930s that included

Fr. Teilhard de Chardin and the Abbé Breuil. Desmond Clark excavated there in 1974, as did K.D. Williamson in 1975–6, and the material from the latter excavations has only been recently discovered and analyzed. Temporal span and how dated? The age of the Porc-Épic sequence remains poorly constrained. Three **obsidian hydration dating** age estimates of c.61–77 ka from artifacts from the 1930s excavations stored at the Field Museum in Chicago lack stratigraphic provenance. Three **AMS radiocarbon dating** assays on gastropod shell fragments range from c.33 ka to more than 43 ka. Overall, these results suggest a **Late Pleistocene** age for the Porc-Épic artifacts and fossils. Hominins found at site Mandibular fragment including two premolars and three molars. Archeological evidence found at site **Middle Stone Age** artifacts primarily made of locally available **chert**, with lesser amounts of other materials including **basalt** and **obsidian** from unknown sources occur in **breccia** interstratified with **speleothem**. Small Levallois, discoidal, and single and double platform cores produced flakes, blades, and bladelets, many retouched into a wide range of point forms (approximately 40% of the formal tools) and scrapers. The well-preserved faunal assemblage is dominated by bovids, lagomorphs, and hyrax, and cutmarks and bone breakage patterns suggest that it is primarily hominin-accumulated. The dominance of high-utility bones suggests effective hunting by hominins and selective food transport to the cave. Porc-Épic Cave is situated in a difficult to access topographic high point that affords excellent visibility of the surrounding area, possibly resulting in its use as a hunting station. The material recovered within the Middle Stone Age layers includes 419 complete perforated opercula of the terrestrial gastropod *Revoilia guillainnopsis*. Their spatial distribution, evidence of polish within the perforations, and the lack of any evidence that they were used as food suggests a possible symbolic use, perhaps as beads. Later Stone Age material from overlying loamy sands has not been published in detail. Key references: Geology, dating, and paleoenvironment Clark et al. 1984b, Assefa 2006; Hominins Vallois 1951; Archeology Clark et al. 1984, Pleurdeau 2005, Assefa 2006, Assefa et al. 2008a.

porcupines The informal name for part of the suborder Hystricomorpha of the order **Rodentia**. Porcupines are of interest from a taphonomic

perspective, as they are well known to accumulate large bone assemblages that can include remains of small (e.g., rabbit-sized) and large (e.g., wild-beest-sized) mammals. Such assemblages are characterized by high frequencies (60–100%) of specimens with evidence of porcupine-gnawing. *See also* **Rodentia**.

portable confocal scanning optical microscope A portable version of a **confocal scanning light microscope** developed by Tim Bromage and colleagues. The portable confocal scanning optical microscope is based on the Nipkow disc technology. The microscope provides images in real time in a very thin optical plane, thus with the minimum of superimposition. It can generate images less than 50 μm beneath the surface of an object such as a tooth or a long bone (Bromage et al. 2009). *See also* **confocal scanning light microscope**.

positive allometry (Gk *allo*=other and *metron*=measure) This term refers to a relative size relationship in which part of an organism, or a variable that functions as a proxy for part of an organism, increases in size at a faster rate than the overall size of the organism, or a variable that functions as a proxy for the whole of an organism (i.e., the variable becomes proportionally larger as overall body size increases). *See also* **allometry**; **scaling**.

positive assortative mating *See* **positive assortment**.

positive assortment In simple terms, this occurs when individuals choose to mate with those who are similar to themselves (i.e., when “like” mates with “like”). Examples of positive assortative mating in modern humans include matings between individuals who share religious beliefs, education, height, and skin color (e.g., Spuhler 1972, Mascie-Taylor 1987). When positive assortative mating is based on heritable traits, it tends to reduce overall variation.

positive selection *See* **directional selection**.

positron emission tomography [etym. A positron, which is the antimatter equivalent of an electron, is emitted by radioactive material; emission refers to emitted positrons and photons and Gk *tomos*=a cutting (from *temnein*=to cut) and

graphein=to write refers to the name of the detection system that detect photons in virtual slices through the brain] (or PET) A noninvasive neuroimaging modality that enables researchers to visualize and measure specific biochemical reactions *in vivo* (i.e., in the case of PET the subjects are alive *and* conscious). It involves the injection or consumption of radioactive compounds (called radiotracers), which are then differentially distributed, and their concentration is captured by detectors that respond to photons generated by radioactive decay. Much like autoradiography, PET can also be used to image the distribution and density of neurotransmitter receptors and transporters in the brain by employing radioactively labeled ligands. Oxygen and glucose are commonly used as radiotracers because they accumulate in tissues that are metabolically active. In the brain, this heightened metabolic signal is correlated with activity at synapses. The radiotracers accumulate in cells proportional to the latter’s rate of metabolism. When the radioactive material decays, it emits a positron. After traveling a short distance in the brain, the positron collides with an electron. The positron and the electron annihilate each other and in the process emit two photons that travel in opposite directions (i.e., at 180 degrees to each other). The photons are detected as “pairs in coincidence” by a series of specialized detectors arranged in a ring around the subject. Subsequently, these signals can be assembled into three-dimensional images by a computer. The image generated by detecting the emitted photons shows the distribution of radioactivity in the brain, which is a reflection of regional metabolism during the period when the tracer was taken up. Applications of this method include (a) the description of changes in regional brain glucose metabolism during development in modern humans and Old World monkeys, (b) the comparison of resting brain glucose consumption in modern humans, chimpanzees, and macaque monkeys, and (c) the visualization of the brain areas that are activated during communicative and cognitive tasks in chimpanzees. PET is currently the only feasible method for imaging brain function in living apes.

post-incisive planum A feature that is found when the mandibular symphysis and the perisymphyseal part of the mandibular corpus are thick. In that event the bone immediately posterior to the incisors is not vertically oriented as it is in modern

humans, but instead it slopes more horizontally and posteriorly.

post-reproductive life span *See* grandmother hypothesis; life history.

post-talonid basin The term used by Hershkovitz (1971) for the area others refer to as fovea posterior (mandibular). *See also* fovea posterior (mandibular).

post-weaning dependency *See* age at weaning.

postcanine teeth A tooth that is distal to the canine in the tooth row. In the deciduous dentition it refers to the first and second deciduous molars, and in the permanent dentition to the two premolars and the three permanent molars.

postcanine tooth *See* postcanine teeth.

postcanine tooth row In the deciduous dentition it refers to the first and second deciduous molars, and in the permanent dentition the two premolars and the three permanent molars.

postcentral gyrus (Gk *gyros*=circle, ring) This area of the cerebral hemispheres of the brain is located in the parietal lobe, posterior to the central sulcus and anterior to interparietal sulcus. The postcentral gyrus corresponds to Brodmann's areas 1, 2, and 3 and is the primary somatic sensory cortex. The cortex of the postcentral gyrus contains a sensory map (or topographic representation) of the surface of the body, although not all body parts are represented equally. The representation of the hands and orofacial region are disproportionately large in modern humans and other primates, reflecting the important role of sensory information from these body parts in primate behavior.

postcingulid A term used by Schwartz and Tattersall (2002) for an enamel crest on the postcanine mandibular teeth more commonly referred to as the distal marginal ridge. *See* distal marginal ridge.

postcingulum A term used by Schwartz and Tattersall (2002) for an enamel crest on the postcanine maxillary teeth more commonly referred to as the distal marginal ridge. *See* distal marginal ridge.

postcristid *See* distal marginal ridge.

postcuspidal fossa The term used by Hrdlička (1924) for a tooth crown feature that others call fovea posterior (mandibular). *See* fovea posterior (mandibular).

postentoconid cristid A term used by Pilbrow (2006) for an enamel crest that runs distally from the tip of the entoconid on a mandibular postcanine tooth crown.

postentoconule A term introduced by Hershkovitz (1971) for an accessory cusp on the lingual end of the distal enamel ridge of a maxillary molar tooth crown (syn. distoconule, distoconulus, hypostyle, tuberculum accessorium posterium internum). *See also* distal accessory tubercle.

postentoconulid A term introduced by Hershkovitz (1971) for an accessory cusp on the crown of a mandibular molar; others more commonly refer to this feature as a tuberculum sextum. *See also* tuberculum sextum.

postentocristid A term introduced by Hershkovitz (1971) and used by Grine (1984) for a ridge of enamel in a mandibular molar tooth crown that runs between the entoconid and the hypoconulid, mesial to the distal marginal ridge.

posterior fovea *See* fovea.

posterior fovea (mandibular) *See* fovea posterior (mandibular).

posterior fovea (maxillary) *See* fovea posterior (maxillary).

posterior margin A term sometimes used for an enamel feature more commonly referred to as a distal marginal ridge on a maxillary postcanine tooth crown. *See also* distal marginal ridge.

posterior maxillary plane (or PM plane) Called a plane, but Enlow and Azuma (1975) defined it as a line, one terminus of which is the location in the mid-sagittal plane of a line joining the most inferior and posterior points on both maxillary tuberosities (called the pterygomaxillary point), the other terminus being the location in the mid-sagittal plane of a line joining the most

anterior points on the lamina of the greater wings of the sphenoid (called the posterior maxillary point). Strictly a plane cannot be defined by fewer than three points, so to be a “proper” plane it needs to be defined by the locations of the two pairs of bilateral reference points listed above. The superior terminus of the PM plane marks the boundary between the middle and anterior cranial fossae (*see basicranium*), and the inferior termini mark the posterior extent of the face. Enlow and Azuma (1975) suggest that one of the architectural constraints in the cranium is that the angle between the posterior maxillary plane and the neutral horizontal axis of the orbit (i.e., a line joining the midpoint of the orbital opening with the midpoint of the optic canal) is 90°, and because of this some researchers have suggested that the PM plane should be used more widely as a reference for functional studies of the cranium. Bromage et al. (2008) used this relationship to reconstruct the face of KNM-ER 1470 as being more prognathic than in the original reconstruction.

posterior parietal cortex (*L. parietalis*=of, or belonging to, walls and *cortex*=husk, shell) This region of the neocortex, which contains Brodmann’s areas 5, 7, 39, and 40, is located between the occipital lobe and the primary somatosensory cortex. It is involved in the coordination of somatic sensation, auditory information, and vision. It is a crucial region for integrating sensory perception of the spatial location of objects in the external world and information about body position. By integrating information about the state of the animal with that of potential targets for behavior, areas within the posterior parietal cortex are thought to create a context or frame of reference for guiding movement. Because this region is densely connected with the frontal lobe, it may contribute to the ability to voluntarily inhibit behavior, as well as adapt movements according to novel sensory stimuli. The posterior parietal cortex is functionally lateralized, such that the posterior parietal cortex of the left hemisphere is specialized for processing linguistic information whereas in the right hemisphere it is specialized for spatial information. Some functional regions within the posterior parietal cortex of modern humans do not have homologues in macaque monkeys. These regions provide additional central visual field representations and greater sensitivity to extract three-dimensional form related to motion. These regions in the dorsal

interparietal sulcus are activated in positron emission tomography (PET) imaging studies of modern humans learning how to fashion Oldowan-style stone tools (Stout et al. 2008). In the absence of comparable data from apes, however, it is not clear whether these posterior parietal areas are specific to *Homo sapiens* or whether they are shared with our close relatives. In addition, it has been argued by Raymond Dart, Ralph Holloway, and others that the posterior shift of the lunate sulcus and the relative reduction of the adjacent primary visual cortex in the modern human brain indicate that areas of the posterior parietal cortex have disproportionately expanded within the hominin clade.

posterior teeth *See* postcanine teeth.

posthypocone crista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs distally from the tip of the hypocone (syn. posthypocrista).

posthypoconid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs distally from the tip of the hypoconid.

posthypoconulid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs distally from the tip of the hypoconulid.

postmetaconid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs distally from the tip of the metaconid.

postmetaconulid A discrete area of elevated enamel on the occlusal surface of a mandibular molar distolingual to the metaconid. Some regard this as the weakest expression of a tuberculum intermedium (also called a C7). *See also tuberculum intermedium*.

postmetacrista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs distally from the tip of the metacone.

postparacrista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary

molar tooth crown that runs distally from the tip of the paracone.

postprotocone crista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs distally from the tip of the protocone (syn. postprotocrista).

postprotoconid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs distally from the tip of the protoconid (syn. postprotocristid).

postprotocrista *See* distal trigon crest; postprotocone crista.

postural feeding hypothesis This is one of several hypotheses put forward to explain the origin of upright posture and bipedal locomotion in the hominin clade. Like the **seed-eating hypothesis**, it is based on a set of careful observations of both primate behavior and anatomy. The hypothesis was proposed by Hunt (1996), who suggested that among chimpanzees and baboons it was more likely that a bipedal posture was linked to feeding rather than a bipedal mode of locomotion. He showed that bipedal postures were employed during both arboreal and terrestrial feeding, and typically involved reaching into higher branches to gather fruits. While standing bipedally, chimpanzees frequently used one of their upper limbs to steady themselves by simultaneously hanging from a branch. Hunt further noted that the postcranial skeleton of australopiths retains several ape-like features associated with arm-hanging, but lacks features that would have made bipedal locomotion energetically efficient. Given that this postcranial morphology appears to have persisted for several million years, Hunt doubts that selection for bipedal locomotion played a major role in hominin origins. Rather, he suggests that the earliest hominins may have been dependent on arboreal fruit resources, and evolved anatomical adaptations to bipedal posture as a result of habitually employing an upright posture during feeding. These adaptations allowed facultative bipedal locomotion, but selection favoring the evolution of energetically efficient obligate, or endurance, bipedalism did not occur until later in hominin evolution. *See also* bipedal.

posture (L. *positura* = position) The position, or attitude, of the whole body or of a part of the body. When the long axis of the trunk is orien-

tated vertically this is referred to as an upright or orthograde posture; when the long axis of the trunk is orientated horizontally this is referred to as a horizontal or pronograde posture. Musculoskeletal adaptations for posture and locomotion are not always the same. For example, in chimpanzees, suspensory arm-hanging under a branch is the only behavior requiring complete abduction of the arm (Hunt 1991), suggesting that some morphology related to shoulder mobility (e.g., the superiorly narrow “cone-shaped” rib cage) may be adaptations to an arm-hanging posture rather than to a climbing form of locomotion.

Potamochoerus The name of the genus that contains the extant and extinct bush pigs. *See* Suidae.

potassium-argon dating (or $^{40}\text{K}/^{39}\text{Ar}$ dating) A radioisotopic dating method that uses potassium-bearing minerals often from layers of volcanic **tephra**, usually in the form of ash, in which case they are called **tuffs**. It compares the amounts of ^{40}K and its daughter product ^{39}Ar . Because in this method the potassium is measured as a solid and the argon daughter product as a gas, these measurements are made on two different samples of rock and from many mineral crystals from each sample. The error introduced tends to limit its application for hominin evolution to sediments that are more than 1 Ma. Because relatively large amounts of material are needed the method is only suitable for samples that are not likely to be contaminated with older or younger crystals. The potassium-argon technique had early and important implications for the understanding of the time depth of human evolution, particularly in East Africa. In 1965 Evernden and Curtis published K-Ar ages for the Olduvai Gorge sequence that placed the base of Bed I at 1.85 Ma and the top of Bed II as >500ka. These had important implications especially for the age of what was then called *Zinjanthropus boisei* (OH 5), which was associated with the 1.85 Ma date, as well as for *Homo habilis* (OH 7) and pre-Chellean man (OH 9) from Bed II. Subsequent work has shifted the ages of the Olduvai stratigraphy earlier, especially those for Bed II (see the Olduvai Gorge entry). Nonetheless, this first set of dates had immediate consequences for understanding human evolution by providing sound evidence of a greater antiquity of hominins than had been previously accepted. The method has been largely superseded by **argon-argon dating**.

Powell Cotton Collection The “Powell Cotton” of the Powell Cotton Collection refers to Major P.H.G. Powell Cotton (1866–1940), who was an avid collector with a special interest in natural history and in particular with African “big game.” The specimens in the Powell Cotton Collection were collected by two associates, Fred Merfield and Kurt Zenker, and by local villagers in Cameroon, the former French and Belgian Congos, Guinea, and Ethiopia. The relevance of the Powell Cotton Collection to human evolution is that it includes the world’s largest collections of both Western gorillas (*Gorilla gorilla*) and Central African chimpanzees (*Pan troglodytes troglodytes*). The former are represented by 204 skulls (139 of them with skeletons, many also with skins) and the latter by 173 skulls (130 of them with skeletons, many also with skins). In addition there are six skulls and skeletons of chimpanzees from the Ituri Forest (*Pan troglodytes schweinfurthii*). The greater part of the great ape skeletal collection is backed by field notes that include the date of collection, the name of the locality, the latitude and longitude, and the weight and the linear measurements of the cadaver. Contact person Malcolm Harman (e-mail harman-malcolm@btconnect.com). Postal address The Powell Cotton Museum, Quex House & Gardens, Quex Park, Birchington, Kent CT7 0BH, UK. Website www.quexmuseum.org. Tel +44 (0)1843 842168.

Powell Cotton Museum The Powell Cotton Museum in Quex Park, Birchington, Kent, England, was founded in 1898 to provide a home for the collections generated by Major P.H.G. Powell Cotton (1866–1940) during his expeditions to Africa and Asia. He was a keen naturalist, collector, and hunter who traveled extensively in Africa and parts of Asia. His total number of collecting trips spanned from 1887 to 1939, with 22 out of the total of 28 covering the African continent. Powell Cotton set up a business relationship with two professional collectors, Kurt Zenker and Fred Merfield (both of whom operated out of the Cameroon). The collection at the Powell Cotton Museum grew out of the arrangement with the two collectors that the museum would retain a specimen for every specimen it sold to other institutes or researchers. The purpose-built Museum is adjacent to the fine Regency country house that was formerly the home of the Powell Cotton family. *See also* **Powell Cotton Collection**.

power grip A grip in which the object is held by the fingers and palm, with the thumb as a buttress (Napier 1993). When gripping large objects, the thumb may flex around the object in opposition to the fingers. A distinctive modern human form of the power grip is the squeeze grip of cylindrical tools (e.g., hammer handles), held obliquely along the palm. This type of grip is facilitated in modern humans by shorter fourth and fifth metacarpals compared to the rest of the palm, increased mobility in the ulnar direction of both the wrist and the fingers, and enhanced robusticity of the ulnar side of the hand. Chimpanzees and other apes are not capable of using this grip, and instead grasp the object transversely or diagonally across the fingers, usually without active involvement of the palm or the (relatively short) thumb (Marzke et al. 1992).

power scavenging *See* **confrontational scavenging**.

power stroke Refers to the slow close phase of the **chewing** cycle, which ends at minimum gape. It used to be thought that the power stroke consisted of two phases, phase I being the last part of slow close phase and phase II being the start of the slow open phase. However, it is now clear that among primates little or no bite force is generated after minimum gape, so that the power stroke is equivalent only to phase I. *See also* **chewing**.

Praeanthropus (L. *prae*=before and Gk *anthropos*=human being) The genus name introduced by Musaffer Şenyürek (1955) to accommodate the maxilla found at Garusi (now called **Laetoli**) by Kohl-Larsen in 1939 that was attributed by Hans Weinert (1950) to *Meganthropus africanus*. *Praeanthropus* is the genus name that should be used by those who support removing *Australopithecus afarensis* from *Australopithecus*. *See also* *Praeanthropus afarensis*.

Praeanthropus afarensis (Johanson, 1978) (L. *prae*=before, Gk *anthropos*=human being, and *afarensis* recognizes the contributions of the local Afar people) A new combination suggested by Strait et al. (1997). The results of a cladistic analysis carried out by Strait et al. (1997) suggested that *Australopithecus afarensis* was the sister taxon of *Australopithecus africanus* and other later hominins. Thus, they argued that to continue to use the same genus name for *Au. afarensis* and *Au. africanus*

made it inevitable that *Australopithecus* would be a **paraphyletic** taxon and they suggested the hypodigm of *Au. afarensis* be transferred to a different genus. They argued correctly that the genus name *Praeanthropus* was available, but if *Praeanthropus* was used as the genus name, then the species name *afarensis* no longer had priority, for *Meganthropus africanus* Weinert, 1950 obviously had priority over *Au. afarensis* Johanson et al., 1978. However, this latter change in nomenclature would result in two hominin species called “*africanus*,” *Australopithecus africanus* Dart, 1925 and *Praeanthropus africanus* (Weinert, 1950) Şenyürek, 1955. Application was made to the **International Commission on Zoological Nomenclature** (or ICZN) to have the specific name “*africanus* Weinert, 1950” suppressed, and in “Opinion 1941” published in the *Bulletin of Zoological Nomenclature* (1999) the ICZN upheld the application. The ICZN also ruled that a news report in the *New Scientist* magazine should have priority over Johanson et al., 1978. So, if the *Au. afarensis* hypodigm is to be removed from *Australopithecus*, then the taxon should be referred to formally as *Praeanthropus afarensis* (Johanson, 1978).

***Praeanthropus africanus* Weinert, 1950** (L. *prae*=before, Gk *anthropos*=human being, and L. *africanus*=pertaining to Africa) A new combination introduced by Musaffer Şenyürek (1955) for the maxilla found at what was then called Garusi (now called *Laetoli*) by Kohl-Larsen in 1939 and attributed by Hans Weinert (1950) to *Meganthropus africanus*. Ferguson (1986) claimed that if the Garusi maxilla belongs to the same taxon as **LH 4**, then *Praeanthropus africanus* has priority and should be used in place of *Australopithecus afarensis*. However, an application was made to the **International Commission of Zoological Nomenclature** (ICZN) to have the specific name “*africanus* Weinert, 1950” suppressed, and in “Opinion 1941” published in the *Bulletin of Zoological Nomenclature* (1999) the ICZN upheld the application. So the taxon that was known as *Pr. africanus* should now be referred to as *Praeanthropus afarensis* (Johanson 1978). *See also Praeanthropus; Praeanthropus afarensis.*

pre-eminent bipedalism *See* bipedalism.

pre-Neanderthal theory *See* pre-Neanderthal hypothesis.

pre-Neanderthal *See* pre-Neanderthal hypothesis.

pre-Neanderthal hypothesis A hypothesis that asserted that both the modern human and Neanderthal lineages evolved from populations that succeeded *Homo erectus*, but which pre-dated the emergence of “classic” Neanderthals in Europe. Also known as the pre-Neanderthal theory, it was accepted by a number of leading human paleontologists during the mid-to-late 20thC, including Clark Howell, Sergio Sergi, Wilhelm Gieseler, William (Bill) Howells, and Emil Breitingner. The term pre-Neanderthal (Fr. *anté-Néandertalien*) is also used to refer to hominin remains from Europe that date from about **Oxygen Isotope Stages 8–13**. The “pre-Neanderthal theory” was formally named by Henri-Victor Vallois in his overview of modern human origins, published as the concluding chapter to his 1958 monograph about the hominins from Fontéchevade. Vallois specifically contrasted the pre-Neanderthal theory with the **pre-sapiens hypothesis**, which suggested that the modern human branch extended back even earlier, and the **Neanderthal phase hypothesis**, in which all Neanderthals were seen as ancestral to modern humans. The first scholar to promote the pre-Neanderthal perspective was Sergio Sergi in the 1940s. He argued that the pre-Neanderthals (including the specimens from **Swanscombe** and **Fontéchevade**), which he named the **Prophaneranthropi**, exhibited characteristics of both Neanderthals and modern humans (the **Phaneranthropi** and **Palaeanthropi**, respectively). He held that this pre-Neanderthal stock was the probable ancestor of both the Neanderthal and modern human lineages, with early members of the Neanderthal lineage (e.g., **Saccopastore 1**) possessing some “phaneranthropine” features (Sergi 1953). Howell (1951) differentiated “progressive” Neanderthals from “classic” Neanderthals. Progressive Neanderthals included early Neanderthals from Europe (e.g., **Saccopastore**, **Krapina**) as well as specimens such as **Teshik-Tash**, **Zuttiyeh**, and **Skhul/Tabun**; classic Neanderthals were the **Würm**-age specimens from Europe (e.g., **La Chapelle-aux-Saints**, **La Ferrassie**, **La Quina**). Howell maintained that the progressive Neanderthals gave rise to both the classic Neanderthals in Europe and modern humans via the **Mount Carmel** hominins from the Near East. Theoretically, the pre-Neanderthal hypothesis

can be seen as the intellectual precursor of the **out-of-Africa hypothesis** for modern human origins in which modern humans are seen as evolving from **Middle Pleistocene** ancestors outside of Europe (Smith 1997).

pre-sapiens hypothesis This hypothesis (also called the pre-sapiens theory) was a model of human evolution advocated by a number of prominent scientists during the early 20thC. According to the pre-sapiens hypothesis, fossil hominins morphologically similar to modern humans had existed since at least the early **Pleistocene**, if not earlier. This meant that other more recent forms of hominin (i.e., *Homo neanderthalensis* in Europe, *Sinanthropus* in China, and *Pithecanthropus* in Java) could not be ancestral to modern humans. At the time of the heyday of the pre-sapiens hypothesis there were archeological, paleontological, and theoretical reasons for believing that anatomically modern-looking humans evolved very early. In 1895 a modern human-like skeleton (the skull was discovered in 1888) was found at **Galley Hill** in Kent, England, in geological deposits that at the time were considered to be very old. In addition, geologists throughout northern Europe were finding what were considered to be the earliest evidence of simple stone tools, called **ooliths**, in Lower Pleistocene and even Pliocene deposits. Although there was some debate over whether these pieces of flint were really tools, or had been chipped by natural processes, these implements were taken as evidence of hominins of one sort, or another, occupying Europe in the Pliocene. When a modern human skeleton was found in Ipswich, East Anglia, in 1911, in Pliocene deposits where ooliths had been discovered, this was seen as further evidence of the great antiquity of anatomically modern humans. One of the earliest and most influential advocates of the pre-sapiens hypothesis was the British anatomist Arthur **Keith**. In his *Antiquity of Man* (1915) Keith noted that the archeological and fossil evidence hinted that the **Cro-Magnon** peoples with their **Aurignacian** industry had abruptly replaced the Neanderthals with their **Mousterian** industry, suggesting that modern *Homo sapiens* had not evolved from the Neanderthals, but already existed elsewhere. He also interpreted the recently unearthed **Pitldown** fossils in light of the pre-sapiens hypothesis, and suggested that among the general phylogenetic consequences of the pre-

sapiens hypothesis was the implication that the divergence between the hominin line and that leading to the great apes may have occurred as early as the late Oligocene. He also suggested that the races of modern humans had emerged during the late Pliocene or early Pleistocene. The discovery in 1935 at **Swanscombe**, Kent, England, of a partial cranium from deposits in the Thames river valley that also contained **Acheulean** implements and fossil mammals from the Lower or Middle Pleistocene appeared to provide additional support for the pre-sapiens hypothesis. A little earlier **Louis Leakey** claimed he had found evidence of *H. sapiens* at two sites in East Africa. In 1932 at **Kanjera** in western Kenya Leakey found two modern human-like skulls in association with fossils he considered to date from the Middle Pleistocene, while at **Kanam** (also in western Kenya) Leakey found a mandible in deposits he considered to be Lower Pleistocene (Leakey 1936). These discoveries convinced Leakey that he had found the oldest remains of *H. sapiens* then known. A controversy soon erupted over the accuracy of the dating of these discoveries, and the debate was fuelled by Leakey's inability to locate exactly where the bones had been found, and by disagreements over the age of the deposits. However, these factors did not deter Louis Leakey, who remained an ardent supporter of the idea that modern human-like hominins had emerged relatively early in human evolution. In *Adam's Ancestors* (1934) Leakey argued that the line leading to *Pithecanthropus*, *Sinanthropus*, and Neanderthals diverged from the line leading to modern humans during the Miocene and that the human races had appeared by the Middle Pleistocene. During the 1940s and 1950s a number of developments all tended to undermine the evidence for the pre-sapiens hypothesis. Evidence began to accumulate suggesting that the supposedly ancient skeletons found at Galley Hill and Ipswich were in fact intrusive burials of late prehistoric skeletons into earlier deposits. Then between 1953 and 1955 investigations of the Pitldown remains supported by **Wilfrid Le Gros Clark** and carried out by **Kenneth Oakley** and **Joseph Weiner** were published that showed that Pitldown was a hoax. Thus, this large-brained early hominin with an ape-like dentition was removed from human phylogeny. Likewise, skepticism about the Kanam and Kanjera fossils led many paleoanthropologists to

question their validity as exemplars of anatomically modern humans. Meanwhile, discoveries in southern Africa of australopiths and the recovery of numerous *Sinanthropus* fossils in China was strengthening the view that modern humans had evolved from an ape-like ancestor through an australopith stage followed by a “pithecanthropine” stage, the latter being represented by *Sinanthropus* in China and by *Pithecanthropus* in Java. Support for the pre-sapiens hypothesis did not necessarily disappear in the face of this new evidence. Instead, its supporters simply adjusted the theory to fit the new evidence. During the 1940s the American physical anthropologist William (Bill) Howells promoted the view that anatomically modern humans arose as early as the Lower Pleistocene and that the other known hominins were side branches of the hominin phylogenetic tree. In the 1950s Howells altered this model, suggesting that modern humans had emerged in the Middle Pleistocene, and that they may well have evolved from a pithecanthropine form. Howells backed even further away from the pre-sapiens hypothesis in later years. Perhaps the most prominent advocate of the pre-sapiens hypothesis during the 1940s and 1950s was the French paleoanthropologist Henri Vallois. Vallois originally believed that anatomically modern humans had evolved by the Lower Pleistocene, with *Sinanthropus*, *Pithecanthropus*, and the Neanderthals representing parallel lines of hominin evolution. While his general conception of hominin evolution remained the same, in the 1950s he modified his view of when anatomically modern humans appeared, arguing that they emerged in the Middle Pleistocene. Vallois had been a strong supporter of Piltown Man and when it was shown that the fossils were a hoax, he had to rely on the Swanscombe cranium and the hominin cranial fragments discovered at Fontéchevade in France in 1947 as evidence for the existence of pre-sapiens man. The pre-sapiens hypothesis became untenable as discoveries in Africa during the 1960s and 1970s brought new hominin species to light and radiometric dating methods provided a more reliable chronology for hominin evolution. The growing number of australopith species found in East Africa along with the discovery of *Homo habilis*, *Homo erectus*, and *Homo ergaster* in Africa strengthened the view that modern humans had evolved from an australopith-like ancestor through *Homo habilis* and *Homo erectus* stages, with anatomi-

cally modern humans emerging *c.*200 ka. The primary impact of the pre-sapiens hypothesis during the early 20thC was to push other hominin species out of the evolutionary lineage leading to modern humans and to encourage researchers to search for the fossil remains of our pre-sapiens ancestors. However, the popularity of the pre-sapiens hypothesis helps to explain why during the early 20thC so many scientists rejected the australopiths and the Neanderthals as modern human ancestors, and why there was so much influential support for the fraudulent Piltown fossils.

pre-sapiens theory *See* pre-sapiens hypothesis.

pre-Zinjanthropus The term Louis Leakey used to refer to the hominin remains that were subsequently included in the species *Homo habilis* (Leakey et al. 1964).

preadaptation A feature or trait that is well designed to perform a functional role it does not currently perform. Preadaptations may be co-opted to perform the new functional role, and in the process become **exaptations**, a term introduced in 1982 by Gould and Vrba. The term may also be used as a verb in much the same way as the term **adaptation**. For example, the **vertical climbing hypothesis** suggests that the manner in which the lesser gluteal muscles are recruited by apes when climbing vertical supports makes those primates preadapted for terrestrial bipedalism. In other words, when our ape ancestors were forced to travel on the ground, bipedalism presented itself as a mode of locomotion that could be easily performed. In historical context, the concept of preadaptation was difficult for evolutionary biologists to explain because the term often seemed to infer an orthogenetic preordination that was inconsistent with the principle of **evolution** by means of **natural selection**.

precentral gyrus (Gk *gyros*=circle, ring) The precentral gyrus of the cerebral hemispheres of the brain is located in the frontal lobe, anterior to the central sulcus and posterior to the precentral sulcus. The cortex of the precentral gyrus mostly corresponds to Brodmann's area 4, which is the primary motor cortex. The anteriormost portion of the precentral gyrus also contains

Brodmann's area 6, which is the premotor cortex. The cortex of the precentral gyrus contains a motor map (or topographic representation) of the entire body, although not all body parts are represented equally (e.g., regions used in tasks requiring precision and fine control, such as the face and hands, are disproportionately large in modern humans and other primates). The primary motor cortex forms part of the agranular cortex, because it lacks a clear granular layer IV, and its layer V contains the giant Betz pyramidal cells. The relative size of the primary motor cortex remains relatively constant across primates in proportion to overall body size.

precession (L. *praecedere*=to go before) The Earth's orbital geometry is affected by three "rhythms," or "cycles." The *c.*23 ka precessional cycle is due to changes in the gravitational pull exerted on the Earth by the sun and moon, and these affect the orientation of the Earth's axis so that it "wobbles" in a predictable way. Until 3 Ma the *c.*23 ka precessional cycle was the dominant influence on global climate. *See also* **astronomical time scale**.

precingulid A term used by Schwartz and Tattersall (2002) for an enamel crest on postcanine mandibular tooth crowns more commonly referred to as the mesial marginal ridge. *See also* **mesial marginal ridge**.

precingulum A term used by Schwartz and Tattersall (2002) for an enamel crest on postcanine maxillary tooth crowns more commonly referred to as the mesial marginal ridge. *See also* **mesial marginal ridge**.

precision (L. *praecision*=to cut off) The quality of being able to do something within well-defined limits. A precise value is one that has very little error. A series of precise measurements are not necessarily close to the actual value being measured, however. Imagine a tightly clustered group of darts on a dartboard that is far from the bullseye, the intended target. The placement of these darts is precise, but not accurate. *See also* **accuracy**.

precision grip Any grip that uses the thumb and one or more of the fingers, with or without the palm serving passively as a prop for the object being grasped (Marzke 1997). Although historically the

term precision has often been used to refer specifically to grasping a small object between the thumb and the tip of the finger, there are several different types of precision grip, including two-jaw (i.e., between the thumb and index finger), three-jaw (i.e., between the thumb, index finger, and middle finger), and four- to five-jaw (i.e., between the thumb and three or more fingers) grips. Two-jaw grips include pad-to-pad (e.g., when pinching a coin), tip-to-tip (e.g., when threading a needle), or pad-to-side (e.g., when using a key) grips between distal end of the thumb and the index finger. A three-jaw thumb/full-finger grip is used when holding spherical objects such as a baseball whereas a four- or five-jaw grip involving just the distal pads may be used when unscrewing the lid of a jar. Nonhuman primates are not capable of many of the precision grips used by modern humans. Instead, chimpanzees more often use a pad-to-side grip between the thumb and the side of the index finger. Among extant primates baboons come closest to being able to use the pad-to-pad grip because their hand proportions are most similar to that of modern humans.

precocial (L. *praecox*=early ripening) Compared to **altricial** taxa, the offspring of precocial organisms are born at a relatively advanced stage of development. Precocial offspring are usually fully furred or feathered, are able to move about on their own shortly after birth, and are born with their eyes and ears open. For example, horses are a precocial taxon, for newborn foals are able to stand up and start walking around shortly after birth. While modern humans are described as **secondarily altricial** by most, they have also been described as semi-precocial. This is because although they are altricial in many respects, modern human neonates come into the world with their eyes open, and with hair. However, they fall short in many criteria for independence when compared to truly precocial animals.

precuspidal fossa The term used by Hrdlicka (1924) for a feature on the tooth crown of mandibular molars that others call the fovea anterior. *See* **fovea anterior (mandibular)**.

predation (L. *praedari*=to rob, or plunder) Predation is when one organism, the predator, hunts and kills another organism, the prey, for food. Most extant primate species are at risk from predators of one sort or another, and this has probably been true throughout primate evolution-

ary history. A cranium of *Notharctus* (a North American adapiform, dated to the early Eocene) exhibits puncture marks that correspond to the teeth of the arboreal predator *Vulpavus* (Hart and Sussman 2005), and evidence of puncture marks and of the deliberate disarticulation of early anthropoid skeletons from the Fayum strongly suggest carnivore predation (Gebo and Simons 1984). Patterns of damage in the orbits and on the cranial vault of the **Taung** cranium are compatible with it being killed by a **raptor** (Berger 2006), and leopard tooth marks have been found on hominin fossils from **Swartkrans** (Brain 1981). In response to the risk of predation, primates have evolved many anti-predator behaviors. Vervet monkeys, for example, have a range of calls to warn conspecifics against different key predators, including eagles, snakes, and large cats (Struhsaker 1967). Predation pressure has also been linked to changes in primate group composition, shifts in activity patterns and sexual dimorphism. Others speculate it may have been part of a feedback mechanism that drove the tendency for large brains in primates (Shultz and Dunbar 2006). Some primates are also highly effective predators themselves. Baboons have been observed to capture and eat vervet monkeys, small antelopes, and birds. Chimpanzee hunting pressure appears to have altered group composition in red colobus monkeys (Stanford 1995). There is abundant evidence from Plio-Pleistocene archeological and paleontological sites in southern and East Africa of hominins butchering animals (including ungulates and possibly primates). Although the discovery that hominins were prey animals (*sensu* Brain 1981) contradicted the views of some early paleoanthropologists who believed that hominins were “bloodthirsty killers” (Dart 1953), observations of modern primate behaviour alongside taphonomic evidence from fossils and stone tools suggest that in early hominins there was no clear division between “the hunter” and “the hunted.”

predator *See* predation.

predentine *See* dentine development.

Předmostí (Location 49°30'N, 17°25'E, Czech Republic; etym. named after a nearby village) History and general description This open-air site is located in northeastern Moravia, 1 km/0.6 miles north of Přerov. It was first excavated in 1880

by J. Wankel. The first hominin remains were recovered in 1884. Excavations continued intermittently throughout the 20thC and later, with the most recent one in 2006. In 1894 a communal grave was discovered by Maška with the remains of 18 individuals, covered by limestone slabs and mammoth bones, and associated with Pavlovian (**Gravettian**) lithic artifacts and symbolic and decorative objects. Additional hominin remains (*Homo sapiens*) were recovered in later excavations, for a total number of up to 29 individuals. Subadult, juvenile, and adult specimens are represented, as are both sexes. Most remains were destroyed by fire in 1945. Temporal span and how dated? **Radiocarbon dating** of the Pavlovian occupation provided dates between 27 and 29 ka BP. Hominins found at site Předmostí 1–29; several crania and associated skeletons, as well as individual elements are represented; all are assigned to *H. sapiens*. Archeological evidence found at site **Mousterian**, **Aurignacian**, and Pavlovian (**Gravettian**) artifacts have been recovered from different layers at the site. The hominin remains are associated with the Gravettian cultural layer. Key references: Geology, dating, and paleoenvironment Svoboda 2008; Archeology Svoboda 2008; Hominins Vlček 1971, Smith 1982.

preentoconid A term sometimes used for an accessory cusp on the occlusal surface of a mandibular molar that is more commonly referred to as a tuberculum intermedium. *See also* **tuberculum intermedium**.

preentoconid cristid A term used by Szalay and Delson (1979) for an enamel crest on a mandibular molar tooth crown that runs mesially from the tip of the entoconid (syn. pre-entoconid cristid).

prefossilid The term used by van Valen (1966) for a feature on a mandibular molar tooth crown others call the fovea anterior. *See* **fovea anterior (mandibular)**.

prefrontal cortex (L. *cortex*=husk, shell) The prefrontal cortex is the part of the cerebral cortex that lies anterior to the premotor cortex, which, in turn, is anterior to the primary motor cortex. The prefrontal cortex is defined as the part of the frontal cortex that has a relatively thick granular layer IV, which receives inputs from the med-

iodorsal nucleus of the thalamus. In contrast to other parts of the frontal cortex, electrical stimulation of this region does not evoke movements. The prefrontal cortex is involved in so-called executive functions, which include differentiating among conflicting goals, evaluating different behavioral strategies, and the inhibition of immediate desires for the maximization of long-term gains. As such, the prefrontal cortex is important for decision-making, moderating social behavior, and the planning of complex sequences of actions. The prefrontal cortex can be subdivided according to anatomy, connectivity, and function. For example, the dorsolateral prefrontal is associated with tasks that require an animal to inhibit certain motor responses at appropriate times, regardless of spatial elements. This region is densely interconnected with the posterior parietal cortex and they both send connections to numerous common cortical and subcortical structures. The orbitofrontal cortex is part of the limbic cortex, and has been specifically implicated in regulating aggressiveness and emotional responsiveness, as well as general arousal and some autonomic responses. Because of its involvement in higher-order cognition, one might expect the prefrontal cortex to be selectively modified in the evolution of modern humans. Accordingly, there have been many studies of gene expression, cellular composition, and the neurochemical architecture of the modern human prefrontal cortex in comparison to other primates, including great apes. In sum, most of these studies have revealed striking similarities in the gene expression and histology of the prefrontal cortex of modern humans and our close relatives. The most consistent differences indicate a higher level of gene expression associated with heightened metabolism and synaptic activity in modern humans (Preuss et al. 2004). Additionally, while it is clear that the prefrontal cortex of modern humans comprises a relatively larger proportion of the frontal lobe than in great apes (Rilling 2006), there is debate (e.g., Semendeferi et al. 2001, Holloway 2002, Schoenemann et al. 2005, Sherwood et al. 2005) about whether the entire prefrontal cortex or any of its subdivisions have undergone disproportionate expansion in modern humans beyond what would be predicted by the known allometric relationships within higher primates. *See also* **allometry**.

prehensile (L. *prehensus*=to grasp) A hand (or foot, or lips) capable of isolating, pinching, and lifting an object. *See also* **hand function**.

prehominine A term used by, among others, John Robinson to refer to australopithecines or “early members of the family of man” (Robinson 1961, p. 3).

prehyppocone crista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs mesially from the tip of the hypocone (syn. prehyppocrista).

prehyppoconid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs mesially from the tip of the hypoconid.

prehyppoconulid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs mesially from the tip of the hypoconulid.

premetaconid cristid A term used by Szalay and Delson (1979) and by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs mesially from the tip of the metaconid.

premetaconulid An accessory cusp on a mandibular molar crown situated mesial to the metaconid, either on the mesial crest of the metaconid or on the lingual portion of the mesial marginal ridge. This cusp has also been sometimes described as paraconid, although the homology with this cusp, which is absent in hominoids, is questionable (syn. paraconid, mesial accessory cusp).

premetacrista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs mesially from the tip of the metacone.

premutation In diseases such as Huntington’s disease or fragile X syndrome, which are caused by an expansion of trinucleotide repeats, unaffected carriers have a higher number of repeats than is typical and these repeats are unstable during replication, resulting in many more repeats in the allele found in the affected offspring. For example, most people have fewer than 28 copies of the CAG repeat in the *HTT* gene whereas people with Huntington’s disease have more than 36 copies. Individuals with 28–35 copies are unaffected but are described as

having the unstable premutation. *See also* **micro-satellite**.

preoccupied This term is not formally defined in the **International Code of Zoological Nomenclature**, but it is commonly used to denote a name that is a junior homonym. *See* **homonymy**.

preparacrista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs mesially from the tip of the paracone.

prepared core Refers to a stone core that shows signs that the **striking platform** or flake release surface has been abraded or chipped to increase the likelihood of successful flake removal. Some authors treat the terms “prepared core” and “Levallois core” as synonymous. *See also* **Levallois**.

preprotocone crista A term used by Szalay and Delson (1979) for an enamel crest on a maxillary molar tooth crown that runs mesially from the tip of the protocone (syn. preprotocrista).

preprotoconid cristid A term used by Pilbrow (2006) for an enamel crest on a mandibular molar tooth crown that runs mesially from the tip of the protoconid (syn. preprotocristid).

preprotocrista *See* **mesial marginal ridge**; **preprotocone crista**.

pressure pad Devices (also known as pressure-distribution systems) that use capacitive (i.e., electric) sensors to measure forces. They are typically arranged in a matrix within a pad (rigid or flexible) that allows normal forces (those perpendicular to the surface) to be measured across an area over time. Pressure pads have been used most commonly to examine the forces exerted by the foot from heel contact through toe-off, but they are also used to measure the force distributions during hand grips, across seats or saddles, as well as other interactions between the body and a substrate. For example, Wunderlich and Jungers (2009) presented the first quantitative data on pressures on ape fingers during **knuckle-walking**. Their results, which show that pressure is highest on digits 2–4, but that pressure varies with support type (branch or ground) and hand posture,

are broadly consistent with the hypothesis that the fusion of the **os centrale** with the scaphoid is an adaptation to knuckle-walking.

prey-choice model A model derived from **optimal foraging theory** designed to predict whether or not a forager will pursue or ignore a prey item when it is encountered. The prey-choice model (also known as the “encounter-contingent prey-choice model”) assumes that the objective of the forager is to maximize energetic returns, that the forager is aware of the energetic returns associated with different types of prey, and that the forager searches for prey in a patch where encounter rates with different prey types are random. The model suggests that **high-ranking prey** will always be preferentially incorporated in the diet because they provide higher-than-average energetic returns. Energetically less profitable **low-ranking prey** will only be added to the diet when encounter rates with high-ranking prey decline and overall **foraging efficiency** declines.

prey rankings *See* **high-ranking prey**; **low-ranking prey**.

Prezletice (Location 50°09'N, 14°34'E, Czech Republic; etym. named after a nearby town) **History and general description** Extinct fauna was found in a small quarry in 1938, and subsequent excavations in the late 1960s led by Oldrich Fejfar employed fine screening, which resulted in the recovery of a small, possibly hominin, tooth fragment. **Temporal span and how dated?** No radiometric dating has been attempted, but stratigraphic correlation has suggested an age that spans the Günz and Mindel glacial cycles (i.e., c.600 ka). If the deposits are in fact that old, they represent some of the oldest human inhabitation in Europe. **Hominins found at site** A single fragment of a tooth that was originally interpreted as a hominin molar fragment has since been determined to belong to a bear. **Archeological evidence found at site** The approximately 250 stone tools belong to the proto-Acheulean. Key references: **Geology, dating, and paleoenvironment** Fejfar 1969; **Hominins** Fejfar 1969, Vlček 1978b; **Archeology** Fejfar 1969.

primate archeology This was the name proposed in a multi-authored review (Haslam et al. 2009) as an inclusive term to describe the study of the “past and present material record of all members of the order Primates” (*ibid.*, p. 339). The early reports of tool use in nonhuman primates focused on the way chimpanzees made and used tools (Boesch and Boesch 1990, McGrew 1992) and this led to various suggestions of terms such as “cultural panthropology” (Whiten et al. 2003) and “chimpanzee archeology” (Carvalho et al. 2008) for the study of this phenomenon. However, tool manufacture and tool use in primates is emphatically not confined to chimpanzees (see the references in Haslam et al. 2009), so a more inclusive term was needed. The goals of primate archeology are to provide a “primatocentric” perspective to balance the “anthropocentric” interpretations of the early hominin archeological record, and to investigate the spatial, environmental, and other circumstances under which modern humans, early hominins, and nonhuman primates use probing, pounding, and digging tools.

primer Primers are short single-stranded fragments of DNA (usually 15–25 base pairs long) that are complementary to a portion of the DNA sequence of interest and which define the segment of DNA to be amplified. *See* polymerase chain reaction.

primitive (L. *primitivus*=first of its kind) A morphological feature or character is described as being primitive if it is present in the outgroup, or in the hypothetical common ancestor. A primitive or **symplesiomorphic** character state is the character state at the primitive end, or pole, of a morphocline (syn. primitive condition).

principal components analysis (or PCA) A form of **multivariate analysis** in which variation is analyzed for a data set of n variables, and then a new set of n variables is produced which are

linear transformations of the original variables in which the first variable (or first principal component) contains the most variation in the data set, the second variable contains the most variation that is independent of the first variable, the third variable contains the most variation that is independent of the first two variables, and so on. For a more intuitive explanation, consider a cloud of points in space shaped like a baguette. A PCA finds the axis which describes the most variation in the data set; in this case, an axis running from end to end lengthwise along the loaf. Each data point can be projected into this axis and thus has a value or score for the first axis or first principal component. However, most points in the baguette do not fall exactly on this axis, so there is still more variation in the data set. The remaining variation is independent of the first axis, so it is at right angles to the first principal component; this can be visualized by looking at the baguette end-on or by slicing the baguette perpendicular to the first axis (as if you were cutting slices for bruschetta rather than slicing the loaf lengthwise to make one giant sandwich). The PCA now fits a second axis (principal component) which describes the most variation in the portion of the data visible from this angle; in this case, an axis running from side to side through the loaf. The remaining variation can all be described by a third axis running from top to bottom in the loaf. In effect, the new principal components are new axes that result from rotating the baguette in space. In practice all of the new axes or principal components are fit simultaneously and any number of original dimensions or variables can be accommodated (not just three). The resulting principal components have the following properties. First, there are as many principal components as there were original variables. Second, all principal components are independent of each other (i.e., the **correlation** between any pair of principal components from a single analysis is equal to zero). Third, the first principal component accounts for the most variation in the data set, the second accounts for a proportion of variance equal to or less than the first, and so on. Many researchers use PCA to reduce a data set with many variables to a data set with relatively few principal components that account for the majority of the variation in the original data set; this procedure makes it easier to visualize patterns in data. It can also minimize the number of variables in an analysis such as multiple regression,

thus reducing the number of degrees of freedom lost by having a large number of variables. This reduction is most effective when the original variables are highly correlated with each other, and will be ineffective when the original variables are mostly independent of each other. When all of the original variables are highly correlated, the first principal component will account for the overwhelming majority of the variation in the data set. For example, if 12 cranial measurements are collected for a sample of skulls spanning a size range including mouse lemurs and gorillas, all measurements are expected to be highly correlated (large species have absolutely larger skulls than small species, and thus absolutely larger cranial measurements), and the first principal component will typically account for 90% or more of the variation in the data set in such a scenario. This first principal component is clearly driven by the size difference between skulls, and indeed researchers have occasionally used the first principal component of such an analysis as a measure of **multivariate size**. However, it is important to note that the first principal component also incorporates shape differences that are correlated with size differences, and thus is not a measure of size alone. PCA is performed on standardized data (i.e., for each variable, every measurement has the mean of that variable subtracted and is divided by the standard deviation of the variable). Many computer programs provide the loadings or coefficients for the various principal components produced by aPCA; these loadings refer to the relative contribution of each standardized variable to the principal component (high magnitude loadings indicate a strong contribution of the original variable, positive loadings indicate that increases in the original variable are associated with increases in the principal component, negative loadings indicate that increases in the original variable are associated with decreases in the principal component). These loadings can be used to identify those variables in the original data set which are most responsible for the overall variation present in a data set.

priority (L. *prior*=first) A principle used in **nomenclature**. It holds that the taxon name with the earliest publication date should be regarded as the senior name and thus should have priority over any other name for that taxon published thereafter. *See also* **synonym**; **synonymy**.

prism (L. *prisma*=something that has been sawn off) *See* **enamel prism**.

probability density function The concept of a probability density function (sometimes abbreviated as pdf) generalizes the idea of a probability function for a discrete variable to the case of a continuous variable. The probability density for any given value within the defined range of the function cannot be negative, but unlike a probability function the density can be above 1.0. A proper probability density function must integrate to 1.0, which means that, for example, a uniform density on the interval 0 and 0.4 will have a density value of 2.5 at any point within this range. This is true because the area of the rectangle is then $0.4 \times 2.5 = 1.0$. In hazards analysis the probability density function is often used to represent the probability density of death at exactly age a , and is usually written as $f(a)$. This is equal to the product of survivorship to age a ($S(a)$) and the hazard of death at that age ($h(a)$).

probability of death, age-specific The probability that an individual who enters an age interval in a life table will die within that interval. Although there are a number of equivalent ways to express this probability, the most straightforward uses survivorship. As an example, consider a case where 252 individuals survive to 1 year of age but by 5 years of age there are only 215 individuals still surviving. This gives $(252-215)/252=0.1468$ as the probability of death between ages 1 and 5 years. Note that the difference in survivorship at age 1 and at age 5 ($252-215$) gives the number of deaths in the 4-year interval (equal to 37 deaths), while dividing by the number of individuals surviving to age 1 year gives the number of deaths per the number of individuals who enter the age interval. If no 1 year-olds had died before reaching age 5 years then the age-specific probability of death would be $(252-252)/252=0.0$ while if all had died in the interval the age specific probability of death would be $(252-0)/252=1.0$. The usual symbol for the age specific probability of death is q_x , where x is the age at the beginning of the age category. In the example just given q_x corresponds to q_1 in the series $q_0, q_1, q_5, q_{10}, \dots$, where q_0 is the age-specific probability of death between birth and age 1 year, q_1 is the age-specific probability of death between 1 and 5 years, q_5 is the age-specific probability of death between 5 and 10 years, and so on.

probe A fragment of single-stranded DNA used to identify and/or quantify a specific DNA sequence in a sample. For example, an allele-specific probe can be used to identify the presence and quantity of a specific allele in either a DNA sample (for genotyping purposes) or in the cDNA (i.e., complementary DNA) obtained from a specific tissue (to assess gene expression). Some types of quantitative polymerase chain reaction (or PCR) use a probe for quantifying the amount of a specific PCR product that is produced. *See also* **complementary DNA**; **oligonucleotide**; **DNA hybridization**.

problem-solving The ability to overcome various kinds of obstacles to achieve a desired goal; the manufacture of a stone artifact requires problem-solving skills. In the early 20thC the psychologist Wolfgang Kohler conducted an experiment in which he gave chimpanzees a variety of tasks, all of which required the animals to obtain a directly inaccessible food reward (Köhler 1925). In one experiment, the apes were presented with a banana hanging from the ceiling of their enclosure, where several kinds of objects, such as crates and poles, were available. After failing attempts to jump at the food reward, the apes stopped, looked around the enclosure, and came up with various ways to reach the otherwise inaccessible food, such as stacking a couple of crates underneath and climbing on top of them. Based on such observation, Kohler argued that the chimpanzees observed and used the behavior of other apes to inform their own strategies. More recently, researchers have examined seemingly insightful problem-solving abilities in orangutans (Mendes et al. 2007). They presented the apes with a vertical Plexiglas tube that was securely attached inside their cage mesh. The tubes were filled one quarter full with water and then baited with floating peanuts. All of the tested orangutans were able to retrieve the food on the first trial by collecting mouthfuls of water from a water source and then spitting the water into the tube to raise the water level. Whether or not one is a good problem-solver depends on cognitive skills such as flexibility, better inhibitory control, planning, and causal reasoning. For instance, suppose that the subject is presented with a horizontally secured Plexiglas tube with a trap mid-way, which makes the apparatus' shape look like letter "T." The tube is baited with a food reward that is out of reach of the subject. In this task, the subject has

to be flexible enough to look for any potential tool (e.g., stick) to extract the food and make tools if necessary out of available objects (e.g., making a stick out of branches or combining short sticks to make a long one). She/he also has to inhibit impulsive, fruitless responses such as poking fingers through the tube or blindly pushing/raking the food with the tool without considering the position of the trap. She/he should be skillful at planning and should have a good understanding of causation when judging whether the potential tool would be appropriate for the task (whether the tool is thin enough to go through the tube, long enough to reach the food, strong enough to rake or push the reward, etc.). Moreover, she/he should anticipate the outcome of this action and try to avoid the reward falling into the trap. Great apes have demonstrated successful problem-solving skills in the aforementioned trap-tube task, but with substantial individual variations (Mulcahy and Call 2006). Furthermore, they were more successful when they were allowed to rake the reward instead of being given an option of only pushing it, showing some limitation in their ability to effectively solve the task (Limongelli et al. 1995).

Proboscidea (Gk *proboscis*=elephant's trunk, from *pro*=forward and *boskein*=to nourish or feed) The order that includes hoofless mammals with elongated trunks. The modern examples of this order are the African elephant, *Loxodonta*, and the Asian elephant, *Elephas*, both of which are subsumed within the only remaining extant family of proboscideans, the **Elephantidae**. During the early stages of human evolution, the Proboscidea were a more diverse group than they are today. Members of the family **Deinotheriidae** (proboscideans with downward curving tusks) are known from African early hominin sites, and the family **Gomphotheriidae** (proboscideans with shovel-shaped tusks) is known from South American paleoindian sites. Numerous other families of proboscideans were extant during the course of earlier hominoid and hominin evolution. Most proboscideans are regarded as **megafauna**, although some very early and dwarfed lineages are exceptions to this. The earliest known proboscidean is the 15 kg *Phosphatherium* known from the Paleocene of northern Africa.

proboscidean (Gk *proboscis*=elephant's trunk, from *pro*=forward and *boskein*=to nourish or

feed) The informal term for the order that includes hoofless mammals with elongated trunks. *See also* Proboscidea.

processual archeology *See* Binford, Lewis (1930–).

Procrustes analysis (etym. In Greek mythology, Procrustes, a son of Poseidon, was an innkeeper who insisted his guests were an exact fit for the only bed provided for them. Short guests were stretched and tall ones had their legs amputated!) A method for comparing the shape of objects. This procedure, which is based on the least-squares principle, involves three steps. First, the landmark configurations of the objects are translated so that they share the same centroid. Second, they are scaled so that they all have the same centroid size (i.e., the square root of the summed squared deviations of the coordinates from the centroid is the same). Third, they are rotated around the centroid until the sum of the squared Euclidian distances between the homologous landmarks is minimized. For more than two objects, this algorithm has been extended to generalized Procrustes analysis (Gower 1975, Rohlf and Slice 1990). In practice, all centered and scaled landmark configurations are rotated to one configuration (e.g., the first specimen in the dataset) to minimize the distances between homologous landmarks. The resulting coordinates are averaged and the procedure is repeated until the distances are minimized. The coordinates of the resulting centered, scaled, and rotated landmarks are called Procrustes shape coordinates. Their average (the consensus configuration) is the shape whose sum of squared distances to the other shapes is minimized (Dryden and Mardia 1998). The differences between any individual and the average shape are called Procrustes residuals. The Euclidian distance between two sets of Procrustes shape coordinates (i.e., the square root of summed squared coordinate-wise differences) is referred to as the Procrustes distance, which is a summary of the similarity or dissimilarity in shape between two landmark configurations.

Procrustes distance *See* Procrustes analysis.

Procrustes metric *See* Procrustes analysis.

Procrustes shape coordinates *See* Procrustes analysis.

progenesis Equivalent to time hypomorphosis. *See* hypomorphosis.

prognathic (L. *pro*=forward and *gnathos*=jaws) Literally the degree to which the jaws project forwards, but also used for mid- and upper facial projection. Prognathism can be midline, or lateral, or both, and can affect the upper, middle, lower, or all parts of the face. It is usually quantified by measurements of the distance between a landmark on the base of the cranium (e.g., basion, porion) and a landmark on the front of the face (e.g., subnasale, alveolare), but it can also be measured using landmarks confined to the face (e.g., sellion, prosthion). For example, *Australopithecus afarensis* faces are more prognathic than those of *Homo erectus*. Prognathism usually increases during ontogeny, and it is usually more pronounced in males than in females. The projection of the nasoalveolar clivus beyond the nasal aperture is known as subnasal prognathism. As a generalization, hominins have experienced a long-term trend towards the reduction of prognathism. Flat or weakly projecting faces are called **orthognathic** (ant. orthognathic).

prognathism (L. *pro*=forward and *gnathos*=jaws) The tendency for a face to be prognathic. *See* prognathic.

programmed cell death *See* apoptosis.

“progressive” Neanderthals *See* pre-Neanderthal hypothesis.

projectile point In archeology this term refers to a pointed stone or bone artifact that is thought to have been attached to the tip of a flight weapon, such as a javelin, a spearthrower dart, or an arrow. The functions of projectile points are inferred from wear-pattern analysis, residues, and metric comparisons with ethnohistoric and experimental projectile points. Current evidence suggests projectile point technology developed in Africa between 50 and 100 ka and that it spread to Eurasia after 40–50 ka. Examples of African **Middle Stone Age** projectile points include bone specimens from **Blombos** and **Katanda**. Likely stone projectile points include tanged **Aterian** points from North Africa, and foliate bifaces from all over the continent. Eurasian **Upper Paleolithic** projectile points take a wide range of

forms, including various bone/antler types and many local variants made on blades (El Wad points, Font Robert points, Gravette points) as well as foliate bifaces and shouldered points. After 40 ka in sub-Saharan Africa and 30 ka in Eurasia, stone and bone projectile points were either augmented or supplanted by backed microlithic weapon armatures. Knecht (1997), Shea (2006), and Shea and Sisk (2010) provide more detailed treatments.

prokaryote (Gk *pro*=before and *karyote*=nut or having nuts) An organism (e.g., bacteria and Archaea) comprised of a single cell(s) without a nucleus or any membrane-bound organelles.

promontory (L. *promontorium*=mountain) The term is used in anatomy in two ways that are relevant for human evolution. The promontory of the middle ear is the elevated part of the medial wall of the middle ear that covers the basal turn of the cochlea part of the bony labyrinth. Behind and above the promontory is the oval window (fenestra ovalis) that accommodates the footplate of the stapes, and behind and below the promontory is the round window (fenestra rotundum) that accommodates a membrane that seals the scala tympani of the inner ear off from the middle ear. The sacral promontory is the upper part of the anterior surface of the sacrum that projects into the pelvic cavity.

promoter (L. *promotus*=to move forward, or advance) The part of the gene where **transcription** is initiated and often where regulation of gene expression occurs. Promoters are typically located at the 5' flanking end (i.e., upstream) of the gene.

pronation (L. *pronare*=to turn face downwards) Internally rotating the forearm so that it moves from the anatomical position, with the palm facing anteriorly, to the pronated position, with the palm facing posteriorly. Also applies to the foot when the leg is internally rotated. When the foot is in contact with the ground it is pronated during the part of the walking cycle when the leg moves forward over the foot and the ankle joint is dorsiflexed.

pronograde *See posture.*

Prophaneranthropi *See Sergi, Sergio (1878–1972).*

prosencephalon *See forebrain.*

protein (Gk *protos*=first) A large molecule made up of one, or more, chains of amino acids. Proteins are fundamental components and products of cells (e.g., enzymes, hormones, and antibodies are all proteins) that are specified by the triplet DNA code. DNA is transcribed into messenger RNA, and then the nucleotide sequence of the RNA is translated into sequences of amino acids. *See also DNA.*

protein clock *See molecular clock.*

protein domain (L. *dominicus*=a lord, hence the territory under the control of a lord) A portion of a protein with a specific structure or function. The same domain may be present in multiple members of a protein family or related groups of proteins. For example, the *HOX* genes all contain a protein domain known as the **homeodomain** that can bind DNA. It is encoded by a 180 bp DNA sequence known as the homeobox (*see homeobox genes*).

proteome All of the **proteins** in a cell, a tissue or an organism.

proto-language *See language, evolution of.*

protobifaces *See Developed Oldowan.*

protocone (Gk *protos*=first and *konos*=pine cone) One of the terms proposed by Osborn (1888) for the main cups of mammalian molar teeth. It refers to the main mesial cusp on the lingual aspect of a maxillary (upper) molar tooth crown, and also to the main lingual cusp of a bicuspid upper premolar. It forms part of the trigon component of an upper molar crown (syn. deuterocone, epicone, mesiolingual cusp, tuberculum anterium internum).

protocone basin The term introduced by MacIntyre (1966) for a tooth crown feature that others call the central fovea (maxillary). *See central fovea (maxillary).*

protoconid (Gk *proto*=first and *konos*=pine cone) One of the terms proposed by Osborn (1888) for the main cups of mammalian molar teeth. It refers to the main mesial cusp on the

buccal aspect of a mandibular (lower) (hence the suffix “-id”) molar tooth crown, and also to the buccal cusp of a bicuspid mandibular premolar. It forms part of the trigonid component of a mandibular postcanine tooth crown (syn. eoconid, mesiobuccal cusp, tuberculum anterium externum).

protoconule A term introduced by Osborn (1907) for an accessory cusp on the occlusal surface of a maxillary molar located on the mesial marginal ridge mesiobuccal to the protocone. *See also* epiconule; mesial accessory tubercle; mesial marginal ridge.

profossa The term introduced by van Valen (1966) for a tooth crown feature that others call the central fovea (maxillary). *See also* central fovea (maxillary).

protostyle A term used by Schwartz and Tattersall (2002) for an accessory cusp on the occlusal surface of a maxillary molar that other researchers refer to as Carabelli(’s) trait. *See* Carabelli(’s) trait.

protostylid A term introduced by Dahlberg (1945) for an accessory cusp on the crown of a mandibular molar located on the buccal face of the protoconid. It ranges in its expression from a pit to a well-developed cuspid; it is sometimes associated with the buccal groove (syn. tuberculum paramolare, paramolar tubercle, distoconid, eoconulid).

provenance (L. *provenire*=to come forth, from *pro*=forth and *venire*=to come) The provenance of a fossil or an artifact is the horizon from which it was excavated, or, if it is a surface find, the horizon from which it originated. This includes the exact find context of an object (e.g., spatial location, lithostratigraphic, and chronostratigraphic contexts) and for artifacts it may include sourcing an object to its point of origin (e.g., determining the primary source for the obsidian used to make tools; Carter et al. 2006, Carter and Shackley 2007). If a fossil or an artifact is excavated from its horizon of origin then its provenance is not in doubt. However, most fossils and artifacts are not found *in situ*, but found already exposed of on the surface of the landscape. In such cases geologists try to trace the horizon of origin by looking for evidence of likely overlying fossiliferous strata nearby, or by matching the rock

matrix adhering to the fossil to the appearance (called **lithology**) of the overlying strata exposed nearby. In some circumstances the provenance of a surface find can be determined precisely; in others the provenance, and thus inferences about the age of the paleoenvironment, of a fossil are much less precise. The term provenance is sometimes used synonymously with provenance, particularly by North American researchers (syn. provenience).

provenience *See* provenance.

provisioning hypothesis This hypothesis is one of several devised to explain the origin of upright posture and bipedal locomotion within the hominin clade. Proposed by Lovejoy (1981) the provisioning hypothesis models human origins within a demographic and evolutionary socioecological framework. Lovejoy notes that primates exhibit a trend towards longer life spans, and thus prolonged life histories, which reaches its zenith in African apes and modern humans. As part of this trend, modern humans and chimpanzees exhibit a later age of sexual maturity, meaning that individuals must survive for a relatively long period before reproducing. This delayed reproduction in turn implies fewer offspring, and as a consequence individuals in these species must invest heavily in the few offspring they have to ensure their survival. However, primate mothers must typically balance the need to care for their infants with the need to care for themselves and accidents when infants accompany mothers during maternal foraging are a major source of infant mortality. To offset accidental infant death, one solution is for males to provision both the mother and child. Males forage for themselves, but also bring food back to their mate and offspring. Provisioning behavior should favor the evolution of bipedalism because this mode of locomotion frees the hand for carrying. Provisioning reduces the need for female mobility and in turn should minimize the incidence of accidental infant death. Males will only be selected for this behavior if (a) they can be assured that they are the biological father of the infant and (b) they have exclusive reproductive privileges with the female in question. This, in turn, should favor the evolution of monogamy. Lovejoy expanded on the provisioning hypothesis (Lovejoy 2009), but it is difficult to evaluate because it makes few predictions that can be tested using the fossil record. *See also* bipedalism.

proximal (L. *proxime*=nearest) In the direction of the root of a limb (i.e., where it is attached to the body). Thus, the shoulder joint is proximal to the elbow joint and the ankle joint is proximal to the hallucial metatarsophalangeal joint.

proximal humerus, evolution in hominins

Apes and modern humans share a relatively rounded humeral head with a relatively low greater tubercle that does not project superiorly; quadrupedal monkeys have a relatively larger greater tubercle (Larson 1995). Modern human and African ape humeri display a high degree of torsion, which means that the humeral head is “twisted” relative to the plane of the distal humerus. Most cursorial mammals have humeral heads that face posteriorly, in the same plane as the distal humerus. Torsion appears to be determined by scapula position, which in modern humans and African apes is situated on the dorsal aspect of the thorax. Thus, for the distal humerus (elbow) to remain in the anteroposterior plane, the proximal humerus is “twisted” to articulate with the glenoid. In animals where the scapula is situated more laterally, the humeral head faces more posteriorly to articulate with the glenoid cavity. Early hominin humeri appear to have lower humeral torsion values than modern humans and African apes, and it has been suggested that high humeral torsion may have evolved independently in modern humans and African apes (Larson 2007). *See also* **scapula, evolution in hominins**.

proxy (L. *procurare*=to take care of) The term proxy used to refer to a person authorized to act for someone else, but it now refers to any sort of substitute. So a variable (e.g., $^{18}\text{O}/^{16}\text{O}$ ratio) that tracks climate is called a proxy, as is a variable (e.g., femoral head size, or orbital area) that is correlated with body size or body mass.

pseudogene (Gk *pseudes*=false) A term for a **gene** that is not functional. For example, pseudogenes include genes that have arisen by **duplications**, **frameshift mutations**, or **deletions**. Pseudogenes are of interest to evolutionary biologists because they share ancestry with functional genes (for example, the beta globin gene cluster includes several pseudogenes) and they can be used to understand the evolution of a gene family. Once a gene becomes nonfunctional it evolves neutrally, so pseudogenes can be used to construct the phylogeny of a gene.

pterygoid (Gk *pteryx*=wing and *eidōs*=resembling) Thin, wing-like, vertical plates of bone, medial and lateral, that project inferiorly from the body of the sphenoid bone.

puberty An event of short duration that takes place in the central nervous system. Puberty is generally characterized by pulsatile secretion of gonadotropin-releasing hormone (GnRH), which stimulates the production and release of gonadotropins [e.g., luteinizing hormone (LH) and follicle-stimulating hormone (FSH)] from the pituitary. These, in turn, stimulate the production of gonadal steroid hormones (estrogen, testosterone), and production and maturation of gametes, from the gonads (ovaries, testes). The increased levels of gonadal steroids act to hasten bone ossification, setting a limit on growth in stature. However, the starting point for this complex feedback network is debated: some see decreased hypothalamic sensitivity to circulating steroid hormones (which acts to initiate the pattern of pulsatile GnRH secretion from the hypothalamus) as the key event; others point to an increased production of gonadotropins in response to GnRH as the beginning of the cascade, and still others point to increased gonadal steroid production as initiating the process. In any case, the event of puberty “reawakes” a process initially begun during fetal and early postnatal life, but held in check during the juvenile phase of development. Once this process is begun again, full sexual maturation and reproduction follow at varying lengths of time. For example, there is a delay of approximately 4–5 years between puberty and reproduction in chimpanzees, and a delay ranging from 5 to 10 years in modern humans. Puberty typically commences at an earlier age in females relative to males. In modern humans, puberty is initiated on average 2 years earlier in girls relative to boys, although there is substantial variation within and among populations. *See also* **life history**.

Pucangan Formation *See* Sangiran Formation.

pulp (L. *pulpa*=fleshy part of an animal or fruit) Soft dental tissue found deep within the tooth crown and root that supports the vitality of the **dentine**. During dentine development, the dental papilla supplies the mesenchymal cells that eventually become odontoblasts, and this papilla

subsequently becomes the pulp as the dentine grows and encapsulates it. The pulp contains the blood vessels and nerves that supply the tooth. *See dentine development.*

pulp chamber (L. *pulpa* = fleshy part of an animal or fruit) Enlarged end of the pulp cavity (root canal) within the dentine. It has been argued that pulp chamber proportions may distinguish *Homo neanderthalensis* from modern humans, with the former having larger (taurodont) molar pulp chambers (but see Constant and Grine 2001). However, because the pulp chamber decreases in size with advancing age (due to secondary and tertiary dentine development) it is important that comparisons are made between teeth of approximately the same age and degree of wear (Constant and Grine 2001). *See also taurodont.*

PUMC Acronym for Peking Union Medical College (*which see*).

pumice A pyroclastic rock, a common component of **tephra**, which is formed by the rapid cooling (or quenching) of molten rock (magma) which has a high proportion of volatile material (gas). Because of the latter, solidified bubbles or vesicles make up the majority of the rock volume, and they give pumice its characteristic buoyancy that allows it to float on water. In addition to the vesicles and the glass that forms the vesicle walls, pumices commonly contain primary volcanic minerals including feldspar, pyroxene, quartz, and zircon. Pumice can occur in any size grade, ranging from small size particles (i.e., ash and lapilli) to large-size boulders. Potassium-rich feldspars extracted from **pumice clasts** have long been a mainstay of isotopic dating efforts, as they can be unequivocally related to the eruptive event that generated the tephra deposit.

pumice clast (Gk *clastos* = to break down into pieces) A clast is a single particle, so a pumice clast is a single particle of **pumice**. A single grain of pumice of any size (i.e., small as in ash or lapilli, or large as in a boulder) would be a pumice clast.

punctuated equilibrium The name given to the phenomenon frequently observed in the fossil record in which an ancestral species persists more or less unchanged over long stretches of geological

time before suddenly speciating into one or more descendant species. The term was coined by Eldredge and Gould (1972) as an alternative to the paradigm of **phyletic gradualism** that had previously been used to explain the evolutionary transformation of one species into another. Eldredge and Gould argued that the periods of morphological stasis commonly observed in fossil species over stretches of geological time were, in fact, meaningful data and not merely an artifact of poor sampling in the fossil record. According to them, these long periods of stasis (or equilibrium) were periodically punctuated by short periods of rapid evolutionary change, hence the name. They further argued that punctuated equilibrium was a logical consequence of evolutionary theory, insofar as species are often thought to originate through the process of **allopatric speciation**. In this mode of speciation a small-to-medium sized subpopulation becomes geographically isolated from a much larger parent population. In such modest-sized populations natural selection and genetic drift can be relatively powerful, and can result in relatively rapid evolutionary change. This change would not be saltational (i.e., truly sudden) but might appear to be instantaneous in the fossil record, which may not preserve information at a sufficiently fine temporal scale and thus enable researchers to detect the evolutionary transformation of the subpopulation. Such evolutionary changes are more likely to result in extinction, but in some cases they may result in speciation. In contrast, in the larger parent population, the influence of selection and drift is relatively weak, and although its morphological parameters may oscillate over time these changes would only rarely result in a directional change. In theory, it is possible to test whether or not a given species may have evolved due to punctuated equilibrium by determining whether or not that species exhibits a significant temporal trend in some aspect of morphology. In practice, such analyses require large numbers of specimens whose stratigraphic and temporal context is well understood and very few fossil hominin taxa have a good enough contextual record. The two studies that have looked at the fossil records of hominin taxa across substantial periods of geological time [i.e., *Paranthropus boisei* (Wood et al. 1994) and *Australopithecus afarensis* (Lockwood et al. 2000)] both concluded that stasis rather than gradual change was the predominant signal.

purifying selection A type of **natural selection** whereby alleles that are deleterious are removed from the gene pool (syn. negative selection). *See also* **negative selection**.

push-off The propulsive phase of the modern human walking cycle in which the center of mass travels over the forefoot and the foot lifts off the ground and generates forward momentum; it is also known as “toe-off.” This part of the gait cycle occurs at approximately the 60% point of the walking cycle in modern humans. It is initiated by activity of the soleus and gastrocnemius plantarflexing the foot at the ankle joint. During the push-off phase inversion of the hindfoot locks the calcaneocuboid joint, limiting mobility in the mid-tarsal region. As the heel lifts, and the metatarsophalangeal joints dorsiflex, the plantar aponeurosis (fascia) tightens in what is called the “windlass effect,” causing the foot to stiffen and thus be an effective lever. Activity of the plantar-flexing muscles pushing the forefoot against the substrate causes the ground reaction forces on the foot to be as high, or higher, during this push-off phase of walking as during the heel-strike phase. *See* **foot arches**; **walking cycle**.

Putjangan Formation *See* **Sangiran Formation**.

pygmy chimpanzee *See* *Pan paniscus*.

pyramidal cells Pyramidal cells are a type of neuron in the cerebral cortex of the cerebral hemispheres of the brain that are characterized by a cell body with a triangular, or pyramidal, shape, with the apex giving rise to an apical dendrite, which runs toward the outermost layers of the cortex. The comparatively large base of the cell body gives rise to several basal dendrites that course horizontally within the layer containing the cell body and those closely adjacent. Pyramidal neurons typically project the main trunk of their axon into the white matter and it terminates either in another area of the cerebral cortex or at a more distant site in the central nervous system. Pyramidal neurons express the excitatory neurotransmitter glutamate. Elston

et al. (2006) have shown that pyramidal neurons in the granular prefrontal cortex have relatively more complex dendritic arbors and a higher density of spines in association with brain-size enlargement among primates. In contrast the pyramidal neurons of primary visual cortex do not show such dramatic differences. As a consequence, the pyramidal neurons of the modern human prefrontal cortex appear to be the most morphologically complex neurons of the cerebral cortex among all primates. Such modifications of pyramidal neurons in modern humans may serve as an underlying neuroanatomical substrate that contributes to enhancements of higher-order cognitive functions.

pyriform aperture *See* **piriform aperture**.

pyriform cortex *See* **piriform cortex**.

pyroclastic (Gk *puro*=fire and *klastos*=broken) A term used to describe rock fragments that have been ejected explosively from a volcanic source. Ash is an example of a pyroclastic material.

pyrotechnology (Gk *puro*=fire and *teckne*=skill) This term, which literally means “fire-skills,” applies to the skills used in the making, curation, and use of controlled fire. The first sound evidence for controlled fire takes the form of discrete scatters of burned flint chips surrounded by unburned materials at the Israeli site of **Gesher Benot Ya’aqov** at just under 780 ka (Goren-Inbar et al. 2004). Other claims for controlled fire prior to that time are difficult to substantiate because of the potential to confuse a burned-out tree stump with a hearth. Attempts to reconstruct the maximum temperature in a paleofire to discriminate between controlled fires and natural fires yielded inconclusive results. Most of the explanations for the use of controlled fire have focused on its utility for cooking and protection, but Brown et al. (2009) suggest that as early as 164 ka at **Pinnacle Point** fire was being used to pre-treat silcrete to make it easier to work to produce flakes.

PySC Acronym for the phylogenetic species concept. *See* **phylogenetic species concept**; **species**.

Q

q_x The term used to express the age-specific probability of death in a life table. *See also* **life table**; **probability of death, age-specific**.

q arm *See* **chromosome**.

Qafzeh (Location 32°41'N, 35°18'E, Israel; etym. Ar. الجبل *djebel*=mountain and قفزه *qafzeh*=jump or leap) History and general description Qafzeh cave is situated about 2.5 km/1.5 miles southeast of Nazareth in the Wadi el-Hadj. The first excavations from 1933–5 were undertaken by R. Neuville and M. Stekelis. A description of the stratigraphy was published in 1951, but Neuville died before a proper description of the remains could be completed. After an extended hiatus the site was excavated again from 1965 to 1979 by Bernard **Vandermeersch**. The two excavation programs focused on different areas of the cave (Neuville and Stekelis focused on the floor of the interior of the cave whereas Vandermeersch primarily worked in the narrow cave entrance, or “vestibule”) and thus the levels are not named under the same scheme (the earlier work uses letters and the more recent work uses roman numerals). Temporal span and how dated? The stratigraphic levels were dated using **thermoluminescence dating** on burned flints, **electron spin resonance spectroscopy dating** (or ESR) using both an early-uptake model and a linear-uptake model was applied to mammalian teeth, and the skull was dated using gamma spectrometric **uranium-series dating**. Thermoluminescence dates on the Middle Paleolithic levels XXIII–XVII were *c.*92 ka. ESR dates on levels XXI–XV vary based on the uptake model: late-uptake estimates average to 115 ka, whereas early-uptake estimates average to 96 ka. Hominins found at site The remains of 14 individual hominins are known from the site. Two (Qafzeh 1 and 2) are from the **Upper Paleolithic** levels excavated by Neuville and the rest are from Middle Paleolithic levels (Qafzeh 3–7 were excavated by Neuville and

Stekelis, and Qafzeh 8–18 by Vandermeersch). The Middle Paleolithic Qafzeh remains are generally interpreted as sampling a robust population of anatomically modern humans, and Howell (1958) commented on the affinities between the Qafzeh and the hominin remains from **Skhul**. Because the Skhul and Qafzeh remains represent the earliest known modern human remains outside of Africa, they have played a crucial role in understanding the radiation of modern humans from Africa. Archeological evidence found at site There are very few artifacts in the Upper Paleolithic levels, and this makes a precise identification of the industry difficult. The assemblage in the Middle Paleolithic levels is broadly defined as **Levantine Mousterian**. Key references: Geology, dating, and paleoenvironment Neuville 1951, Valladas et al. 1988, Schwarcz and Rink 1998, Grün and Stringer 1991, Yokoyama et al. 1997; Hominins Howell 1958, Vandermeersch 1971, Vandermeersch 1981; Archeology Vandermeersch 1971.

Qafzeh 6 Site Qafzeh, Israel. Locality Cave interior. Surface/in situ *In situ*. Date of discovery September 3–6, 1934. Finders R. Neuville and M. Stekelis. Unit N/A. Horizon Layer L. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 94–80 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Well-preserved, but fragmented cranium that lacks the upper right I², P³⁻⁴, M³, and left M³. Announcement Köppel 1935. Initial description Vandermeersch 1971. Photographs/line drawings and metrical data Vandermeersch 1981. Detailed anatomical description Vallois and Vandermeersch 1972, Vandermeersch 1981. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions None. Current conventional taxonomic allocation Early modern *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Qafzeh 6 is the most complete cranial specimen from Qafzeh, and outside of Africa it is one of the oldest specimens

of anatomically modern humans. Like many other early modern human specimens from Africa and the near East, Qafzeh 6 exhibits some primitive morphology, particularly the presence of a supraorbital torus. Location of original Institut de Paléontologie Humaine, Paris, France.

Qafzeh 9 Site Qafzeh, Israel. Locality Vestibule. Surface/in situ *In situ*. Date of discovery 1969. Finder Bernard Vandermeersch. Unit N/A. Horizon Levels XVII–XXIV. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 80–100 ka. Developmental age Adult. Presumed sex Female. Brief anatomical description Fragmentary skull with incomplete postcranial skeleton. Announcement Vandermeersch 1969. Initial description Vandermeersch 1971. Photographs/line drawings and metrical data Vandermeersch 1981. Detailed anatomical description Vandermeersch 1981. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions None. Current conventional taxonomic allocation early modern *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Qafzeh 9, which is the most complete postcranial skeleton of any Qafzeh hominin, appears to have been part of a double burial. Location of original Department of Anatomy and Anthropology of the Sackler Faculty of Medicine, Tel Aviv University, Israel.

Qafzeh 11 Site Qafzeh, Israel. Locality Vestibule. Surface/in situ *In situ*. Date of discovery 1969. Finder Bernard Vandermeersch. Unit N/A. Horizon Levels XVII–XXIV. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 80–100 ka. Developmental age Immature, *c.*10 years old. Presumed sex Male. Brief anatomical description Fragmentary skeleton. Announcement Vandermeersch 1970. Initial description Vandermeersch 1971. Photographs/line drawings and metrical data Vandermeersch 1981. Detailed anatomical description Vandermeersch 1981. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions None. Current conventional taxonomic allocation Early modern *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Qafzeh 11 was almost certainly buried intentionally, as the pit in which it was located was carved into the bedrock. The child also seemed to have been arranged so that it appeared to be holding the antler

of a deer (*Dama mesopotamica*) to its chest. Location of original Department of Anatomy and Anthropology of the Sackler Faculty of Medicine, Tel Aviv University, Israel.

Qesem Cave (Location 32°11'N, 34°98'E, Israel) History and general description Discovered during construction in 2000, this cave site preserves well-dated sequence of Acheulo-Yabrudian (terminal Lower Paleolithic) technology. The dates suggest that the Acheulo-Yabrudian represents a distinct and quite long cultural phase between the Acheulean and Mousterian phases in the Near East. Temporal span and how dated? Uranium-series dating on speleothems provide a range of dates between 382 and 207 ka. Hominins found at site None. Archaeological evidence found at site Several distinct archaeological layers, all attributed to the Acheulo-Yabrudian. Key references: Geology, dating, and paleoenvironment Barkai et al. 2003; Hominins Mann and Vandermeersch 1997, Hershkovitz et al. 2010; Archeology Barkai et al. 2003, Stiner et al. 2011.

QTL Acronym for quantitative trait locus. *See* quantitative trait linkage analysis; quantitative trait locus.

qualitative variants *See* non-metrical traits.

quantitative genetics The genetic basis of traits that do not vary in a discrete manner. Quantitative traits such as height plot out in a continuous distribution, hence they are also referred to as continuous traits; discrete traits, such as yellow or green coat color in peas, do not follow this statistical pattern. The variation in such traits is controlled by several genes (e.g., they are polygenic) combined with environmental effects. Quantitative genetics measures changes in the frequency of these quantitative/continuous traits across generations and within and among populations. Overall, the main thrust of quantitative genetics is to implement methodologies that allow measurement of variation in quantitative traits to be teased apart: calculating the proportion of variation due to effects from several genes, each perhaps contributing a small amount of influence, and that variation due to effects of the environment. This discipline is important because much of the morphological variation within and among human populations can be attributed to variation in quantitative traits. *See also* polygenic trait.

quantitative trait locus (or QTL) A genetic variant that segregates with a quantitatively measured phenotype (often with a normal distribution) (e.g., height or levels of low-density lipoproteins). These loci (QTLs) are typically regions of DNA (genetic markers) that have significant variation within and between populations, but which do not necessarily have an effect themselves on the phenotype. Their statistical association with phenotypic variation indicates that a genomic region close to that locus significantly influences the phenotype. This may be a known gene (called a “candidate gene”) or one that has yet to be identified. Quantitative traits, like height, are often influenced by more than one gene and are influenced by the effects of environment, sex, and age, as well as interactions between them; this is why quantitative traits are often referred to as “complex” traits. The goal of QTL research is to discover genes and gene variants that influence quantitative, or complex traits. QTL analyses have yielded important information about the genes that underlie many genetic disorders and are frequently used in medical research. QTL analyses have also been employed to elucidate how genes influence normal variation in traits that are important to evolutionary biology (such as skull shape, pigmentation patterns, and behavior). Marker number and type, as well as sample size and structure of the population can influence the results of a QTL analysis.

quantitative traits *See polygenic trait.*

quarry A term used for any area repeatedly visited by hominins to obtain stone raw material. Stone raw material may be freely available on the surface but in other instances quarries provide evidence that raw material has been extracted after hominins have used simple lever systems to remove subsurface boulders. Quarry sites typically include large amounts of debris associated with stone tool production (particularly in the early stages of their manufacture) as well as evidence of the tools (e.g., hammers) needed to make stone tools (Doelman 2008, Ericson and Purdy 1984). The

MNK “chert factory site” at **Olduvai Gorge** (Stiles et al. 1974) is a good example of a quarry site. *See Olduvai Gorge.*

quartz Crystalline silica (SiO_2) is one of the most common rock-forming minerals in the continental crust and is found in many different types of rock. Although quartz is widely used in the production of stone tools (e.g., **Matupi Cave**), its texture is often poorly suited to the production of stone tools as it is prone to shatter, rendering the manufacture of large pieces difficult. Agate, chert, and flint are all varieties of chalcedony. Chalcedony is a variety of silica composed of microscopic quartz crystals, micro-porosity, and variable amounts of water. Because it lacks the regular crystal structure of more crystalline forms of quartz chalcedony has better flaking characteristics and thus is used to make stone tools. *See also conchoidal fracture; percussion.*

quartzite A typically coarse granular to crystalline rock composed primarily of **quartz**, which may be either sedimentary or metamorphic in origin. Metaquartzites are varieties of quartzite formed by recrystallization due to metamorphism; orthoquartzites formed as the result of secondary silica cementation of quartz sand following sedimentation. Although its material properties are dependent upon the size of the individual quartz grains, quartzite generally fractures in a rough, hackly fashion, but percussion does result in a conchoidal fracture and quartzite artifacts retain a durable sharp edge. When it is readily available it is widely used at archeological sites (e.g., **Olduvai Gorge** and **Klasies River**).

Quaternary (*L. quarter*=four times) This term, introduced by Desnoyers in 1829, refers to a unit of geological time (i.e., a **geochronologic unit**). As of 2009, the International Union of Geological Sciences redefined the Quaternary as the most recent of the three **periods** that comprise the **Cenozoic** era. Thus, it spans the time interval from 2.58 Ma (Gelasian) to the present and is divided into the **Pleistocene** and **Holocene** epochs.

Quina Mousterian *See La Quina.*

R

r See correlation coefficient.

R A statistical and graphical programming language widely used in quantitative biology and which is rapidly being adopted by physical anthropologists. Developed by Robert Gentleman and Ross Ihaka of the Statistics Department of the University of Auckland in the mid-1990s (Ihaka and Gentleman 1996) it is a free, open source, platform-independent language that is particularly good at manipulating large matrices (www.r-project.org/). User-contributed "packages" contain functions that allow for specific types of analyses common in human evolutionary studies such as discriminant function analysis, cluster analysis, and phylogenetic comparative analysis. In addition, the programming language is flexible and can be used to create customized analyses such as resampling analyses which are often used in studies of shape and size variation in fossil samples. The basic interface is command-line-driven, which presents a steep learning curve to some users but free menu-driven windows interfaces have also been developed (e.g., R Commander; <http://cran.r-project.org/web/packages/Rcmdr>). There also exist a number of text editors which facilitate programming in R by highlighting functions and arguments in different colors, highlighting matched parentheses, quotation marks, and brackets, and allow direct communication between the text editor and R (e.g., Tinn-R; www.sciviews.org/Tinn-R).

***r*-selection** See *r/K*-selection.

***r/K*-selection theory** This theory captures the idea that there is a systematic relationship between the type of environment experienced by a taxon, and the type of reproductive strategy it adopts to maximize its likely success in that environment (MacArthur and Wilson 1967, Pianka 1970). In *r*-selected species the individuals are small-bodied, they mature early, they tend to have many widely

dispersed offspring, and their generation times and lifespans are short. This contrasts with *K*-selected species in which the individuals are larger-bodied, they mature later, they tend to have fewer offspring that require intensive investment, and their generation times and lifespans are relatively long. Modern humans are usually categorized as a *K*-selected species. However, rather than falling neatly into either category, organisms instead often show a mixture of traits from opposing ends of the *r/K* continuum.

***r*²** See coefficient of determination.

Rabat See Kébibat.

race In the field of genetics, "race" has been used historically to describe strains, groups, or subspecies within a species. In modern humans, the term has become tied to political and sociocultural concepts that do not correspond to meaningful biological units or biological realities, and thus race is not appropriate as a biological term or as a classificatory unit for modern humans. Compared with other species, including most hominoids, modern humans have relatively little genetic variation. Modern human variation is typically clinal (i.e., subject to geographic patterning affected by selection and migration) and cannot be pigeonholed into the boxes corresponding to socially defined racial categories. Despite all of this, race is often used (however inappropriately) as a proxy for ancestry or environment in medical genetics and forensics research [see Bamshad et al. 2004, Duster 2005, and a whole Symposium Issue (139:1–102) of the *American Journal of Physical Anthropology* devoted to the topic of race].

radial unit hypothesis (L. *radius*=ray) Proposed by Pasko Rakic in the 1980s to account for the expansion of the cerebral cortex in ontogeny and evolution. Each "radial unit" is initially generated by the symmetrical mitotic division of founder cells in the ventricular zone of the fetal telencephalon.

Each progenitor cell divides to produce two daughter progenitor cells, so with each round of symmetrical divisions the number of progenitor cells doubles. In the next phase, progenitor cells in the ventricular zone begin to divide asymmetrically so that each round of mitosis yields one daughter cell that no longer divides (called postmitotic) and one daughter cell that remains in the ventricular zone and continues mitosis. The postmitotic cell that is destined to be a cortical neuron detaches from the ventricular surface and begins to migrate along a transient glial fiber that extends towards the surface beneath the pia mater, eventually resting in the cortical plate, a developmental precursor of the cerebral cortex. After arriving at the cortical plate, the more recently generated neurons bypass neurons formed at an earlier stage, so that the neurons come to rest along an “inside-out” gradient. Each proliferative unit in the ventricular zone produces approximately 100 neurons that come to occupy a vertical **minicolumn** in the cerebral cortex. The radial unit hypothesis is an attempt to account for the precise, appropriate migration of neurons from their birthplace to their final functional location in the cerebral cortex. This hypothesis also provides a mechanism by which evolutionary variation in the size of the cerebral cortex can occur by modifying the number of founder cells in the ventricular zone prior to the onset of neuronal proliferation and migration within each radial unit. Accordingly, it is proposed that genetic mutations affecting either the dynamics of **mitosis** (i.e., cell division), or **apoptosis** (i.e., cell death) of the founder cell population, or both, result in differences in the surface area of the cerebral cortex. In confirmation of some of the predictions of the radial unit hypothesis, there is evidence that several genes (e.g., *ASPM*, *microcephalin*, and several caspases) that play a role in cell-cycle regulation and programmed cell death of cortical progenitors have been positively selected for during the course of hominoid and modern human evolution. *See also* **brain size evolution**, **molecular basis of**

radiocarbon dating A radioisotope-based dating method that can be applied to the remains of a wide range of organisms (i.e., bones, teeth, seeds, charred wood/charcoal) and some inorganic precipitates (i.e., carbonates) that contain sufficient amounts of ^{14}C (also called radiocarbon). **Principle** Radiocarbon dating is based on the regular decay of the radiocarbon isotope ^{14}C to ^{14}N . All living organisms incorporate some ^{14}C into their body tissues, either during photosynthesis (plants) or from dietary car-

bon (animal consumers). When an animal or plant dies, it no longer adds new ^{14}C to its tissues. Because ^{14}C decays to ^{14}N at a constant rate, the relative amount of ^{14}C left in organic material can be used to estimate an age for the material. However, because the half-life of the breakdown of ^{14}C to ^{14}N is 5730 ± 40 years, the method can only be applied to material that is less than $\approx 50\text{--}60$ ka (i.e., less than 1% of the temporal span of the hominin fossil record); samples older than this do not contain enough ^{14}C to date. **Suitable materials** Carbon dating can be applied to bone, tooth, shell, charcoal, and other plant remains. Three methods of measuring radiocarbon are currently used. Two of the methods are “conventional” methods, which measure the radioactive decay of ^{14}C via the emission of beta particles (electrons). This is done by either liquid scintillation counting (or LSC) or by gas proportional counting (or GPC). The third method, first used in 1977, is a direct ion-counting technique. It uses a particle accelerator to produce ions with a $+3$ charge state and in this state many of the ions that interfere with the counting of ^{14}C can be easily removed, thus allowing the accurate measurement of very low concentrations of ^{14}C . Because this third method, called accelerator mass spectrometry (or AMS), enables the direct measurement of individual ^{14}C atoms much smaller samples can be processed; AMS can routinely date samples of 1 mg of carbon. This means that previously undateable samples, such as single hominin teeth and individual grains of domesticated cereals, can now be dated. Typical starting weights required for AMS (e.g., 10–20 mg of seed/charcoal/wood, 500 mg of bone, 10–20 mg of shell carbonate) are about 1000 times less than the weights required by conventional counting systems. The AMS method also allows for more thorough chemical pretreatment of samples, this is particularly important for older samples (>25 ka BP) where small amounts of modern carbon contamination may have a large effect on the measured ^{14}C fraction and hence the date. **Potential limitations.** Differences in the atmospheric production of ^{14}C through time due to changes in the Earth’s geomagnetic field and solar output mean that ^{14}C ages (also known as uncalibrated radiocarbon ages) need to be calibrated to correct for these potentially substantial errors. The calibration method needs to be based on a system whose own chronology is independent of radiocarbon dating and ideally it should faithfully preserve evidence of annual, or **sidereal**, events. For the period between the present back to $\approx 10\text{--}12$ ka researchers successfully used the

annual rings preserved in long-lived trees such as the bristle-cone pine to calibrate ^{14}C ages in the northern hemisphere. Between the older end of the range of high-resolution tree-ring calibration and *c.*21 ka researchers have managed to identify precise global climatic events in coral growing in Tahiti and Mururoa. These coral calibrations were the basis of the calibration curve INTCAL98 and this curve was subsequently updated and extended to 26 ka as INTCAL04 (Reimer et al. 2004). However, between *c.*21 and 26 ka the two most precise calibrations, one using annual sediment layers (called varves) in Lake Suigetsu in Japan, the other based on stratigraphy preserved in carbonates (called **speleothems**) in a submerged cave in the Bahamas that can be linked to independently dated events in the Greenland Summit ice cores, did not agree. This difference has now been explained (see Hofmann et al. 2010 for a full explanation of the discrepancy). The Intcal calibration curve has been subsequently updated to INTCAL09 (Reimer et al. 2009) and this extends the calibration curve back to *c.*50 ka cal. years BP. Although it is provisional for the region of the curve >26 ka cal. years BP, currently it provides the best estimate. Ongoing work on new cores from the varved sequence in Lake Suigetsu (Staff et al. 2010) and marine cores from the Cariaco Basin off the coast of Venezuela and an Atlantic/Iberian Margin deep sea core (MD952042) hold the promise of a better-validated calibration curve for the period between 10 and >50 ka. Due to ocean circulation patterns, carbon in the southern hemisphere tends to be *c.*50 years younger than carbon in the northern hemisphere. As a result, calibration curves for the northern hemisphere cannot be used in the southern hemisphere. Instead, an independent curve has been developed for the southern hemisphere (McCormac et al. 2004; SHCal04), but SHCal04 can only be used back to 11 ka. For samples older than this, INTCAL04 calibrations can be combined with a hemispherical time-lag correction (i.e., 56 ± 24) (McCormac et al. 2004). The discrepancies between raw ^{14}C ages and the calibrated radiocarbon ages can be substantial. Around 6–8 ka the ^{14}C ages are 750–1000 years too young, but *c.*20 ka the ^{14}C ages may be *c.*3 ka too young and between 35–40 ka the ^{14}C ages may be *c.*5 ka too young. When researchers provide new dates in these time ranges, they should always quote both the “raw” uncalibrated date in radiocarbon years and the calibrated date. Mellars (2006) reviewed the impact these recent efforts at calibration have had on radiocarbon

dates for sites in Europe, but his use of the NotCal calibration curve, which was not designed for this purpose, was controversial (e.g., Turney et al. 2006). A further complication is the “reservoir effect,” where an apparent age is obtained from a sample that contains carbon from a source or reservoir other than atmospheric carbon dioxide. The marine reservoir effect is one example. Because there is a delay in the exchange of atmospheric carbon dioxide with ocean bicarbonate and there is mixing of older upwelled deep water with the surface waters in the ocean there is a variable offset in apparent ages obtained from marine samples. Thus a reservoir correction must be made to account for the incorporation of “old carbon” in the sample. Human bone samples may sometimes be prone to this problem if there has been significant consumption of marine resources in the diet (e.g., for coastal Mesolithic populations). **Recent developments** In addition to the improvements in calibration of ^{14}C ages recent developments in the chemical pretreatment of samples has led to dramatic changes in dates for some events of interest in human evolution, particularly for the timing of the earliest anatomical modern humans in Europe. The use of techniques such as ultrafiltration to remove more of the exogenous carbon contamination from bone collagen has led to the re-dating of fossils [e.g., the so-called Red Lady of Paviland (Jacobi and Higham 2008) and the reassessment of chronologies for sites such as **Abri Pataud** (Higham et al. 2011)]. Improvements in the pretreatment of charcoal samples, particularly the development of the acid base oxidation technique (or ABOX) has allowed the re-dating of key sites where bone collagen does not survive [e.g., **Border Cave** in South Africa (Bird et al. 2003) and Devil’s Lair in southwestern Australia (Turney et al. 2001)]. A further development that is making significant improvements in the construction of ^{14}C -based chronologies is the availability of online calibration coupled with sophisticated statistical techniques such as Bayesian analysis (e.g., Oxcal 4.1). *See also radiometric dating.*

radiocarpal joint (aka antebrachiocarpal joint) In modern humans this is the articulation between the distal radius and the scaphoid and lunate. Modern humans and the great apes have lost the articulation between the ulnar styloid process and the triquetrum and pisiform seen in other primates so that the radius is the only connection between the hand and the rest of the forelimb. In hominoids, the ulnar styloid process is reduced in size and an interarticular disc takes its place between it

and the triquetrum, probably allowing for a greater range of pronation and supination of the hand (Lewis 1989). This mobility is advantageous for suspensory and climbing behaviors and modern humans have retained this mobility. In most other nonhominoid primates the ulnar–triquetrum–pisiform articulation is extensive and provides additional stability on the medial side of the wrist during quadrupedal locomotion.

radiogenic dating *See* geochronology; radiometric dating.

radioisotopic dating *See* geochronology; radiometric dating.

radiometric dating (L. *radiare*=to emit beams, from *radius*=ray and *metricus*=relating to measurement) A family of dating methods based on measuring radiation. The methods measure the amount of parent material that remains, and/or the amount of daughter product accumulated, or the amount of radiation received (e.g., optically stimulated luminescence dating and electron spin resonance spectroscopy dating). One or more of these two measurements, in combination with the decay constant, allow scientists to determine how long the decay process has been running. Some radiometric methods (e.g., potassium–argon dating, argon–argon dating, radiocarbon dating, and fission track dating) work independently of local levels of cosmic and other background radiation. Other radiometric methods are sensitive to local burial conditions. To be useful for dating fossil hominins a radiometric system must: have an appropriate length half-life (i.e., one that is long enough for there to be more than a small number of atoms to measure – this is why standard radiocarbon dating is unreliable above *c.*40 ka – and short enough that there are perceptible changes in the ratio of the parent to the daughter atoms within the past 5–8 Ma); have a stable daughter product; be a “closed” system, which means that there is no other source of daughter product, nor can the accumulated daughter product be removed; and be such that the beginning of the process of the decay of the parent atom must coincide approximately with either the death of the animal, or the formation of the rock.

radix The number of individuals chosen as the basis for a life table. The radix is usually chosen so that it is a power of 10. Common radix values

for life tables are 100 (e.g., a survivorship of 50 represents the point where half of the population has died), 1000, and 100,000.

rain forest Most early hominins were associated with tropical woodlands, but it is also likely that some hominids and perhaps even hominins (particularly those in the Miocene and Pliocene) existed in areas that contained tropical rain forest. However, tropical forest is seen as a less favorable habitat for hominins than woodland because of the inaccessibility of fruits in the higher canopy and the cryptic nature of forest animals. Nonetheless, there is increasing archeological evidence for forest exploitation by hominins in Africa during the Pleistocene (Mercader 2002). Archeological and paleontological data also strongly suggest that modern humans colonizing Southeast Asia 46–34 ka exploited a range of habitats, including rain forest (Barker et al. 2007).

Rancah (Location 7°15'S, 108°12'E, West Java, Indonesia; etym. named after a local village) History and general description This is the site of a controlled excavation carried out in 1999 on the banks of the Cisanca River that produced an isolated hominin right I₂. Temporal span and how dated? **Electron spin resonance spectroscopy dating** applied to bovid teeth found below RH 1 yielded an average age of *c.*606 ka, but this age estimate is likely younger than the actual age for there is evidence the bovid teeth had been heated during their depositional history. Hominin found at site RH 1 is a right I₂ crown that has been referred to *Homo erectus*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Weeks et al. 2003, Bogard et al. 2004; Hominins Kramer et al. 2005.

Rancah hominid 1 *See* RH 1.

random assortment Occurs in unlinked genes, so that alleles of different genes assort independently during gamete formation. During metaphase I in eukaryotic organisms pairs of homologous chromosomes align randomly at the metaphase plate (i.e., which of a pair of chromosomes is from the male parent, and which is from the female, is due to chance). This process creates an unpredictable mixture of maternally and paternally inherited alleles in the newly formed gamete. This phenomenon, along with chromosomal crossing over in prophase

I and fertilization, helps increase genetic diversity by producing new genetic combinations. *See also Mendelian laws.*

random drift *See genetic drift.*

random mating A mating “system” in which every individual has an equal chance of interbreeding with every other individual of the opposite sex, regardless of genetic, physical, or social preferences. This type of mating system contrasts with a situation such as that described for positive assortment. *See also positive assortment.*

randomization This term refers to a type of resampling analysis used in hypothesis testing. It is also known as a permutation test (although “combination test” would be more accurate, as will be explained further below). Randomization uses an iterative process of sampling without replacement to generate P values for a test statistic. For example, suppose a researcher has a sample of 10 fossil crania from site A and 12 fossil crania from site B, and wishes to know whether the median endocranial volume differs significantly between the two sites. There is no equation that allows the P value to be calculated directly for a test of difference in medians (as opposed to means), but a randomization procedure can be developed to do this. To test the hypothesis of no difference using randomization, the researcher would first calculate the actual difference in median values between sites A and B. Under a null hypothesis of no difference in median endocranial volume between the two sites, crania at sites A and B can be considered to belong to a single population, in which case the difference in medians between the crania should be similar to a difference in medians calculated for any arbitrary grouping of all 22 crania into one group of 10 and one group of 12. For this particular example there are 646,646 unique ways to split the sample into groups of 10 and 12 if order does not matter (order is unimportant since regardless of whether a group consists of specimen X followed by specimen Y or specimen Y followed by specimen X, the median will be the same). In most randomization tests the order will not matter, but since permutations calculate the number of possible ways to sample data when order *does* matter and combinations calculate the number of possible ways when order *does not* matter, this is why “combination test” would be a more appropriate name. If one were to calculate the difference in medians for all 646,646 ways to split the

data in this example, one would perform an “**exact randomization.**” However, in this case (and in many cases where this technique is likely to be used) the number of total possible combinations is too high to reasonably work through every single possibility. Thus, a large number (typically $n \geq 5000$ or more) of randomly selected possibilities is used as a proxy for the full set of possible combinations (i.e., this is a version of the **Monte Carlo** methods). In the example, the difference in medians between groups A and B is calculated for n total resampled data sets, each of which randomly selects 10 crania from the full data set of 22 crania to place in group A, and the remainder of which are placed in group B. As stated above, if there is *no* difference between groups then the actual difference in medians should be similar in value to those generated from the randomly rearranged data set and should fall somewhere in the middle of the range of resampled differences in median. However, if there *is* a difference in the populations from which site A and site B crania are drawn, then the actual difference in medians should be at the extreme of values from the resampled data. To generate a P value, the number of resampled differences in median that are equal to, or greater than, the actual differences are counted (call this value x); the P value is calculated as $(x+1)/(n+1)$. The additional 1 in the numerator represents the actual value for the difference in medians, and the denominator represents the total number of resampled values plus the original observation from the actual data set; see Manly (2007) for a fuller discussion of the method. A variant on standard randomization is often used in paleoanthropology. In many cases some measure is calculated for a fossil sample (e.g., a measure of size or shape variation) based on a small number of specimens, and researchers wish to know whether that value differs significantly from the value of that measure calculated for a sample drawn from a comparative taxon with a larger sample size (e.g., comparative samples of extant great apes or modern humans). In this case the extinct taxon is considered to fall into two samples: those individuals recovered as fossils and those individuals that have not been recovered as fossils (e.g., individuals that never fossilized, fossils that were destroyed by taphonomic processes, or fossils that simply have not yet been discovered). Thus, the fossil sample represents only one of the two possible groups for that extinct taxon. The samples of the extant taxa are thus resampled without replacement into two subsamples: one whose sample size is equal to that of the fossil sample, and one that contains the

balance of the comparative sample. Since the variable of interest is calculated *only* for those extinct individuals that are recovered as fossils, it is similarly calculated *only* for the extant individuals that are randomly selected to simulate the “fossil” group (i.e., the group whose sample size equals that of the fossil sample). This resampling procedure is repeated *n* times for the comparative sample, and the fossil value is compared to the values generated for the comparative sample. This type of procedure has been used to assess size and shape variation in hominin cranial, dental, mandibular and postcranial samples (e.g., Richmond and Jungers 1995, Lockwood et al. 1996, Reno et al. 2003, Harmon 2006, Skinner et al. 2006, Gordon et al 2008). *See also* **resampling**.

range expansion A type of dispersal that occurs when the area in which a population is found increases but still encompasses the original ancestral area. For example, towards the end of the Pliocene a trend toward environmental aridity led to an expansion of grasslands in Africa. Many grazing mammalian species, and the carnivores that preyed on them, might be expected to have experienced range expansion during this time period.

range shift A type of dispersal that occurs when the area in which a population is found changes geographic position. For example, during aridification trends in the southern hemisphere, **mesic** vegetational zones shifted their geographic positions towards the equator (e.g., Vrba 1992). This resulted in mammals that were adapted to mesic conditions experiencing a northward range shift.

raptor (*L. raptor*=thief, from *rapere*=to carry off) An informal but common term for birds of prey, primarily referring to those which hunt vertebrates during daylight; the term can also include the nocturnal birds of prey, such as owls, but this use is less common. Raptors are of significance in paleoanthropology because several taphonomic studies have demonstrated that accumulations of micromammal remains at fossil sites are the result of raptor behaviour: notably feces or pellets resulting from feeding activities, sourcing prey which would have been gathered over a wider area than rodents would travel in life, unaided. Therefore paleoenvironmental reconstructions of a site that rely on micromammalian paleoecology must consider the taphonomy of the microfaunal assemblage. *See also* **Taung 1**.

rarefaction A statistical technique developed by ecologists and often employed by paleontologists and zooarcheologists to compare **species richness** (i.e., the number of species) across fossil samples of different sample sizes. Because the number of species observed in an assemblage is influenced by the number of specimens that are sampled, rarefaction is used to correct for sampling effects. This is accomplished by estimating species richness from a subsample of the total assemblage. For example, consider fossil assemblage A with 1000 specimens belonging to 15 species and fossil assemblage B with 500 specimens sampling 10 species. The greater number of species in fossil assemblage A could be indicative of a more species-rich faunal community or its larger sample size, or both. Rarefaction can be used to determine how many species one would expect to observe in fossil assemblage A at a sample size equivalent to fossil assemblage B (500 specimens), facilitating a more meaningful comparison of species richness between fossil assemblages. Rarefaction is also used to determine whether a faunal community has been sufficiently sampled. This is accomplished by generating rarefaction curves, which are graphs plotting the number of species relative to the number of specimens sampled. Rarefaction curves typically have steep slopes at first, as the most common species are sampled, and slowly plateau as rare species are recovered at increasingly large sample sizes. When the number of species no longer increases at larger samples, it can be concluded that further collecting is unlikely to yield additional species.

ray (*L. radius*=radiating line) A manual digit plus its metacarpal or a pedal digit plus its metatarsal. Rays are normally numbered (e.g., second manual ray or fourth pedal ray), whereas manual digits are normally named (e.g., ring finger, thumb).

Raymond A. Dart Collection Taxon *Homo sapiens*. History Raymond Dart was appointed the Chair of Anatomy at the University of the Witwatersrand in 1923. While a Senior Demonstrator with Sir Grafton Elliot Smith in the Department of Anatomy at University College London, Dart had paid a short visit to T. Wingate Todd at Case Western Reserve University, Cleveland, Ohio, USA and a more extended visit to Richard J. Terry at Washington University Medical School, St. Louis, Missouri. Inspired by the collections of modern human skeletons at Cleveland and St. Louis,

Dart began his own collection at the University of the Witwatersrand. This involved devising a sequence of dissection that did not involve damage to the skeleton. When Phillip Tobias took over from Dart as Professor of Anatomy at the University of the Witwatersrand there were over 2000 individuals in the collection, and in 2009 it was reported that there were 2605 cadaver-derived skeletons in the collection. An excellent account of the history and the nature of the Raymond A. Dart Collection can be found in Dayal et al. (2009). Curator/contact Brendon Billings (e-mail brendon.billings@wits.ac.za). Postal address 7 York Road, Parktown, Johannesburg, 2193, South Africa. Relevant references Tobias 1987, Rankin-Hill and Blakey 1994, Hunt and Albanese 2005, Dayal et al. 2009.

RC 911 *See* HCRP RC 911.

reaction norm (*Ge. reaktionsnorm*) A term introduced by Richard Woltereck to describe the range of phenotypes an individual could exhibit in response to an infinite range of environments. A reaction norm is usually illustrated by plotting the curvilinear relationship between a measure of the phenotype and a measure of the environment (e.g., body size and average annual rainfall). This method is used to show the contribution of environmental variation to phenotypic variation in different species, or how differing genotypes within a species respond to varying environments. The relationships between genetic, phenotypic, and environmental factors can be complex, and the numbers of possible norms of reaction for each genotype underlines this fact. The shape of the curve(s) can range from a narrow distribution, indicating a highly predictable phenotype from any given genotype (little to no contribution from the environment), to a broad distribution, indicating that phenotypic variation is mostly a consequence of variation in the environment. *See also* **phenotypic plasticity**.

reading frame *See* open reading frame.

reassembly Bones and teeth that are fragmented, but otherwise undamaged and undistorted, can be reassembled. The process of reassembly is painstaking work, and researchers used to have to sit down with the original pieces and try and fit them together by hand (e.g., Alan Walker's work on KNM-ER 3733). However, recently researchers have been using computer software to create a

“virtual fossil” the fragments of which can be moved and rotated on the screen. This means that researchers can work at reassembling hominin fossils without risking damage to the originals (e.g., Zollikofer et al. 1998, Ponce de León 2002).

recent out-of-Africa hypothesis *See* out-of-Africa hypothesis.

recessive trait A recessive trait is one that will only manifest phenotypically if both alleles at a diploid locus are the same recessive alleles. For example, an individual with blood type O has the genotype OO at the ABO blood group locus, whereas people with genotypes AO or BO have blood types A and B, respectively. This is because the A and B alleles are dominant to the O allele, which is said to be recessive. Thus, recessive alleles are not expressed in the heterozygote form.

recognition species concept (or RSC) This is a process definition of a species that tries to overcome the relational aspect of the biological species concept. The recognition species concept was defined by Hugh Paterson (1985) as “the most inclusive population of individual, biparental organisms which shares a common fertilization system.” In other words species are composed of animals that share a specific mate-recognition system (or SMRS). *See also* **species**.

recombination The exchange of DNA between individual chromosomes in a pair during prophase I of meiosis. Recombination, also known as **crossing over**, results in the shuffling of genetic material between homologous chromosomes so that alleles at different loci that are located far apart will not be linked. The frequency of recombination varies across physical distance on a chromosome and there are recombination hotspots which are short regions (just a few thousand base pairs) of the genome at which recombination is substantially elevated relative to the genome average. The frequency of recombination between two loci can be used to calculate relative distance in the genome (known as a genetic map and measured in centimorgans). One centimorgan equals the distance between two loci for which one recombination occurs out of 100 meioses. *See also* **linkage**.

recombination fraction The proportion of meioses in which a given set of loci will be separated by **recombination**. The recombination fraction is

usually denoted by the symbol θ , which can range from 0.0 (e.g., for two loci that are located within a block of loci in the same segment of a chromosome – i.e., in a single **haplotype** – and that are rarely, if ever, separated during **crossing over**) to 0.5 (e.g., for two loci that are located on different chromosomes or very far apart on the same chromosome and are, thus, assorted independently). The recombination fraction is generally higher for loci that are more distant from each other on a single chromosome because the probability that they will be separated by crossing over is greater. *See also* **recombination**.

recombination hotspot *See* **recombination**.

reconstruction If only part of an undistorted fossil bone or tooth has been preserved, the missing parts can be reconstructed to provide estimates of variables such as measured crown area for postcanine teeth, or endocranial volume for crania. This may involve duplication if the missing piece is a bilateral structure and the other side (called the **antimere**) is preserved, or it may involve extrapolation if there is no antimere, or if only part of a structure is preserved. In general, the more complete a tooth or bone is, the more reliable the reconstruction. The most difficult problems occur when a fossil has been affected by plastic deformation. If the deformation has affected only one side of a bilateral structure then the undeformed side can be used to reconstruct the deformed side. If both sides are deformed the only recourse for researchers is to use computed tomography (or CT) to image the fossil, and then use software programs based on D’Arcy Thompson-type transformation grids to try and estimate the undeformed shape of the fossil (e.g., Zollikofer et al. 2005). The problem with these methods is that in most cases extant taxa have to be used to generate the reconstruction algorithms, and it is difficult to determine which parts of a virtual fossil are “real” and which are reconstructed, albeit on the basis of a careful and scientifically based reconstruction process.

reconstruction algorithm *See* **reconstruction**.

recursion (*L. recurre* = to return or recure) A term used in language studies for the computational mechanism by which a finite set of basic elements are combined to create an infinite set of discrete

expressions. Certain grammatical rules can be repeatedly applied *ad infinitum* as with “and” or “that.” Both can be used to string an infinite number of sentences together. The same can be said of numerical rules where adding 1 to a product leads to an infinite number. Hauser et al. (2002) argue that recursion is a unique feature of modern human communication and forms the basis of *all* modern human languages. Thus, recursion consists of basic elements (e.g., signs) that can be combined and recombined to generate an infinite number of larger linguistic elements.

reduced major axis regression (or RMA)

A form of **regression** in which model **parameters** are fitted by minimizing the sum of products of differences between observed values and the best-fit line in both the independent and dependent variables. The principles of RMA are similar to those of **major axis regression**, but RMA is preferred in cases where the independent and dependent variables are not measured in the same units. Because RMA takes into account error in all variables and not just the independent variable when fitting model parameters it is an example of a **model II regression**.

reduction sequence *See* *chaîne opératoire*.

reduction strategy *See* *chaîne opératoire*.

reduncine *See* **Reduncini**.

Reduncini (*L. reduncus* = curved back) A tribe of antelopes (family **Bovidae**) comprising the reedbucks (*Redunca*), kobs (*Kobus*), and allies. Their modern distribution is limited to Africa but they originated in Eurasia during the late Miocene. Modern examples prefer well-watered environments and many live close to permanent sources of water. Fossil reduncines are frequently found at hominin sites, where they can be a good indicator of the local availability of marshy habitats.

reference Reference refers to an organism establishing a relationship between a given sign (e.g., visual, auditory, gustatory, olfactory, or tactile) and something that exists in the world, the **referent**. Signs may be linked with internal states such as emotions (e.g., fear, submission, sexual interest), external entities such as predators (e.g., alarm or affiliative/contact calls), or abstract concepts (e.g., home, yesterday, beauty). Some of the most controversial questions in the comparative sciences have to

do with whether or not animal signs are open or closed, bound or displaced. Open/closed reference has to do with the rigidity between a given sign and its referent and whether or not the referential relationship is biologically or genetically specified as opposed to being a socially learned convention. Another controversy has to do with whether or not reference is dependent upon the availability of the referent to the senses (i.e., a bound reference) or whether a sign can refer to a given referent in its absence (i.e., a displaced reference). Generally, non-human animal communication is considered to be largely closed and bound (Deacon 1997, Pinker 1994, but see Cheney and Seyfarth 2007). The distinctiveness of modern human language is that it is largely open and unbounded.

reference digit The digit of the hand or foot that determines the names that are given to the sideways movements of the other digits and thus the names of the muscles responsible for those movements. Therefore, because the middle finger is the reference digit of the hand the act of moving the index finger away from it is called abduction, and any muscle that moves the index finger away from it is called an abductor. The movement of any other digit away from the reference digit is also called abduction. Likewise, the movement of any other digit towards the reference digit is called adduction. *See also* **abduction**; **adduction**.

referent Referent is used in connection with the principle of reference. It refers to something that exists in the world for which an organism has established some sort of sign (e.g., visual, auditory, gustatory, olfactory, or tactile) to represent it. It is also the term used for the source of the model in referential modeling. *See also* **reference**; **referential modeling**.

referential modeling (L. *referre*=to carry and *modus*=standard) One of the two types of behavioral modeling suggested by Tooby and DeVore (1987). In referential modeling the real behavior of one, or more, living animal(s) is used to reconstruct the behavior of a fossil taxon (the referent). For example, if in extant forms closely related to fossil hominins substantial levels of canine-crown-height sexual dimorphism are always associated with a multimale social structure, then the principles of referential modeling suggest it is reasonable to infer that a fossil hominin with similar

levels of canine-crown-height sexual dimorphism most likely had a multimale social structure. *See also* **modeling**.

refit A term used in the analysis of stone tools that refers to flakes and flake fragments that have been “put back together.” Refits are generally divided into two types: refitted breaks and reduction refits (Conrad and Adler 1997). Refitted breaks conjoin broken artifacts, and reduction refits conjoin two or more artifacts within a reduction sequence. The extent of refitted breaks can be important in revealing post-depositional processes such as trampling, whereas reduction refits allow the precise reconstruction of how ancient hominins knapped stone, literally in a “blow-by-blow” fashion (e.g., Roche et al. 1999). Reduction refits of long sequences of removals have been critical in demonstrating the varied ways in which a single block of stone may be modified over the course of its reduction; for example, the production of Levallois points as well as blades (Marks and Volkman 1987). *See also* **reduction sequence**.

refugia Plural of **refugium** (*which see*).

refuging This model of Oldowan site formation proposes that hominins transported carcasses relatively short distances to stands of trees where food would have been consumed in relative safety (Isaac 1983, Blumenschine 1991). Recurrent visits would lead to the accumulation of artifacts and processed bones that would eventually be manifest as an archeological site.

refugium (L. *refugium*=a place of safety) The discrete location of a small residual population of a species that was once much more widespread. Refugial populations arise when inhabited areas get cut off from the rest of the range occupied by a species. For example, during the Pleistocene glaciations, it is likely the land bordering the Mediterranean acted as a refugium for hominins and other animals that were not well adapted to the extreme cold conditions that prevailed in the higher latitudes. The populations in these refugia would then have re-expanded into higher latitudes during interglacial periods. Climatic fluctuations that reduced the total area of tropical African forest in the Pleistocene may also have created small pockets of forest refugia that would have been conducive to speciation within arboreal primates such as guenons. Any isolated

population separated from their parent population in refugia offers the potential for allopatric speciation. Refuge populations can also lead to **endemism** (i.e., a species that is unique to a particular, often small, area) (pl. refugia).

Regourdou (Location 45°03'N, 1°11'E, France; etym. of unknown origin. The name is often written le Régourdou, but according to the current excavators this is a misnomer and should be avoided) History and general description A collapsed cave site, located along the Vézère River in the Dordogne area of France, on the same hillside as Lascaux cave. The owner of the land discovered a human skeleton in 1957 and the site was subsequently excavated by Eugène Bonifay and Bernard Vandermeersch. Temporal span and how dated? Chronostratigraphic comparison to other sites and **biostratigraphy** have suggested an age of late **Oxygen Isotope Stage** (OIS) 5 or early OIS 4 (c.70 ka) for the layer containing the burial. No radiometric dating has been attempted. Hominins found at site **Regourdou 1**, an intentional burial in the **Mousterian** layers, consisting of a mandible and several postcranial elements including nearly complete left and right upper limbs, has been determined to be a young adult *Homo neanderthalensis*, sex unknown. If the dating is correct, this individual is one of the oldest known Neanderthal skeletons. Vandermeersch and Trinkaus (1995) suggest that a second individual (Regourdou 2) may be represented by one or more foot bones. Archeological evidence found at site The two main archeological layers both contain stone tools assigned to the Quina Mousterian (*see La Quina*), although the assemblage is surprisingly poor in artifacts. Key references: Geology, dating, and paleoenvironment Bonifay and Vandermeersch 1962, Bonifay 1964; Hominins Piveteau 1959, 1963, 1964, 1966, Vandermeersch and Trinkaus 1995; Archeology Bonifay and Vandermeersch 1962, Bonifay 1964.

Regourdou 1 Site Regourdou, France. Locality N/A. Surface/in situ *In situ*. Date of discovery September 1957. Finder Roger Constant. Unit Layer 4 (**Quina Mousterian**). Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon None. Geological age End of Oxygen Isotope Stage (OIS) 5 or beginning of OIS 4 (c.70 ka). Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Mandible,

eight vertebrae, sacrum, os coxae, sternum, ribs, both humeri, both radii, both ulnae, both clavicles, one patella, and several hand and foot bones. Announcement Piveteau 1959. Initial description Piveteau 1959. Photographs/line drawings and metrical data Piveteau 1959, 1963, 1964, 1966, Maureille et al. 2001. Detailed anatomical description Piveteau 1959, 1963, 1964, 1966, Vallois 1965, Senut 1985, Maureille et al. 2001. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance This individual is one of the most complete Neanderthal postcranial skeletons, and was intentionally buried with several bear bones. The teeth are unusually small. Location of original Musée d'Art et d'Archéologie de Périgord, Périgueux, France.

regression (L. *regress*=to step back) Earth science Contraction of a body of water (lake or sea) to expose as part of the land surface an area that used to be part of the lake or sea bed. For example, Lake Turkana is smaller than it was when the Koobi Fora Research Camp was built in the 1970s. Then the beach was within 30 m of the camp, now the beach is more than 500 m away. The additional land exposed by the contraction of the lake is the product of lake regression. Statistics A statistical approach used to identify the relationship between two or more **variables** in which values for one variable (the dependent variable) are predicted based on the values of one or more other variables (the independent variables). In **simple regression**, a line is fit to a plot of two sets of continuous measurements. The slope, the intercept, and the scatter about the line are all **parameters** that can be used to describe a data set. **Multiple regression** predicts values of the dependent variable based on multiple independent variables with associated parameters identifying the effect size and significance of each independent variable. Logistic regression is a technique used to predict binary outcomes in a dependent variable which is not commonly used in paleoanthropology but sees use in paleodemography (e.g., given a set of factors, does a certain outcome occur, such as death). Regression techniques can be split into **model I regression** and **model II regression** on the basis of whether models attempt to minimize errors in independent and dependent variables or the independent variable alone. *See also* **model I regression**; **model II regression**.

Reilingen (Location 49°17'N, 8°33'E, Germany; etym. the name of a nearby town) History and general description A hominin partial calvaria together with 38 non-hominin mammalian fossils were discovered early in 1978 during a commercial dredging operation in gravel pit. Temporal span and how dated? Biostratigraphy from the dredged mammalian fauna suggests the **Holstein** interglacial/Late **Würm** glacial. Hominins found at site Partial calvaria recovered in four pieces. Archeological evidence found at site None. Geology, dating, and paleoenvironment Ziegler and Dean 1998. Hominins Czarnetzki 1989, Dean et al. 1998.

Reilingen calvaria Site **Reilingen**. Locality N/A. Surface/in situ It was recovered by workers using a mechanical dredger in a commercial gravel pit. Date of discovery 1978. Finder Workmen at the gravel pit. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Holstein interglacial/Late **Würm** glacial. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Most of the posterior part of an adult calvaria, including both parietals, much of the squamous part of the occipital bone and an almost complete right temporal bone. Announcement Czarnetzki 1989. Initial description Czarnetzki 1989. Photographs/line drawings and metrical data Dean et al. 1998. Detailed anatomical description Dean et al. 1998. Initial taxonomic allocation *Homo erectus reilingensis* Czarnetzki, 1989. Taxonomic revisions “Archaeomorphous” *Homo sapiens* (Adam 1989), early *Homo neanderthalensis* (Dean 1993). Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance Researchers who interpret *H. neanderthalensis* as an evolving lineage would interpret the Reilingen calvaria (plus e.g., hominins from **Sima de los Huesos**, **Steinheim**, and **Swanscombe**) as examples of “Stage 2” in this lineage, a stage also referred to as the pre-Neanderthal stage (e.g., Dean et al. 1998). Location of original **Staatliches Museum für Naturkunde**, Stuttgart, Germany.

relative dating (*L. relatus*=to relate or compare with something else) A dating method that relates a horizon, or an assembly of fossils or artifacts, to an externally validated sequence of change of some kind (e.g., changes in climate, changes in the direction of the Earth’s magnetic field, or morphological

changes within an evolutionary lineage, or in artifact design). Fossils or artifacts incorporated within a horizon are used to link that horizon to an absolutely dated horizon elsewhere. For example, mammalian fossils within the caves in southern Africa are used to date their parent horizon by matching them with the same type of fossils found in absolutely dated horizons at East African sites.

relative rate test *See* molecular clock.

relative risk The risk for a particular individual (e.g., for developing a genetic disorder) relative to the risk of another individual (e.g., a control, such as someone not exposed to a particular environment or someone who is not taking a specific drug). Estimates of relative risk are used in epidemiology and medical genetics to assess low-probability events, but they can also be applied to models that have one group of hominins involved in one set of behaviors and a second group doing nothing, or undertaking a different set of behaviors.

relative taxonomic abundance In a fossil assemblage, relative taxonomic abundance quantifies the numerical abundance of a given taxon relative to the total number of all taxonomic groups in that assemblage. For example, the relative abundance of wildebeest in an assemblage comprising 25 wildebeest, 15 impala, and 10 buffalo is 0.50 (=25/50). Relative taxonomic abundances are typically quantified using the **number of identified specimens** (or NISP) or **minimum number of individuals** (or MNI), although any quantitative abundance index will suffice. Relative taxonomic abundances are particularly useful for making paleoenvironmental reconstructions. For example, if the relative taxonomic abundance of **alcelaphine bovids** increases through time at a paleontological locality, one might infer an expansion of grassland environments through time. In zooarcheological assemblages, relative taxonomic abundance is used to examine how human subsistence strategies varied through time and space, particularly in response to environmental change, the development of new technology, or demographic shifts.

relative tooth size The absolute sizes of tooth crowns provide valuable taxonomic and functional information, but there is a long tradition of investigating the size of the whole, or parts, of the dentition in relation to body mass, or to variables that serve as a

proxy for body mass. Researchers have also investigated the taxonomic utility of relating various components of the dentition (e.g., the size of individual tooth crowns and incisor, premolar, and molar tooth row chords, etc.). Attempts to relate the size of the whole, or parts, of the dentition to body mass, or to various proxies for body mass (e.g., the size of the cranium) have a long history. For example, Flower's dental index (Flower 1879) related the premolar-molar chord (i.e., the length of the postcanine tooth row) to basion-nasion length, a proxy for the size of the cranium. More recently, Henry McHenry introduced the **megadontia quotient** (MQ) that relates the area of three postcanine teeth to estimated body mass. By analogy with the better-known **encephalization quotient**, $MQ = \text{observed tooth area} / 12.15 (\text{body mass})^{0.86}$, where "observed tooth area" is the sum of the areas of the P₄, M₁, and M₂ (McHenry 1988, p. 144).

relative warps *See* geometric morphometrics.

remodeling *See* bone remodeling.

Rensch's rule *See* sexual dimorphism.

replacement substitution *See* nonsynonymous mutation.

replacement with hybridization A variant of the out-of-Africa hypothesis. Replacement with hybridization, originally called the Afro-European sapiens hypothesis, was proposed by Günter Bräuer (1984), who suggested that the earliest evidence of modern human morphology appeared in East and southern Africa and that members of these populations migrated out of Africa to populate Eurasia, eventually replacing archaic hominins in those regions. These early African populations of *Homo sapiens* would thus be the direct ancestors of all modern human populations, but unlike the adherents of the strong version of the out-of-Africa hypothesis, Bräuer also accepted that these early modern humans may have interbred with pre-modern *Homo* groups such as *Homo neanderthalensis* and aboriginal East Asians, presumably *Homo erectus*.

replication The process whereby DNA is copied into two identical daughter sequences by DNA polymerase. Replication occurs during interphase in mitosis and meiosis. Replication errors lead to

point mutations and they occur at a rate of about 10^{-9} – 10^{-10} in modern humans (i.e., one replication error occurs for every 1 in 10 billion base pairs).

reproductive effort The proportion of energy or materials an organism devotes to reproduction rather than to growth and maintenance. Reproductive effort in female modern humans and nonhuman primates has been described as being higher than in males, due to anisogamy, internal gestation, and lactation. Relative to nonhuman primates, it might be expected that total lifetime reproductive effort in modern humans is comparatively high due to aspects of our life history (e.g., cooperative foraging and breeding, long juvenile periods). However, a recent study suggests that actual human lifetime reproductive effort is not unusually high (Burger et al. 2010). *See also* life history.

reproductive investment The energy invested by females or males in sexual maturation, sexual behavior (including competition, copulation, and mate guarding), gestation, and postnatal support of offspring. In most mammals, including primates, where reproduction is a costly event, reproductive investment is higher per reproductive event for females compared to males. Various factors have the potential to impact maternal effects on offspring development, as well as mate quality. Life history theory predicts that reproductive investment should be high when high fitness returns are expected. This, combined with the cost/benefit calculation regarding current versus future reproduction (which is affected by offspring number, sex ratio, etc.), should determine an individual's level of reproductive investment throughout their reproductive lifetime.

reproductive success The ability of an individual to reproduce, thereby passing on his or her genes to the offspring. Reproductive success is often quantified as the number of offspring that an individual has who survive or who survive and reproduce.

resampling A set of statistical techniques that rely on sampling from a data set to produce confidence intervals for a sample parameter (e.g., mean, median, standard deviation, etc.) or significance tests for some test statistic (e.g., difference in the mean between two groups, difference in a correlation coefficient from some pre-specified value such as zero, etc.), or to validate predictive models (e.g., to

assess the accuracy and precision of predictions from regression or discriminant function analysis). Resampling techniques are sometimes preferred over more traditional techniques because they can find confidence intervals and *P* values for test statistics that do not have standard analytical solutions (e.g., there is no equation for calculating a confidence interval for the median), and/or because resampling methods are nonparametric in that they do not assume the data follow a particular distribution. Resampling techniques used in studies of human evolution include the bootstrap, jackknife, randomization (also known as permutation tests), and cross-validation. In each of these techniques a subset of data is sampled to generate either a parameter, test statistic, or predictive model and then this procedure is repeated multiple times to generate a confidence interval, *P* value, or measure of model validation. If all possible versions of a subset of the data are used then it is an exact test (this is required for the jackknife and is usually the case in cross-validation), but in many cases there are more possible ways to sample the data than can feasibly be performed (as is often the case in bootstrapping and randomization). In these cases a large number (e.g., 10,000) of randomly selected subsets of data are used; these versions are known as **Monte Carlo** methods. *See also* **cross-validation**; **bootstrap**; **jackknife**; **randomization**.

resharpening spall A small flake removed from a stone or bone tool to sharpen an edge dulled by use.

residue analysis The study of biotic and abiotic residues left on the surfaces of stone, bone, or metal tools or on pottery to understand what the tool or pottery was used for. These residues can be identified by microscopy (in the case of large particles, like fur, feathers, or plant residues), by spectroscopy methods (e.g. infrared spectroscopy) that allow the identification of chemical signatures (for more amorphous or invisible residues, like amino acids, peptides, and lipids), or by a variety of other tests designed to identify specific residues (like immunology assays to identify blood types). Residue analysis must take into account the possibility that the residue did not result from an intentional contact with the substance, but rather by precipitation, secondary deposition, or other forms of contamination. Odell (2004) describes four ways by which the authenticity of the residue can be established: (a) if

similar residues are not found on non-utilitarian or non-cultural items from the same site, (b) if similar residues are not found in the sediments from that site, (c) if the distribution of the residue on the surface of the tool is "aggregated and coincides with areas of use" (*ibid*, p. 156), and (d) if the residue is found in the same area as and matches the **use wear** on the tool (i.e. wood fibers and starch grains are found in the same area as wood striations). Odell (2004) and Evershed (2008) provide summaries of residue analysis.

resorption (L. *resorbere*=to suck back) The process of resorbing bone tissue. Resorption occurs when bone is remodeled during growth or after a fracture, or when the overall volume of a bone is reduced because it no longer has a function (e.g., the alveolar process of the mandible resorbs after the teeth have been lost) or because of a pathology. Bone resorption is carried out by cells with many nuclei called osteoclasts, and their activity leaves distinctive areas of localized erosion called Howship's lacunae. These have been used to identify taxonomically distinctive areas of bone resorption on surface of the face (e.g., Bromage 1990). Resorption also refers to the process whereby the roots of deciduous teeth are cleared out of the path of the developing permanent teeth during the passage of the latter through the mandible or maxilla. *See also* **bone remodeling**; **eruption**; **ossification**.

resource defense model A model of **Oldowan** site formation that rests on the hypothesis that the hominins responsible for the activities that resulted in such an archeological site were entering the predator guild. The model suggests that hominins would have responded to predation risk by increasing their social interactions. Cooperating would (a) provide protection against predation and (b) would enable them to defend resources more effectively (Rose and Marshall 1996). In this view meat from hunted and scavenged carcasses was transported to places with fixed, defensible resources (e.g., trees, water, plant foods, sleeping sites). Group defense allowed these focal sites to be used regularly for activities that would lead to the gradual accumulation of archeological debris and thus their eventual recognition as an archeological site. The model resembles **Glynn Isaac's home base hypothesis** (e.g., delayed consumption, food transport to a central place, and potentially extensive food-sharing),

but it lacks the latter's emphasis on a sexual division of labor.

resource depression A reduction in the abundance or availability of prey that results directly from the foraging behavior of the predator. In archeological contexts resource depression is associated with diminished access to **high-ranking prey** and may be reflected an expansion of **diet breadth** and increased utilization of **low-ranking prey**. There is much interest in understanding prehistoric resource depression in an effort to understand how hominin foragers have impacted and structured the ecosystems that they inhabited.

restriction enzyme An enzyme that cleaves a specific sequence (usually 4–5 base pairs) of double-stranded DNA. Restriction enzymes are named based on the organism in which they were discovered. For example, the enzyme *EcoRI* was discovered in *Escherichia coli*. It recognizes the sequence GAATTC and cuts between the G and the A. Since the complementary sequence to GAATTC is the same when read from the opposite direction, this enzyme produces cuts in the double-stranded sequence that result in a single-stranded overhang on each end. Other restriction enzymes can cut symmetrically, resulting in blunt ends. For example, the restriction enzyme *AluI* (for *Arthrobacter luteus*) recognizes the sequence AGCT and cuts between the G and C. Restriction enzymes are used to assess DNA sequence **polymorphism** and to prepare DNA for cloning or other laboratory methods. *See also* **restriction fragment length polymorphism**.

restriction fragment length polymorphisms (or RFLP) A **polymorphism** characterized by differences in the lengths of restriction fragments (i.e., a segment of DNA cut by a restriction enzyme). RFLP analyses can be used to assess polymorphism in a DNA sequence. It has traditionally been faster and cheaper than DNA sequencing but not all polymorphisms may be identified (depending on the enzymes used and their recognition sites) and two individuals that have lost the same cut site may not be identical by descent (i.e., the cut site may have been lost because of different changes to the recognition sequence). A classic example of RFLP analysis in a study of modern human variation is that by Cann et al. (1987) who used 12 restriction enzymes

to identify polymorphisms in the mitochondrial genomes of five geographic modern human populations. They concluded that all of the mitochondrial diversity originated in the last 200 ka thus supporting the **out-of-Africa hypothesis** of human evolution.

retention index A measure of the goodness of fit between a **cladogram** and a **character state data matrix**. The retention index was developed by Farris (1989a, 1989b) and is equivalent to Archie's (1989) homoplasy excess ratio maximum index. In contrast to the **consistency index**, the retention index is *not* sensitive to the number of taxa or the number of characters included in a character state data matrix. The retention index for a single character (ri) is calculated as $g-s/g-m$, where g is the maximum possible amount of change required by a completely unresolved cladogram (i.e., a cladogram in which all the taxa are equally closely related), s is the number of character state changes required by the cladogram being investigated, and m is the minimum amount of change required by any conceivable cladogram. The retention index of a group of characters (RI) is calculated as $(G-S)/(G-M)$, where G , S , and M are the sums of the g , s , and m values for the individual characters. In principle, RI values can range between 1 and 0. An RI of 1 indicates a cladogram requires no **homoplasy**, with the level of homoplasy increasing as the index approaches 0. *See also* **cladistic analysis**.

reticulate evolution (*L. reticulum*, dim. of *rete*=net) In reticulate evolution species are seen as components of a complex genetic network, and the mechanism of speciation is interpreted very differently than it is in more traditional models of speciation (i.e., species form by the **hybridization** of two existing species rather than by bifurcation). This model of evolution is close to how some researchers interpret evolution in geographically widespread groups such as contemporary baboons. In this interpretation, peaks of morphological distinctiveness are equivalent to what in other taxa are interpreted as species differences (Jolly, 2001). Yet at the boundaries between these peaks of morphological distinctiveness there are evident **hybrid zones** where baboons are less morphologically distinct. In the reticulate evolution model it is likely that the location and nature of the peaks of morphological distinctiveness and of the hybrid zones will have changed over time.

retouch (Fr. *retouch*=to alter or touch up) The removal of one, or more, small flakes to shape a stone or bone tool. The amount of retouch and the number and shape of edges that have been retouched are key elements in many formal stone tool classification schemes (e.g., Bordes 1961a, Debénath and Dibble 1994).

retrotransposition A process used by a mobile DNA element or retrovirus to insert itself into the genome. It uses reverse transcriptase to copy an RNA version of the element or virus into DNA that can then be inserted into the genome. For example, the modern human immunodeficiency virus (HIV) is a retrovirus that uses retrotransposition to insert itself into the genome.

Retzius, Anders Olaf (1796–1860) Educated in both medicine and veterinary science at Lund University, Sweden, and in Copenhagen, Denmark, Anders Retzius was appointed Professor of Anatomy and Supervisor at the Karolinska Institute in Stockholm, Sweden, in 1824. He was both an anatomist and an anthropologist, and early in his career he coined the terms dolichocephaly and brachycephaly. He was first to describe many comparative histological structures of enamel and dentine, including the primary and secondary curvatures of dentine tubules, and the **striae of Retzius** (also referred to as **long-period incremental lines**) in enamel. *See also* **striae of Retzius**.

Retzius' line *See* **striae of Retzius**.

reverse fault In structural geology a reverse fault is a **fault** or fracture with a compressional geometry. The dominant component of the displacement is up the **dip** of the affected strata so that the hanging wall rocks (i.e., the rocks above the fault plane) is displaced upwards relative to the rocks of the footwall (i.e., the rocks below the fault plane).

reverse transcription polymerase chain reaction (or RT-PCR) A variant of the **polymerase chain reaction** in which **ribonucleic acid** (or RNA) is reversed transcribed into its DNA complement and then the DNA is amplified the same way as in a normal PCR.

RFLP Acronym for **restriction fragment length polymorphism** (*which see*).

RH Prefix for fossils recovered from **Rancah**, Java, Indonesia.

RH 1 Site Rancah, Indonesia. Locality Near the village of Rancah. Surface/in situ *In situ*. Date of discovery 1999. Finder A local landowner employed as part of the excavation team. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Electron spin resonance spectroscopy dating** methods applied to bovid teeth found below RH 1 yielded an average age of 606 ka, but this age estimate is likely younger than the actual age for there is evidence the bovid teeth had been heated during their depositional history. Developmental age Adult. Presumed sex Unknown. Brief anatomical description RH 1 is a faintly shoveled right I₂ crown with a weakly developed basal tubercle. Announcement Kramer et al. 2000. Initial description Kramer et al. 2000. Photographs/line drawings and metrical data Kramer et al. 2005. Detailed anatomical description Kramer et al. 2005. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance RH 1 is the first hominin specimen recovered from West Java and one of very few hominins recovered as a result of controlled excavations on the island of Java. Location of original Archaeological Research and Development Center, Bandung, Indonesia.

Rhafas Cave (Location 34°48'N, 1°53'W, Morocco; etym. unknown) The cave has also been referred to as the Grotte du Rhafas) History and general description This small (10 m × 6 m) cave located in the Oujda Mountains was discovered in 1979 by Luc Wengler, and excavations began in the 1980s. In 2007 a joint team from the Max Plank Institute of Evolutionary Anthropology and the Institut National des Sciences de l'Archéologie et du Patrimoine (INSAP) reinvestigated the **Middle Paleolithic-to-Aterian** transition at the site. Wengler had identified 72 sedimentary strata within a depth of *c.*4.4 m. These are divided from top to bottom into four major units (I–IV). Thirty-nine of the levels have archeological evidence and they span the period between the **Middle Stone Age** and the **Neolithic**. The site is notable for containing a transitional **Mousterian–Aterian** level and for dates of the Aterian that are beyond the limits of radiocarbon

dating. Temporal span and how dated? Twelve chalcidony artifacts from the strata of Unit II at the Mousterian–Aterian “boundary” have been dated by **thermoluminescence dating** to *c.*60–90 ka. Sediment from Mousterian levels in Unit III have been dated with optically stimulated **luminescence dating** to 107 ± 12 ka. **Hominins found at site** None. **Archeological evidence found at site** The archeological evidence recovered from Unit III (**Mousterian**) and the overlying Unit II (which includes the shift from Mousterian to Aterian) are the only ones to be published. The Aterian from Rhafas Cave is distinguished by the appearance of tanged points. Throughout the sequence, most stone tools are made of materials available in the vicinity of the cave, but rare chalcidony tools from sources more than 60 km away are also present. **Flakes** are produced by a variety of **Levallois** methods and they are found in multiple refitted sets; the retouched tool component is dominated by **scrapers**. Unit III preserves several **hearths** that include charcoal from cypress, olive, and juniper trees, as well as a diverse fauna that includes various bovinds, equids, and rhinoceros, and **ostrich egg shell** fragments. Key references: **Geology, dating, and paleoenvironment** Mercier et al. 2007b; **Archeology** Wengler 1997, 2001.

rhinocerotid Informal name for the family **Perissodactyla**, comprising the rhinoceroses and their allies, whose members are found at some hominin sites. *See also* **Artiodactyla**.

Rhinocerotidae One of the perissodactyl families comprising the rhinoceroses and their allies, whose members are found at some hominin sites. Members of the **Rhinocerotidae** family are referred to informally as rhinocerotids. *See also* **Perissodactyla**.

rhyolite Gk *rhyax*=a stream of lava) A term used for fine-grained volcanic rocks, often rich in phenocrysts of alkali feldspar and quartz. The proportions of silica, sodium, and potassium are used to define lava types, with rhyolite having SiO₂ abundances of greater than 69% and total alkali (Na₂O+K₂O) abundances ranging from about 1 to 15% (Le Bas et al. 1986). Where available rhyolite is used for artifact production (e.g., archeological sites in the **Kibish Formation**, Ethiopia).

RI Acronym for **retention index** (*which see*).

ribonucleic acid (or RNA) A nucleic acid whose components are bases (i.e., the four standard RNA bases are adenine, guanine, cytosine, and uracil), and a phosphate and sugar backbone. In RNA, the sugar is ribose, and it alternates with phosphate (derived from phosphoric acid) in the backbone. These are the three components of each nucleotide (i.e., sugar plus phosphate plus one of the four bases), and the nucleotides are joined together by phosphodiester bonds to form a single-stranded RNA molecule. RNA is produced from **DNA** during the process of transcription via the enzyme RNA polymerase. The many different kinds of RNA are important components of protein synthesis and gene regulation. They include messenger RNA (or mRNA), ribosomal RNA (or rRNA), transfer RNA (or tRNA), microRNA (or miRNA), small interfering RNA (or siRNA), and small nuclear RNA (or snRNA). RNA may be processed before it reaches its final form. For example, mRNA is produced in the nucleus from a gene that undergoes transcription. However, before it leaves the nucleus and goes to the cytoplasm for protein translation, it is spliced to remove the intron sequences, and it may undergo further modifications (e.g., polyadenylation on the 3' end and capping on the 5' end). The mature RNA may then move into the cytoplasm and be translated into protein, or it may become one of the varieties of functional RNA (e.g., tRNA).

ribosomal ribonucleic acid (or rRNA) A structural component of the ribosome. In modern humans four different rRNAs can be distinguished by size and they interact with a network of 82 proteins to make up a ribosome.

ribosome The component of a cell that uses the information encoded in messenger RNA (or mRNA; *see* **ribonucleic acid**) to combine amino acids to form proteins. Ribosomes are made of protein and ribosomal RNA (or rRNA) and are the organelles that are responsible for the translation process. They interact with transfer RNA (or tRNA) by supplying peptidyl transferase, an enzyme that creates peptide bonds between adjacent amino acids activity to form the growing polypeptide chain.

ridge (OE *hrycg*=spine) Refers to a crest of enamel on the surface of a tooth crown; the term ridge is usually used for the mesial or distal border of a tooth. It may also be used to refer to a linear prominence on a bone that is less marked than a

crest. *See also* distal accessory ridge; distal marginal ridge; mesial marginal ridge.

Riencourt-lès-Bapaume *See* Bapaume.

Rietputs Formation General description Younger river gravels in the lower reaches of the Vaal River, South Africa, near Windsorton. Sites or localities where the formation is exposed The type site is on the east side of the Vaal River near Windsorton. The Rietputs Formation has been exposed by diamond mining on both sides of the river, but the most extensive exposures are on the east side. Temporal span and how dated? Formerly dated using biostratigraphy to the middle Pleistocene, now cosmogenic nuclide dating ages suggest a temporal span of 1.89 ± 0.19 – 1.34 ± 0.22 Ma. Hominins recovered from the formation None. Archeological evidence recovered from the formation Bifacial tools corresponding to “an early phase of the Acheulean” (Gibbon et al. 2009, p. 152) have been recovered *in situ* from the lowermost part of the formation in a stratum referred to as the “coarse gravel and sand unit” (*ibid*, p. 152) and the “lower coarse alluvium” (*ibid*, p. 157). Key references: Geology, dating, and paleoenvironment Helgren 1978, de Wit et al. 2000, Gibbon et al. 2010; Hominins N/A; Archeology Klein, 2000, Gibbon et al. 2010.

Rift Valley Research Mission in Ethiopia (or RVRME) An organization established in 1975 by geologist Jon Kalb [other US participants included Clifford Jolly, Glenn Conroy, and Douglas Cramer (paleoanthropology) and Fred Wendorf (archeology)] to conduct paleoanthropology research in the **Afar Triangle**, Ethiopia. The RVRME was affiliated with Addis Ababa University and in 1977 it established the country’s first vertebrate paleontology laboratory in collaboration with that University’s Department of Biology. Students trained by the RVRME include Tsrha Adefris, who was the first Ethiopian to receive a PhD in paleoanthropology. Following aerial surveys over the **Middle Awash** by Kalb in mid-1974 that revealed extensive exposures, the RVRME undertook fossil surveys in the area in early 1975. Ground surveys revealed fossil- and artifact-bearing sediments both older and younger than *Australopithecus afarensis* at **Hadar**. Archeological remains included sites that provided evidence of both the **Late and Middle Stone Age**, with *in situ* tools and faunas, including the forest-adapted **Sangoan** culture, to multiple levels and

stages of **Acheulean** artifacts. The Middle Pleistocene hominin site of **Bodo** produced a hominin cranium, **Bodo 1**, and many artifacts, and older archeological sites (e.g., **Dakanihylo** and **Matabaietu**) yielded evidence of both early Acheulean and **Oldowan** industries. Exposures of Middle Pliocene age in the eastern and western of what is now the **Middle Awash study area** were located by the RVRME and have since been assigned to the **Sagantole Formation**, and exposures of late Miocene age further west have since been assigned to the **Adu-Asa Formation**. The activities of the RVRME ceased involuntarily in 1978 and authority to search for fossils in the same region was transferred to the **Middle Awash Research Project** led by Desmond Clark and later by Tim White. In 1993 *Australopithecus ramidus* fossils (they were subsequently assigned to *Ardipithecus ramidus*) were found in the Sagantole Formation and a year later, in 1994, fossil evidence initially assigned to *Ardipithecus ramidus kadabba* and later to *Ardipithecus kadabba* was recovered from the Adu-Asa Formation.

Rijksmuseum van Natuurlijke Historie

The forerunner of the present museum was founded in 1820 in Leiden in The Netherlands to house the part of the collections that made up the “Cabinet du Roi” of Louis Napoleon that belonged to Leiden University, and the private bird and mammal collection of Coenraad Jacob Temminck. In 1878 the mineralogical and paleontological part of the collections were split off and were established in a new museum in the Hooglandse Kerkgracht, also in Leiden, called the “Rijksmuseum voor Geologie en Mineralogie.” At this time, whereas the “Rijksmuseum van Natuurlijke Historie” was a scientific institute without exhibitions, the “Rijksmuseum voor Geologie en Mineralogie” embraced both a scientific mission and exhibitions. In 1990 the two museums were reunited as the Nationaal Natuurhistorisch Museum, which translated into English means the “National Museum of Natural History,” now known as “Naturalis.” A new building in the Darwinweg 2 with seven exhibition halls was opened in April 1998, and Naturalis is now the largest national history museum in the Netherlands with about 10 million specimens. The paleoanthropological collections in Naturalis come from the fieldwork of Eugène Dubois. Between 1887 and 1900 Dubois, working as a medical officer in the army, collected fossils in Java, then part of

the Dutch Indies colony. Dubois worked first in Sumatra, where he collected fossil rain forest mammals, including orangutan fossils. When a fossil skull was found at **Wajak** (old spelling Wadjak) in Java he turned his attentions to Java and at Wajak he found fragments of a second skull and then at **Trinil** he found a hominin molar, calotte, and femur, together with some 40,000 specimens of mammals and reptiles. Between 1895 and 1900 the collection was transferred to the Rijksmuseum van Natuurlijke Historie and Dubois became the first director of what was later called the Dubois Collection. The Dubois Collection was catalogued by Father J.J.A. Bernsen and much of it was described by D.A. (Dick) Hooijer, and it is presently housed in the Naturalis museum. Hominin fossil collection The hominin fossils collected by Eugène Dubois in 1887–1900: e.g., **Trinil 1**, the third molar found in September 1891, the calotte designated **Trinil 2** found in October 1891 and assigned as the **holotype** of *Anthropopithecus erectus*, and a femur, **Trinil 3**, found in August 1892, that was presumed to be associated with the calotte. riparian (L. *ripa*=bank or shore) Refers to the bank of a river or lake, so a “riparian” paleoenvironment would be one that related to the bank of a stream, river or lake (NB: “riparian rights” are what you pay for when you buy a fishing license).

Riparo di Fumane *See* Fumane.

Riss *See* glacial cycles.

riverine (ME *rivere*=river, or riverbank via from the OF, from L. *ripa*=bank or shore) Refers to a river, or to the bank of a river. A “riverine” paleoenvironment would be one that focused on a river, if it was aquatic, or on the bank of a river, if it was terrestrial. Thus a terrestrial riverine paleoenvironment is one where the flora and fauna are like those found on the banks of contemporary ephemeral or permanent rivers. In the latter case this usually means a forest-like environment.

RMA Acronym for **reduced major axis regression** (*which see*).

RNA Acronym for **ribonucleic acid** (*which see*).

Robertsonian fusion *See* **Robertsonian translocation**.

Robertsonian translocation A chromosomal rearrangement where two nonhomologous acrocentric chromosomes (where the centromere is located near one end of the chromosome) break at the centromere, and the long arms join together to form one chromosome. The short arms also fuse to form a new chromosome, but that is usually lost after a few rounds of mitosis; short arms seldom contain essential genes. Thus, a person with a Robertsonian translocation only has 45 chromosomes, but may be phenotypically normal. In modern humans, the acrocentric chromosomes that are commonly involved in Robertsonian translocations include chromosomes 13, 14, 15, 21, and 22. It is thought that Robertsonian translocation may have been the process responsible for producing the modern human chromosome 2 from two ape chromosomes (thus explaining the difference between the 48 chromosomes of the great apes and the 46 chromosomes of modern humans) during our evolutionary past (Yunis and Prakash 1982).

Robinson, John Talbot (1923–2001) John Robinson was born in Elliot, South Africa, and grew up on a farm where he acquired an interest in natural history. He studied zoology at the University of Cape Town where he completed a BSc in 1943 and a MSc in 1944. The following year he became a research fellow in marine zoology at the University of Cape Town and enrolled in the PhD program in marine biology, but he did not complete his degree because he accepted a position in 1946 as Assistant Professional Officer at the **Transvaal Museum** in Pretoria, in the museum’s Division of Physical Anthropology and Vertebrate Palaeontology. In this capacity, Robinson worked as an assistant to the Scottish-born paleontologist Robert **Broom**, who had spent much of the previous decade collecting and studying australopithecus fossils from southern Africa. Broom and Robinson embarked on an extensive series of excavations at the sites of **Sterkfontein** and **Swartkrans**. In 1947 at Sterkfontein they discovered **Sts 5**, the cranium of an archaic hominin, and later that year Broom and Robinson found the associated skeleton **Sts 14**. Their excavations at Swartkrans between 1948 and 1951 were equally productive, with the discovery of two crania and a mandible belonging to *Paranthropus crassidens*, a

more robust australopith than that found at Sterkfontein. Robinson also unearthed a mandible (SK 15) at Swartkrans in 1949 that appeared to be more modern human-like than the *Paranthropus* fossils found at the site. Broom and Robinson argued it belonged to a hitherto unknown species of hominin they named *Telanthropus capensis*, although it was later reclassified by Robinson and others as *Homo erectus*. After Broom's death in 1951, Robinson became Professional Officer in the Department of Vertebrate Palaeontology and Physical Anthropology at the Transvaal Museum, where he remained until 1963. He completed a seminal study of australopith teeth that was published in the Transvaal Museum Memoir series under the title *The Dentition of the Australopithecinae* (1956) and for this work the University of Cape Town awarded Robinson a DSc degree in 1955. He also continued his research at Sterkfontein and Swartkrans focusing on the process of the formation of the fossil deposits, occasionally in collaboration with C.K. (Bob) Brain, who as a graduate student in the mid-1950s worked with Robinson on establishing the sequence of strata in the deposits. In 1956 Brain discovered the first stone artifacts at Sterkfontein in deposits that had produced australopith remains, and Robinson found additional stone artifacts in 1957 and 1958 along with some fossil teeth and a jaw fragment that suggested to Robinson that at least some australopiths were capable of making tools from stone. During the 1950s and 1960s Robinson devoted considerable time to investigating the problems of australopith taxonomy and anatomy. He had published, with Robert Broom and Gert. W.H. Schepers, a monograph on the Sterkfontein fossils entitled *Sterkfontein Ape-man Plesianthropus* (1950) and he published together with Broom a volume called *Swartkrans Ape-Man, Paranthropus crassidens* (1952), both of which appeared in the Transvaal Museum Memoir series. The inclination early in the 20thC to create new species and frequently new genera with the discovery of each new tranche of hominin fossils began to shift during the 1950s. In an important paper published in the *American Journal of Physical Anthropology* in 1954 entitled "The genera and species of the Australopithecinae" Robinson classified the hominins from Taung, Sterkfontein, and Makapansgat as *Australopithecus africanus*, whereas the hominins from Kromdraai and Swartkrans were assigned to *Paranthropus robustus*. Moreover, in a paper published in 1956 Robinson argued that the morphology of the teeth suggested that the robust australopiths were herbi-

vores whereas the gracile australopiths were omnivores that ate a significant quantity of meat. During this period Robinson accepted a position as a part-time lecturer at the University of Witwatersrand where he taught human evolution from 1954 to 1963. He was also appointed to be the assistant director of the Transvaal Museum in 1960, but controversies over the presentation of evolution at the museum contributed to his decision to resign from the museum in 1963. In the same year Robinson left South Africa to accept a position at the University of Wisconsin at Madison as Professor of Anthropology and Zoology; besides the difficulties at the Transvaal Museum it has been suggested that his opposition to the apartheid system in South Africa influenced his decision to leave and go to the USA. Although the position at the University of Wisconsin was originally a joint appointment to the Departments of Anthropology and Zoology, in 1967 Robinson left the Anthropology Department to serve full time in the Department of Zoology. Robinson continued his work on hominin evolution, publishing *Early Hominid Posture and Locomotion* in 1972 in which he argued that the australopiths were efficient bipeds. He served as the director of the University of Wisconsin Zoological Museum from 1979 to 1981, but persistent health problems led him to stop teaching in 1983 and he retired in 1985.

robust (*L. robustus*=strength, from *robus*=oak)
Morphology A morphological variant that is stronger than other variants. In the mandible this means mandibular bodies (corpora) that are relatively wide, and in the limbs long bones with a relatively thicker layer of cortical bone.
Taxonomy Used to describe the archaic hominin taxa assigned to either *Australopithecus* or to *Paranthropus* (i.e., *P. robustus*, *P. boisei*, and *P. aethiopicus*) that are distinguished by postcanine megadontia and thick (i.e., robust) mandibular bodies. *See also* robust australopithecine.

robust australopithecine Informal term introduced by John Robinson for an archaic hominin species with postcanine megadontia and thick (i.e., robust) mandibular bodies (i.e., *Paranthropus robustus*). The term has subsequently been applied to *Paranthropus boisei* and *Paranthropus aethiopicus*. Many researchers now avoid the term because several non-*Paranthropus* archaic hominin taxa exhibit postcanine megadontia and relatively robust mandibular bodies, but lack the derived morphology of *Paranthropus*.

"robust" australopithecine Fred Grine's solution to his disapproval of the use of "robust" in the informal term "robust australopithecine" was to put double quotes around "robust." This is why he insisted his influential edited volume about the taxa included in the genus *Paranthropus* was entitled the *Evolutionary History of the "Robust" Australopithecines*.

robusticity (*L. robustus* = strength, from *robustus* = oak) The tendency to be **robust**. For example, in mandibles this means having a high value for the mandibular robusticity index (corpus width/corpus height), and for long bones a high value for an index that relates a long bone's width to its length.

Roc de Combe-Capelle *See* Combe-Capelle.

Roc de Marsal (Location 44°54'21"N, 0°58'45"E) History and general description This small cave overlooks a tributary valley of the Vézère River not far from its confluence with the Dordogne River in southwest France. The site was first excavated in 1953 by an amateur, Jean Lafille, who continued to work there until his death in 1971. In 1961 he discovered a nearly complete skeleton of a *Homo neanderthalensis* child reportedly placed in a pit near the back of the cave. The site was re-excavated by Dibble, Goldberg, McPherron, Sandgathe, and Turq from 2004 to 2010. Temporal span and how dated? The site contains only **Middle Paleolithic** industries including a Denticulate Mousterian with small flake production similar to the Asinipodian of Pech de l'Azé IV, a Levallois Mousterian, and a Quina Mousterian. Published thermoluminescence dates on sediment and heated flints taken from the Lafille sequence provide an age range of *c.*90–60 ka for the base of the sequence. The fauna show a gradual shift from a more temperate climate at the base of the sequence to a cold climate at the top. Hominins found at site Roc de Marsal 1 is a nearly complete skeleton of a 2–3-year-old individual. It was found in anatomical contiguity, face down, on its right side, and with its legs bent backward. The stratigraphic association of the skeleton is unclear, although from the descriptions it likely comes from the lower portion of the sequence. Isolated teeth of additional individuals have been recovered from the more recent excavations. Archaeological evidence found at site Two of the lower levels at Roc de Marsal contain multiple, well-

preserved, and sometimes stacked hearths. The fauna, particularly in the Quina levels, are also well preserved. The stone tool industries show significant temporal technological and typological variability. Key references: Geology, dating, and paleoenvironment Guibert et al. 2008; Archeology Lafille 1961, Turq 1989, Turq et al. 2008, Bordes and Lafille 1962, Madre-Dupouy 1991.

rock A rock is a naturally occurring solid, composed of one or more mineral phases, native elements, or organic accumulations. There are three fundamental types of rock: igneous (solidified from a molten phase, or melt), metamorphic (formed by solid-state recrystallization, usually under high pressure and/or temperature), and **sedimentary rock** (otherwise formed under Earth-surface conditions). A rock is the basic unit of **lithology**, or rock type. With very few exceptions hominin fossils are to be found in sedimentary rocks.

Rockefeller Foundation The Rockefeller Foundation was founded in 1913 by John D. Rockefeller to "promote the well-being of mankind throughout the world." It supported the **Peking Union Medical College**, financed its **Cenozoic Research Laboratory**, funded excavations at Choukoutien (now called **Zhoukoudian**), and provided support for other paleoanthropological research in China.

Rockefeller Museum Description The Rockefeller Archaeological Museum in Jerusalem, Israel, opened in 1938 and houses antiquities unearthed in excavations conducted in the country mainly during the time of the British Mandate (1919–48). It contains thousands of artifacts ranging from prehistoric times to the Ottoman period. Its collections include a 9000-year-old statue from Jericho, gold jewelry from the Bronze Age, and the Dead Sea Scrolls. The latter date from the 2ndC BCE to the 1stC CE and include books of the Hebrew Bible as well as other noncanonical texts. Hominin fossil collections **Skhul I** (mainly post crania), **Skhul IV**, **Zuttiyeh**, **Qafzeh 1**, and **Qafzeh 2**. Contact information James S. Snyder, Director (e-mail jsnyder@imj.org.il; tel +972 2 670 8801) and Yigal Zalmona, Chief Curator (e-mail zalmonay@imj.org.il; tel +972 2 670 8972). Postal address The Israel Museum, Jerusalem POB 71117 Jerusalem, 91710 Israel. Street address No official street address. The museum is located off Sultan

Suleiman Street, adjacent to the Flower Gate of Jerusalem's Old City walls. [Website](http://www.english.imjnet.org.il/HTMLs/Home.aspx) www.english.imjnet.org.il/HTMLs/Home.aspx.

Rodentia (L. *rodere*=to gnaw, or eat, away) A diverse group of mammals that have continuously growing central incisors. Although the largest rodent, the capybara, can reach 50 kg, most rodents are both small-bodied and are fast breeders. In the most commonly used pre-molecular taxonomy of rodents five suborders of rodents are recognized, each characterized by a particular masticatory apparatus and named for their main group; the Anomaluomorpha (scaly tailed flying squirrels and spring hares), Castorimorpha (beavers and allies), Hystricomorpha (porcupines and cavius), Myomorpha (mice and allies), and Scuriomorpha (squirrels). Unsurprisingly, molecular phylogenies differ significantly from this classification. The primary importance of rodents in the study of human evolution is as paleoecological indicators, for their relatively species-specific habitat preferences and diets make them very useful in the reconstruction of past ecosystems. Rodents make up much of the **microfaunal** evidence found at early hominin sites. In recent pre-history the significance of rodents is that they are notoriously destructive of both crops in the fields and also of stored resources, particularly grain, so from the standpoint of an agriculturalist they are pests. Rodents have also been vectors of disease in historic times and presumably this was also true in the past.

root (OE *rot*=root) When used with respect to the dentition it refers to the part of a tooth embedded in the bony **alveolus**. It is made up of an inner core of **dentine** and the enclosed pulp that is covered with **cementum**. The boundary between the crown and the root on the outside of the tooth is called the **cemento-enamel junction** (or CEJ), or the **cervix**, and the boundary between the crown and the root within the tooth is called the **enamel-dentine junction** (or EDJ or DEJ). Incisors and canines usually have a single root, premolars may have one or more roots, and molars usually have two or more roots. Root is also used to describe the place where one structure is attached to another (e.g., the root of the zygomatic process of the maxilla). It is also used to refer to the base of a **cladogram**.

rostra The plural of **rostrum** (*which see*).

rostral (L. *rostrum*=beak, muzzle, or snout) The rostral direction is in the direction of where the beak (or its equivalent) is. Thus, the term rostral can be equivalent to ventral (i.e., anterior) or to cranial.

rostrum (L. *rostrum*=bill of a bird, beak) In vertebrate anatomy, the rostrum is an informal term for the snout or muzzle. As a practical matter, in primates, the rostrum refers to the pre-maxilla and that portion of the **maxilla** that projects anterior to the orbits and to the roots of the **zygomatic arches**. The rostra (pl. of rostrum) of cercopithecines and strepsirrhines (Old and New World monkeys, respectively) are particularly pronounced, and it determines the very strong **prognathism** exhibited by these taxa. In hominins, and particularly in *Homo*, the trend towards facial **orthognathism** has resulted in extremely reduced rostra.

routed foraging A model for Oldowan site formation that proposes hominins were recurrently drawn to fixed resources (e.g., stone outcrops, stands of trees acting as midday resting sites, water sources). At such locations carcass parts would have accumulated over time and because of these accumulations the location would subsequently have become visible as an archeological site (Binford 1984).

Royal College of Surgeons of England

The Royal College of Surgeons of England in Lincoln's Inn Fields, London, was, until the development of human origins research at the Natural History Museum, London, one of the main foci of interest in human evolution in the UK. Until they were transferred on permanent loan to the Natural History Museum, it housed important collections of modern human skeletons, and until 1955 it was also the repository of the **Gibraltar 1** cranium and of one of the crania recovered from **Mugharet es-Skhul** in Israel. The Gibraltar 1 cranium came to the College because of the eclectic scientific interests of one of its Presidents, George Busk. In addition to being a surgeon, Busk had wide interests in zoology and a genus of colonial aquatic animals (the *Buskia*) carries his name. In 1862 Busk traveled with the paleontologist Hugh Falconer to visit the excavations at **Gibraltar**, and they were shown a hominin cranium, Gibraltar 1, that had been recovered from **Forbes' Quarry** in 1848. Falconer assigned the cranium to a new species, *Homo calpicus* (Falconer 1864). However, when

Busk reported on the cranium to the annual meeting of the British Association for the Advancement of Science in Bath in 1864, he commented on its affinities with the specimen recovered from the **Kleine Feldhofer Grotte** in 1856. Busk caused the cranium to be presented to the Royal College of Surgeons of England in 1868, where it remained until 1955 when it was transferred to what was then called the British Museum (Natural History), and which is now called the Natural History Museum, London. The second connection between the College and human evolution came when Sir Arthur Keith was invited by Theodore McCown to participate in the analysis of the hominins that had been recovered by Dorothy Garrod from the site of Mugharet es-Skhal. The first material from Skhal was transferred to the College in 1931, and between 1933 and 1936 Keith and McCown worked on the remains, first at Lincoln's Inn Fields, and then at a laboratory in the College's research facility at Downe, Kent, near to Down House, Charles Darwin's former home which at the time was Keith's home. Some of the Skhal remains were returned to Israel (Skhal 1 and 4), and the bulk of them went to the Peabody Museum at Harvard University (Skhal 2, 3, and 5–8), but one cranium (Skhal 9) was deposited with the College and was part of its Hunterian Museum until 1955 when it was transferred on permanent loan to what is now the Natural History Museum, London. See also Arthur Keith.

Royal Museum for Central Africa (Belgium is a bilingual country, with both French and Dutch being spoken, depending on the part of the country. Notwithstanding the location of Tervuren in a Dutch-speaking region of Belgium, most researchers know the museum by its French name, the Musée Royal de l'Afrique Centrale. The Dutch name is Koninklijk Museum voor Midden-Afrika) The museum had its origin in 1897 when King Leopold II organized an exposition of what was then his African fiefdom, the Congo Free State. Subsequently the King was stripped of his African possessions and they were made a colony of Belgium, under the name Belgian Congo, which in 1960 was given independence and since then has become known as, successively, Zaire and the Democratic Republic of the Congo. The items in the expo quickly outgrew the building to which it was assigned and in 1904 construction of a new building was commenced in the Royal Gardens. The present enormous neoclassical building was

opened in 1910 under the name "Museum of the Belgian Congo." The name was later changed to the "Royal Museum of the Belgian Congo," and after the Congo was granted independence it was changed once again to its present name, which in English means "Royal Museum for Central Africa." In its first years, the museum acquired large collections of Congolese fauna and flora, and later fauna and flora from other African countries. The mammal collection comprises more than 120,000 specimens, including approximately 75,000 rodents, 18,000 bats, and 10,000 primates, including cercopithecus, mangabey, and colobus monkeys, and gorillas, chimpanzees, and bonobos. The collection includes the world's largest collections of Eastern gorillas (*Gorilla beringei*) and bonobos (*Pan paniscus*), the latter being assembled by Drs Schouteden and Vandebroek between 1927 and 1960 (Thys van den Audenaerde 1984). The gorilla and bonobo collections consist mainly of skulls, but there are also postcranial skeletons, skins, and some whole specimens preserved in alcohol. Almost all of the specimens have precise contextual and other information. Comparative collections *Pan paniscus*: Whole skeletons Adults=11 (females=7, males=4, sex uncertain=N/A); juveniles=3 (females=1, males=1, sex uncertain=1); infants=3 (females=0, males=2, sex uncertain=1). Crania Adults=62 (females=25, males=24, sex uncertain=13); juveniles=86 (females=19, males=17, sex uncertain=50); infants=38 (females=4, males=11, sex uncertain=23). *Pan troglodytes schweinfurthii*: Whole skeletons Adults=9 (females=5, males=1, sex uncertain=3); juveniles=4 (females=1, males=2, sex uncertain=1); infants=3 (females=0, males=0, sex uncertain=3). Crania Adults=172 (females=40, males=47, sex uncertain=85); juveniles=106 (females=21, males=16, sex uncertain=69); infants=45 (females=7, males=4, sex uncertain=34). *Pan troglodytes troglodytes*: Whole skeletons Adults=4 (females=0, males=3, sex uncertain=1); juveniles=N/A; infants=N/A. Crania Adults=46 (females=6, males=7, sex uncertain=33); juveniles=10 (females=0, males=0, sex uncertain=10); infants=N/A. *Pan troglodytes verus*: Whole skeletons N/A. Crania Adults=3 (females=0, males=2, sex uncertain=1); juveniles=1 (females=0, males=0, sex uncertain=1); infants=1 (females=0, males=0, sex uncertain=1). *Pan troglodytes subsp. indet.*: Whole skeletons Adults=5 (females=0, males=3, sex uncertain=2); juveniles=2 (females=

2, males=0, sex uncertain=0); infants=1 (females=0, males=0, sex uncertain=1). Crania Adults=10 (females=0, males=3, sex uncertain=7); juveniles=7 (females=0, males=1, sex uncertain=6); infants=16 (females=0, males=0, sex uncertain=16). *Gorilla sp. indet.*: Crania Infants=1 (females=0, males=0, sex uncertain=1). *Gorilla gorilla gorilla*: Whole skeletons Adults=2 (females=0, males=1, sex uncertain=1); juveniles=N/A; infants=N/A. Crania Adults=75 (females=5, males=6, sex uncertain=64); juveniles=14 (females=0, males=0, sex uncertain=14); infants thin sp.=3 (females=0, males=1, sex uncertain=2). *Gorilla beringei graueri*: Whole skeletons Adults=10 (females=4, males=4, sex uncertain=2); juveniles=5 (females=4, males=0, sex uncertain=1); infants=N/A. Crania Adults=102 (females=39, males=47, sex uncertain=16); juveniles=21 (females=9, males=6, sex uncertain=6); infants=16 (females=0, males=1, sex uncertain=15). *Gorilla beringei beringei*: Whole skeletons Adults=2 (females=1, males=1, sex uncertain=0); juveniles=N/A; infants=N/A. Crania Adults=7 (females=3, males=4, sex uncertain=0); juveniles=4 (females=2, males=0, sex uncertain=2); infants=1 (females=0, males=0, sex uncertain=1). Contact department Biology – Vertebrates. Ryukyu Islands (Location approximately 26° 19'N, 127°44'E, Japan; etym. also referred to as the Nansei Islands and “Nansei” in Japanese means “southwest”) History and general description The Ryukyu Islands form a chain off the southernmost part of the larger Japanese archipelago. The Ryukyu islands are themselves divided into the Satsunan Islands in the north and Ryukyu Shoto in the south; the largest and best known of the Ryukyu Islands is Okinawa. The southernmost island in the chain is approximately 120 km/74 miles from Taiwan and similarities in flora and fauna suggest that during glacial periods a land bridge likely connected the Ryukyus to the Asian mainland, although some suggest Okinawa could only have been colonized by boat. Beginning in the late 1960s, Pleistocene human fossils were identified in deposits being mined for limestone. These localities included caves, collapsed caves, and fissures from several islands, although most of the major finds were identified on Okinawa. The primary sites are Yamashita-cho and Minatogawa (Okinawa), Pinza-abu Cave (Miyako Island), Shimojibaru Cave (Kume Island), and Shiraho-Saonetabaru (Ishigaki Island). Temporal span and how dated? Evidence from **biostratigraphy** suggests that all of these sites date to the latter half of the Late Pleistocene. Currently, the oldest hominin fossils on the Japanese archipelago are from Yamashita-cho, which has been **radiocarbon dated** to *c.*32 ka. Radiocarbon dates for the other sites are Pinza-abu *c.*26 ka and Shimojibaru *c.*15 ka, and the hominins from Shiraho-Saonetabaru were **AMS radiocarbon dated** to between 20 and 16 ka. Hominins found at site The Yamashita-cho specimens comprise femoral and tibial proximal metaphyses and diaphyses of a juvenile (*c.*6 years old). Based on diaphyseal robusticity the juvenile lower limbs are considered to be robust, within the range of archaic *Homo sapiens*, but the presence of an incipient pilaster and a high neck-shaft angle more closely align the specimens with early modern humans. The most complete and best-studied collection of hominin fossils is from Minatogawa (*c.*18 and 16 ka). This skeletal assemblage includes four almost complete skeletons and other fragments. Morphologically, the Minatogawa hominins more closely resemble Late Pleistocene humans from Niah cave (Borneo), Liujiang (south China), and Wadjak (Java), rather than populations from north-east Asia (e.g., Zhoukoudian Upper Cave). That

the Minatogawa anatomically modern humans originated from Southeast Asia should not be that surprising given that during glacial periods (e.g., Oxygen Isotope Stage 2: **Last Glacial Maximum**) the Ryukyus were connected to Taiwan, which was connected to the Asian mainland. Detailed comparative analysis of the mandibles from Minatogawa with those of the later Jomon people (Japanese Neolithic) suggests that the Minatogawa hominins were absolutely and relatively smaller and more prognathic than those of the later Jomon people and they lacked the typical “squarish” chin of the Jomon mandibles. Nine hominin fossils identified in the Shiraho-Saonetabaru Cave on Ishigaki Island were directly dated using AMS ^{14}C dating. The Pinzabu hominin assemblage comprises a parietal, a occipital, three isolated teeth, a lumbar vertebra, and a few hand bones. The Shimojibaru hominin infant comprises a mandible, right humerus, and right

femur. Archeological evidence found at site Paleolithic artifacts have been reported from Yamashita-cho, but some consider them to be geofacts. Unambiguous artifacts have been reported from other sites in the Ryukyu Islands (e.g., Tanegashima Island); thus the possibility of discovering hominin fossils and paleolithic artifacts in the same context remains high in the region, particularly because of the good bone preservation in these limestone caves and fissures. Saccopastore (Location 41°57'N, 12°32'E, Italy; etym. from Sacco Pastore, the name of a meander in the Aniene River) History and general description The site was an active gravel quarry on the left bank of the Aniene River, a tributary of the Tiber, within the boundaries of modern Rome. Workmen at the quarry found the first cranium (**Saccopastore 1**) in May 1929 and it was passed to Sergio **Sergi** of the University of Rome who identified it as belonging to *Homo neanderthalensis*. The second cranium, Saccopastore 2, was found 6 years later when Alberto **Blanc** and H. Breuil were examining the now-abandoned quarry. Further excavations were carried out, but no additional hominin remains have been discovered. Temporal span and how dated? Biostratigraphy suggests an age *c.*130–100 ka. Hominins found at site Two adult crania unearthed in 1929 and 1935. Archeological evidence found at site Some **Mousterian** artifacts were found in the same horizon as Saccopastore 2. Key references: Geology, dating, and paleoenvironment Sergi 1944, Segre 1983, Caloi et al. 1998; Hominins Sergi 1929, 1944, 1948, Condemi 1992, Bruner and Manzi 2006; Archeology Blanc 1948.

Saccopastore 1 Site Saccopastore. Locality N/A. Surface/in situ Probably *in situ*. Date of discovery May 1929. Finder A. Giovannini and V. Casorri. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*130–120 ka. Developmental age Adult. Presumed sex Female. Brief anatomical description Cranium lacking part of the supraorbital, the zygomatic arch region, and some teeth. Announcement and Initial description Sergi 1929. Photographs/line drawings and metrical data Sergi 1944, Condemi

1992, Bruner and Manzi 2006. Detailed anatomical description Sergi 1944, Condemi 1992, Bruner and Manzi 2006. Initial taxonomic allocation *Homo neanderthalensis* as *Homo neanderthalensis aniensis* 1935. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The presumed geological age (Riss-Würm interglacial, or **Oxygen Isotope Stage 5**) and the combination of morphological features have suggested to some that the Saccopastore crania could possibly belong to an intermediate stage between *Homo heidelbergensis* and *H. neanderthalensis*. Location of original Sapienza – Università di Roma, Rome, Italy.

Saccopastore 2 Site Saccopastore. Locality N/A. Surface/in situ *In situ*. Date of discovery July 1935. Finders A.C. Blanc and H. Breuil. Unit/horizon N/A. Bed/member Layer of fluvial gravels, intermediate in the stratigraphic sequence and associated with large mammal remains, just above a thick lens of silt. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*130–100 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Partial cranium lacking most of the vault, the left side of the basicranium, and some teeth. Announcement Breuil and Blanc 1935. Initial description Sergi 1929. Photographs/line drawings, metrical data, and detailed anatomical description Sergi 1944, Condemi 1992, Bruner and Manzi 2006. Initial taxonomic allocation *Homo neanderthalensis* as the paratype of *Homo neanderthalensis aniensis* Sergi, 1944. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The presumed geological age (Riss-Würm interglacial, or **Oxygen Isotope Stage 5**) and the combination of morphological features have suggested to some that the Saccopastore crania could possibly belong to an intermediate stage between *Homo heidelbergensis* and

H. neanderthalensis. Location of original Sapienza – Università di Roma, Rome, Italy.

Saegul See Turubong.

SAG Abbreviation for **Sagantole** (*which see*).

Sagala One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Sagantole A concentration of fossil localities situated in the **Central Awash Complex** in the Afar Rift section of the East African Rift System in the **Middle Awash study area**, Ethiopia. Fossils attributed to *Ardipithecus ramidus* have been found there.

sagittal (L. *sagitta*=an arrow) Refers to a plane corresponding to the midline of the body. It takes its name from the arrow-shaped interparietal cranial suture in the cranium of a neonate/infant that runs in that plane from bregma (the tip of the arrow) to lambda (the feathers of the arrow).

sagittal crest (L. *sagitta*=an arrow and *crista*=cock's comb, or a tuft of feathers, in the midline of a bird's head) A sharp crest of bone running along the course of the inter-parietal, or sagittal, suture. The bony crest forms when the medial borders of the fascia covering the temporalis muscles fuse. When the fusion is complete there is just one crest. If the fusion is incomplete it is referred to as a **compound sagittal crest**, and if the separate crests are either side of the sagittal suture strictly they should be referred to as **parasagittal crests**. A sagittal crest is seen in male gorillas and orangutans, and in larger-bodied, presumed male, *Paranthropus aethiopicus* and *Paranthropus boisei* crania such as **KNM-ER 406**. See also **sagittal keel**.

sagittal keel (L. *sagitta*=an arrow and ME *kele*=the main longitudinal timber in a wooden boat, now used for the underside of a boat, or any projection designed to prevent a boat from "keeling over.") Refers to a blunt bony prominence running longitudinally along the course of the inter-parietal, or sagittal, suture. Most, but not all, *Homo erectus* crania have a sagittal keel, but it is better expressed in the larger, presumed male, crania.

Sahel (etym. *Sahel*=region to the south of the Sahara) Semiarid region of north-central Africa to

the south of the Sahara. The fossil evidence for *Sahelanthropus tchadensis* comes from sites in the Sahel.

Sahelanthropus Brunet et al., 2002 (etym. *Sahel*=region to the south of the Sahara; Gk *anthropos*=human) Hominin genus established in 2002 by Brunet et al. (2002) to accommodate a new species they introduced for cranial remains recovered from the *c.*7 Ma Anthracotheriid unit at locality TM 266 at **Toros-Menalla** in the Chad Basin. The authors claimed that various features of the cranium either distinguished the new fossils from *Pan*, or could not be accommodated in any of the existing hominin genera. White et al. (2009a) suggest the morphological differences between species assigned to *Ardipithecus* and to *Sahelanthropus* do not justify their being assigned to different genera, in which case the former genus would have priority, and *Sahelanthropus* would be the junior synonym of *Ardipithecus*. Type species *Sahelanthropus tchadensis* Brunet et al., 2002.

Sahelanthropus tchadensis Brunet et al., 2002 (etym. *Sahel*=region to the south of the Sahara; Gk *anthropos*=human; *tchadensis*=Chad) Hominin species established by Brunet et al. (2002) to accommodate cranial remains recovered from the Anthracotheriid unit at **Toros-Menalla** in the Chad Basin; the former has been dated by **biostratigraphy** and **cosmogenic nuclide dating** to *c.*7 Ma. The authors believe that, despite primitive features in the cranium and dentition, this taxon is a primitive hominin and not a panin because of its small, apically worn canines and the intermediate thickness of the postcanine enamel. It was virtually reconstructed by Zollikofer et al. (2005), who claimed that the reconstruction of the cranial base demonstrated that *S. tchadensis* is bipedal. A further, phenetic, analysis of 3D landmark data obtained from the virtually reconstructed cranium by Guy et al. (2005) concluded that whereas the reconstructed cranium shared some basicranial features with archaic hominins, for example "long, flat (more horizontally orientated) nuchal plane," "shortened occipital," and "anteriorly-positioned foramen magnum" (*ibid.*, p. 18838), other features on other regions of the cranium (e.g., the face) were either primitive or unique among hominins. If the hominin classification is upheld, and the age of the specimen is confirmed, then *S. tchadensis* would be the oldest known hominin and it would be a refutation of the hypothesis that

hominins were confined to the area either within, or to the east of, the East African Rift System. There are no postcranial remains. White et al. (2009a) suggest that the morphological differences between *Ardipithecus ramidus* and *S. tchadensis* do not justify their being assigned to different genera, in which case the latter taxon would be transferred to the genus with priority (i.e., *Ardipithecus*) as a new name combination *Ardipithecus tchadensis* (Brunet et al., 2002) White et al., 2009. First discovery TM 266-01-060-1 (2001). Holotype TM 266-01-060-1. Paratypes TM 266-01-060-2, TM 266-01-447, TM 266-01-448, TM 266-02-154-1, TM 266-02-154-2. Main site **Toros-Menalla**, Chad.

Sahul (etym. Ballard 1993 suggests that it may be a word used by the Macassan people for a sandbank or shoal on the northwestern continental shelf of Australia to the southwest of the Aru Islands and separated from Timor by the deep waters of the Timor Trough). The name “Sahull” or “Sahoel” for this shoal appears in Dutch maps as early as 1598. The first time the name Sahul was used in its contemporary sense was in a report of a Dutch marine life and bathymetric survey known as the Siboga Expedition (organized by the Society for the Advancement of Scientific Research in the Netherlands’ Colonies in 1889, now called Treub Maatschappij). The terms “Greater Australian Bank” and “Great Asiatic Bank” had been introduced by Earl(e) in 1845, but in their 1919 summary of the Siboga Expedition, Molengraaff and Weber suggest that those terms be replaced by the “Sahul Shelf” and the “Sunda Shelf,” respectively. The name Sahul is used today for the continental landmass, also known as Australasia, that comprises present-day Australia, Tasmania, and New Guinea. During particularly cold periods when substantial volumes of water were locked up in ice accumulations at high latitudes, sea levels would have fallen low enough for Sahul to have been one continuous land mass. However, even during the coldest periods hominins would have had to make a deep-water crossing, accidental or deliberate, to reach Sahul from Sunda. The northwestern margin of Sahul marks the eastern boundary of Wallacea. Ballard (1993) suggests that Rhys Jones introduced the term Sahul into archeology when he used it in the title of a session called “Sunda and Sahul: hunters in the tropics” at the 13th Pacific Science Congress in Vancouver in 1975. Its usage was consolidated in a 1977 book called *Sunda and Sahul: Prehistoric Studies in Southeast Asia, Melanesia and Australia*.

St. Acheul *See* Saint-Acheul; Acheulean.

Saint-Acheul (Location 49° 52'N, 2° 19'E, France; etym. named after the neighborhood in which it is located) History and general description This open-air site in the suburbs of Amiens is the type site of the Acheulean technocomplex. Handaxes were found in the gravel pits in the mid 19thC, and as unequivocally hominin-made artifacts they helped prove the antiquity of hominins (contrary to the creationist view prevalent at the time). Temporal span and how dated? Recent electron spin resonance spectroscopy dating on quartz from near the artifact-bearing layers provides an age of 403±73 ka. Hominins found at site None. Archeological evidence found at site Handaxes, mollusc shells, and other fauna were recovered. Key references: Geology, dating, and paleoenvironment Antoine et al. 2003; Hominins N/A; Archeology de Mortillet 1872, Rigollot 1854.

Saint-Césaire (Location 45° 44' 57" N, 0° 30' 11" E, France; etym. named after the nearby village) History and general description This site, near a local cliff called "La Roche à Pierrot," was discovered in 1978, and excavated by François Lévêque. The *Homo neanderthalensis* fossil was found in a Châtelperronian layer and its discovery confirmed that the Châtelperronian was, in fact, an **Upper Paleolithic** culture made by Neanderthals, not by modern humans. When discovered, the Saint-Césaire hominin was the subject of considerable debate, for some (ApSimon 1980, Wolpoff 1981) argued it was evidence of a unilinear model of evolution through Neanderthals to Upper Paleolithic modern humans, whereas others (Stringer et al. 1981, Stringer 1982) argued that the appearance of a late Neanderthal overlapping significantly with anatomically modern humans elsewhere essentially disproved the **multi-regional hypothesis**, at least in Europe. Temporal span and how dated? Thermoluminescence dating of burned flints has provided dates of c.40 ka for the **Mousterian**. Flints near the fossil had thermoluminescence dates of 36.3±2.7 ka and overlying Proto-Aurignacian deposits were dated at 32.1±3 ka for the Châtelperronian deposits. Hominins found at site A very fragmentary and compressed skeleton was recovered in the upper Châtelperronian layer. Most body elements are represented, except the feet. Aspects of the cranium securely identified this individual as *H. neanderthalensis*. Although the post-cranium is robust and similar in overall form to that of

other Neanderthals, the cross-sectional anatomy of the long bones of this individual are similar to later those of Upper Paleolithic modern humans, suggesting that this individual was engaging in locomotor patterns comparable to those of the modern humans. Studies of the carbon, nitrogen, strontium, barium, and calcium isotopes in the collagen of this individual compared to those of the fauna from the site suggest that it consumed almost no plant foods. Fish may have made up a portion of its diet, but there is no evidence of this from the faunal remains. A recent computerized reconstruction of the cranium showed evidence of a healed injury from a blade-like object, which has been interpreted as evidence of interpersonal (probably intragroup) violence (Zollikofer et al. 2002). However, the fact that this individual did not die from this injury suggests that it received a level of care and support from others. Archeological evidence found at site Seventeen archeological layers that document the transition from the Mousterian through the Châtelperronian to the Aurignacian have been identified. The hominin fossil was found associated with *Dentalium* shells; some have interpreted these as grave goods associated with an intentional burial. Key references: Geology, dating, and paleoenvironment Lévêque et al. 1993, Mercier et al. 1991; Hominins ApSimon 1980, Wolpoff 1981, Stringer et al. 1981, Stringer 1982, Lévêque et al. 1993, Trinkaus et al. 1998, 1999a, Balter and Simon 2006, Bocherens et al. 2005, Zollikofer et al. 2002; Archeology Guilbaud et al. 1994, Lévêque et al. 1993, Morin et al. 2005, Morin 2008.

Saitune Dora A concentration of fossil localities situated up against the Western Margin of the Afar Rift section of the East African Rift System in the **Middle Awash study area**, Ethiopia. Remains attributed to *Ardipithecus kadabba* have been found there.

Šala (Location 48°15'N, 17°05'E, Western Slovakia; etym. name of nearby town) History and general description Šala, also known as Šal'a, is a site composed of secondary gravel deposits in a sandbar of the river Váh, near the town of Šala, 50 km/31 miles northeast of Bratislava. Hominins were found 1961 (Šala 1) and in 1993 and 1995 (Šala 2). Temporal span and how dated? Evidence from **biostratigraphy** suggests possibly the last interglacial. Hominins found at site A complete, presumed female, adult frontal bone (Šala 1), and isolated cranial vault bones, presumed to be from one individual (Šala 2). Both are attributed to *Homo neanderthalensis*. Arche-

ological evidence found at site None. Key references: Geology, dating, and paleoenvironment Vlček 1969; Archeology N/A; Hominins Vlček 1969, Jelinek 1969, Smith 1982, Jakab 1996, Sládek et al. 2002.

Saldanha *See* Elandsfontein.

Saldanha 1 Site Elandsfontein. Locality Hopefield. Surface/in situ Surface find on a deflated dune surface. Date of discovery 1953. Finders K. Jolly and Ronald Singer. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Middle Pleistocene** on the basis of associated fauna. Developmental age Adult. Presumed sex Male based on the basis of the large **supraorbital torus**. Brief anatomical description A rugged, long, low, and broad calvaria with a massive, swept-back, supraorbital torus and strong angulation between the upper and lower scales of the occipital bone. Announcement Drennan 1953a, 1953b. Initial description Drennan 1953b. Photographs/line drawings and metrical data Singer 1954, Schwartz and Tattersall 2003. Detailed anatomical description Drennan 1955, Drennan and Singer 1955. Initial taxonomic allocation *Homo saldanensis* Drennan, 1955. Taxonomic revisions *Homo sapiens rhodesiensis* (Campbell 1964), *Homo heidelbergensis* (Rightmire 1996), *Homo rhodesiensis* (Bermúdez de Castro et al. 1997). Current conventional taxonomic allocation *H. heidelbergensis* or *H. rhodesiensis*. Informal taxonomic category Pre-modern *Homo*. Significance The preserved portions of the calvaria closely resemble the analogous parts of the **Bodo**, **Kabwe**, **Petralona**, and **Arago** crania. Like Kabwe, the Saldanha cranium is one of the key specimens in the hypodigm of *H. heidelbergensis* (Rightmire 2008). Location of original **South African Museum (Iziko Museums of Cape Town)**, Cape Town, Cape Province, South Africa.

Salé (Location 34°02'N, 6°48'E, Morocco; etym. named after the nearby city) History and general description An open-air site located 5 km/3 miles northeast of Salé city on the Atlantic coast. A partial hominin cranium was discovered in a fossil dune in 1971 during sandstone quarrying. Temporal span and how dated? **Biostratigraphy** and **electron spin resonance spectroscopy dating** suggest a date of *c.*400 ka and other evidence placing it at the end of the Amirian, or the beginning of the Tensiftian, local Maghreb continental stage

(Geraads et al. 1980), is consistent with this assessment. Hominins found at site Cranium tentatively assigned to *Homo erectus* or “archaic *Homo sapiens*.” Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Geraads et al. 1980, Debénath 2000, Hublin 1985; Hominins Rightmire 1990, Hublin 2001; Archeology N/A .

Salé 1 Site Salé. Locality N/A. Surface/in situ *In situ*. Date of discovery 1971. Finders Local quarrymen, but collected by Jean-Jacques Jaeger. Unit Fossil dune (aeolianite). Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Paleosol with microfauna of “Presolatian” age. Nearest underlying dated horizon N/A. Geological age *c.*400 ka. Developmental age Adult. Presumed sex Female. Brief anatomical description Occipital, parietals, frontal fragments, partial left maxilla with heavily worn I²-M², and a natural sandstone endocast, all from the same individual. Endocranial volume Approximately 880 cm³ (Holloway et al. 2004). Cranial distortion and muscular trauma indicate craniosynostosis and congenital torticollis, respectively (Hublin 1991). Announcement Jaeger 1975. Initial description Jaeger 1975. Photographs/line drawings and metrical data Jaeger 1975, Hublin 1991. Detailed anatomical description Hublin 1991, 2001. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. erectus* or archaic *Homo sapiens*. Informal taxonomic category Pre-modern *Homo*. Significance Cranium exhibits a mosaic of *H. erectus* and *H. sapiens* features. Location of original Laboratoire d'Anthropologie Biologique, Université de Bordeaux 1, Bordeaux, France.

“Sally-Anne” task *See* theory of mind.

Salzgitter-Lebenstedt (Location 52°09'N, 10°19'E, Germany; etym. name of a nearby town) History and general description This open-air site was first excavated in 1952 and again in 1977. The abundant faunal remains have been used as evidence of **Middle Paleolithic** hunting strategies (notably of reindeer). Temporal span and how dated? Radiocarbon dating suggests an age of more than *c.*50 ka (the site is at or beyond the limit of radiocarbon dating). Stratigraphic correlation and palynological analysis suggest a date somewhere in **Oxygen Isotope Stages** (OISs)

5–3, most likely at the beginning of OIS 3 (*c.*53 ka). Hominins found at site A fragment of occipital and right parietal, labeled Lebenstedt 1 and assigned to *Homo neanderthalensis*. Archeological evidence found at site A Middle Paleolithic lithic assemblage was recovered, along with rare Middle Paleolithic bone tools. The large faunal assemblage was overwhelmingly of reindeer, suggesting specialization in Middle Paleolithic hunting patterns. Key references: Geology, dating, and paleoenvironment: Gaudzinski and Roebroeks 2000, Street et al. 2006; Archeology Tode 1953, 1982; Hominins Hublin 1984.

Sambungmacan (Location 7°21'S, 111°07'E, Indonesia; etym. named after a local village) History and general description An open site on the south bank of the Solo River in Central Java, 12 km/7.4 miles east of Sragen. The site is an exposure of calciferous sandstone above the black clay in the lowermost portion of the **Bapang Formation**. An adult calotte (Sm 1) was discovered at the site in 1973. Temporal span and how dated? Initially assigned a **Lower to Middle Pleistocene** age, but recent **electron spin resonance spectroscopy dating** and **uranium-series dating** of the deposits suggest a young age of 27–53 ka for both Sambungmacan and **Ngandong**. Hominins found at site In addition to the adult calotte recovered in 1973, two other crania from this site were recently announced. The first (Sm 3) was “discovered” in a New York City curio shop and the second (Sm 4) was recovered from the site in 2001. These three hominin fossils have been variably attributed to *Homo erectus* and *Homo soloensis*. In 1977, a partial tibial shaft, generally attributed to *H. erectus*, was discovered at Sambungmacan. Archeological evidence found at site There is a brief reference to “stone tools” in a 1978 report (Jacob et al. 1978). Key references: Geology, dating, and paleoenvironment Swisher et al. 1996, Anton et al. 2002; Hominins Jacob 1973, Matsu'ura et al. 1990, Márquez et al. 2001, Baba et al. 2003; Archeology Jacob et al. 1978.

Sambungmachan *See* Sambungmacan.

sample A set of measurements used in the calculation of a test statistic. A sample is a subset of a larger **population** of possible measurements. For example, a sample of cranial capacities can be drawn from the population of all chimpanzee crania that have ever existed. Statistics based on a sample (i.e., sample

statistics) are used to make inferences regarding the population from which the sample is drawn.

sample statistics *See* parameter.

sampling with replacement In statistics, a distinction is made between sampling with replacement and sampling without replacement. When generating a random sample of size n where $n > 1$, one typically chooses a randomly selected sample from a population or larger sample in one of two ways. Consider the following examples, both of which involve drawing two tiles from a bag of nine tiles, each marked with a different digit from 1 to 9. A person could draw a tile at random, record the number on it, replace it in the bag, and draw again. This is an example of sampling with replacement. Alternatively, one could draw a tile at random, record the number on it, leave the tile out of the bag, and draw a second tile from the bag. This would be sampling without replacement. In the first case it is possible to draw the same tile twice, but that is not possible in the second case. The difference between the two sampling methods is relatively unimportant when choosing a small sample from a large population because in that case the probability of selecting the same individual twice is relatively low (to put this in the context of the population of the USA, imagine randomly pulling the same tile twice in a row from a bag of 300 million tiles). However, the difference between the two types of sampling is important for **resampling** analyses. In the case of the **bootstrap** a sample of size n is drawn from a population of size n ; in the case of **randomization** two or more samples are generated whose combined sample size is equal to that of the total population. Consider again the bag of tiles, and let us suppose that the order in which tiles are drawn out of the bag does not matter. Draw a sample of nine tiles. If sampled without replacement, there is only one possible sample that can be drawn: the sample that includes a single instance of each digit from 1 to 9 (i.e., all of the tiles). However, when sampling with replacement tiles are replaced in the bag between draws, and so that technique allows over 24,000 possible samples in this example because each digit may be represented multiple times, or not at all, in a given sample. This latter example demonstrates how sampling occurs in bootstrapping. Consider another example using the same bag of tiles. We know the bag contains four even-numbered tiles (2, 4, 6, 8) and five odd-numbered tiles (1, 3, 5, 7, 9). Let us call these groups *E* and *O*. In randomization some mea-

sure comparing the two groups (e.g., the mean of group *E* minus the mean of group *O*) is compared for the actual data set to a set of measures from randomly resampled data sets of equal size. In this case, group *E* consists of four tiles and group *O* consists of five. If four tiles are drawn randomly from the bag without replacing them between draws, then the data set has randomly been split into two groups of equal size to the first; four tiles outside of the bag, and five tiles inside of the bag. If the order of tiles in a group does not matter, there are 126 possible ways to split nine tiles into a group of four and a group of five (this is an example of a combination). If the tiles were sampled with replacement to produce the group of four tiles, then the remaining tiles would not equal the sample size for the second group. Consequently the difference in these two types of sampling is very important in resampling analyses: the bootstrap uses sampling with replacement, whereas randomization uses sampling without replacement.

sampling without replacement *See* sampling with replacement.

San A term used to refer to the hunter-gatherer people of southern Africa, who live in Botswana, Zambia, Zimbabwe, and South Africa. Other terms, including Khwe, Sho, Bushmen, and Basarwa, have also been used to refer to this group, but all are problematic as they are or have historically been used by outsiders in a perjorative manner. All the San groups speak Khoisan language variants, and as recently as 1990 some practiced an entirely foraging-based economy; today, almost all of the San rely heavily or entirely on farming. This group has been the subject of many ethnographic studies, which have allowed researchers to better understand subsistence strategies and test hypotheses derived from behavioral ecology.

sand Sedimentary materials defined primarily on the basis of particle size (i.e., a mean diameter between 2 and 0.063 mm). Loose (unlithified) sediment in this range is referred to as sand, whereas consolidated or cemented (lithified) examples would be termed sandstone. Two essential characteristics of sand and sandstone make them a common medium for the preservation of fossils. First, the physical processes responsible for accumulation of sands are likely to associate bones and teeth in the same deposits; second, the porosity inherent in sands facilitates mineralization of the fossil material and hence its

long-term preservation. The rich Plio-Pleistocene fossil assemblages of the **Turkana Basin** are derived primarily from the sands of the ancient river channels that flowed through the basin, or into the lake when there was a lake in the basin.

sandstone *See* sand.

Sangiran (Location 7°20'S, 110°58'E, Indonesia; etym. named after a local village) History and general description The most productive fossil hominin locality in Indonesia, it is now recognized as a UNESCO **World Heritage Site**. It is located near the village of Sangiran approximately 12 km/7.4 miles north of Surakarta, Central Java, Indonesia. Almost 80 hominin fossils including 10 well-preserved crania, 14 mandibular and maxillary specimens, and dozens of isolated teeth, have been recovered from Sangiran. The first hominin fossils were collected by local individuals on behalf of Ralph von Koenigswald from 1936 to 1941. Following a hiatus during the war years, from 1950 to the present day local farmers and other individuals have continued to collect hominin fossils for researchers including P. Marks, Teuku Jacob, and S. Sartono. The hominin fossils from Sangiran are currently housed in the following Indonesian and German institutions: Gadjah Mada University (Yogyakarta, Central Java), **Geological Research and Development Center** (Bandung, Indonesia), Institute of Technology (Bandung), and the **Senckenberg Forschungsinstitut und Naturmuseum** (Frankfurt, Germany). Today, the **Sangiran Dome** is a relatively low-lying massif surrounded by large volcanoes. The fossil hominin-bearing geological formations of the dome are the **Sangiran Formation** with the **Bapang Formation** overlying it; these were formerly known as the Pucangan Formation and the Kabuh Formation, respectively. The two formations are the result of different geological formation processes, and are separated by a fossil-rich layer (formerly known as the **Grenzbank Zone**). The oldest hominin specimens derive from the upper levels of the Sangiran Formation, but most of the fossils are derived from the Bapang Formation. The lower layers of the Bapang were characterized by high-energy deposition so many of the mammalian fossils, including the hominins, are abraded and fragmentary. Higher in the Bapang Formation, the sediments are finer-grained (indicating lower-energy deposition) and the fossils from those strata are better preserved and more complete. Temporal span and how dated? Through the 1980s it was thought that none of the

Sangiran Dome hominins were older than 1.0 Ma, but in 1994 **argon-argon dating** suggested age of 1.66 Ma for a Sangiran hominin fossil originally discovered during canal-cutting operations in the early 1970s with ages derived from stratigraphic evidence indicating that even the Bapang Formation hominins were older than 1.0 Ma. In 2001, an argon-argon geochronology generated by a different team confirmed these ages. The Sangiran Formation has argon-argon dates of 1.92–1.58 Ma, with only the uppermost section of the formation being hominin-bearing. The Bapang Formation has argon-argon dates of 1.58–1.0 Ma. The Notopuro Formation, which caps the section but has yet to yield hominins, has an argon-argon date of 780 ka. Thus, today, the geologically youngest (not the oldest) fossil hominins from Sangiran are dated to 1.0 Ma. Hominins found at site Many hominin fossils have been discovered eroding from the Sangiran Dome deposits over the years, but most are without provenance because they were surface collections made by local farmers and other non-scientists. **Sangiran 2** (discovered in 1937) was the first partial cranium discovered at the site. **Sangiran 4** (discovered in 1939), a partial cranium and palate with much of the upper dentition preserved, is the holotype of *Pithecanthropus dubius*. **Sangiran 6** (discovered in 1941) is the holotype of *Meganthropus palaeojavanicus*, a fossil taxon once thought to belong to the type of megadont archaic hominin that is found in East Africa. The **Sangiran 17** cranium (discovered in 1969) is the most complete fossil hominin cranium to be discovered in Indonesia. Archeological evidence found at site In 1992 at **Ngebung**, a locality found in the Bapang Formation in the northwestern part of the Sangiran Dome, stone tools including utilized large flakes and bolas stones were reported. Key references: Geology, dating, and paleoenvironment Watanabe and Kadar 1985, Swisher et al. 1994, Larick et al. 2001, Antón and Swisher 2004; Hominins Weidenreich 1944, von Koenigswald 1968, Jacob 1972, Sartono 1976, Pope and Cronin 1984, Kramer 1994, Kaifu et al. 2005a; Archeology Sémah et al. 1992.

Sangiran 1a Site Sangiran. Locality There is no information about where it was found but the preservation is similar to that of Sangiran 6b. Surface/in situ Surface. Date of discovery 1936. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation von Koenigswald, in an unpublished manuscript (entitled “Early Man in Java IV. *Meganthropus palaeojavanicus*” dated 1949, in the von Koenigswald Archive at the **Senckenberg**

Forschungsinstitut und Naturmuseum), implies that Sangiran 6b comes from the **Sangiran Formation**, so by implication Sangiran 1a may also have come from the Sangiran Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Heavily mineralized posterior part of the left maxilla including the distal half of the broken crown and root of the left M¹, the broken crown and root of the left M², and the well-preserved crown and root of the left M³. Announcement None, but listed by Jacob in Oakley et al. (1975). Initial description None. Photographs/line drawings and metrical data None. Detailed anatomical description None. Initial taxonomic allocation None. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance According to the unpublished manuscript referred to above, von Koenigswald originally regarded Sangiran 6b as belonging to a fossil ape, but he later added it to the collection of hominin fossils from Sangiran, and Jens Franzen (pers. comm.) suggests that Sangiran 1a was transferred into the hominin collection at the same time. That would make it among the earliest, if not the first, hominin to be recovered from the Sangiran region after the discoveries at **Trinil**. Location of original Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt, Germany.

Sangiran 1b Site Sangiran. Locality The location is described as being south of **Bukuran** and west of Kertosobo, along the right bank of the western tributary of the Cemoro river (von Koenigswald 1940, Itihara et al. 1985). Surface/*in situ* Surface. Date of discovery 1936. Finder Atmowidjojo. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Sangiran Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right side of the mandibular corpus extending from a section through the right I₁ alveolus to posterior to the right M₃. The lateral incisor and canine, and P₃ alveoli are empty, but the roots and crowns of the P₄-M₃ are preserved. Announcement von Koenigswald 1937. Initial description von Koenigswald 1940. Photographs/line drawings and metrical data von Koenigswald 1940. Detailed anatomical description von Koenigswald 1940. Initial taxo-

omic allocation *Pithecanthropus*. Taxonomic revisions *Pithecanthropus modjokertensis* (von Koenigswald 1950). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The first fossil hominin to be recognized from the Sangiran Formation. According to von Koenigswald (1940) it was called Mandible B because he considered the mandible from Kedungbrubus to be Mandible A. Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany (syn. Mandible B, *Pithecanthropus* B, *Pithecanthropus* Mandible B).

Sangiran 2 Site Sangiran. Locality Approximately 0.5 km/0.3 miles downstream from Bapang village along the left bank of the Cemoro River (von Koenigswald 1940, p. 78, Itihara et al. 1985). Surface/*in situ* Surface. Date of discovery 1937. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Bapang Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.47 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Calotte that lacks the right side and the medial part of the left side of the frontal region, and much of the base except for the mandibular fossae. Announcement von Koenigswald 1938. Initial description von Koenigswald 1938. Photographs/line drawings and metrical data von Koenigswald 1940. Detailed anatomical description von Koenigswald 1940. Initial taxonomic allocation *Pithecanthropus*. Taxonomic revisions *Pithecanthropus erectus* (Weidenreich 1945). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The first relatively well-preserved evidence of the cranium from Sangiran. Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany (syn. *Pithecanthropus* II, Skull II).

Sangiran 3 Site Sangiran. Locality Southern end of the top of a high hill behind the village Tandjoeng (von Koenigswald 1940, p. 102, Itihara et al. 1985). Surface/*in situ* Surface. Date of discovery 1938. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Bapang Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.47 Ma. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Calotte that preserves most of the right parietal, the medial part of

the left parietal, and part of the right side of the occipital squame. Announcement von Koenigswald and Weidenreich 1938. Initial description von Koenigswald 1940. Photographs/line drawings and metrical data von Koenigswald 1940. Detailed anatomical description von Koenigswald 1940. Initial taxonomic allocation *Pithecanthropus*. Taxonomic revisions *Pithecanthropus erectus* (Weidenreich 1945). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The first evidence of the calotte of a young adult from Sangiran. Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany (syn. *Pithecanthropus* III, Skull III).

Sangiran 4 Site Sangiran. Locality North of Glagahombo village. Surface/in situ Surface. Date of discovery 1938–9. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation Sangiran Formation, but close to the boundary with the Bapang Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Cranium that lacks the upper part of the face, the frontal bone and the body, and parts of the wings of the sphenoid. Announcement von Koenigswald and Weidenreich 1939. Initial description Weidenreich 1945. Photographs/line drawings and metrical data Weidenreich 1945. Detailed anatomical description Weidenreich 1945. Initial taxonomic allocation *Pithecanthropus*. Taxonomic revisions *Pithecanthropus robustus* (Weidenreich 1945). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The first evidence of a cranium, albeit incomplete, from the Sangiran Formation, and although Weidenreich (1945) attributed it to a separate species of *Pithecanthropus*, it is now widely accepted as part of the hypodigm of *Homo erectus*. Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany (syn. *Pithecanthropus* IV, Skull IV).

Sangiran 5 Site Sangiran. Locality “South of the small path that connects Ngebung with Blimbing” (unpublished manuscript by von Koenigswald entitled “Early Man in Java IV. *Meganthropus palaeojavanicus*” dated 1949, in the von Koenigswald Archive at the **Senckenberg Forschungsinstitut und Naturmuseum**). Sur-

face/in situ Surface. Date of discovery 1939. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation Sangiran Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragment of the right side of the corpus of an adult mandible that extends from the alveolus of I₁ medially to the distal end of the M₂. The anterior fracture surface is oblique and exposes the alveolus of I₂, the tip of the canine root, the alveolus of P₃, and the broken crown and root of the P₄. Announcement von Koenigswald 1938, 1940. Initial description Weidenreich 1945. Photographs/line drawings and metrical data Weidenreich 1945. Detailed anatomical description Weidenreich 1945. Initial taxonomic allocation In 1945 Weidenreich wrote that “I deem it best to put aside the Sangiran mandible of 1939 for the present and to return to it when we have more reliable information” (*ibid*, p. 62), so von Koenigswald (1950) was the first to allocate it to a taxon as *Pithecanthropus dubius*. Taxonomic revisions *Homo erectus* (Le Gros Clark 1955). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Its relatively primitive premolar root morphology is a reminder of the range of morphological variation subsumed within a single taxon solution to the Javan hominins. Kaifu et al. (2005b) suggest that it may be evidence of a second “older” (*ibid*, p. 517) and “more robust” (*ibid*, p. 518) morph; Tyler (2004) claims it belongs to a *Pongo*-like ape. Location of original **Senckenberg Forschungsinstitut und Naturmuseum**, Frankfurt, Germany (syn. Sangiran 1939 mandible).

Sangiran 6a [NB: the original Sangiran 6 has *de facto* become 6a to avoid confusion after Grine and Franzen 1994 introduced a hitherto undescribed hominin mandibular fragment from Sangiran as Sangiran 6b (*ibid*, p. 91)] Site Sangiran. Locality von Koenigswald, in an unpublished manuscript (entitled “Early Man in Java IV. *Meganthropus palaeojavanicus*” dated 1949, in the von Koenigswald Archive at the **Senckenberg Forschungsinstitut und Naturmuseum**), describes the location of its discovery as “near Glagahombo, north of Sangiran” and he writes that “the place is only a few hundred m. away from the spot where the skull of *Pithecanthropus Modjokertensis* has been discovered in 1939” (*ibid*, first manuscript page of the section on *Meganthropus palaeojavanicus*). According to the

map in Itihara et al. (1985) the location is to the south of the site of the discovery of Sangiran 4. Surface/*in situ* Surface. Date of discovery 1941. Finder Kromopawiro. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Sangiran Formation.** Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragment of the right side of the corpus of an adult mandible that extends from an anterior oblique break that passes through the distal wall of the alveolus of I₂ anteriorly and the symphysis posteriorly, to the posterior fracture surface that has exposed the distal aspect of the distal root plate of M₁. The posterior fracture surface is also oblique, extending more posteriorly at the base than at the alveolar margin. Announcement Weidenreich 1945. Initial description Weidenreich 1945. Photographs/line drawings and metrical data Weidenreich 1945. Detailed anatomical description Weidenreich 1945. Initial taxonomic allocation *Meganthropus palaeojavanicus*. Taxonomic revisions *Homo erectus* (Le Gros Clark 1955). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The overall size of the corpus and the inferred relatively primitive P₃ root morphology caused Franz Weidenreich to support von Koenigswald's contention that this mandible belonged to a large-bodied hominin taxon other than *H. erectus*, but several authors (e.g., Kramer 1989) have shown that the size of the mandible is not exceptional. Location of original Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt, Germany (syn. 1941 mandible, *Meganthropus A*).

Sangiran 6b Site Sangiran. Locality N/A. Surface/*in situ* Surface. Date of discovery 1936. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation von Koenigswald, in an unpublished manuscript (entitled "Early Man in Java IV. *Meganthropus palaeojavanicus*" dated 1949, in the von Koenigswald Archive at the Senckenberg Forschungsinstitut und Naturmuseum), implies that Sangiran 6b comes from the **Sangiran Formation**, for he describes it as coming from "a deeper layer in the Black Clay than the Pithecanthropus mandible" (i.e., Sangiran 1b). Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Heavily mineralized posterior part of

the left mandibular corpus. The anterior fracture surface exposes the mesial aspect of the broken crown of the M₁; the oblique posterior fracture surface exposes the distal aspect of the distal root plate of the M₃. The crowns of the M₂ and M₃ are preserved. Announcement Grine and Franzen 1994. Initial description Grine and Franzen 1994. Photographs/line drawings and metrical data Grine and Franzen 1994. Detailed anatomical description None. Initial taxonomic allocation None. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance In an unpublished manuscript (see Formation, above) von Koenigswald refers this mandibular specimen to *Meganthropus palaeojavanicus*. Grine and Franzen (1994) make no comment about its taxonomy. Location of original Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt, Germany.

Sangiran 7 The prefix "S7" was introduced by Jacob (1975). Prior to that von Koenigswald had given *all* of the 52 isolated teeth recovered from Sangiran the prefix "FS" [i.e., an acronym for "fossils (from) Sangiran"] followed by a number, but only those teeth subsequently determined to be hominin were given the prefix S7. These teeth carried their FS number with them (e.g., FS 89 became S7-89). Jacob (1975) divided the Sangiran 7 collection of isolated teeth into Sangiran 7a (or S7a), for those from the **Sangiran Formation**, and Sangiran 7b (or S7b), for those from the **Bapang Formation**. Site Sangiran. Locality N/A. Surface/*in situ* Surface. Date of discovery 1937–41. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation See above. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.60 Ma. Developmental age All but four of the teeth (the three, FS 67, 72, and 83, described in Grine 1984, plus S7-13) are permanent. Presumed sex Unknown. Brief anatomical description Three isolated deciduous teeth [a left upper dc (FS 83), and a right dm₁ (FS 67), and a right dm₂ (FS 72)] were described in detail by Grine (1984); the remainder were described in detail by Grine and Franzen (1994). The teeth described by Grine and Franzen (1994) are all given "S7" numbers (e.g., S7-1 is a right I¹; S7-10 is a right M¹), but the three deciduous teeth described by Grine (1984) do not have S7 numbers. Franzen (pers. comm.) suggests that when he and Fred Grine reviewed all the S7 plus the FS 67, 72, and 83 teeth in the early 1990s

they both came to the conclusion that the three deciduous "FS" teeth described by Grine (1984) were most likely pongid and not hominin. Announcement FS 67, von Koenigswald 1953; FS 72, von Koenigswald 1950; FS 83, Grine 1984; the remainder Grine and Franzen 1994. Initial description, photographs/line drawings and metrical data, and detailed anatomical description FS 67, 72, and 83, Grine 1984; the remainder Grine and Franzen 1994. Initial taxonomic allocation FS 67, *Homo modjokertensis*; FS 72 and 83, *Meganthropus paleojavanicus*, with all of the other 52 teeth by implication being referred to *Homo*. Taxonomic revisions FS 67, 72, and 83, *Pongo* sp. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The collection is a rich source of information about dental variation in the Javan part of the hypodigm of *H. erectus*. Location of the originals Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt, Germany.

Sangiran 8 Site Sangiran. Locality Near the village of Glagahombo. Surface/in situ Surface. Date of discovery 1952. Finder A local villager. Unit N/A. Horizon N/A. Bed/member Between underlying top of Sangiran Formation and the bottom of the Grenzbank Zone. Formation Sangiran Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Heavily damaged mandibular corpus preserving root fragments of the left I₁–M₁, the right I₁, and the right P₄–M₂. The complete crown of the right M₃ is present. The right side of the corpus is broken such that it appears more robust than it was in its pristine state; the damage has been interpreted as evidence of a perimortem crocodile bite (von Koenigswald 1968). Announcement Marks 1953. Initial description Marks 1953. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description von Koenigswald 1968, Kaifu et al. 2005a. Initial taxonomic allocation "*Meganthropus*" (Marks 1953). Taxonomic revisions *Pithecanthropus erectus* (Le Gros Clark 1955), *Homo erectus* (Le Gros Clark 1964). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Initially interpreted as representing an indigenous, hyper-robust lineage referred to as "*Meganthropus*" (Marks 1953, von Koenigswald 1968), or a southeast Asian form of australopith or archaic hominin (Robinson 1953). Later, it was inter-

preted as being within the range of variation of *H. erectus* (Le Gros Clark 1964, Lovejoy 1970, Kramer 1989). Location of original Geological Research and Development Center, Bandung, Indonesia (syn. *Meganthropus* B).

Sangiran 9 Site Sangiran. Locality from the slope of a hill near the village of Mandingan or Bojong. Surface/in situ Surface. Date of discovery 1960. Finder A local villager. Unit N/A. Horizon N/A. Bed/member Between the top of Sangiran Formation and the bottom of the Grenzbank Zone. Formation Sangiran Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Heavily mineralized right side of the mandibular corpus preserving the symphysis distal to just beyond the M₃. The alveoli of the left I₁, and on the right side the I₁₋₂ alveoli, the broken crown of the canine, the complete P₃₋₄ crowns, the alveolus of M₁, and the complete M₂₋₃ crowns are preserved. Announcement Sartono 1961. Initial description Sartono 1961. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description Kaifu et al. 2005a. Initial taxonomic allocation "*Pithecanthropus*" (Sartono 1961). Taxonomic revisions *Pithecanthropus dubius* (von Koenigswald 1968), *Homo erectus* (Kramer 1994). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Sangiran 9 extended the range of morphological and metrical dento-gnathic diversity of early *H. erectus* from Java (Kaifu et al. 2005b). Location of original Geological Research and Development Center, Bandung, Indonesia (syn. Mandible C).

Sangiran 10 Site Sangiran. Locality Near the village of Tanjung. Surface/in situ Surface. Date of discovery 1963. Finders Sartono, Jacob, and local villagers. Unit N/A. Horizon N/A. Bed/member Within the middle to upper levels of the Bapang Formation. Formation Bapang Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.33–1.24 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A young adult calotte, presumably male based on the size of the supraorbital torus; a left zygomatic is also attributed to this individual. Endocranial volume Approximately 975 cm³. Announcement Jacob 1964. Initial

description Jacob 1966. Photographs/line drawings and metrical data Jacob 1966. Detailed anatomical description Jacob 1966. Initial taxonomic allocation “*Pithecanthropus erectus*” (Jacob 1966). Taxonomic revisions *Homo erectus* (Le Gros Clark 1978). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Sangiran 10 exemplifies the **total morphological pattern** of *H. erectus* crania from Java, including the thick cranial wall, robust cranial superstructures, and an endocranial volume of approximately 1000 cm³. Location of original **Gadjah Mada University**, Yogyakarta, Indonesia (syn. Skull VI).

Sangiran 17 Site Sangiran. Locality near the village of Pucung. Surface/in situ Surface. Date of discovery September 13, 1969. Finder Mr. Tukimin, a local farmer working for S. Sartono. Unit N/A. Horizon N/A. Bed/member Between the Lower and Middle Tuffs within the **Bapang Formation**. Formation Bapang Formation. Group N/A. Nearest overlying dated horizon Middle Tuff (1.02 Ma). Nearest underlying dated horizon Grenzbank boundary layer between the Bapang and **Sangiran Formations** (1.51 Ma). Geological age *c.*1.25 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description. The most complete Javanese *Homo erectus* cranium including most of the face, base, and cranial vault. Endocranial volume 1004 cm³ (Holloway 1981). Announcement Sartono 1971. Initial description Sartono 1971. Photographs/line drawings and metrical data Sartono 1971, Kaifu et al. 2008. Detailed anatomical description Baba et al. 1998. Initial taxonomic allocation “*Pithecanthropus erectus*” (Sartono 1971). Taxonomic revisions *H. erectus* (Le Gros Clark 1978). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Documents the total morphological pattern of *H. erectus* crania from Java, including a continuous, bar-like, supraorbital torus, thickened cranial vault, pronounced angular torus, and broad and robust face. Its cranial morphology indicates likely phylogenetic continuity with succeeding **Ngandong** and **Sambungmacan** hominins in Java (Kaifu et al. 2008). Location of original Quaternary Geology Laboratory of the **Geological Research and Development Center**, Bandung, Indonesia (syn. Skull VIII).

Sangiran 21 Site Sangiran. Locality Near the village of Ngebung. Surface/in situ Surface. Date

of discovery 1973. Finders Local collectors. Unit N/A. Horizon N/A. Bed/member Within the lowest levels of the **Bapang Formation**, just above the underlying top of the **Grenzbank Zone**. Formation Bapang Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.47 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A fragmentary right mandibular ramus preserving the condyle and the most distal portion of the right side of the corpus preserving the crown of M₃. Announcement Sartono 1974. Initial description Sartono 1974. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description Kaifu et al. 2005a. Initial taxonomic allocation “*Pithecanthropus*” (Sartono 1974). Taxonomic revisions *Homo erectus* (Tyler et al. 1995). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Sangiran 21 documents dentognathic size reduction in later *H. erectus* from Java (Kaifu et al. 2005b). Location of original **Geological Research and Development Center**, Bandung, Indonesia (syn. Mandible E).

Sangiran 27 Site Sangiran. Locality Near the village of Sangiran, north of the Chemoro River. Surface/in situ Surface. Date of discovery 1978. Finders Local workers during the construction of a dam. Unit N/A. Horizon N/A. Bed/member Within the “Black Clays” of the upper levels of the **Sangiran Formation**, above Tuff 10 and below the overlying **Grenzbank Zone**. Formation Sangiran Formation. Group N/A. Nearest overlying dated horizon Grenzbank Zone. Nearest underlying dated horizon Tuff 10. Geological age *c.*1.66–1.58 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A partial cranium preserving portions of the face, the anterior vault, and maxillary dentition including the right P³–M³, and on the left side a partial P⁴ crown and M¹⁻²; the specimen is highly mineralized and underwent significant post-mortem crushing and deformation. Announcement Jacob 1980. Initial description Jacob 1980. Photographs/line drawings and metrical data Indriati and Antón 2008. Detailed anatomical description Indriati and Antón 2008. Initial taxonomic allocation “*Meganthropus*” (Jacob 1980). Taxonomic revisions *Homo erectus* (Indriati and Antón 2008). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Sangiran 27 documents

the “hyper-robust” cranio-facial morphology seen in the earliest Javan *H. erectus* and it is consistent with the derived nature of these hominins (especially the dentition) in comparison to their contemporaries from **Dmanisi** and the **Turkana Basin** of East Africa (Indriati and Antón 2008). Location of original **Gadjah Mada University**, Yogyakarta, Indonesia.

Sangiran 38 Site **Sangiran**. Locality Near the village of Sendangbusik. Surface/*in situ* Surface. Date of discovery 1980. Finders Local workers. Unit N/A. Horizon N/A. Bed/member Lower levels of the Bapang Formation. Formation Bapang Formation. Group N/A. Nearest overlying dated horizon Lowest tuff. Nearest underlying dated horizon **Grenzbank Zone**. Geological age *c.*1.58–1.47 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A partial cranium preserving portions of the frontal, parietal, and occipital. Announcement Jacob 1980. Initial description Jacob 1983, Grimaud-Herve and Widiyanto 2001, Indriati and Antón 2010. Photographs/line drawings and metrical data Indriati and Antón 2010. Detailed anatomical description Indriati and Antón 2008. Initial taxonomic allocation *Homo erectus* Jacob, 1983. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Sangiran 38 shows depressed lesions of the vault consistent with a scalp or systemic infection (Indriati and Antón 2010). Location of original Gadjah Mada University, Yogyakarta, Indonesia.

Sangiran 1941 mandible *See* Sangiran 6a.

Sangiran Dome A relatively low-lying massif surrounded by large volcanoes in Central Java, Indonesia. The fossil hominin-bearing geological formations of the dome are the **Sangiran Formation** and the **Bapang Formation** overlying it. The older Sangiran Formation was primarily deposited from freshwater lakes and swamps and the sediments include dense clay and organic components. The oldest hominin specimens from Sangiran are attributed to the upper levels of the Sangiran Formation. A coarse-grained conglomeratic layer rich with fossil bone (formerly known as the **Grenzbank Zone**) lies between the older Sangiran and younger Bapang Formations. In contrast to the Sangiran Formation,

the Bapang Formation is largely a product of local uplift, volcanism, and sedimentary deposition from river and stream activity. Most of the hominin fossil specimens from the Sangiran Dome are derived from the Bapang Formation. The lower layers of the Bapang were characterized by high-energy deposition so many of the mammalian fossils, including the hominins, are abraded and fragmentary. Higher in the Bapang Formation, the sediments are finer-grained (indicating lower-energy deposition) and the fossils from those strata are better preserved and more complete. The fossil hominin-bearing sites of the Sangiran Dome include **Blimbingskulon**, **Bukuran**, **Ngrejeng**, **Sangiran**, and **Sendangbusik**. Stone tools have been report from **Ngebung**.

Sangiran Formation (etym. named after the site of **Sangiran** where it is exposed) General description The older of the two fossil-hominin-bearing geological formations of Central and East Java, Indonesia. Formerly known as the Pucangan Formation, the Sangiran Formation includes sediments primarily deposited from freshwater lakes and swamps that include dense clay and organic components. The oldest hominin specimens from Sangiran are attributed to the upper levels of the Sangiran Formation. A coarse-grained conglomeratic layer rich with fossil bone (formerly known as the **Grenzbank Zone**) marks the transition between the older Sangiran and younger **Bapang Formations**. Sites where this formation is exposed Hanoman, **Mojokerto**, and sites within the Sangiran Dome. Geological age **Argon-argon dating** suggests the formation dates between 1.92 and 1.58 Ma, and that the hominins at the Sangiran Dome localities are from the upper part of this formation between Tuff 10 (1.66 Ma) and the **Grenzbank Zone** (1.58 Ma); those from sites elsewhere (e.g., **Mojokerto**) may be as old as 1.8 Ma. Most significant hominin specimens For example **Mojokerto 1**, **Sangiran 4**, and **Sangiran 27**. Key references: Geology, dating, and paleoenvironment Watanabe and Kadar 1985, Swisher et al. 1994, Larick et al. 2001; Hominins Weidenreich 1944, von Koenigswald 1968, Jacob 1972, Sartono 1976, Pope and Cronin 1984.

Sangoan (etym. Named after the artifacts recovered from Sango Bay, Uganda, on the western shore of Lake Victoria) The Sangoan is an artifact **industry** found across Central Africa and portions of East Africa. The Sangoan is defined typologically by the presence of heavy-duty tools such as **picks**,

choppers, and **core-axes** as well as a number of light-duty tools such as **scrapers** (see McBrearty 1987, 1991). At **Kalambo Falls**, Zambia, Sangoan assemblages overlie **Acheulean** ones, and are in turn overlain by strata containing evidence of the **Middle Stone Age**, a pattern that is repeated at other sites, particularly in the Lake Victoria basin. Many of the elements found at Sangoan sites (e.g., picks, **Levallois** cores) also are found in Acheulean or Middle Stone Age ones, and thus the Sangoan has figured in some discussions of the relationship between these two industries (e.g., Tryon and McBrearty 2002). Sangoan tools co-occur with **Lupemban** tools at several sites, and the distribution of both Sangoan and Lupemban assemblages broadly coincides with the past and present distribution of equatorial forests. This coincidence led Clark (1970) to suggest that the Sangoan and Lupemban reflect forest adaptations, and may signal the initial hominin exploitation of this habitat type, but subsequent site-specific paleoenvironmental reconstructions (McBrearty 1992) have not always supported this hypothesis. The Sangoan industry is poorly dated, but it is most likely **Middle Pleistocene** in age.

sanidine A mineral of the **feldspar** group, with the formula $KAlSi_3O_8$. A common potassium-bearing mineral, sanidine is especially suitable for **potassium-argon dating**. The pumices encountered in **tuffs** of the **Koobi Fora Formation** have proved to be a rich source of the sanidine crystals that are the basis for dating that fossiliferous sequence.

sapropel (Gk *sapros*=rotten and *pelagos*=sea) A sedimentary rock (usually a mud or marl) that contains more than 5% organic material. Sapropels occur in **lacustrine** and marine deposits. The **Neogene** strata of the eastern Mediterranean Sea are characterized by sapropel beds, generated by precessionally driven precipitation delivered via the Nile River. These sapropels provide **proxy** records of monsoonal rainfall in East Africa (particularly in the Blue Nile headwaters in the Ethiopian Highlands) and they are also used for the **orbital tuning** of the associated marine sequences and in the construction of age models for the **cores** and outcrops in which they are recognized.

Sarich, Vincent M. (1934–) Vincent Sarich received his BS in chemistry from the Illinois Institute of Technology and his MS and PhD in

anthropology from the University of California at Berkeley. From 1966 to 1994 Sarich was a faculty member in the Department of Anthropology at the University of California at Berkeley, after which became an Emeritus Professor. He then served as a Lecturer in Anthropology at the University of Auckland in New Zealand. Sarich is best known for his work on **molecular clocks**. Working with the biochemist Allan **Wilson**, Sarich co-published two important papers in 1967. Using microcomplexed fixation, Sarich and Wilson (1967a) examined the pattern of immunological differences among primate species with respect to the protein **albumin**. The degree of difference in the reaction of target albumin antibody to antisera of other primates was expressed as the index of dissimilarity; $\log(\text{index of dissimilarity}) \times 100$ equals the immunological distance (or ID). Sarich and Wilson were able to demonstrate that immunological distance between the proteins of two species is proportional to the number of **amino acid** differences, which in turn is proportional to the time of species separation. But the most important insight was the description of the so-called rate test (Sarich and Wilson 1967b) in a paper that sadly is seldom cited. Given three taxa A, B, and C in which A and B are **sister taxa** and C is the outgroup, comparison of the ID of A and C with the ID of B and C will demonstrate the extent to which immunological (=amino acid=evolutionary) change is more or less constant. To the surprise of Sarich and Wilson, broad surveys of primate albumin immunological distances showed, via the rate test, that molecular change was regular, or clock-like [in the hypothetical case above, this conclusion would follow if ID_{AC} was equal or subequal (nearly equal) to ID_{BC}]. Having demonstrated the evolutionary clock-like behavior of primate albumins, Sarich and Wilson could therefore generate a so-called proportional tree. This proportional tree could then be calibrated using the fossil record; Sarich and Wilson assumed a date of 45 Ma for the divergence of New and Old World anthropoids and 30 Ma for the divergence of hominoids and cercopithecoids. The latter calibration yielded a divergence age of 5 million years for modern humans, chimpanzees, and gorillas (the relationship of these taxa then being an unresolved trichotomy), a surprisingly young date given the then widely held fossil-based belief that modern humans diverged from other primates at least three times as long ago as suggested by Sarich and Wilson. For a variety of reasons, these results were taken seriously by far too few in the relevant scientific communities. In

particular the refusal or inability to understand the logic of the rate test meant that Sarich and Wilson were widely accused of *assuming* rate constancy, when in fact they were always *inferring* it. In an interesting "retrospective" Sarich (1983) generously noted that the germ of the rate test idea might have lain in a 1963 paper by Margoliash. The general approach and conclusions of Sarich and Wilson have been widely validated and are now accepted by all competent evolutionary biologists. Indeed, the articulation of the rate test could be counted as one of the most important insights of later 20thC systematics and evolutionary biology. The later phases of Sarich's career have involved more controversial issues.

Sarstedt (Location 52°14'N, 9°51'E, Germany; etym. named after a nearby town) History and general description Amateur collectors have recovered several *Homo neanderthalensis* cranial fragments, Pleistocene fauna and Middle Paleolithic tools in the gravel dumps from quarries near Sarstedt, Leine valley, Lower Saxony, Germany. Temporal span and how dated? Due to their lack of context, these finds are hard to date. Direct **radiocarbon dating** on the fossils was unsuccessful, so the best estimates for the age range are between 117 and 25 ka based on geological and stratigraphic analysis. Hominins found at site Three cranial fragments have been reported, although others are known to have been recovered. Sarstedt I is a temporal bone, Sarstedt II is an occipital bone, and Sarstedt III is a parietal bone; all have been attributed to *Homo neanderthalensis*. Archeological evidence found at site Middle Paleolithic assemblage attributed to the Keilmessergruppen technocomplex, along with several faunal pieces. Key references: Geology, dating, and paleoenvironment Street et al. 2006; Archeology Czarnetzki et al. 2002; Hominins Czarnetzki et al. 2001, 2002, Street et al. 2006.

SASES Acronym for the Standardized African Site Enumeration System, which was developed in the 1960s as a way of recording African archeological sites. *See also* **Standardized African Site Enumeration System**.

satellite DNA Satellite DNA comprises large arrays of **tandemly repeated sequences of DNA** that are the primary components of constitutive heterochromatin. This type of DNA does

not undergo **transcription** (i.e., its message does not get converted into an RNA version) and it is commonly found at the centromeres and telomeres (i.e., the ends) of chromosomes. The composition of the bases in satellite DNA is dictated by the composition of the tandemly repeated units (e.g., there may be a preponderance of As or Cs) and thus it may differ from the average base composition of the rest of the genome.

satellite imagery The traditional ways of identifying potential hominin fossil sites are to use conventional geological maps, or to comb the records of local geological or natural history societies for records of fossil finds by amateurs. When aerial photographs were available (these were flown for military or some other nonpaleontological purpose, or they were commissioned by research groups) they could also be used to locate possible sites. However, the availability of satellite images (e.g., NASA's Advanced Spaceborne Thermal Emission and Reflection radiometer, ASTER, <http://asterweb.jpl.nasa.gov>; Google Earth, <http://earth.google.com>) means that these images can now be used to locate previously unrecognized locations whose geological structures and reflectance match those of existing hominin fossil sites. The first time satellite imagery was used on a large scale to locate sites was as part of the systematic inventory of paleontological and archeological sites in Ethiopia in the 1980s (Asfaw et al. 1990). This resulted in the identification of productive new localities such as **Aramis, Bouri, Fejej, Kesem-Kebena, and Konso-Gardula**. *See also* **Paleoanthropological Inventory of Ethiopia**.

savanna (Taino *zabana*=grassland) The inclusive term savanna covers a large number of African biomes including **woodland, bushland, shrubland, and grassland**. Because of this, it has been suggested that the term is not helpful in discussions of early hominin habitats (e.g., Reed 2007). Savanna biomes are generally characterized as a landscape with grass and with either scattered trees or open canopy trees. Savannas tend to occur on land surfaces of little relief, the soils tend to be low in nutrients, they have distinct wet and dry seasons, poor vertical structure root system and extensive horizontal structure root system, and they are often associated with precipitation ranging between 500 and 2000 mm per year. The current evidence suggests that what are claimed to be the

earliest hominins are found in a range of "savanna" biomes, ranging from closed woodlands to open grasslands.

"savanna" chimpanzees A term used to describe chimpanzees living in habitats where the annual rainfall is around 1000 mm or less and where the dominant ground cover is tropical (i.e., C₄) grass (Moore 1992). These mosaic environments vary from wooded grassland to miombo (i.e., *Brachystegia*-dominated) woodland. Moore and others claim that chimpanzees at "savanna" sites such as Mt Assirik in Senegal, and at Kasakati and Ugalla in Tanzania, make useful behavioral models for the most recent (i.e., last) common ancestor of the hominin and panin clades (Moore 1996). Preutz and Bertolani (2007) reported that savanna chimpanzees from Fongoli, Senegal, were observed to fashion pointed wooden sticks using up to five steps, and then use them to extract prosimians from hollow tree trunks.

SB Abbreviation of Sendangbusik that is used as a prefix for fossils recovered from that site. It is also an abbreviation used to refer to the Stillbay industry. *See also* Sendangbusik; Stillbay.

SB 8103 Site Sendangbusik. Locality The base of an outcrop of the Bapang Formation near the village of Sendangbusik. Surface/in situ Surface. Date of discovery 1981. Finder Mr Djoko, a local villager. Unit N/A. Horizon N/A. Bed/member N/A. Formation Bapang Formation. Group N/A. Nearest overlying dated horizon Middle Tuff, Bapang Formation. Nearest underlying dated horizon Lower Tuff, Bapang Formation. Geological age c.1.02–1.51 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Moderately mineralized fragmentary right side of the mandibular corpus together with the well-preserved crowns of P₄–M₃. Announcement Aziz 1981. Initial description Aziz 1981. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description Kaifu et al. 2005a. Initial taxonomic allocation "*Pithecanthropus*" (Aziz 1981). Taxonomic revisions *Homo erectus* (Aziz et al. 1994). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The SB 8103 mandible is consistent with the proposition that later *H. erectus* from Java underwent dento-gnathic size reduction (Kaifu et al. 2005b). Location of

original Geological Research and Development Center, Bandung, Indonesia.

scaling (L. *scalae*=ladder) The relationship between a variable and size (however it is defined). Scaling subsumes **isometry** (no change in a variable with changes in size) and **allometry** (changes in a variable accompanying changes in size). For example, brain size scales with negative allometry relative to body mass. Thus, although larger-bodied taxa generally have larger brains than smaller-bodied taxa, because their brain size increases at a slower rate than their body mass, their brains are *relatively smaller* when scaled to body mass than those of smaller taxa. Scaling relationships are typically examined between species as interspecific allometry, within species as intraspecific allometry, or in a growth series as ontogenetic allometry. The scaling relationship may differ in all of these approaches; thus these different sorts of scaling should not be conflated, or confused, with one another. Scaling relationships can also be used for functional analysis, and may reflect functional equivalence or **adaptation** (Fleagle 1985). Functional equivalence refers to underlying structural relationships between a variable and size. For example, long bones must be wider in large taxa to maintain the same strength relationship relative to body size, because mass is a function of the volume (i.e., length cubed) of an organism whereas bone strength is a function of the cross-sectional area (i.e., length squared). Thus, a species that is twice the body length of another (geometrically similar) species may have eight times (2³) the mass, and would need bones with greater cross-sectional area than expected by isometry (twice the width of the small species) to maintain the functionally equivalent relationship. Often, however, scaling relationships do not reflect functional equivalence and may instead describe differences in adaptations at different sizes. For example, large primates tend to have relatively long forelimbs and short hindlimbs (a high **intermembral index**) compared to small primates. This does not reflect functional equivalence, but rather the different strategies large and small primates have taken to traverse gaps between trees during travel. Small primates tend to use their hindlimbs to leap across gaps, whereas large primates tend to use their forelimbs to reach and clamber across gaps. *See also* allometry.

scaphoid-os centrale fusion Modern humans and African apes share fusion of two wrist

bones, the scaphoid and the os centrale. This condition is not typically found in most other primates, including the Asian apes. Scaphoid-os centrale fusion is considered by some as a stabilizing adaptation to knuckle-walking locomotion and evidence that modern human bipedalism may have passed through a knuckle-walking phase (Richmond et al. 2001). Fusion of these two bones occurs early in development (e.g., *in utero*) in modern humans and African apes (Kivell and Begun 2007). In contrast, fusion in orangutans and other monkeys is rare and if it does occur, it is usually during adulthood. The only other primates to show consistent fusion of these two bones are a few species of vertical-clinging and leaping strepsirrhines (e.g., *Lepilemur*, *Indri*) and the suspensory subfossil lemur *Babakotia*. The highly suspensory subfossil lemur *Palaeopropithecus* displays fusion in roughly half of the specimens. Because regular scaphoid-os centrale fusion is found only in two primate lineages (Hominoidea and Lemuroidea) and it is associated with a variety of different positional behaviors, some consider its functional significance to be unclear (Kivell and Begun 2007).

scapula, evolution in hominins The scapula, which is a complex, flat bone that develops from multiple ossification centers, lies against the dorsolateral portion of the ribcage, spanning ribs 1–7 in modern humans. The modern human glenohumeral joint faces laterally, whereas the joints of the great apes are situated more superiorly, producing a permanent “shrugged” shoulder appearance that provides strength and stability for the arm when raised above the head, as in suspensory climbing behaviors. Modern humans have a medio-laterally relatively broad scapula; *Gorilla* and *Pongo* approach the modern human condition, while the scapulae of *Pan* and *Hylobates* are narrower (Shea 1986, Green 2010). The relative size and shape of the dorsal scapula fossae also set modern humans apart from the great apes. Modern humans have the relatively tallest infraspinous region, but it is also relatively narrow mediolaterally. In contrast, *Gorilla*, *Pan*, and *Hylobates* all have superoinferiorly short and relatively wider infraspinous fossae; their supraspinous fossae are broader than those of modern humans. *Pongo* has an ape-like infraspinous fossa, but it is unique in having a narrower supraspinous fossa than modern humans (Young 2008, Green 2010). These differences in the proportions

of the dorsal scapula fossae are reflected in the obliquity of the scapula spine. Most apes have a markedly oblique scapula spine, with *Hylobates* the most oblique (its spine is nearly parallel to the axillary border) whereas modern humans have a more transversely oriented spine. Modern humans are unique in having an infraspinous region that is shaped like a right-angled triangle, with the angle between the spine and medial border approaching 90°; this angle is significantly more obtuse in other hominoid taxa (Green 2010). The hominin scapula fossil record is sparse and most of the specimens are fragmentary; this is not unexpected given that the scapula blade can be so thin as to be nearly transparent. Most of the preserved scapulae consist primarily of glenoid fragments with more or less of the scapula spine and axillary border attached. All the scapula specimens attributed to *Australopithecus* (i.e., A.L. 288-1, Sts 7, Stw 162, and DIK-1-1) display the ape-like condition of a relatively cranially oriented glenohumeral joint, while KNM-WT 15000 has a more laterally facing joint (Vrba 1979, Stern and Susman 1983, Alemseged et al. 2006, Green 2010). The functional relevance of the cranial orientation of the very small A.L. 288-1 individual has been dismissed by some as a consequence of allometry (Inouye and Shea, 1997), but the larger size of Sts 7 and Stw 162, which have cranially oriented joints, does not support this explanation. Furthermore, the diminutive *H. floresiensis* scapula specimen (LB6/4) displays a laterally oriented glenohumeral joint, despite it being roughly the same size as A.L. 288-1 (Larson 2007, Larson et al. 2007). The Dikika infant (DIK-1-1) is the first archaic hominin scapula to preserve most of the blade of the scapula. It has an obliquely oriented scapula spine like modern apes and a dorsal scapula fossa configuration that is intermediate between extant apes and modern humans (Alemseged et al. 2006, Green 2010). This is in contrast to KNM-WT 15000, which in many respects is “hyper-human” (Larson 2007, Green 2010). Two other relatively well-preserved archaic hominin scapulae are the adult female scapula (MH2) from Malapa in South Africa and the KSD-VP-1/1g specimen from Woranso-Mille, Ethiopia. The former specimen was described as possessing a cranially oriented shoulder joint (Berger et al. 2010), and the latter specimen has a narrow scapula blade relative to modern humans, and is reported to have a more transversely oriented, modern human-like scapula spine (Haile-Selassie et al., 2010), but it was not clear how the authors took into account the preservation of the spine, which was

described as being bent post-mortem. The supraspinous region in KSD-VP-1/1g is not preserved, thus limiting what can be said about the relative size of the dorsal scapula fossae. *See also proximal humerus, evolution in hominins.*

scavenger *See scavenging.*

scavenging (ME *skawager*=a collector of tolls, from the OF *escauper*=to inspect; thus, someone who lives off another) Scavenging is the acquisition of meat or marrow from the carcasses of animals that were killed by predators, or from an animal that died due to other natural causes. Perhaps the best-known contemporary scavengers are vultures, although some carnivores that primarily hunt, such as lions or spotted hyenas, are known to scavenge on an opportunistic basis (i.e., **passive scavenging**) or engage in **confrontational scavenging**. Modern human **hunter-gatherer** groups obtain the majority of meat through **hunting**, although some forms of scavenging are occasionally practiced. The extent to which early hominins hunted versus scavenged is of particular interest, since a **carcass acquisition strategy** based primarily on scavenging is considered to be outside the range of **modern human behavior** (i.e., there are no extant modern human groups that use scavenging as a major component of their subsistence strategy).

Schepers, G. (Gerritt) W.H. *See* Robert Broom; Sterkfontein.

schlepp effect (Yidd. *shlepn*=to drag or haul) A model of carcass transport behavior predicated on the assumption that **hunter-gatherers** are more likely to transport appendicular rather than axial skeletal parts from kill sites to base camps, and that the number of elements transported varies inversely with carcass size and/or transport distance. According to the schlepp effect, sites that are dominated by appendicular elements represent residential sites and sites that are dominated by axial elements represent kill or primary butchery sites. For example, a preponderance of appendicular elements at **FLK-Zinjanthropus** has been interpreted as evidence that hominins had access to fully fleshed animal carcasses and preferentially transported limbs to the site while discarding vertebrae, pelves, and ribs at the point of acquisition. Ethnographic support for the schlepp effect remains mixed, particularly as it relates to the preferential transport of appendicular

skeletal parts. Experimental observations also indicate that **carnivore ravaging** is capable of mimicking the schlepp effect.

Schmerling, Philippe-Charles (1790 or 1791–1836) Philippe-Charles Schmerling was born in Delft, The Netherlands, and began studying medicine at the University of Leiden, The Netherlands, but completed his studies at the University of Liège, Belgium, in 1825. Schmerling began excavating and collecting fossils in 1829 after seeing fossil bones in a patient's home. He focused on caves along the Meuse River and at one of the caves in the **Engis** complex, Schmerling found flint implements in deposits containing the bones of hyenas, rhinoceros, and large carnivores. In a different cave in the Engis complex he found two hominin crania and some postcranial bones. Almost all scientists in the early 19thC were convinced that the diluvium was deposited very long ago, and that the extinct mammals found in the diluvium therefore were also of great antiquity. Moreover, it was agreed that modern humans certainly could not have existed at the time of the extinct mammals, especially since it was accepted dogma that human history was very short in comparison with the history of the Earth. The few discoveries of human artifacts or bones in association with extinct mammals had been explained as relatively recent intrusive burials that accidentally mixed modern human remains with those of much older animal fossils. But Schmerling found more examples of flint artifacts among extinct mammal fossils at Engihoul, Chokier, and Fond-de-Forêt, and he began to suspect that these were not accidental associations, for there was no evidence that the soil had been disturbed by a burial and the nature of the cave deposits strongly indicated that the extinct mammals and the human artifacts and remains had been deposited at the same time and by the same processes. These discoveries convinced Schmerling that human ancestors were present on the Earth at a geologically remote period in time. Schmerling recorded his discoveries and his interpretation of them in *Recherches sur les ossements fossils découverts dans les caverns de la province de Liège* [*Researches on the Fossil Bones Discovered in the Caverns of the Province of Liège*] published in two volumes in 1833 and 1834. While few scientists were willing to accept Schmerling's interpretation of his discoveries as evidence for the great antiquity of modern humans, it did contribute to a growing debate during the 1830s and 1840s over similar evidence discovered elsewhere

in Europe that eventually led in the 1860s to the acceptance by geologists of the coexistence of humans and extinct mammals. At the end of the century, and after the discovery of the first recognized *Homo neanderthalensis* remains in Germany in 1856, one of the Engis crania was recognized as a juvenile *Homo neanderthalensis*. Unfortunately Schmerling died before the ideas he espoused gained wide acceptance.

Schöningen (Location 52°08'N, 10°59'E, Germany; etym. named after the nearby town) History and general description Pleistocene sediments exposed in a brown coal mine have been monitored and excavated by archeologists since 1983. In 1995 several well-preserved wooden spears were recovered, and at the present time these are the oldest-known organic artifacts. Temporal span and how dated? Correlation to glacial cycles has suggested a range of Elster-Saale glacial periods [i.e., approximately **Oxygen Isotope Stages** (OISs) 12–10]. The wooden spears come from a layer at the middle of the sequence, during interglacial OIS stage 11, which dates to *c.*400 ka. Hominins found at site None. Archeological evidence found at site Two kinds of wooden spears were recovered. The older spears from OIS 11 are merely pointed, but were found in close association with flint tools and numerous horse bones that show signs of butchery. The more recent spears, from approximately OIS 10 show grooves that might have been slots for flint spearheads. These spears are the oldest known evidence for both spears and composite tools. Key references: Geology, dating, and paleoenvironment Thieme 1997; Hominins N/A; Archeology Thieme 1997.

Schwalbe, Gustav Albert (1844–1916)

Gustav Schwalbe was born in Quedlinburg, Germany, and received his MD from the University of Berlin in 1866, having studied also in Zürich and Bonn. Schwalbe passed his medical boards in 1867, and he turned immediately to research. He first worked under his major professor in Bonn, where he made his first significant contribution to science, the biological identification of taste buds. Schwalbe also held academic posts in Amsterdam (1868–70), Halle (1870), Freiburg (1871), Leipzig (1871–3), Jena (1873–81), Königsburg

(1881–3), and finally Strasbourg; his appointment at Jena was his first as *ordentlich* (full) Professor of Anatomy. Schwalbe's early research focused on a variety of topics in human anatomy and physiology. In addition to his discovery of taste buds, Schwalbe made significant contributions to the understanding of the lymphatic system, the central nervous system, and additional sense organs. He published an influential textbook on neurology in 1881 and another on sense organs published in sections between 1883 and 1887. A characteristic feature of all Schwalbe's work was his insistence on precision in methodology and comparative analysis. By the late 1880s he had begun to focus more of his attention to the discipline of anthropology, which in the European tradition was limited to biological or physical anthropology. He stressed that accurate comparative anatomy of mammals, and particularly of the order Primates, was a necessary background to understanding human biology. Schwalbe began his anthropological work by focusing on various aspects of living human "races" as he felt that such studies were crucial to unraveling human evolutionary history. Schwalbe recognized that physical anthropology was in need of improved theoretical focus and methodological precision, so in 1899 he founded the journal *Zeitschrift für Morphologie und Anthropologie* with the goal of applying detailed comparative and developmental studies to the understanding of human evolution. He developed a methodology for comparative analysis of the emerging human fossil record which he referred to as *Formanalyse* (the analysis of form) and began to apply this precise, metrical technique to major questions then prominent in human evolution. Using this approach, Schwalbe correctly recognized that the so-called "Canstatt race" was made up of a mixture of *Homo neanderthalensis* individuals and a group of late Diluvial (Pleistocene) specimens. Similarly, Schwalbe held that his analysis of form clearly established the early Diluvial (Pleistocene) Neanderthals as a distinct species of humans, which he named *Homo primigenius*, as opposed to simply a primitive "race" as many other scholars claimed. From this basis, he argued strongly against Rudolf Virchow's interpretation that the original Neanderthal 1 specimen represented a pathological individual from a recent human race. By applying his analysis of form to extant species, Schwalbe concluded that anatomical comparisons supported a strong phylogenetic

connection between great apes and modern humans. A devotee of both Charles Darwin and Ernst Haeckel, Schwalbe argued that both Neanderthals (for Schwalbe *H. primigenius*) and Eugène Dubois' original *Pithecanthropus erectus* from Java represented stages that bridged the gap between modern humans and apes. Because, based on his analysis, the latter had a smaller brain and a more ape-like form, Schwalbe considered it to be a more primitive stage than his *H. primigenius*. Further, Schwalbe argued that early modern humans (e.g., the "late Diluvial" members of the "Cannstatt race") provided an additional link between his *H. primigenius* (i.e., Neanderthals) and living people. Because of this linear "stage" view, Schwalbe is widely recognized as one of the founders of the unilineal interpretation of human evolutionary history. True to this perspective, Schwalbe denied the existence of a pre-sapiens lineage and presented detailed objections to specimens (e.g. Galley Hill, Ipswich, and Piltown) used to argue for such a lineage in early 20thC Europe and elsewhere (e.g., Ameghino's claims for Pliocene humans in Argentina). It was Aleš Hrdlička's misunderstanding of Schwalbe's reaction to Marcellin Boule's analysis of La Chapelle-aux-Saints that led him to label Schwalbe a pre-sapiens hypothesis supporter. This likely stemmed from confusion surrounding Schwalbe's view that the known *Pithecanthropus* and Neanderthal specimens might not represent the exact ancestral populations but could be side branches of the ancestral modern human lineage. Schwalbe felt that regardless of whether the known fossils were actually ancestral to recent humans, those ancestors would have had to be essentially identical to the known *Pithecanthropus* and Neanderthal specimens; he did not retreat from a unilineal view of human evolution as has been claimed. Schwalbe's focus from 1899 on was almost entirely on topics related to physical anthropology. Among his most influential works are: 'Studien über *Pithecanthropus erectus* Dubois' (*Zeitschrift für Morphologie und Anthropologie* 1: 1–240; 1899), 'Der Neanderthalschädel' (*Bonner Jahrbuch* 106: 1–72; 1901), 'Die Vorgeschichte des Menschen' (Braunschweig, Vieweg; 1904), 'Studien zur Vorgeschichte des Menschen' (Stuttgart, Schweizerbartsche Buchhandlung; 1906), and 'Kritische Besprechung von Boule's Werk: "L'homme fossile de la Chapelle-aux-Saints" mit eigenen Untersuchungen' (*Zeitschrift für Morphologie und Anthropologie* 16: 527–610; 1914), and his final (posthumous)

work 'Die Abstammung des Menschen und die ältesten Menschenformen' (In: P. Hinneburg, ed. *Die Kultur der Gegenwart*. Leipzig/Berlin: Teubner; 1923). Schwalbe's one paper in English was 'The descent of man' (In: A.C. Stewart, ed. *Darwin and Modern Science*. London: Cambridge University Press; 1910). Schwalbe served as University Rector (1893–4) at Strasbourg and as chairman of the medical examination commission; he retired from all his Strasbourg posts in 1914.

sciurids The informal name for the suborder of the **Rodentia** that includes the squirrels. *See* **Rodentia**.

Scladina (Location 50°29'9.64"N, 5°1'36.27"E, Belgium; etym. named the Grotte Scladina or the Cave of Scladina after the nearby village of Sclayn) History and general description A site in a limestone cave in the north wall of the Ri de Pontainne Valley, near the town of Andenne, in Namur Province, Belgium. Intensive excavations have been conducted at the site since 1978, but it was not until 1993 that a **Late Pleistocene** hominin, subsequently assigned to *Homo neanderthalensis*, was recovered *in situ*. Mitochondrial DNA extracted from a molar formed part of the evidence that suggested a high level of genetic diversity among Neanderthals. Temporal span and how dated? The dates suggest an age for the hominins of *c.*100 ka. Hominins found at site Both sides of the corpus of a *c.*8-year-old juvenile mandible with both right and left M₁₋₂ and the right M₃ in its crypt, a right maxillary fragment with dm¹⁻², plus associated isolated teeth. Key references: Geology, dating, and paleoenvironment Toussaint et al. 1998, Toussaint and Pirson 2006; Hominins Otte et al. 1993, Smith et al. 2007.

Sclayn *See* **Scladina**.

sclerotome (Gk *skleros*=hard and *temnein*=to cut or slice) Sclerotomes are one of the expressions of the segmental nature of the body. They develop from somites and all but the first four or so sclerotomes (which are incorporated into the basicranium) contribute to the development of the vertebrae, the intervertebral discs, and ribs. Each vertebra is formed from the caudal half of its equivalent sclerotome, plus the cranial half of the sclerotome below it (e.g., the C4 vertebra is formed from the caudal half of the C4 sclerotome and the cranial half the C5 sclerotome). *See also* **vertebral number**.

SCLF Acronym for single-crystal laser fusion. *See argon-argon dating.*

scraper A term used to describe stone tools with **retouched** edges that meet at an angle of approximately 60–90°. The function of scrapers has been inferred by ethnographic analogy, actualistic studies, and subsequent use-wear analysis. Although scrapers are reported from **Oldowan** sites in Africa, they are particularly common at **Middle Paleolithic** sites in Western Europe (Bordes 1961a, Debénath and Dibble 1994).

SE Prefix used for fossils recovered from the Sterkfontein “Extension Site.” *See Sterkfontein.*

Sea Harvest (Location 33°01'23"S, 17°57'0"E, Cape Province, South Africa; etym. unknown) History and general description This site consists of a series of fossil-rich pockets of sandy sediment overlain with sand and shell deposits and **Middle Stone Age** (or MSA) shell **middens** on the north side of Saldanha Bay. Fossil collection was begun by Brett Hendy in 1969, and has been continued by Graham Avery and Richard **Klein**, and it was they who recovered the Sea Harvest hominins. Temporal span and how dated? The archeological, biochronological, and geomorphological evidence are consistent with the infinite (>40 ka) conventional **radiocarbon dating** on associated ostrich egg shell, and suggest the site spans 128–40 ka. Hominins found at site A manual distal phalanx and a left P⁴. Archeological evidence found at site None in direct association with the hominins, but MSA artifacts occur in midden deposits in slightly higher strata. The hominin fossils and many of the other vertebrates likely derive from hyena dens that were intrusive into underlying sediments. Key references: Geology, dating, and paleoenvironment Hendy 1984, Fairall et al. 1976, Butzer 1984, 2004; Hominins Grine and Klein 1993; Archeology Volman 1978, Butzer 2004.

sea surface temperature (or SST) This climate indicator can be reconstructed from a variety of paleoclimate proxies including species assemblages, oxygen isotopes, Mg/Ca, alkenones, and TEX86. SSTs vary widely between –1.8°C (the freezing point of seawater) in polar waters to more than 30°C in some **tropical** waters in restricted basins (e.g., the Gulf of Aden). SSTs generally decrease from the tropics to the poles,

although in the tropical Pacific a strong longitudinal temperature gradient occurs and is associated with the **El Niño Southern Oscillation** phenomenon. SST reconstructions are available for many marine sediment sites; however, the most complete spatial coverage has been achieved for **Last Glacial Maximum** comparison projects (e.g., CLIMAP, which used oxygen isotopes, and most recently MARGO, which used multiple SST proxies).

seasonality Regular changes in weather pattern (in both tropical and temperate regions) and day length (in temperate regions) that occur within an annual cycle. These changes are driven by changes in the **orbital geometry** of the Earth that varies the amount of sunlight reaching the Earth's surface (i.e., **insolation**) received during the year. At higher latitudes, weather is determined primarily by temperature, because the tilt of the Earth's axis means that the intensity of the insolation varies throughout the year. Thus, there are warm (summer) and cool (winter) seasons. In the tropics, rainfall is an important determinant of weather with wet and dry seasons within the annual cycle. Seasonality influences habitat and the availability of food. Primates cope with seasonal shifts in resources and habitat quality by altering their behavior (e.g., by switching to **fall-back foods**). Seasonality was almost certainly an important influence on evolution within the hominin clade, and it likewise probably affected hominin behavior. It is also possible that some characteristics of modern humans, such as the propensity to gain body fat very quickly, was an adaptation to highly seasonal environments in which it was beneficial to gain weight during seasons of plenty to provide a buffer in times of scarcity. Modern humans use an array of cultural tools to buffer against seasonality (e.g., food storage), thus allowing them to inhabit regions normally inaccessible to primates. Initially, the transition within *Homo* to greater dependence on meat is likely to have helped hominins exploit high latitudes, as meat is available all year round whereas many plant foods are only available seasonally.

seasons *See seasonality.*

secondarily altricial *See altricial.*

secondary cartilaginous joints *See joint.*

secondary centers of ossification *See ossification.*

secondary dentine *See* dentine.

secondary homonymy This refers to the circumstance when identical species/subspecies names that were initially used in different genera were to later be placed in the same genus (e.g., if the two original genera are combined). *See also* homonymy.

secondary sexual characteristics Physical characteristics that are associated with reproductive maturation in males and females of sexually dimorphic species, and are differentiated from primary sexual characteristics (e.g., gonads). They include differences in skin, feather, and fur coloration, distribution and thickness of hair, body size differences, differences in the size of teeth, tusks, and antlers, musculature, fat deposition, and limb proportions. The development of secondary sexual characteristics may occur at different rates, and depending on several factors (e.g., health, dominance rank) they may be more or less developed in different individuals within a population. Since the appearance of these traits is often dependent on circulating levels of gonadal steroids, inter-individual differences in hormone levels probably also explain variation in manifestations of these features. Secondary sexual characteristics are hypothesized to have evolved through mate choice and intrasexual competition. Several traits have been described as secondary sexual characteristics in modern humans. For males, these include growth of facial hair, increased muscle mass and bone robusticity, broad shoulders relative to hips, and deepening voice. In females, some secondary sexual characteristics include enlarged breasts, lower waist/hip ratio, longer upper limbs, and more subcutaneous fat. In both sexes, growth of body hair (including axillary and pubic hair) and increased secretions of sebaceous and sweat glands are considered to be secondary sexual characteristics. The Tanner scale is regularly employed by medical professionals to assess the degree of maturity of boys and girls, based on the development of the genitalia, axillary and pubic hair, and breasts. However, the relationship of the stages used in assessment to chronological age varies widely. The fossil record is mute about the soft-tissue aspects of important topics such as this.

section Geology A term for the place where strata are exposed. They may have been exposed naturally or researchers may have deliberately dug

a trench to expose the strata. Morphology It refers to the surface of a bone or tooth exposed by either a natural break or a deliberate saw cut. Sections provide information about the internal structure of bones and teeth. *See also* cross-section.

sectorial (L. *secare*=to cut) In those primates in which the upper canine and the anterior lower premolar form a honing complex, the latter tooth develops a “blade-like” edge such that it is called a sectorial premolar. The loss of a honing complex and therefore also the sectorial premolar is assumed to be related to a shift in behavior where males do not need to fight with their teeth to get access to mates, and thus the presence or absence of this feature in early hominins is much discussed. *See also* sexual selection.

secular trend (L. *seculum*=generation) The use of this term in physical anthropology is usually in reference to the marked changes that have occurred in the growth and development of certain modern human populations over the past 100–200 years. “Secular” refers to the fact that these changes have occurred over successive periods of time. Specifically, there have been significant changes in height, with children especially from developed countries being of taller stature at every age from infancy onward. There have also been documented changes towards increased hand, foot, and facial dimensions. Similarly, girls from several countries have demonstrated a secular trend in earlier age at menarche (first menstrual period), with a decrease in this age by 1–3 years. It is important to note that while this trend has been towards increased stature, or earlier age at menarche, in many populations, so-called “reverse secular trends” have also been documented in some populations (e.g., size has decreased). While the mechanistic cause of these secular trends remains unclear, it has been hypothesized that the trends toward increased height and earlier ages at maturation are due to improved nutrition, hygiene, and decreased disease burden. A recent hypothesis explains these trends as a return to the ancestral age at maturation and exploitation of full potential for size, which has been altered to this point by nutritional inadequacy and chronic infections. *See also* stature.

sedge The common name for a family of monocotyledonous flowering plants, the Cyperaceae,

which superficially resemble grasses or rushes (Govaerts et al. 2007). Many sedges are found in wetlands and they belong to a group of plants, including warm-season grasses, some herbs, and a variety of shrubs which use a photosynthetic system that initially fixes carbon dioxide in molecules containing four carbon atoms; thus they are **C₄ plants**. Some researchers have suggested that sedges may have been a source of forage for early hominins. *See also C₃ and C₄; C₄ plants.*

Sedia del Diavolo (Location 41°57'N, 12°32'E, Italy; etym. It. the devil's chair) History and general description Small quarry in the hills overlooking the Aniene river in the suburbs of Rome. Original surveying work was done in 1882 by R. Meli, but excavation did not begin until 1956 under A. Blanc. Level 4 contained the hominin and archeological remains. Increasing urbanization in the second half of the 20thC has made further study of the relevant deposits impossible. Temporal span and how dated? **Biostratigraphy** suggests the site formed during the Riss glacial (c.240–130 ka). Hominins found at site Two specimens, a femoral diaphysis and a right II metatarsal, were recovered, but they have not been assigned to any taxon. The metatarsal shows traces of microtrauma that occurred during the individual's life. Archeological evidence found at site Fifteen lithic implements were recovered from level 4, most of which are side scrapers. This assemblage has been defined as pre-Mousterian. Key references: Geology, dating, and paleoenvironment Blanc 1956; Hominins Mallegni 1986; Archeology Mussi 2001.

sediment (L. *sedimentum*=the act of settling) Material that settles in the bottom of a liquid. The rocks in which most hominin fossils are preserved are rocks that have formed from sediment. The sediment can be coarse, like gravel, or finer, like sand, or much finer, like silt.

sedimentary rock Rocks that are formed from **sediment**. There are two categories of sedimentary rock. Clastic sedimentary rocks are formed from the fragments of other rocks transported from their source and deposited in water. The second category includes all the rocks formed by precipitation. For example, **limestone** is formed by the precipitation of calcium carbonate that comes from marine organisms.

seed-eating hypothesis One of several hypotheses put forward to explain the origin of upright posture and eventually bipedal locomotion within the hominin clade. Proposed by Clifford Jolly (1970), the seed-eating hypothesis has had a profound influence on paleoanthropology on many levels. At the time it was proposed it presented a formidable challenge to the prevailing wisdom of the time that bipedalism had evolved in hominins in association with tool use. It also provided a compelling synthesis of careful anatomical and ecological observations that served as a model for other workers, and it led to the consensus that small hard objects were a critical component of the diet of the **australopiths** (i.e., archaic hominins). The core of the seed-eating hypothesis rests on the observation that australopiths apparently share many derived characteristics with gelada baboons (*Theropithecus*). Such inferred shared traits include those related to manual dexterity, efficient and powerful **mastication**, a reduced reliance on incision, and an upright trunk (employed by *Theropithecus* while sitting and eating). These shared features were evidently not inherited from the most recent common ancestor of these taxa, but rather represent examples of **convergent evolution** in hominins and **papionins**. Jolly's (1970) insight was to suggest functional and/or ecological explanations for these **homoplasies**. He noted that the suite of features seen in gelada baboons is related to seed-eating, and he suggested that a similar diet may have spurred the evolution of those features in the hominin clade. However, because of their different evolutionary histories (for unlike gelada baboons, which are descended from quadrupedal ancestors, hominins were more likely to have descended from suspensory apes) the routine adoption of truncal erectness in proto-hominins apparently led eventually to the evolution of an upright posture and bipedalism. Jolly (1970) predicted that the earliest hominins evolved in **edaphic** (wet) grasslands in which grain resources would have been plentiful, but most recent fossil discoveries suggest that the earliest hominins lived in wooded or mosaic environments (Pickford and Senut 2001, Vignaud et al. 2002, WoldeGabriel et al. 2004), so a diet based heavily on grain seeds seems unlikely. However, the hypothesized link between diet and bipedalism remains relevant insofar as some researchers have suggested that the dental morphology of the earliest known bipeds may indicate a novel diet (e.g., Haile-Selassie et al. 2004a). *See also bipedal locomotion; tool-use hypothesis.*

segregation A process that occurs during anaphase I of **meiosis** (i.e., during gametogenesis). During segregation, pairs of **homologous chromosomes** are separated, with one member of each pair going to the opposite pole and eventually contributing to a different haploid daughter gamete.

segregational distortion This term describes the situation when one particular allele of a gene is present in more than half of the gametes (NB: during a normal meiosis, an allele should be present in half of all gametes).

selection *See natural selection.*

selection coefficient A measure of the fitness reduction of a given **phenotype** relative to another fitter phenotype. The selection coefficient is usually denoted by s , and it is calculated as the proportionate difference in offspring number of a given phenotype relative to another more favorable phenotype. An s value of 0 represents neutrality of the given phenotype relative to the other phenotype (i.e., no selection against the phenotype), whereas an s value of 1 equates to a total lack of surviving offspring or to complete lethality. The selection coefficient is equivalent to the **Darwinian fitness** of a phenotype.

selective sweep The relatively rapid **fixation** (i.e., an increase to an incidence of 100% in a given population) of an **allele** and all the alleles linked to it; the latter phenomenon is known as **genetic hitchhiking**. When a selective sweep occurs, nucleotide diversity is reduced in the region around the selected allele. This property of reduced diversity is useful for identifying regions of the genome that have been recently subjected to **directional selection**. For example, in modern Europeans there is evidence of a selective sweep around the lactase gene because of the spread of an allele conferring lactose tolerance into adulthood (Bersaglieri et al. 2004)

Selenka Collection *See Zoologische Staatssammlung München.*

selfish DNA DNA that copies itself and inserts itself within a genome, but does not contribute to the reproductive success of the host. Endogenous retroviruses and transposable elements such as **SINEs** or **LINEs** are examples of selfish DNA.

sellion The deepest point on the sagittal contour of the infraglabellar area of the upper face.

semantic memory (Gk *semantikos* = meaning) The form of memory that relates to knowledge of everyday facts or concepts. Semantic memory is declarative and as such it can be explicitly articulated. In contrast to episodic memory, semantic memory is impersonal and it is detached from autobiographical knowledge or experiences. For example, our knowledge (or memory) of everyday objects such as paper, computer, and banana, as well as concepts such as planet, animal, and President are all forms of semantic memory. Semantic memory is not uniquely human. Many authors have reported important homologies in the semantic memories of birds and primates, including modern humans (Terrace 2005, Wright 2007). However, there is evidence to suggest that semantic memory systems may be shaped by selection to serve unique ecological demands such as seed caching in birds (Sherry and Schacter 1987).

semicircular canals The semicircular canals of the ear form one of the three main subdivisions of the bony and membranous labyrinths. The three canals each comprise two-thirds of a circle; the separate lateral canal is in the horizontal plane, whereas the conjoined anterior and posterior canals are in the vertical plane. The anterior and posterior canals are at right angles to each other and each is oriented approximately 45° to the sagittal plane. They are arranged so that the anterior canal on one side and the posterior on the opposite side are “coplanar” (i.e., the long axis of the anterior canal on one side is parallel to the long axis of the posterior canal on the opposite side). The lateral membranous semicircular canal has a swelling, or ampulla, at both ends; the anterior and posterior each have a single swelling at their free ends. Motion is detected by the relative movement that occurs between the hairs of the hair cells embedded in the walls of the part of the membranous labyrinth that lines the ampulla, and the endolymph that fills the membranous labyrinth. Perilymph separates the membranous semicircular canals from the bony labyrinth that encloses them. Spoor et al. (1994, 1996) showed that modern humans differed from all four of the living great apes in that the “arc sizes” of the two vertically oriented canals (i.e., the anterior and posterior) are larger (i.e., they are taller) than those of the great apes, whereas the “arc size” of the single, separate, lateral canal is smaller (i.e., it is narrower) than that of the great

apes. Thus far, investigations of the semicircular canals of fossil hominins suggest that the modern human-like semicircular canal morphology is first seen in crania such as KNM-ER 3733 assigned to early African *Homo erectus* or *Homo ergaster* (Spoor et al. 1994), but Hublin et al. (1996) claim that the vertical canals of *Homo neanderthalensis* are smaller than those of modern humans. It should be noted that Graf and Vidal (1995) are skeptical about the functional inferences that have been made on the basis of relatively small differences in the size and shape of the semicircular canals of modern humans and the great apes. *See also bony labyrinth; membranous labyrinth.*

semilandmarks The landmarks used in **geometric morphometrics** must be homologous across specimens (i.e., they must represent the same biological locations in every individual). However, for some regions and structures (e.g., cranial vault, tooth crowns) there are only a limited number of possible landmarks (e.g., suture intersections and cusp tips, respectively) and substantial amounts of morphology between the landmarks would be lost unless there was some other way of capturing it. Bookstein (1991) introduced the concept of semilandmarks (also called sliding landmarks) as a way of extending landmark-based statistics to smooth curves and surfaces. Semilandmarks were initially applied to 2D outlines (Bookstein 1997), but subsequently Gunz (2001, 2005) and Gunz et al. (2005) developed the algebra needed to capture curves and surfaces in 3D. The same number of semilandmarks is placed in roughly homologous locations on every specimen of the sample. What that number is depends on the complexity of the curves or surfaces to be captured and on the level of detail being investigated. These semilandmarks are then allowed to slide along the curves and surfaces so as to remove the effect of the arbitrary initial placement. The two main semilandmark algorithms differ in their optimization criteria: in one the bending energy of the **thin-plate spline interpolation** between each specimen and the sample mean shape is minimized and in the other algorithm the Procrustes distances are minimized. It is through the sliding algorithm that semilandmarks acquire their geometric “**homology**,” so that in the subsequent statistical analyses they can be treated as if they were formal landmarks. *See* Gunz et al. (2005, 2009b) for a more technical description and Gunz et al. (2009a), Skinner et al. (2009a, 2009b), and Neubauer et al. (2009) for

examples of the use of semilandmarks. *See also geometric morphometrics; landmark* (syn. sliding landmarks).

Senckenberg Forschungsinstitut und Naturmuseum

The institution now called the Senckenberg Forschungsinstitut und Naturmuseum was founded as the Senckenberg Natural History Society in 1817. It is named after Johann Christian Senckenberg, a Frankfurt physician who died in 1772 and whose endowment laid the foundation for the Natural History Society, the Anatomical Institute, and the University Library in Frankfurt, Germany. The present main building was opened 1907 and houses a research institute and a Natural History Museum. Today the Senckenberg Forschungsinstitut comprises a cluster of seven research institutions and museums in Germany. While a Professor of Anthropology at Johann Wolfgang Goethe University between 1928 and 1933, Franz **Weidenreich** prepared an exhibition outlining the stages of human evolution at the Senckenberg Natural History Museum. But Weidenreich’s book on race and his own Jewish background made it increasingly difficult to remain in Germany and he was dismissed from his position at Frankfurt in 1933. The close cooperation between the Johann Wolfgang Goethe University, Frankfurt University, and the Senckenberg Natural History Museum was renewed in the 1960s when the University re-established a center for palaeoanthropological research. In 1986 the Werner Reimers Foundation provided facilities for enable Ralph von **Koenigswald**, who had retired from the Chair of Palaeontology at the Rijksuniversiteit, to establish the Palaeoanthropology Department at the Senckenberg Natural History Museum. von Koenigswald brought with him the part of the **Sangiran** Collection that he collected after the Dutch Geological Survey in Java had stopped supporting his research. After von Koenigswald’s death in 1982 the Department was headed by Jens Franzen, followed in 2001 by Friedemann Schrenk. Hominin fossil collections The von Koenigswald Collection at the Senckenberg includes three fragmentary crania (**Sangiran 2, 3, and 4**), six mandibular fragments (**Sangiran 1a, 4, 5, 6a, 6b, and 6c**) and 52 isolated teeth (**Sangiran 7**). The von Koenigswald Collection includes the holotypes of *Pithecanthropus dubius*, *Meganthropus palaeojavanicus*, *Hemantropus peii*, *Sinanthropus officinalis*, *Gigantopithecus blacki*, and *Chinjipithecus atavus*. Comparative collections The Department of

Palaeoanthropology also houses a collection of around 280 skulls or crania of *Pan troglodytes verus* from Liberia. They were purchased by Hans Himmelheber from the Dan and Kran people in the “northeast region of the central province of Liberia” (Protsch and Eckhardt 1988, p. 13). All stages of ontogeny are represented in the collection, but some specimens are very severely damaged, including damage to the basicranium inflicted when the brain was removed. Contact department For the hominin fossils and the comparative collections contact the Department of Paleoanthropology. Contact person Birgit Denkel (e-mail bdenkel@senckenberg.de). Postal address Senckenberganlage 25, 60325 Frankfurt am Main, Germany. Website www.senckenberg.de. Tel +49 69 7542 1260. Fax +49 69 7542 1558.

Senckenberg Museum *See* Senckenberg Forschungsinstitut und Naturmuseum.

Sendangbusik (Location 7°20'S, 110°58'E, Indonesia; etym. named after a local village) History and general description In 1981 a hominin mandibular fragment was found on the surface at this site, which lies within the **Sangiran Dome**. The specimen was most likely derived from a stratum between the Lower and Middle Tuffs of the **Bapang Formation**. Temporal span and how dated? Trace element analysis of a bone sample drilled from the corpus, the degree of mineralization, the adhering sandstone matrix, and the color of the specimen are consistent with the proposed stratigraphic assignment. The most recent radiometric dating estimates of this deposit range between 1.24 and 1.51 Ma. Hominin found at site **SB 8103** is a fragment of the right side of the mandibular corpus preserving the crowns of P₄-M₂ and the distal root of M₃. It has been referred to *Homo erectus*. Archaeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Matsu'ura et al. 1995a, 1995b, Larick et al. 2001; Hominins Aziz et al. 1994, Kaifu et al. 2005a.

senescence The biological process of dysfunctional change with age in organisms. This is in contrast to the concept of “aging” in which objects, both biological and nonbiological, show the effects or characteristics of increasing age. Through the process of senescence, which is universal among sexually reproducing organisms, individuals become less proficient at maintaining homeostasis, and mortality rates increase due to

intrinsic causes. Several evolutionary theories have been proposed to explain senescence, which can occur at widely varying rates among individuals and between species. The senescent processes that occur in modern humans are not unique. However, due to a relatively extended life span and medical interventions, they may proceed somewhat more slowly. Similarly, patterns of biocultural evolution may provide selection for longer life spans and slower senescence in modern humans, due to contributions of older individuals to measures of inclusive fitness. *See also* **antagonistic pleiotropy theory; mutation accumulation hypothesis; grandmother hypothesis.**

senior synonym The name for a taxon that has historical priority. *See also* **synonymy.**

sensu lato (L. *sensu*=sense and *lato*=lax) A more inclusive, less restrictive, interpretation of a taxon (e.g., *Homo habilis sensu lato* includes both *Homo habilis sensu stricto* and *Homo rudolfensis*, and *Paranthropus boisei sensu lato* includes both *Paranthropus boisei sensu stricto* and *Paranthropus aethiopicus*).

sensu stricto (L. *sensu*=sense and *stricto*=strict) A more restrictive, less inclusive, interpretation of a taxon (e.g., *Homo habilis sensu stricto* does not include *Homo rudolfensis*, and *Paranthropus boisei sensu stricto* does not include *Paranthropus aethiopicus*).

Sergi, Giuseppe (1841–1936) Giuseppe Sergi was born in Messina, Sicily, and as a young man joined Giuseppe Garibaldi's military forces in their unsuccessful attempt to unify the Kingdom of Italy. After the end of the campaign, Sergi completed his studies at the University of Messina, where he studied comparative philology and philosophy, and at the University of Bologna. After completing his degree, Giuseppe Sergi became interested in anatomy, Charles Darwin's theory of evolution, and the racial anthropology of Cesare Lombroso. Giuseppe Sergi developed an early interest in human psychology in the 1870s and began to investigate it in relation to physiology, leading to the publication of *Elementi di psicologia* (*Elements of Psychology*; 1873–4). Sergi accepted a position as Professor of Anthropology at the University of Bologna in 1880 and played an important role in establishing anthropology as a science at the university. In 1884 Giuseppe Sergi left

Bologna to become Professor of Anthropology at the University of Rome. He continued to study psychology and anthropology there and in 1889 he established and directed the Laboratorio di Psicologia Sperimentale and founded the Società Romana di Antropologia (the Roman Society of Anthropology), which changed its name to the Istituto Italiano di Antropologia (the Italian Institute of Anthropology) in 1937. His scientific interests remained broad, encompassing psychology, anthropology, biology, and philosophy. In anthropology he shared his contemporaries' focus on racial classification and the use of craniometry. However, he opposed the use of the cephalic index and argued that the general cranial morphology of human skulls was a better means of classifying crania. Giuseppe Sergi wrote extensively on the question of human and primate evolution. Like some other prominent anthropologists and biologists, Sergi adopted a view of evolution where many phylogenetic lineages had evolved parallel to one another, sharing similar traits not because they shared a recent common ancestor but because similar traits could evolve in distinct lineages independently under similar conditions. Thus, in primate evolution, Sergi argued that from a distant unknown primate ancestor three primate groups emerged – Cercopithecidae, Simiidae, and Homiidae – each a lineage that developed independently from each other. He viewed human evolution in similar terms. In his book *Varietà umana: Principio e metodo di classificazione (Human Varieties: Principle and Method of Classification)*; 1893) Giuseppe Sergi suggested that the earliest Mediterranean Europeans derived from populations from the Horn of Africa and were therefore related to so-called Hamitic peoples. This was a controversial hypothesis, but it attracted some attention among anthropologists at the time. Equally controversial were the claims made in *Origine e diffusione della stirpe mediterranea* (1895; translated into English in 1901 as *The Mediterranean Race: a Study of the Origin of European Peoples*) where Sergi argued for a polygenist origin of the different human races. He maintained that the first modern humans to enter Europe migrated from Africa and that from this original African group three racial groups emerged: Africans, Mediterraneans, and Nordic. These three races constituted what Sergi called a Eurafrikan group that is distinct from Aryan peoples, whom he considered to be of an Asiatic origin and were part of what he called a Eurasian group of humans. These ideas were directly opposed to some of the prevailing Aryan theories promulgated

by German and British anthropologists. In works published in 1912–14 Sergi continued to promote a polygenist origin of human races, arguing that the different races diverged from one another early in the evolution of the primates and in fact represent distinct genera represented by existing groups such as African races (*Notanthropus*), Asian races (*Heoanthropus*), American races (*Hesperanthropus*), as well as extinct groups such as the **Neanderthals** (*Palaeanthropus*), and the now defunct **Pitdown Man** (*Eoanthropus*). So, not only did the different hominins not share a recent common ancestor, they also did not share a common ancestry with monkeys or apes, which also diverged from the human line at some very early period and evolved along independent lines parallel with the hominins. Given the popularity of **neo-Lamarckism** and orthogenetic theories of evolution, such **parallelism** in evolution was acceptable during the early 20thC. Giuseppe Sergi retired from teaching in 1916 but continued to publish until his death. His son, Sergio Sergi, followed his father into anthropology.

Sergi, Sergio (1878–1972) Sergio Sergi was born in Messina, Sicily, son of the prominent Italian anthropologist Giuseppe Sergi. Sergio Sergi studied medicine at the University of Rome and after completing his degree in 1902 he entered the University of Berlin where he studied physiology and the anatomy of the brain with Wilhelm von Waldeyer and anthropology with Felix von Luschan. Sergio Sergi returned to Rome in 1908 and in 1916 he accepted a position in the Faculty of Sciences at the University of Rome where he taught anthropology. His early research dealt with the neuroanatomy of apes and humans, craniometry, and the biomechanics of the human skeleton. In 1912 Sergio Sergi published *Crania habessinica: contributo all'antropologia dell'Africa orientale*, a craniometric study of peoples of Ethiopia, and through much of his career the anatomy of the skull in modern humans and other primates remained a major subject of inquiry. This is reflected in his study of gibbon neuroanatomy, *Le variazioni dei solchi cerebrali e la loro origine segmentale nell'hylobates (Variations of the Cerebral Sulci and their Segmental Origin in Hylobates)*, published in 1940. Sergio Sergi became the director of the Institute of Anthropology at the University of Rome in 1926, although he had effectively assumed those duties the previous year, and he remained the Institute's director until 1951. Sergio Sergi was a member of the anthropological and archeological

mission to the Fezzan region of central Libya sponsored by Reale Societa Geografica Italiana from 1933 to 1934, which excavated an ancient necropolis containing modern human remains from the 5thC BCE to the 4thC CE. Soon thereafter he began a series of investigations of two crania found in **Saccopastore**, Italy, in 1929 and 1935, and housed at the Institute of Anthropology. These two *Homo neanderthalensis* crania had a significant influence on Sergio Sergi's thinking about hominin phylogeny. Sergio Sergi also examined Neanderthal fossils discovered in 1939 (additional finds were made in 1950) at the site of San Felice, or **Monte Circeo**. From his investigation of these Neanderthal remains and comparisons with the anatomy of modern humans Sergio Sergi became convinced that there might be a direct hereditary link between *some* groups of Neanderthals and early *Homo sapiens*, but he considered that the classic Neanderthals were a distinct group with no close relationship to modern humans. As a result of his work on the Saccopastore and Monte Circeo fossils, in a series of papers published during the 1940s and 1950s Sergio Sergi developed a novel conception of modern human phylogeny. He used the term **Palaeanthropi** to refer to the wide range of different Neanderthal specimens from Europe, Asia, and Africa, and according to Sergio Sergi these Palaeanthropi interbred with groups of early humans from the Middle Pleistocene (e.g., **Swanscombe** and **Fontéchevade**) that he called the **Prophaneranthropi**. These Prophaneranthropi were the common ancestors for the more specialized classic Neanderthals and modern *Homo sapiens*, which he called **Phaneranthropi**. Although he never satisfactorily explained the origin of the Prophaneranthropi and despite other difficulties with his phylogenetic hypotheses Sergio Sergi's ideas influenced later paleoanthropologists (e.g., Clark **Howell**). During WWII Sergio Sergi remained in Italy and is credited with protecting the Saccopastore fossils by hiding them from German officers who were plundering fossil treasures. From 1913 to 1943 he served as secretary of the Istituto Italiano di Antropologia (the Italian Institute of Anthropology), and after the fall of the fascist government in Italy Sergio Sergi once again acted as secretary of the institute from 1947 to 1967 and he was responsible for its reorganization after the war. His monograph on the Circeo I Neanderthal skull, *Il cranio neanderthaliano del Monte Circeo (Circeo I)*, was published posthumously in 1974.

seriation (L. *serere*=to join) The process by which archeological or fossil evidence is assembled into ordered series. For example, in archeology pots are sorted into a temporal series on the basis of their shape, or on the basis of the design of the decorations on the pottery. Hominin fossils, or collections of crania of higher primates, could also be sorted, or seriated, on the basis of one, or more, attributes such as cranial capacity. In this case the collection would be listed in order of the value of that attribute (e.g., a list of fossil hominin crania based not on geological age or taxonomy, but on endocranial volume) (syn. ordination).

series The **chronostratigraphic unit** equivalent of an **epoch**; series are subdivided into ages.

sex allocation In sexually reproducing species, the allocation of resources to male versus female reproduction is referred to as sex allocation. This division of resources is dependent upon reproductive strategies and behaviors within a given species (Hamilton 1967). Trivers and Willard (1973) presented data supporting their hypothesis (the Trivers–Willard hypothesis) that environmental and maternal condition could play a role in biasing offspring sex. Depending on whether a mother is in “good” or “poor” condition, they hypothesized that there will be a greater reproductive payoff for having male (“good” condition) or female (“poor” condition) offspring. Evidence supporting the Trivers–Willard hypothesis in modern human populations is lacking, although it is often discussed in the context of families with higher social status and more resources having more sons, or investing more in their sons. The application of this hypothesis to nonhuman primates has produced mixed results. According to some studies, in matrifocal groups, where rank is inherited through the mother and most males leave at sexual maturity, mothers of higher rank and in better condition produce more female than male offspring (e.g., Silk et al. 1981). Others suggest that sex ratio is affected more by local environmental conditions, in both high- and low-ranking females; when there is increased competition over resources, higher-ranking females will produce more daughters and fewer sons do than lower-ranking females (van Schaik and Hrdy 1991). When resource competition is relaxed, higher-ranking females would be expected to produce more sons than lower-ranking females. However, recent meta-analyses provide no consistent support

for either the Trivers–Willard or local resource competition hypothesis in nonhuman primates (Silk et al. 2005).

sex chromosomes The pair of chromosomes that define the sex of an individual. In modern humans and most mammals the sex chromosomes are the **X chromosome** and the **Y chromosome**; males are XY and females are XX. The Y chromosome is substantially smaller than the X chromosome and only the tips of the Y chromosome (known as the pseudoautosomal regions) recombine with the X chromosome during meiosis. The larger, non-recombining, portion of the Y chromosome contains the *SR Y* gene, which is the male sex-determining gene. In modern humans, if the *SR Y* gene is not functional the fetus develops phenotypically as a female, but she is infertile. Although sex chromosomes are contrasted with the autosomal chromosomes, evolutionarily the sex chromosomes in most mammals were once autosomes.

sexual dimorphism (Gk *dis*=twice plus *morphe*=form, shape) Sexual dimorphism describes difference(s) between males and females of a species. Behavior (e.g., bird song), morphology (e.g., horns, teeth, and body size), and color can be sexually dimorphic, although sex differences in color are usually referred to as sexual dichromatism. Darwin (1871) identified the root causes of sexual dimorphism as different types of sexual selection acting through the channels of intrasexual competition and female choice. Sexual dimorphism in body size is common among anthropoids, and sexual dimorphism in general among primate species has been attributed to a wide range of influences in addition to sexual selection such as female body mass, diet, substrate use, and phylogeny. For example, Rensch's rule notes that in birds and mammals sexual size dimorphism (SSD) is more pronounced in larger species (Rensch 1959); further refinements of this rule state that SSD increases with size when males are the larger sex (male-biased SSD) and decreases with size when females are the larger sex (female-biased SSD). The link between male and female body size within a species is usually explained as being the result of genetic correlations between the sexes; therefore, any change in size of one sex usually results in some change in size in the other sex, although not as extreme. Thus Rensch's rule probably results from sexual selection, with intense selection on body size in the larger sex result-

ing in increases in both body mass in the smaller sex and sexual dimorphism (Gordon 2006, Dale et al. 2007). Because sexual dimorphism in body size or of “weaponry” (e.g., canine teeth) has been linked to levels of intrasexual competition, these traits are often utilized in analyses of fossil taxa in an attempt to reconstruct social structure. Evidence from fossil hominins suggests a general decrease in sexual dimorphism of body and canine size through time, with a notable decrease occurring during the time of *Homo erectus* likely brought about by an increase in female body size. However, direct inferences of social structure and mating behavior based on dimorphism in the fossil record are complicated by the fact that multiple types of group-living social structures overlap in the degree of sexual dimorphism produced in living primates (Plavcan 2000, 2002). In addition, archaic hominins, and especially megadont archaic hominins (e.g., *Paranthropus boisei*) are unusual in their pattern of dimorphism in that they exhibit high levels of body size dimorphism, but low levels of canine size dimorphism; in other primates, dimorphism levels are usually similar between body mass and canine size. The unusual hominin pattern may reflect the loss of the canine-premolar honing complex and a change in canine shape in the hominin lineage, shifting the canine away from a weapon shape (Kimbel and Deleuzene, 2009) and thus removing the canine as a target of sexual selection.

sexual selection A type of natural selection in which individual selection is influenced by mate choice (i.e., some individuals reproduce more because the traits they possess are more attractive to members of the opposite sex and/or they are successful in competing with individuals of the same sex for mates). Charles Darwin considered this differential access to mates to constitute a different evolutionary mechanism than his natural selection.

SH Acronym for Sima de los Huesos and the prefix for fossil hominins recovered from Sima de los Huesos, Spain. See **Sima de los Huesos**.

Shanidar (Location 36°50'N, 44°13'E, Iraq; etym. after the nearby village of Shanidar) History and general description Shanidar Cave is located about 645 km/400 miles north of Baghdad in the Zagros Mountains of Iraqi Kurdistan. The cave site lies just outside of the Greater Zab River valley,

about two-thirds of the way up the neighboring Shanidar Valley. Ralph Solecki initially explored the cave in 1951 as part of a general archeological survey of northeastern Iraq. Having found encouraging material in his test pit, Solecki returned in 1953 for 10 weeks of excavation. In June of 1953 a partial skeleton of an infant, now known as **Shanidar 7**, was found. Another two seasons of excavation were undertaken in 1956–7 and 1960, during which the remains of six other individuals were recovered. The detailed study of the fossils was carried out by Trinkaus (1983). One individual (**Shanidar 4**) was found buried in soil that included highly elevated pollen counts, which Solecki interpreted as the remains of flowers that were interred as grave goods. Another individual (**Shanidar 1**) had suffered trauma and injury that would likely have prevented him from procuring his own food. Solecki (1963) interpreted these remains to mean that *Homo neanderthalensis* had complex social behavior that included burial and symbolism, and that they cared for their elderly and invalids. A recent reassessment of **Shanidar 3** by Churchill et al. (2009) revealed that this individual had cutmarks on its ribs that are consistent with damage from a projectile, which suggests that Neanderthals may have engaged in interpersonal conflict. The remains of three other individuals were identified upon closer examination of the collection, the last as recently as 2007. It is worth pointing out that during the excavation the cave was occupied by a group of Kurds, limiting the area that Solecki was able to dig. Temporal span and how dated? **Radio-carbon dating** suggests the **Mousterian** levels are at least *c.*45 ka and the **Upper Paleolithic** levels are *c.*27–33 ka. Hominins found at site The remains of approximately 10 individuals have been recovered and identified, at least four of which appear to have been intentionally buried. The remains are generally grouped with those from **Amud**, **Kebara**, and **Tabun** into a Near-Eastern “late archaic” Neanderthal population. Archeological evidence found at site The four main layers of Shanidar are characterized by their respective industries, and include a deep Mousterian level (Level D), which contained material consistent with the Zagros Mousterian, an Upper Paleolithic level (Level C) with material from Baradostian industry, and two more recent levels. Key references: Geology, dating, and paleoenvironment Vogel and Waterbolk 1963; Hominins Trinkaus 1983, Cowgill et al. 2007, Trinkaus and Zimmerman 1982; Archeology Solecki 1955 and 1963, Leroi-Gourhan 1975.

Shanidar 1 Site Shanidar. Locality N/A. Surface/in situ *In situ*. Date of discovery April 27, 1957. Finders Ralph Solecki and team. Unit N/A. Horizon At the top of level D (**Mousterian**). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 45–50 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Nearly complete skeleton, with all teeth except for the left and right I₁. Announcement Stewart 1958. Initial description Stewart 1959. Photographs/line drawings and metrical data Trinkaus 1983. Detailed anatomical description Stewart 1959, Trinkaus and Zimmerman 1982, Trinkaus 1983. Initial taxonomic allocation *Homo sapiens neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance Shanidar 1 is the most complete specimen from the site and it has been used as a reference in reconstructing other western Asian Neanderthals (e.g., **Amud 1**). This individual suffered massive crushing injuries to the right side of the body which resulted in the amputation of the right forearm and degenerative joint disease throughout the right leg, and cranial trauma that resulted in damage to the left eye. Despite the severity of these injuries, the level of healing suggests that this individual survived for a period of time after the injuries occurred. This has been interpreted as evidence that Neanderthal social behavior was complex enough to include care for the infirm. Location of original Presumably at the National Museum of Iraq, Baghdad, Iraq, but this has not been verified since the looting that took place in 2003 as a result of the second Iraq War.

Shanidar 3 Site Shanidar. Locality N/A. Surface/in situ *In situ*. Date of discovery April 16, 1957. Finders Ralph Solecki and team. Unit N/A. Horizon layer D (**Mousterian**). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 45–50 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Four teeth, the major portions of the thoracic and lumbar vertebrae, sacrum, ribs, clavicles, scapulae, humeri, hand bones, pelvic and foot bones, plus fragments of the ulnae, radii, femora, tibiae, and fibulae. Announcement Solecki 1957. Initial description Solecki 1960. Photographs/line drawings and metrical data Trinkaus 1981. Detailed anatomical

description Trinkaus 1981, Churchill et al. 2009. Initial taxonomic allocation *Homo sapiens neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance Shanidar 3 has cut-marks on its ribs that Churchill and colleagues have suggested is due to damage from a weapon. Location of original National Museum of Natural History, Smithsonian Institution, USA.

Shanidar 4 Site Shanidar Locality N/A. Surface/in situ *In situ*. Date of discovery August 3, 1960. Finders Ralph Solecki and team. Unit N/A. Horizon Middle of Layer D (Mousterian). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Older than c.45 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Fragmentary associated skeleton. Announcement Stewart 1963. Initial description Stewart 1963. Photographs/line drawings and metrical data Trinkaus 1983. Detailed anatomical description Trinkaus 1983. Initial taxonomic allocation *Homo sapiens neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The remains of Shanidar 4 were intermingled with the remains of Shanidar 6, 8, and 9. This assembly is interpreted as a series of multiple sequential burials, with Shanidar 4 being the most recent. The grave has several pollen clusters within it, suggesting that the body was intentionally buried with a variety of flowers in a symbolic nature (Leroi-Gourhan 1975). Location of original Presumably at the National Museum of Iraq, Baghdad, Iraq, but this has not been verified since the looting that took place in 2003 as a result of the second Iraq War.

Shanidar 5 Site Shanidar Locality N/A. Surface/in situ *In situ*. Date of discovery August 7, 1960. Finders Ralph Solecki and team. Unit N/A. Horizon Middle of Layer D (Mousterian). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Older than c.45 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Cranial fragments, including mostly complete facial skeleton and partial vault; fragmentary associated skeleton. Announcement Stewart 1963. Initial description Stewart 1963. Photographs/line drawings and metri-

cal data Trinkaus 1983. Detailed anatomical description Trinkaus 1983. Initial taxonomic allocation *Homo sapiens neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance As originally reconstructed, the cranial vault appeared to be extremely long and low, such that Trinkaus (1983) proposed that the individual had been the subject of intentional cranial deformation in infancy, a "first" for Neanderthals. A later reassessment (Chech et al. 2000) concluded that a piece of parietal bone had been wrongly located and oriented, and that the original shape of the cranial vault was incorrect; consequently, the hypothesis of artificial cranial deformation can no longer be maintained. Location of original Presumably at the National Museum of Iraq, Baghdad, Iraq, but this has not been verified since the looting that took place in 2003 as a result of the second Iraq War.

Shanidar 7 Site Shanidar. Locality N/A. Surface/in situ *In situ*. Date of discovery June 27, 1953. Finders Ralph Solecki and team, Unit N/A. Horizon middle of Layer D (Mousterian). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Older than 45 ka; Shanidar 7 was stratigraphically the lowest specimen, so presumably it was the earliest of the Shanidar hominins. Developmental age Between 6 and 9 months. Presumed sex Female. Brief anatomical description The crushed skeleton of an infant. Announcement Solecki 1955. Initial description Senyürek 1957. Photographs/line drawings and metrical data Trinkaus 1983. Detailed anatomical description Senyürek 1959, Trinkaus 1983. Initial taxonomic allocation Senyürek originally proposed that Shanidar 7 be given its own subspecies, *Homo sapiens shanidarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The Shanidar 7 infant was the first hominin found at the site, and prompted Solecki to return for two more seasons. Although the specimen is badly damaged, much has been learned from it concerning the ontogeny of *H. neanderthalensis*. Location of original Presumably at the National Museum of Iraq, Baghdad, Iraq, but this has not been verified since the looting that took place in 2003 as a result of the second Iraq War.

shape A spatial property of objects that is independent of location (translation and rotation) and size. The **form** of an object is composed of its shape and size. At its most basic, shape can be thought of as the relationship between two or more size variables (e.g., humerus length expressed as a percentage of radius length, or a ratio of first molar occlusal area to total postcanine occlusal area). Shape has been measured in a variety of ways in human evolution studies. For example, shape is often quantified as a measurement which has been adjusted using another measure of size, either through a criterion of subtraction using a **regression** analysis, or by dividing it by another measure of size such as **body mass** or a **geometric mean** of multiple measurements. In **geometric morphometrics**, shape is described using a collection of landmarks which have been adjusted for size by the division of the object's centroid size. Angles are another type of shape measurement. The study of size-related shape change is known as **scaling**, and involves the principles of **isometry** and **allometry**. Shape is used in analyses of **functional morphology** (e.g., relating limb proportions to locomotion, relative tooth size to diet), **alpha taxonomy**, **phylogenetic reconstruction**, and paleoecological reconstruction, among others.

shape space A configuration of shape variables (i.e., the measured shape of a specimen) corresponds to a point in shape space. For triangles the shape space is spherical; for more than three landmarks the geometry of shape space can become very complex (Kendall 1981, 1984, Slice 2001). For most practical applications this complex underlying geometry can be ignored and the analyses are carried out in a linear tangent space instead.

shape variables Variables describing an object that are independent of the overall scale, orientation and location of the object. For example, the distances between the apices of a triangle (i.e., interlandmark distances) describe the **form** of that triangle (i.e., those distances are invariant to rotation and translation) and if they are scaled to overall size they become shape variables (Bookstein 1991) (syn. two-point shape coordinates, Bookstein shape coordinates).

shared-derived character *See* synapomorphy; apomorphy.

shear modulus A material property defined as the ratio of shear **stress** to shear **strain** within a

material that is being deformed elastically (i.e., the material returns to its original shape after the applied force is removed) and is being subjected to forces acting parallel to either a surface of the material or to a plane running through it. The shear modulus, denoted by G , can be thought as the shear stiffness of a material.

Shimojibaru Cave *See* Ryukyu Islands.

Shiraho-Saonetabaru *See* Ryukyu Islands.

short interspersed nuclear element *See* SINE.

short-period incremental lines Features in tooth enamel or dentine that have an intrinsic temporal secretory rhythm equal to, or less than, 1 day. **Cross-striations** in enamel and **von Ebner's lines** in dentine have been shown to have a **circadian** (*c.*24 hour) rhythm (e.g., Bromage 1991). **Intradian lines** in both enamel and dentine appear between two daily increments. Counts and measurements of the circadian features help estimate the **daily secretion rate**, **crown formation time**, dentine formation time, or the root extension rate (reviewed in Dean 2009). Short-period lines in enamel are much easier to visualize than those in dentine. *See also* dentine development; enamel development; enamel microstructure; long-period incremental lines.

short-period markings *See* short-period incremental lines.

short tandem repeat *See* microsatellite.

short-term memory *See* working memory.

shoulder girdle *See* pectoral girdle.

shovel-shaped incisors Upper incisors that show "a pronounced hollow on the lingual surface...surrounded by a well-defined elevated enamel border" (Hrdlicka 1920a, p. 429). Hrdlicka is usually credited with this description, but he points out that although a shovel-shaped incisor was illustrated in an early dental atlas (Carabelli 1844), it was probably Mühlreiter who was the first to liken the crown morphology of upper incisors to "a chisel or a shovel" (Mühlreiter 1870).

The highest incidences of shovel-shaped incisors among modern human populations are to be found in samples from northeast Asia and the Americas.

shrubland Characterized by dwarfed forms of trees that range between 1 and 3 m in height; a more extreme version of bushlands. Shrublands have lower mean annual rainfall than woodlands or bushlands, and have even poorer soil quality. They occur where taller trees cannot thrive because of low rainfall, low temperatures, drought periods, high winds, salinity, or extreme topography. Thus, they tend to be dominated by shrubs, grasses, herbs, and tubers. It has been suggested that the habitat sampled by Sterkfontein Member 4, where most of the *Australopithecus africanus* hypodigm comes from, was similar to shrubland or bushland biomes.

Shungura Formation (etym. The name of a local village) General description A formation of sedimentary rocks that outcrops as an elongated belt (about 60 km/37 miles north–south and less than 7 km/4.3 miles east–west) in the **Lower Omo Basin**, Ethiopia. Emil Brumpt, the naturalist on an expedition led by Comte Richard de Bourg de Bozas, reported the presence of fossils in what is now called the Shungura Formation in 1902. The paleontological potential of the area was further explored by Camille Arambourg in 1933, and Clark Howell carried out a survey of the Lower Omo Basin in 1959. It was Howell’s assessment of the paleontological potential of the Lower Omo Basin that led in 1966 to the detailed plans for an **International Omo Research Expedition**. It began surveys of the region in 1967, and intensive field research continued there until 1976, and in 2006 the **Omo Group Research Expedition** was created to renew paleoanthropology research in the Lower Omo Basin. The Shungura Formation is divided into a shorter (approximately 20 km/12 miles) northern component called the “Type Area” and a longer southern component called the “Kalam (or Kaalam) Area.” It is divided into 13 members named according to the lettered tuff (A–L, from oldest to youngest) that underlies each member, so Member A extends from the base of Tuff A to the base of Tuff B; the sediments below Tuff A are called the Basal Member. The sediments within the members are broken up into numbered units. In those members that contain many units (e.g., Member G) the units are subdivided into “Upper” and “Lower” groups. The

sediments are tilted (down to the west and up to the east), and because the tuffs are generally more resistant to erosion they stand out as a series of lighter-colored strata, with the oldest tuff to the east close to the present river Omo and getting younger as one moves westwards. The depositional environment changes through time. In the Basal Member the sediments were deposited in the bed of a lake; thereafter in Member A to mid-Member G the dominant sedimentary environment is the floodplain of a large meandering river. This was followed by another short **lacustrine** phase in upper Member G, a delta/floodplain environment in upper Member G to Member L, and then back to a lacustrine sedimentary environment. Sites where the formation is exposed The **International Omo Research Expedition** initially comprised three contingents – US, French, and Kenyan – but only the US and the French contingents worked in the Shungura Formation. The localities where fossils were collected by the French contingent were referred to as “Omo” (or “O”) localities and the localities were given numbers (e.g., Omo 18); the American contingent also numbered their localities, but instead of the prefix “Omo” (or “O”) they referred to localities by using the prefix “L” for locality (e.g., L. 396). Within each of these locality systems each significant fossil is assigned a number (e.g., L. 40-19), and in the case of the specimens collected by the French the year of discovery is inserted between the locality number and the fossil number (e.g., **Omo 18-1967-18**). Geological age The oldest sediments are *c.*3.5 Ma, and the youngest *c.*0.8 Ma. Most significant hominin specimens recovered from the formation With respect to hominin fossils the Shungura Formation is best known because of the dental evidence from Member G (i.e., *c.*2.3 Ma ago) (Suwa 1988) that appears to document the shift from *Paranthropus aethiopicus* to *Paranthropus boisei*, and it is the results of Gen Suwa’s detailed analysis of the crown morphology of the mandibular premolars (Suwa 1990) that is still the best guide to what hominins are present in the Shungura Formation. Suwa suggests that Members C through F sample *P. aethiopicus*, and, in addition to the holotype mandible, Omo 18-1967-18, other specimens assigned to that taxon include the juvenile calvaria, L. 338y-6. The Member G and above megadont postcanine tooth crowns resemble those of *P. boisei* found at other sites, and the partial cranium **Omo 323-1976-896**, and the mandibles L. 7a-125 and L. 74a-21 are good examples of the Omo hypodigm of that taxon. Non-megadont postcanine teeth

in the Shungura Formation are more difficult to assign to taxa. Those from the lowermost members (i.e., Members A and B) may sample an *Australopithecus afarensis*-like hominin, whereas the non-megadont postcanine teeth in Members G and H may, like L. 894-76-898, are said to sample early *Homo*. Sibilot One of the current designated subregions of the Koobi Fora region. *See also* **Koobi Fora**.

sidereal (L. *sidereus* from *sidus*=star) Refers to anything that relates to stars or constellations, but particularly to measurements based on events related to stars [e.g., their daily motion, the time it takes for the moon to revolve around the Earth (c.27 days), or the Earth around the sun (c.365 days)]. Sidereal dating methods are methods that utilize such events for dating (e.g., tree ring dating, or dendrochronology). *See also* **geochronology**.

Sidi Abderrahman (Location 33°35'N, 7°40'W, Morocco; etym. Sidi Abderrahmane is the name of the patron saint of Algiers. The cave site has also been referred to as Casablanca and Sidi Abderrahmane) History and general description One of several sites discovered as a result of limestone quarrying activities that began in 1907 during harbor construction near Casablanca, Morocco. R. Neuville and A. Ruhlmann noted the site in their 1941 survey of the sequence of Miocene to Holocene sea-level transgressions and regressions on the Atlantic coast and Pierre Biberson established the basic stratigraphic and archeological framework in the 1950–60s. Since 1978 further research has been undertaken by a joint French-Moroccan research team. Temporal span and how dated? The Casablanca sequence has been dated using **biostratigraphy** and **lithostratigraphy** correlation, **magnetostratigraphy**, **amino acid racemization dating**, optically stimulated luminescence dating (or OSL), **electron spin resonance spectroscopy dating**, and **uranium-series dating** methods, but the destruction of the Grottes des Littorines by quarrying complicates any further attempts to date this material. Current age estimates for Sidi Abderrahman suggest a **Middle to Late Pleistocene** age, with the earliest deposits likely forming before **Oxygen Isotope Stage 11** (i.e., 420–360 ka). Hominins found

at site Two mandibular fragments recovered in 1954 by P. Biberson are attributed to *Homo erectus* or *Homo erectus mauritanicus*. They derive from strata with an estimated age of *c.*400 ka based on overlying OSL age estimates and correlation with OIS 11 sediments in the nearby site of Cap Chatelier. Archeological evidence found at site The Sidi Abderrahman sequence preserves handaxes, cleavers, and other **Acheulean** implements including large **Levallois** peripheral cores, made primarily from local quartzite cobbles, with finer-grained chert becoming more abundant in the Late Pleistocene strata where Levallois flaking develops. Sierra de Atapuerca *See* Atapuerca.

siglecs (etym. Acronym for sialic acid-binding Ig-like lectins) These cell-surface receptors recognize carbohydrates and have immune-modulatory functions. They are members of the immunoglobulin superfamily. There are 16 different genes coding for siglecs in primates. Many of these genes have been found to have undergone modern human-specific changes such as gene inactivation (pseudogenization, siglecs 13, 14, and 16), change of sialic acid-binding preference (siglecs 5, 7, 9, 11, and 12), gene conversion (siglec 11), and change of site of expression (siglecs 1, 5, 6, and 11) (Varki 2010). Some of these changes are hypothesized to have followed the uniquely modern human change in sialic acid biology, namely the loss of the common mammalian sialic acid variant Neu5Gc (*N*-glycolyneuraminic acid) due to an **Alu repeat element**-mediated mutation dated at *c.*2–3 Ma (Chou et al. 2002).

sigmoid sinus (Gk *sigma*=in the older form of the Greek alphabet what is now was written as a C, plus *oides*=shape) The sigmoid sinus is one of the **dural venous sinuses** that belong to the outer of the two components of the intracranial venous system. In most modern humans the veins draining the deep structures of the brain drain as the deep cerebral veins into the left transverse sinus, whereas the

superior sagittal sinus drains into the right transverse sinus. Each transverse sinus drains into a sigmoid sinus, which runs inferiorly in a sigmoid-shaped groove from the lateral end of the transverse sinus to the superior jugular bulb, which marks the beginning of the internal jugular vein. This pattern of dural venous sinuses is known as the **transverse-sigmoid system**, and individuals (e.g., **KGA 10-525**) with transverse and sigmoid venous sinus connections on both sides are said to show transverse-sigmoid system dominance. But in some African apes and in the majority of the crania belonging to *Australopithecus afarensis*, *Paranthropus boisei*, and *Paranthropus robustus* the sigmoid sinuses receive venous blood from the **marginal sinuses** instead of the transverse sinuses. *See also* **cranial venous drainage**.

Silberberg Grotto (etym. named after Dr H.K. Silberberg because in c.1942 he had collected the upper and lower jaw of a fossil hyena, *Chasmodon*). Also known as the “Daylight Cave”) Part of the **Sterkfontein** cave complex that contains exposures of Sterkfontein Members 1, 2, and 3. Systematic exploration, facilitated by the Randfontein Estates Gold Mine, began in 1978. The exploration was intensified in 1992 when some of the *in situ* Member 2 breccia was blasted. Two years later, in 1994, when Ron Clarke was reviewing a bag of “animal” bones that had been recovered in 1980 from some of the breccia blocks removed from the Silberberg Grotto by the lime miners, he recognized four conjoined bones from the left foot of what was to become the **Stw 573** hominin (Clarke and Tobias 1995). Three years later, Clarke recognized more lower-limb bones, apparently from the same individual, to make a total of 12 bones (Clarke 1998). The breaks in the shafts of the bones of the lower leg seemed to be fresh, so Clarke surmised that the blasting had removed the distal elements of a hominin skeleton that must have remained behind in the breccia, and that it should be possible to identify the other side of the break on the surface of the remaining breccia. Stephen Motsumi and Nkwane Molefe were challenged to locate the breaks, and after only a day and a half of searching they located the complementary surfaces of the tibia and fibula. Since then painstaking excavations by Clarke and his team have recovered much of the rest of the skeleton of the the **Stw 573** hominin (Clarke 1999, 2002, 2008). *See also* **Sterkfontein**.

silent substitution *See* **synonymous mutation**.

Siler hazard model A model of animal mortality proposed by William Siler (1979) that Gage (1998) has applied to problems in primate **demography** (including extant and prehistoric humans) and Gurven and Kaplan (2007) have applied to extant **hunter-gatherers**, forager-horticulturalists, and to acculturated hunter-gatherers. The model combines a **negative Gompertz hazard model** of mortality (to represent immature deaths with the parameters a_1 and b_1) with a Makeham model (to represent a "baseline" risk of death independent of age with the parameter a_2 and a "senescent" component with the parameters a_3 and b_3). The total hazard of death at age t in the Siler model is $h(t) = a_1 e^{-b_1 t} + a_2 + a_3 e^{b_3 t}$. **Survivorship** to exact age t can be found by multiplying the survivorship from the negative Gompertz model with the survivorship from the Makeham model. In paleodemography it is common to ignore the "baseline" hazard (a_2) and assume that it is equal to zero. The four-parameter variant of the Siler model combines a negative Gompertz with a positive **Gompertz hazard model**.

silt Sedimentary materials defined primarily on the basis of particle size (i.e., a mean diameter between 0.063 mm and 4 m). Loose (unlithified) sediment in this range is referred to as silt, whereas consolidated or cemented (lithified) examples would be termed siltstone. Silts are common components of upward-fining **fluvial** deposits and they accumulate on levees when flow energy is lost during overbank flooding. Silt is the dominant particle in **loess**, the aeolian deposit associated with glacial activity at sites such as Dolní Vstonice.

siltstone *See* **silt**.

Sima de las Palomas (Location 37°47'59"N, 0°53'45"W, Murcia, Spain; etym. Sp. chasm of doves) **History and general description** The site is a **karstic** shaft in a hill (Cabezo Gordo). The discovery of a crushed hominin facial skeleton in the uppermost breccia in 1991 prompted Michael Walker and J. Gibert to examine the sediment column and fossiliferous rubble left by miners in the 19thC. **Temporal span and how dated?** **Radio-carbon dating** of burnt bones from Level 2f has provided dates of 34,450±600 years BP. **Hominins**

found at site The remains of at least 63 individuals have been recovered from the excavated deposits, and other isolated remains have been found in the rubble left by the miners. Although the hominin fossils have been interpreted as possessing some “modern” features, the overall morphological evidence is consistent with them being assigned to *Homo neanderthalensis*. Archeological evidence found at site A typical Middle Paleolithic assemblage made up of retouched flakes of flint and quartz. Key references: Geology, dating, and paleoenvironment Walker et al. 2008; Hominins Walker et al. 2008, 2010; Archeology Walker et al. 2008.

Sima de los Huesos (Location 42°20'57"N, 3°30'51"W, Spain; etym. Sp. *sima*=pit or pothole and *huesos*=bones, hence “the pit of the bones”) History and general description This site is one of the many breccia-filled cave systems that make up the **Cueva Mayor-Cueva del Silo** within a range of limestone hills called the Sierra de Atapuerca, near Burgos in northern Spain. The cave system was well-known as a source of ancient cave bear (*Ursus deningeri*) teeth, but it was not until 1976 that the first hominin fossils were found. The first 4 years of the systematic excavations that began in 1984 under the direction of Juan Luis Arsuaga were devoted to removing the breccia disturbed by cavers, but from 1988 onwards researchers worked on undisturbed sediments (Arsuaga et al. 1997b). To date, more than 6500 hominin specimens belonging to at least 28 individuals of diverse ages and both sexes (Bermúdez de Castro et al. 2004) and one Acheulean handaxe have been recovered from what appears to be a single unit of breccia (Bischoff et al. 1997). Temporal span and how dated? The sediments are overlain by a speleothem which has yielded a minimum uranium-series dating age of more than 530 ka for the hominin-bearing breccia (Bischoff et al. 2007). Hominins found at site The site is one of the richest sources of hominin fossils and has yielded at least one example of every bone in the body. The hominin remains include numerous crania, mandibles, hundreds of teeth, a nearly complete pelvis, vertebrae, ribs, hand and foot bones, and multiple specimens of long bones, in various states of preservation (Arsuaga et al. 1997b). Among the cranial remains, Cranium 5 (AT-700) is exceptionally complete and Cranium 4 (AT-600) has one of the largest cranial capacities among European Middle Pleistocene hominins.

The cranial and mandibular sample as a whole shows a number of clearly derived features of *Homo neanderthalensis* including pronounced midfacial prognathism, the form of the brow ridge, a flat articular eminence of the glenoid fossa, a retromolar space, and an asymmetrical configuration of the ramus of the mandible. In contrast, the cranial vault is generally more plesiomorphic (e.g., large, projecting, mastoid processes, rounded neurocranium) with some incipient derived traits of *H. neanderthalensis* (e.g., weak expression of the suprainiac fossa). The dental remains combine a pronounced buccolingual expansion of the anterior dentition, similar to that seen in Neanderthals, with a strong reduction in the size of the postcanine tooth crowns. The most complete pelvis from the site (Pelvis 1) is a large, male specimen that shows generally plesiomorphic features for the genus *Homo*, including a wide bi-iliac breadth and long superior pubic ramus, and it has yielded a body-mass estimate of over 90 kg (Arsuaga et al. 1999b). The degree of sexual dimorphism within the sample appears to be similar to that which characterizes present-day modern humans. The age distribution of the hominin sample shows an overabundance of adolescent individuals and it has been suggested that the accumulation of the hominin bones at the site has an anthropic origin (Arsuaga et al. 1997b). The hominin sample from the Sima de los Huesos has been assigned to *Homo heidelbergensis* (Arsuaga et al. 1997a) and the researchers involved suggest that the Sima de los Huesos hominins sample the population that is ancestral to *H. neanderthalensis*. However, there is considerable debate about the systematics of Middle Pleistocene hominins (e.g., Hublin 2009, Rightmire 2008). Archeological evidence found at site One large Acheulean handaxe. Key references: Geology, dating, and paleoenvironment Bischoff et al. 1997, 2007; Hominins Arsuaga et al. 1993, 1997b, 1999b; Archeology Carbonell et al. 2003.

Sima del Elefante (Location 42°20'60"N, 3°31'09"W, Spain; etym. “elephant pit”) History and general description This site is one of the many breccia-filled caves that make up the **Cueva Mayor-Cueva del Silo** within a range of limestone hills called the Sierra de Atapuerca, near Burgos in northern Spain. The Sima del Elefante is 18 m deep and up to 15 m wide. It contains evidence of at least one hominin individual (ATE9-1), and the lithic assemblage of 32 artifacts is consistent with hominin stone tool

manufacture within the cave. Temporal span and how dated? A combination of **biostratigraphic dating** using rodents and insectivores, an observed reversed magnetic polarity (consistent with the TE16 and older lithostratigraphic layers being in the Matuyama), and the results of **cosmic radio-nuclide dating** with ^{26}Al and ^{10}Be giving an age of 1.22 ± 0.16 Ma for TE9c, all point to an age for the sediments in the Sima del Elefante of $c.1.2\text{--}1.1$ Ma. Hominins found at site The only hominin recovered from the Sima del Elefante, ATE9-1, a partial mandible, has been provisionally assigned to *Homo antecessor*. Archeological evidence found at site Mode 1, simple flakes and debitage. Key references: Geology, dating, and paleoenvironment Rosas et al. 2006, Carbonell et al. 2008; Hominins Carbonell et al. 2008; Archeology Carbonell et al. 2008.

simple regression A regression with one independent variable. The coefficient associated with the independent variable is the slope of the best-fit line for the data, and indicates the change in the dependent variable associated with a unit change in the independent variable. The *P* value for the independent variable identifies the significance of the difference between that slope and zero (a slope of zero indicating a flat line). The intercept of the best-fit line with the *y*-axis is also given, as well as an associated *P* value describing the significance of the difference between the intercept and zero. Simple regression generally refers to the **ordinary least squares regression** method for identifying regression parameters; *see* **regression** for alternative techniques.

Sinanthropus Black, 1927 Hominin genus introduced by Davidson Black in 1927. Type species *Sinanthropus pekinensis* Black, 1927.

***Sinanthropus lantianensis* Woo, 1964** A species of *Sinanthropus* provisionally proposed by Woo Ju-kang (aka Wu Ru-kang) in 1964 for the mandible recovered in 1963 from the site of Lantian. When he described the calotte and facial fragments from the same individual (Woo 1966) Wu Ru-kang reaffirmed his suggestion that these remains sampled a novel species, but by the mid-1960s most researchers had subsumed *Sinanthropus* into the genus *Homo* and few outside of China recognized the new taxon.

***Sinanthropus pekinensis* Black, 1927** (Gk *Sinai*=Chinese and *anthropos*=human being) Hominin species established by Davidson Black in 1927 [NB: Black (1927, p. 21) suggested the species be referred to as “*S. pekinensis* (Black and Zdansky)” but Black is the sole author of the 1927 paper so his name alone should be used] to accommodate three fossil hominin teeth recovered in 1921, 1923, and 1927 at Choukoutien (now called **Zhoukoudian**). Wilfrid Le Gros Clark (1940) proposed that *Sinanthropus pekinensis* be transferred to *Pithecanthropus* as either *Pithecanthropus erectus* or *Pithecanthropus pekinensis*. Later that year Franz Weidenreich (1940) formally transferred *S. pekinensis* to *Homo* as *Homo pekinensis*. More recently Antón (2002) and Kaifu et al. (2008) have once again raised the possibility that there are significant differences between the two main fossil samples from Java, namely Ngandong and Bapang-AG. They also suggest that the *Sinanthropus* part of *Homo erectus* is morphologically distinct from the part of the hypodigm that comes from Java. First discovery Ckn. A 1 Upp 1 (recovered in 1923, but not recognized until 1926). Holotype Ckn. A 1. (1927). Paratypes None. Main site Zhoukoudian. *See also* *Homo erectus*.

SINE Acronym for short interspersed nuclear element. Short sequences (i.e., fewer than 500 base pairs) of DNA dispersed throughout the genome. They make up a class of mobile elements or **transposons** that are derived from reverse-transcribed RNA molecules. In modern humans, the most common SINEs are the **Alu elements**, which comprise almost 13% of our genome.

Singa (Location 13°00'N, 33°55'E, Sudan; etym. named after the British District Commissioner's post at the nearby town of Singa) History and general description The **Singa 1** calvaria was recovered, encrusted with **calcrete**, from the bank of the Blue Nile about 320 km/200 miles south of Khartoum. Arthur Smith Woodward's (1938) initial study noted its modern aspect and portrayed it as an ancestral Bushman, largely because of its strongly developed parietal bossing. Later studies have supported its modern affinities, but emphasized that the shape of the cranial vault may be the result of pathology and that claims of a special affinity to Khoesan populations are overstated. It may be an early anatomically modern cranium,

but it retains some archaic features such as a large supraorbital torus and a somewhat low and broad vault. Temporal span and how dated? 145.5 ± 7.5 to 133 ± 2 ka (by uranium-series dating on the calcrite matrix encasing the teeth and calvaria), 89 ± 9.3 to 159 ± 12 ka (based on electron spin resonance spectroscopy dating, early and late uptake, respectively on an associated *Equus* tooth). Hominins found at site Singa 1, a well-preserved calvaria. Archeological evidence found at site Middle Stone Age (“Advanced Levalloisian” or “Proto-Stillbay”) tools. Key references: Geology, dating, and paleoenvironment Woodward 1938, Bate 1951, Grün and Stringer 1991, McDermott et al. 1996; Hominins Woodward 1938, Wells 1951, Tobias 1968, Brothwell 1974, Stringer 1979, Stringer et al. 1985; Archeology Lacaille 1951.

Singa 1 Site Singa. Locality N/A. Surface/in situ *In situ*, but likely eroded from a higher fossiliferous stratum. Date of discovery February 1924. Finder W.R.G. Bond. Unit N/A. Horizon Caliche deposit on the west bank of the Blue Nile. Bed/member N/A. Formation N/A. Group N/A. Near-est overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Late Middle to early **Upper Pleistocene**, 145 ± 7.5 to 89 ± 9.3 ka. Developmental age Adult. Presumed sex Indeterminate. Brief anatomical description A heavily mineralized cranium preserving all of the bones of the vault as well as portions of the left zygomatic, both nasals, and the frontal processes of both maxillae. The forehead recedes only slightly more than in recent crania and the occipital is rounded. The parietal bosses are strongly developed, possibly pathologically, because the vault is also shorter than is common in crania of this antiquity and it is also markedly asymmetrical. The temporal bone shows a rare pathology (Spoor et al. 1998). Announcement Smith Woodward 1938. Initial description Smith Woodward 1938. Photographs/line drawings and metrical data Wells 1951, Stringer et al. 1985. Detailed anatomical description Wells 1951, Stringer et al. 1985. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions *Homo sapiens*, “Pre-Bushman” (Wells 1951), early anatomically modern *Homo sapiens* (Bräuer 1984, 1998), with the unusual parietal morphology possibly due to pathology (Brothwell 1974, Stringer et al. 1985). Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Possibly an early exam-

ple of anatomically modern humans at *c.* 130–150 ka. Location of original Natural History Museum, London, UK.

single-crystal argon-argon dating *See* argon-argon dating.

single-crystal laser fusion $^{40}\text{Ar}/^{39}\text{Ar}$ dating *See* argon-argon dating.

single nucleotide polymorphism A difference between two individuals at a single nucleotide. For example, the difference between whether an individual has dry or wet earwax is due to a single nucleotide difference (Yoshiura et al. 2006) (syn. point mutation). *See also* mutation.

single species hypothesis (or SSH) The single species hypothesis was formulated by Loring Brace and Milford Wolpoff of the University of Michigan during the 1960s and 1970s. During the mid-1960s Brace began to argue for the proposal put forward by Kenneth Oakley that evidence of tool use by early hominins formed the basis for considering them to be members of the genus *Homo*. Moreover, Brace relied upon the widely accepted principle of **competitive exclusion** (see below), which he interpreted as suggesting that no more than one hominin species could inhabit a given environment at any given time since multiple hominin species would have to compete for the same resources. As a result, Brace argued that all hominins must belong to the same species. He proposed that hominins had passed through four stages (**australopithecine**, **pithecanthropine**, **Neanderthal**, and modern) during the course of their evolution, but he argued that the stages should not be considered separate species of hominin. The term single species hypothesis came to the fore when it was used by Milford Wolpoff in 1968 as part of the title of a paper called “‘*Telanthropus*’ and the single species hypothesis”. In that paper Wolpoff (1968) suggested the single species hypothesis was an interpretive “framework” that was derived from the principle of competitive exclusion (i.e., that only one organism at a time can occupy a specific ecological niche). Milford Wolpoff promoted the single species hypothesis in the late 1960s, and in 1971 he published an article in the journal *Man* entitled “Competitive exclusion among Lower Pleistocene hominids: the single species hypothesis” outlining the arguments in support of the hypothesis

(Wolpoff 1971b). The gist of Brace and Wolpoff's argument was that hominin culture constituted an ecological niche and thus any hominin possessing culture, as shown by evidence of tool use, must belong to the same species. The single species hypothesis as interpreted by Wolpoff is a restatement of an earlier proposal set out by Ernst Mayr. Mayr (1950) applied the principle of the "biologically defined polytypic species" (*ibid*, p. 110) to the hominin fossil record. After "due consideration of the many differences between Modern man, Java man, and the South African apeman" Mayr stated that he "did not find any morphological characters that would necessitate separating them into several genera" and he suggested that within the single hominin genus, *Homo*, the only speciation that has occurred "has been phyletic speciation resulting in *Homo sapiens*" (*ibid*, p. 110). Within the genus *Homo* Mayr (1950) recognized three time-successive species: *Homo transvaalensis*, *Homo erectus*, and *Homo sapiens*. Having accepted that throughout hominin evolution "the known diversity of fossil man can be interpreted as being the result of geographic variation within a single species of *Homo*" (*ibid*, p. 116) (i.e., there has been no speciation within hominin evolution involving reproductive isolation) Mayr then speculates about the reasons for "this puzzling trait of the hominid stock to stop speciating" (*ibid*, p. 116). Mayr concludes that the reason is "man's great ecological diversity" (*ibid*, p. 116) which means that if "man occupies successfully all the (ecological) niches that are open for a *Homo*-like creature, it is obvious that he cannot speciate. This conforms to **Gause's rule**" (*ibid*, p. 116), but it is noteworthy that the reference Mayr and others cite for the principle of competitive exclusion [Gause (but sometimes also mis-spelled "Gauss") 1934] deals exclusively with protozoa and yeast. However, although Wolpoff also used Gause's rule, he did so in a different way than Mayr (1950). Wolpoff (1968) suggested that human *culture* is such a specialized ecological **niche** that "no more than one culture-bearing hominid could have arisen and been maintained" (*ibid*, p. 477). Thus, once culture had been acquired there could only ever have been one **synchronic** hominin species. Wolpoff suggests that tool use could only have occurred if a hominin was bipedal, and he credits the "hominid equals bipedalism" hypothesis to Sherwood Washburn (1951), but a year earlier Mayr (1950) had also used bipedalism to define *Homo* when he suggested that "when the *Homo*-line acquired upright posture it entered a

completely different adaptive zone" (*ibid*, p. 111). The single species hypothesis was taken up by Bartholomew and Birdsell (1953) and Wolpoff suggests that these authors "amplified" it (*ibid*, p. 477). Indeed, they did suggest that the "bipedal tool-using mode of life" was a "level of adaptedness" that "had previously been inaccessible" (Bartholomew and Birdsell 1953, p. 492), but instead of concluding that this would have resulted in a "uniform long-persistent type" they suggested the exact opposite, namely that the australopiths were "a variable group of related forms" (*ibid*, p. 492). Only when the australopiths later came into contact with "culturally advanced hominids" did Bartholomew and Birdsell suggest that the australopiths would have been subject to "rapid replacement" (*ibid*, p. 492). As more australopith fossils were discovered during the late 1960s and 1970s, especially in East Africa, evidence for two forms, called "gracile" and "robust," emerged, and Wolpoff argued that the differences between the "gracile" and "robust" australopiths probably represented **sexual dimorphism** in a single species rather than the existence of two separate species, australopith or otherwise. Wolpoff primarily made these arguments on the basis of the southern African australopith evidence, but he later expanded it to the early East African discoveries. Critics, however, noted that the "gracile" and "robust" australopiths in southern Africa were found in separate geographical locations and were separated by approximately half a million years. *Telanthropus* had been put forward as refuting the single species hypothesis because it provided at one site, Swartkrans, evidence of a *Homo erectus*-like hominin alongside *Paranthropus robustus*, but Wolpoff rejected the refutation for two reasons. First he doubted the taxa were synchronic, and second he rejected the taxonomic distinctiveness of *Telanthropus*. By dint of persistent advocacy the single species hypothesis was kept alive for nearly another decade. Its demise came with the demonstration that an undoubted early African *Homo erectus* cranium (KNM-ER 3733) and an undoubted *Paranthropus boisei* cranium (KNM-ER 406), so different that they were evidently from different taxa, had both been found *in situ* in the Upper Member of the Koobi Fora Formation (Leakey and Walker 1976). The term "single species" has also been applied to discussions about whether *Homo sapiens* and *Homo neanderthalensis* are distinct enough to be assigned to different species and whether *Homo erectus sensu lato* is

one, or more than one, species (e.g., Villmoare 2005). The demise of the single species hypothesis, along with the proliferation of the hominin fossil record and better dating methods, has led to the general acceptance that the hominin phylogenetic tree consists of several branches, with hominin species coexisting at various times in the past. *See also* **competitive exclusion**.

sinkhole *See* **mokondo**.

Šipka (Location 49°35'N, 18°10'E, Czech Republic; etym. Czech for "arrow") History and general description This cave site, situated on the northern slope of Kotouč Hill, north of the Morava river valley, was excavated in the 1880s and again in 1950. Temporal span and how dated? Evidence from **biostratigraphy** suggests the hominin remains were associated with a **Mousterian** level, probably dating to **Oxygen Isotope Stage** 5a–c, and the **Upper Paleolithic** lithic remains are linked to the last glacial. Hominins found at site A juvenile mandibular fragment, comprising the perisymphysal region with three erupted permanent incisors, and the anterior part of the right side of the corpus with the germs of the right canine and premolars in their crypts, was found during the course of the 1886 excavation. It has been attributed to *Homo neanderthalensis*. As one of the earliest associations with the Mousterian, the Šipka specimen was prominent in early debates on the significance of Neanderthals. Initial descriptions of the specimen by Hermann Schaaffhausen and H. Wankel emphasized the mandible's archaic character, but Rudolf Virchow claimed it was a pathological modern human: the same argument he used to explain the **Neanderthal** skeleton (Smith 1997). Archeological evidence found at site Mousterian and Upper Paleolithic (**Magdalenian**) lithic industries. Key references: Geology, dating, and paleoenvironment Valoch 1965; Archeology Valoch 1965; Hominins Vlček 1969, Jelinek 1969, Smith 1982.

sister taxa Two taxa that share **synapomorphies**, or a unique combination of **symplesiomorphies**. A pair of sister taxa is the minimum size for a **clade**, or **monophyletic group**, and pairs of sister taxa are the basic units of clades.

site (L. *situs*=location) A location, large or small, where fossils are found. It can vary from a cave the size of a room (e.g., **Tabun**) to an area of hundreds of square kilometers (e.g., **Hadar study**

area, Koobi Fora, Middle Awash study area). Large sites may be subdivided into areas, localities, or collecting regions identified with names or numbers (e.g., Area 103, A.L. 333, **Aramis**), but if the site is small there is no need to specify separate localities.

size The form of an object is composed of its size and **shape**. Size is a spatial property of an object that is independent of its location (translation and rotation) and shape. More generally, size refers to the extent of a physical object's presence in one or more spatial dimensions. Size can be measured in a variety of ways. Size variables have two distinct properties: dimension and scope (e.g., all, or part, of the body). Size measures may be one-dimensional (i.e., linear), two-dimensional (i.e., area), three-dimensional (i.e., volume), or size can be measured by means of the mass (a property of objects in three-dimensional space) of the object. In human evolution, size measurements in common use include canine height, molar crown area, endocranial volume, and body mass. With regard to scope, measurements may reflect overall organismal size (e.g., body mass, a **geometric mean** of measurements from throughout the skeleton), the size of an organ or organ system (e.g., **brain mass**, gut surface area, testicular volume), or the size of a particular anatomical region of interest (e.g., a geometric mean of measurements from the proximal femur). Note that dimension and scope are independent of one another. For example, an overall measure of **body size** can be a measure of length (e.g., stature), an area (e.g., surface area of the skin), a volume (e.g., total body volume), or a mass (e.g., body mass). Furthermore, size can be measured as a single variable or calculated from multiple variables. For example, the volume of a brain can be measured directly by placing it in a beaker of liquid and measuring the volume of liquid displaced, or it can be estimated using formula based on the height, width, and length of the brain (*see multivariate size* for more detail). Size is important in studies of **alpha taxonomy**, **phylogeny reconstruction**, and **sexual dimorphism**. Body size in particular is related to **life history** variables, **biogeography**, and substrate use. *See also* **multivariate size**.

size classes *See* **bovid size classes**.

SK Abbreviation of Swartkrans and the prefix used for all the hominin fossils recovered from **Swartkrans** cave in the Blauwbank Valley,

Transvaal (now Gauteng Province, South Africa), during the excavations by Robert Broom and John Robinson from 1948 to 1953. All of the SK fossils are curated by the Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 6 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery November 1948. Finders Robert Broom and John Robinson. Unit/horizon Pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description Left side of the corpus of an adolescent mandible with P₃–M₃, plus a fragment of the right side of the corpus containing P₄–M₁ and the crowns and roots of the right M₂ and M₃. Announcement Broom 1949. Initial description Broom and Robinson 1952. Photographs/line drawings and metrical data Broom and Robinson 1952. Robinson 1956. Detailed anatomical description Robinson 1956. Initial taxonomic allocation *Paranthropus crassidens*. Taxonomic revisions Robinson (1954a) suggested that *P. crassidens* be transferred to, and would thus be a junior synonym of, *Paranthropus robustus*. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance The holotype of *P. crassidens*. Note that researchers have suggested that SK 100 and SK 13/14 may belong to the same individual. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 15 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery April 1949. Finder John Robinson. Unit/horizon Boundary between Member 1 Hanging Remnant and Member 3. Bed/member Member 1/3. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.5–1.0 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A crushed and distorted mandibular corpus with the left M_{1–3} and the right M_{2–3}. Announcement Broom and Robinson 1949b. Initial description Broom and Robinson 1952. Photographs/line drawings and metrical data Broom and

Robinson 1952. Detailed anatomical description N/A. Initial taxonomic allocation *Telanthropus capensis*. Taxonomic revisions *Homo erectus* (Robinson 1961, Howell 1978a), *Paranthropus crassidens* (Wolpoff 1968), *Homo habilis* (Blumenberg and Lloyd 1983, Strait et al. 1997, Curnoe 2006), *Homo sp. indet.* (Grine 2001). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The hypodigm of *Paranthropus* was relatively meager in 1949, yet even then Broom and Robinson were convinced that the corpus of SK 15 was too small, and the teeth too like those of modern humans, for it to be even an extreme variant of *P. crassidens*, so they opted to erect a new taxon, *T. capensis*, for SK 15. A year later they announced the recovery of a second “non-*Paranthropus*” mandible, SK 45 (Broom and Robinson 1950), and although they did not immediately assign SK 45 to *T. capensis*, its gracile corpus and small molars pointed in that direction. Wolpoff (1968) is willing to subsume SK 15 within the main *Paranthropus* hypodigm, but he is a lone voice, and others (see above) have pointed to affinities between its dentition and that of *H. habilis*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 27 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery 1949. Finders Robert Broom and John Robinson. Unit/horizon Pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Subadult. Presumed sex Male. Brief anatomical description Crushed juvenile cranium with partial dentition. Announcement Broom and Robinson 1952. Initial description Broom and Robinson 1952. Photographs/line drawings and metrical data Robinson 1956. Detailed anatomical description N/A. Initial taxonomic allocation *Paranthropus crassidens*. Taxonomic revisions *Homo* (Clarke 1977, Howell 1978a, Strait et al. 1997), *Homo habilis* (Curnoe and Tobias 2006). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance Features of the vault, base, and the dentition of the SK 27 cranium have suggested to some researchers (e.g., Clarke 1977, Howell 1978a, Strait et al. 1997) that this specimen belongs to

Homo. Clarke (1977) claimed that SK 27 was evidence of a third *Homo* individual (the other evidence included the SK 847 composite cranium and SK 2635, two maxillary premolars) in Swartkrans Member 1. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 45 Site Swartkrans. Locality N/A. Surface/ in situ *In situ*. Date of discovery September 1949. Finders Robert Broom and John Robison. Unit/horizon Equivalent to the pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragment of the right side of the mandibular corpus with the M₁₋₂ and part of the M₃ alveolus. Announcement Broom and Robison 1950. Initial description Broom and Robison 1950. Photographs/line drawings and metrical data Broom and Robison 1952. Detailed anatomical description N/A. Initial taxonomic allocation aff. *Telanthropus capensis*. Taxonomic revisions *Homo erectus* (Robison 1961), *Paranthropus crassidens* (Wolpoff 1968), *Homo habilis* (Howell 1978a, Strait et al. 1997), *Homo sp. indet.* (Grine 2001). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Robison (1961) transferred SK 45 to *H. erectus*. Wolpoff (1968) is willing to subsume SK 45 within the main *Paranthropus* hypodigm, but he is a lone voice. Others have pointed to affinities between its dentition and that of *H. habilis*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa. *See also* SK 15.

SK 48 Site Swartkrans. Locality N/A. Surface/ in situ *In situ*. Date of discovery 1949. Finders Robert Broom and John Robison. Unit/horizon Pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Young adult. Presumed sex Male. Brief anatomical description Partly crushed cranium with the left M¹⁻³ and the roots or crowns of the right C to M³. Announcement Broom and Robison

1952. Initial description Broom and Robison 1952. Photographs/line drawings and metrical data Robison 1956. Detailed anatomical description N/A. Initial taxonomic allocation *Paranthropus crassidens*. Taxonomic revisions Robison (1954a) suggested that *P. crassidens* be transferred to, and would thus be a junior synonym of, *Paranthropus robustus*. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance For a long time SK 48 was the best-preserved evidence of a *P. robustus* cranium, but the DNH 7 skull from Drimolen is more complete and better preserved. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 50 Site Swartkrans. Locality N/A. Surface/ in situ *In situ*. Date of discovery 1949. Finders Robert Broom and John Robison. Unit/horizon Brown breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A damaged and partly crushed right pelvic bone (missing most of the iliac blade) together with a distal humerus. Announcement Broom and Robison 1950. Initial description Broom and Robison 1950. Photographs/line drawings and metrical data Broom and Robison 1952, Robison 1972b. Detailed anatomical description Broom and Robison 1952, Robison 1972b. Initial taxonomic allocation *Paranthropus crassidens*. Taxonomic revisions Robison (1954a) suggested that *P. crassidens* be transferred to, and would thus be a junior synonym of, *Paranthropus robustus*. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance This was the first (TM 1605 from Kromdraai was recovered in 1954) evidence of the pelvic bone of *P. robustus*, and it formed an important part of the evidence assembled by Robison (1972b) to justify his proposal that the locomotion of *P. robustus* was substantially different from that of *Australopithecus africanus*, with the former (i.e., SK 50) showing climbing adaptations not seen in *Au. africanus*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 52/SKW 18 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery 1950. Finders Robert Broom and John Robinson and (see below) C.K. (Bob) Brain. Unit/horizon Brown breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Young adult (the sphenoccipital synchondrosis is unfused). Presumed sex Male. Brief anatomical description SK 52 is a cranial fragment that includes the lower part of the face. The maxillary dentition is represented by both I²s, all four premolars, both M¹s, plus an unerupted right M³. A second fragment, SKW 18, was recovered by Bob Brain in 1968 from breccia that came from the hanging remnant part of Member 1. Clarke (1977) recognized that SKW 18 articulated with SK 52 and described some of its occipital and temporal morphology, but it was not until Daryl de Ruiter used acetic acid to remove the remaining breccia that the extent of the morphology preserved on the SKW 18 fragment was appreciated. Announcement Clarke 1977 (SKW 18). Initial description Clarke 1977 (SKW 18). Photographs/line drawings and metrical data Robinson 1956, de Ruiter et al. 2006. Detailed anatomical description Robinson (1956) for the dentition of SK 52 and de Ruiter et al. (2006) for SKW 18. Initial taxonomic allocation *Paranthropus crassidens* (SK 52). Taxonomic revisions Robinson (1954a) suggested that *P. crassidens* be transferred to, and would thus be a junior synonym of, *Paranthropus robustus*. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance This is the third, and in some ways the best-preserved, cranial base of *P. robustus*. Its morphology confirms the *P. robustus* pattern of basicranial morphology reported by Dean and Wood (1981, 1982) (e.g., including the presence of an occipito-marginal system of endocranial venous drainage). The foramen magnum of SK 52/SKW 18 is oval in shape, thus suggesting that the cardioid-shaped foramen magnum seen in the few available *Paranthropus boisei* specimens and in the only *Paranthropus aethiopicus* specimen is not a *Paranthropus apomorphy*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 63 Site Swartkrans. Locality Unknown. Surface/in situ Recovered from breccia removed in 1949. Date of discovery 1949. Finders Robert

Broom and John Robinson. Unit N/A. Horizon N/A. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Most of the corpus, much of the left ramus and the anterior part of the right ramus, the crowns and roots of the M_{1s}, dm_{2s}, dm_{1s}, dcs, and the right I₁ crown, plus the germs of the permanent lateral incisors, the permanent canines, the permanent premolars, and the second molars. Announcement N/A. Initial description Robinson 1956. Photographs/line drawings and metrical data Robinson 1956, Conroy and Vannier 1991, Dean et al. 1993. Detailed anatomical description Robinson 1956, Dean et al. 1993. Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Archaic hominin. Significance This well-preserved juvenile mandible is notable for several reasons. First, it preserves in a single specimen much information about the dental development of *P. robustus*. Second, the microstructure of the developing dentition was investigated (Dean et al. 1993) and this allowed the researchers who conducted that study to make detailed estimates of the time it took to form the various crowns and roots. These data showed unambiguously that “the data for age at death, for age of M₁ emergence, and for root extension rates...accord with those known for modern great apes and fall beyond the known ranges for modern humans” (*ibid.*, p. 401). Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa. *See also* dental development.

SK 80 *See* SK 847.

SK 82 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery 1949. Finders Robert Broom and John Robinson. Unit/horizon Pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved proximal end of a right femur. Announcement Napier 1964 (but SK 82 is referred

to as SK 83). Initial description Robinson 1972b. Photographs/line drawings and metrical data Robinson 1972b. Detailed anatomical description Robinson 1972b. Initial taxonomic allocation *Paranthropus*. Taxonomic revisions Howell (1978) includes SK 82 as part of the hypodigm of *Australopithecus robustus*. Current conventional taxonomic allocation *Paranthropus robustus*. Informal taxonomic category Megadont archaic hominin. Significance The two proximal right femora, SK 82 and SK 97, from Swartkrans were initially not recognized as hominin [e.g., they were not included in Broom and Robinson's (1970) discussion of the postcranial evidence for *Paranthropus crassidens*]. It was John Napier who pointed out their significance (Napier 1964) and it was the similarities between SK 82 and 97 and OH 20 that prompted Day (1969a) to assign the latter to *Australopithecus boisei* and not to *Homo habilis*. SK 82 and 97 were part of the evidence used by Robinson (1972b) to justify his case that the locomotion of *P. robustus* was substantially different from that of *Australopithecus africanus*, with the former showing substantial adaptations for climbing that were not seen in *Au. africanus*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 84 (NB: This SK number was originally used by Robinson 1956 for an upper canine, but now SK 84 refers to a first metacarpal) Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery 1949. Finders Robert Broom and John Robinson. Unit/horizon Brown breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Well-preserved complete left first metacarpal (MC-1). Announcement Broom and Robinson 1949b. Initial description Broom and Robinson 1949b. Photographs/line drawings and metrical data Napier 1959. Detailed anatomical description Susman 1988a. Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions *Homo erectus* (Susman 1988a). Current conventional taxonomic allocation *P. robustus* or *H. erectus*. Informal taxonomic category Megadont archaic hominin. Significance Susman (1988a) suggested that SK 84 resembled a thumb metacarpal from KNM-WT 15000, assigned by many to *Homo erectus*,

so he concluded that SK 84 also belonged to *H. erectus*. He also suggested that SK 84 did not belong to the same hominin taxon as another hominin first metacarpal, SKX 5020, so he concluded that the latter specimen must sample *P. robustus*. A recent comparative study of the shape of the proximal joint surface of the first metacarpal (Marzke et al. 2010) corroborates the suggestion that SK 84 is more modern human-like than SKX 5020, but others have concluded that the differences between the two Swartkrans Member 1 first metacarpals are evidence of intra- and not inter-specific variation (Trinkaus and Long 1990). If it is confirmed that this specimen is more likely to sample *H. erectus* than *P. robustus* then it would be one of the few hand bones assigned to the former taxon. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 846b *See* SK 847.

SK 97 *See* SK 82.

SK 847 (i.e., SK 80, 846b, and 847, aka SK 847 or “the SK 847 composite cranium”) Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery September 1949 (SK 80) and 1952 (SK 847). Finders Robert Broom and John Robinson (SK 80) and John Robinson (SK 847). Robinson recognized the SK 80 palate as representing *Telanthropus capensis* (i.e., *Homo*) but regarded the SK 847 upper facial fragment as a specimen of *Paranthropus robustus*. It was not until July 1969, when Ron Clarke realized that SK 847, 846, and 80 came from the same individual, that the separately numbered specimens were assembled into the partial cranium known as the “SK 847 composite cranium.” Unit/horizon Member 1 “Hanging Remnant”, pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Part of the left side of the face (SK 847), the temporal component of the left side of the cranial base (SK 846b), and a maxillary fragment (SK 80). Announcement Clarke et al. 1970. Initial description Clarke et al. 1970. Photographs/line drawings and metrical data Clarke and Howell 1972. Detailed anatomical description Clarke and Howell 1972, Clarke 1977. Initial taxonomic

allocation Prior to Clarke realizing that SK 847, 846, and 80 came from the same individual, and then observing the ways its facial morphology differed from that of *P. robustus*, SK 80 was attributed to *Homo* (i.e., *T. capensis*) but SK 847 and probably SK 846b were referred to *P. robustus*. Taxonomic revisions *Homo* sp. (Clarke and Howell 1972), *Homo habilis* (Howell 1978a, Strait et al. 1997, Curnoe and Tobias 2006), *Homo erectus* (Tobias 1991), *Homo* aff. *H. habilis*. (Grine et al. 1993, 1996, Grine 2001), paratype of *Homo gautengensis* (Curnoe 2010). Current conventional taxonomic allocation *Homo* sp. Informal taxonomic category Pre-modern *Homo*. Significance While there is near unanimity that SK 847 is not part of the *P. robustus* hypodigm, there is much less agreement about what taxon SK 847 does sample. The superficial similarities between KNM-ER 3733 and SK 847 have led some researchers to support an allocation to *Homo erectus sensu lato*, but the more detailed analyses of Grine et al. (1993, 1996) and Smith and Grine (2008) suggest that SK 847 has both similarities with, and differences from, *Homo habilis sensu stricto*. Grine expressed it well when he wrote that “the taxonomic affinities of the early *Homo* fossils from South Africa await a comprehensive comparative analysis of all the relevant characters shovel shaped incisors, including details of dental morphology” (Grine 2001, p. 112). Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SK 848 Site Swartkrans. Locality N/A. Surface/in situ *In situ*. Date of discovery 1949–52. Finder Unknown. Unit/horizon N/A. Bed/member ? Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A temporal bone including an incus bone that is complete except for the long process. Announcement The existence of the temporal bone was first mentioned in Tobias et al. in Oakley et al. (1977), but the existence of the incus was announced by Rak and Clarke (1979). Initial description, photographs/line drawings, metrical data, and detailed anatomical description Rak and Clarke 1979 re. the incus. Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic

category Megadont archaic hominin. Significance This incus, recovered from the epitympanic recess of the middle ear cavity of SK 848, was the first middle ear ossicle to be recovered from an early hominin. The acutely angled articular surface and the small short process set this incus apart from those typical of modern humans and extant higher primates. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa. *See also* middle ear.

SK 3155b Site Swartkrans. Locality N/A. Surface/in situ Recovered from breccia removed by miners in 1948/9. Date of discovery 1970 (but the breccia in which it was embedded was recovered by Robert Broom and John Robinson in 1949). Finder Elisabeth Vrba recognized the pelvis in a piece of undeveloped breccia. Unit/horizon Member 1, pink breccia. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.2.0–1.5 Ma. Developmental age Subadult. Presumed sex Unknown. Brief anatomical description Most of the ilium, except for the anterior one-sixth and the posterior one-third of the iliac crest, the unfused acetabulum, and the acetabular portions of the ischium and pubis. Unlike SK 50, there is minimal plastic deformation. Announcement, initial description, photographs/line drawings, metrical data, and detailed anatomical description McHenry 1975. Initial taxonomic allocation “Probably a member of the robust australopithecine group,” and “its relatively small acetabulum and sacral articular surface are enough to exclude it from [*Homo erectus*]” (McHenry 1975, p. 249); thus, by exclusion, *Paranthropus robustus*. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance Given its location, this well-preserved pelvic bone very likely belongs to *P. robustus* and thus it provides important information about the hip joint and swing-phase balancing mechanism of *P. robustus*. This specimen was said by Henry McHenry to share the traits common to other australopithecine pelvic bones (i.e., “a low broad ilium, a relatively small acetabulum and sacral articular surface, a wide flaring of the iliac blades, a well-developed anterior iliac spine with a groove for the iliopsoas muscle, and a relatively deep acetabulum,” McHenry 1975, p. 260), and instead of emphasizing the differences

between the pelvis of *Australopithecus africanus* and *P. robustus*, the evidence from SK 3155b stresses just how much pelvic morphology is likely shared by these taxa. The suite of morphological features set out above differs from the much more modern human-like configuration of the fossil hominin pelvic bones from East Africa such as KNM-ER 3228 and OH 28. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

skeletal element survivorship The probability that a particular skeletal element has survived the destructive taphonomic processes that can alter a bone assemblage following its deposition by hominins, carnivore, or other agents. Destructive taphonomic processes include **carnivore ravaging**, trampling, and dissolution. Skeletal element survivorship is influenced largely by the density of a skeletal element, with high-density elements more likely to survive than their low-density counterparts. Differential survivorship can radically alter the frequencies of skeletal parts in a bone assemblage, which can be especially problematic when making inferences concerning hominin behavioral patterns (e.g., **carcass transport strategies**) in archeological contexts. Skeletal elements can be classified as **high-survival elements** or **low-survival elements**. The high-survival subset is known to be resistant to destructive processes and includes elements mostly characterized by dense cortical bone with relatively little, or no, cancellous bone, such as the long bones, crania, and mandibles of most ungulates. This subset is the best candidate for making hominin behavioral inferences because its high survivorship provides the most accurate representation of the bones originally discarded by hominins. The low-survivorship subset, which is particularly sensitive to destructive processes, includes elements with thin cortical walls and much low-density, grease-rich cancellous bone. This subset includes vertebrae, ribs, pelvis, scapula, and long-bone epiphyses. The phalanges, carpals, and tarsals are also low-survival elements, because they tend to be swallowed whole by carnivores. Because low-survivorship elements are readily destroyed following hominin discard, they are of relatively little utility when examining carcass transport strategies in bone assemblages subjected to destructive processes.

skeletal part frequency The frequency of different skeletal elements or fragments thereof in a fossil bone **assemblage**, typically quantified according to calculated indices such as **minimal animal unit**, **minimum number of elements**, **minimum number of individuals**, or **number of identified specimens**. The study of skeletal part frequencies is used to evaluate the taphonomic history of a bone assemblage, with a particular focus on identifying bone-accumulating agents and depositional processes. In zooarcheological contexts, observed skeletal part frequencies are the result of a complex interaction between the hominin utilization and transportation of animal carcasses (i.e., **carcass transport strategies**) and destructive taphonomic processes operating following human discard, such as **carnivore ravaging**.

skeleton (Gk *skeletos*=to dry up) In vertebrates it refers to the hard tissue (bone and cartilage) elements that make up the endoskeleton that protects and supports the soft tissues. It is divided into the **axial skeleton** (comprising the skull, vertebral column, and thorax) and **appendicular skeleton** (limb girdles and limbs) components.

Skhul (Location 32°40'N, 34°58'E, Israel; etym. from Ar. (مغارة *mugharet*=cave, and (سخور *skhul*= kids) History and general description Skhul cave was first excavated in 1931 by Theodore D. McCown under the auspices of Dorothy Garrod's exploration of the **Mount Carmel** caves. It consists of two parts: a small cave and a larger external rock-shelter/terrace, where most of the archeological and hominin remains were found. Despite somewhat rushed excavation techniques (the nearly 1300 m² area was removed over a period of 8 months), McCown recognized three main levels, including a thick **Mousterian** level (Layer B). This site is one of the oldest early modern *Homo sapiens* sites found outside of Africa, and Shea (2005) argues that it represents an early modern human migration into the Near East that disappeared *c.*75 ka when the environment changed. Temporal span and how dated? Although originally aligned with **Tabun Level C** and believed to be *c.*45 ka based on faunal and lithic similarities assemblages, Skhul Level B has recently been shown to be much more ancient. **Thermoluminescence dating** on burned flints from Level B produced a wide range of 167–99 ka, with a central tendency of 119 ka, and the most

recent uranium-series dating and electron spin resonance spectroscopy dating on some of the hominin and faunal remains suggests a date of 100–130 ka. Hominins found at site Ten numbered individuals (including two infants) and 16 isolated fragments have been recovered from Skhul. McCown (in Garrod and Bate 1937) believed these were all intentionally buried, and one (Skhul V) may have been interred with a pig's mandible as a grave good. McCown and Keith (1939) originally argued that the fossils from Skhul were from the same population as those from Tabun, which they called *Palaeanthropus palestinensis*. They argued that this group was undergoing evolution from a Neanderthal-type to a Cro-Magnon-type, with the Tabun fossils being older and more primitive and the Skhul fossils younger and more advanced. More recent re-evaluations of these fossils have shown that the Skhul fossils are closest to and belong with modern *Homo sapiens* (Howell 1957, Stewart 1960, Higgs 1961, Brothwell 1961) and that they pre-date the fossils from Tabun (Mercier et al. 2003, Grün et al. 2005). Because the Skhul and Qafzeh remains represent the earliest known modern human remains outside of Africa, they have played a crucial role in understanding the radiation of modern humans from Africa. Archeological evidence found at site The archeological material from Level B was thought to be equivalent to Tabun Levels C and D. The technology is a relatively primitive Mousterian with Levallois technique, very similar in type to that found at Tabun. Key references: Geology, dating, and paleoenvironment Garrod and Bate 1937, Higgs 1961, Grün and Stringer 1991, Mercier et al. 1993, 2003, Grün et al. 2005; Hominins Garrod and Bate 1937, McCown and Keith 1939, Howell 1958, Brothwell 1961; Archeology Garrod and Bate 1937.

Skhul I Site Skhul. Locality Terrace. Surface/in situ In situ. Date of discovery 1931. Finders T. McCown and team. Unit Layer B. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 100–130 ka. Developmental age c.4–4.5 years. Presumed sex Unknown. Brief anatomical description Fragmentary remains of cranium, mandible, and several milk teeth, many fragments of postcranial elements. Announcement Garrod and Bate 1937. Initial description Garrod and Bate 1937.

Photographs/line drawings and metrical data McCown and Keith 1939. Detailed anatomical description McCown and Keith 1939. Initial taxonomic allocation *Palaeanthropus palestinensis* McCown and Keith, 1939. Taxonomic revisions *Homo sapiens* (e.g., Howell 1957, Stewart 1960, Higgs 1961). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern *Homo*. Significance The first of the fossils to be recovered from Skhul, this young child is one of the few early modern human juvenile specimens. Location of original Museum of the Department of Antiquities, Jerusalem, Israel.

Skhul IV Site Skhul. Locality Terrace. Surface/in situ In situ. Date of discovery April 30, 1932. Finders Theodore McCown and team. Unit Layer B. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 100–130 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description A nearly complete skull and postcranial skeleton. Announcement Garrod and Bate 1937. Initial description Garrod and Bate 1937. Photographs/line drawings and metrical data McCown and Keith 1939. Detailed anatomical description McCown and Keith 1939. Initial taxonomic allocation *Palaeanthropus palestinensis* McCown and Keith, 1939. Taxonomic revisions *Homo sapiens* (e.g., Howell 1957, Stewart 1960, Higgs 1961). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern *Homo*. Significance The postcranial skeleton of Skhul IV is exceptionally complete, and the position of the skeleton when recovered suggests this individual was intentionally buried. Location of original Museum of the Department of Antiquities, Jerusalem, Israel.

Skhul V Site Skhul. Locality Terrace. Surface/in situ In situ. Date of discovery May 2, 1932. Finders T. McCown and team. Unit/horizon Layer B. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 100–130 ka. Developmental age 30–40 years. Presumed sex Male. Brief anatomical description Fairly complete, though heavily reconstructed mandible and calvaria. The calvaria is missing the midfacial and most of the subnasal regions. Nearly all of the postcranial elements are represented but

some have minor damage. Announcement McCown 1932. Initial description Garrod and Bate 1937. Photographs/line drawings and metrical data McCown and Keith 1939. Detailed anatomical description McCown and Keith (1939). Initial taxonomic allocation *Palaeoanthropus palestinensis*. Taxonomic revisions Howell 1957, Stewart 1960, Higgs 1961, Brothwell 1961. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Skhul V is among the best-preserved remains from the Mount Carmel region. The remains were almost certainly intentionally buried, and the mandible of a wild boar has been associated with the find, possibly having been intentionally placed in the arms of the buried skeleton. Location of original Peabody Museum at Harvard University, Cambridge, MA, USA.

Skildergat *See* Fish Hoek.

skull (ME *skulle*=skull) The bony component of the head, made up of 28 bones, a few of which are unpaired (e.g., the frontal and the occipital), but most of which are in symmetrical pairs (e.g., the parietal and temporal). It consists of the cranium plus the mandible. *See* cranium and mandible, and their components, for more detailed descriptions.

Skull II *See* Sangiran 2.

Skull III *See* Sangiran 3.

Skull IV *See* Sangiran 4.

Skull VI *See* Sangiran 10.

skullcap *See* calotte.

SKW Abbreviation of Swartkrans Cave, University of the Witwatersrand, and the prefix for all fossils recovered from Swartkrans Cave, Blauwbank Valley, Gauteng, South Africa, between 1968 (when the University of the Witwatersrand purchased the property) until 1979 when the prefix was changed to SKX. All of the SKW fossils are curated by the Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SKW 18 *See* SK 52/SKW 18.

SKX The prefix used for all fossils recovered from Swartkrans during excavations *in situ* from 1979 to 1986. All of the fossils with the SKX prefix are curated by the Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

SKX 5020 Site Swartkrans. Locality Excavation coordinates E3/N3, NE Quadrant, 630–640 cm. Surface/*in situ* *In situ*. Date of discovery Sometime between 1979 and 1983. Finder Recovered during ongoing excavations. Bed/member Member 1. Formation Swartkrans Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right metacarpal that lacks part of the proximal and much of the distal articular surface. Announcement N/A. Initial description Susman 1988a. Photographs/line drawings and metrical data Susman 1988a, 1988b, 1993. Detailed anatomical description N/A. Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions None. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance Susman (1988) suggested that the SK 84 hominin first metacarpal resembled the thumb metacarpal from KNM-WT 15000, assigned by many to *Homo erectus*, so he concluded that SK 84 also belonged to *H. erectus*. He also judged the differences between SK 84 and SKX 5020 were too great for them to belong to the same taxon, so he concluded that the latter specimen must sample *P. robustus*. A recent comparative study of the shape of the proximal joint surface of the first metacarpal (Marzke et al. 2010) corroborates the suggestion that SKX 5020 is more primitive than SK 84. However, others have concluded that the differences between the two Swartkrans Member 1 first metacarpals are evidence of intra- and not inter-specific variation (Trinkaus and Long 1990). If it is confirmed that SKX 5020 is more likely to sample *P. robustus* than *H. erectus* then it would be one of the few hand bones assigned to the former taxon. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa.

sliding landmarks *See* semilandmarks.

Sm Abbreviation for Sambungmacan and the prefix used for fossils recovered from that site. *See also* Sambungmacan.

Smith Woodward, Sir Arthur *See* Piltown.

Smithsonian Institution *See* National Museum of Natural History, Smithsonian Institution.

SMRS Acronym for the specific mate-recognition system, the system that has been proposed as the mechanism for species defined on the basis of the individuals (usually females) identifying potential mates. *See also* species; recognition species concept.

Smugglers' Cave (Location 33°55'N, 7°00'W, Morocco; aka the Grotte des Contrebandiers in French, and sometimes referred to Témara, after the nearby town) History and general description This site was discovered in 1955 by Abbé Jean Roche. It is a cave site in a coastal sandstone cliff located 14 m above sea level on the Atlantic coast, 17 km/10.5 miles southwest of Rabat. M. Henrion led the first sounding from 1955 to 1957. Excavations were conducted between 1967 and 1975 by Roche and Texier and the site was reopened and excavated in 1994 by A. Bouzouggar. Temporal span and how dated? Uranium-series dating on shell and radiocarbon dating on bone have provided dates between 125 and 10 ka. Hominins found at site "Témara Man," occipital, parietal, frontal fragments, and a mandible. Archeological evidence found at site Aterian artifacts, Iberomaurean and Neolithic artifacts in the upper layers, shell beads, hearths, ochre use, limpet and mussel shell middens associated with Neolithic deposits. Key references: Geology, dating, and paleo-environment Debénath et al 1986, Roche 1976; Hominins Debénath 2000, Ferembach 1998; Archeology Bouzouggar 1997.

SNP Acronym for single nucleotide polymorphism (*which see*).

Soa Basin This geographic region of central Flores, Indonesia, which is the drainage of the Ae Sissa River, is the location of exposures of the **Ola Bula Formation**. Several Early and

Middle Pleistocene sites, of which **Mata Menge** is the best known, are located in the Soa Basin. *See also* **Ola Bula Formation**.

social enhancement This term describes the phenomenon when an innate, species-typical behavior is more likely when conspecifics are engaged in the same behavior. Examples of social enhancement (also referred to as social facilitation or contagion) in modern humans include reactions to other people laughing, crying, or yawning. In some cases such behaviors are inhibited, and this converse phenomenon is referred to as social inhibition. Both social enhancement and inhibition are defined as motivational (behavioral) states. Often, social enhancement may resemble behavior matching or imitation because the mere presence of another individual has the potential to lead to synchronization of behaviors over space and time. Animal behaviorists believe that social enhancement is crucial in group-living species for group cohesion, behavioral coordination, foraging efficiency, and predator avoidance. While social facilitation alone does not lead to complex behavior matching or imitation, it has the potential to increase the opportunities in which observational learning can occur, and observational learning has been implicated in the development of the ability to manufacture tools. When coordination of behavior occurs among two or more individuals, it is referred to as social contagion, because the mere act of seeing another individual engaging in a species-typical behavior elicits that same response in others. For example, satiated brown capuchin monkeys will resume feeding when a familiar conspecific is seen eating nearby, and will also consume more food in the presence of another monkey than if alone.

social facilitation *See* social enhancement.

social inhibition *See* social enhancement.

social intelligence Social intelligence encompasses a range of skills including pro-social behaviors such as social learning, imitation, teaching, communication, theory of mind, and cooperation. Social intelligence is believed to have evolved in response to the specific and unique pressures associated with group living. The term has its origin in the social intelligence hypothesis originally proposed by Nicholas Humphrey (1976), but it is also known as "Machiavellian intelligence" after the book

Machiavellian Intelligence: Social Experience and the Evolution of Intellect in Monkeys, Apes, and Humans (Byrne and Whiten 1988). The book is named after the Italian political theorist, Niccolò Machiavelli, who argued that in order to be a good Prince, one must employ deceit and engage in various forms of social manipulation (Machiavelli 1532, translated in 1966). Byrne and Whiten (1988) and others have argued that some form of Machiavellian, or social, intelligence is a requirement of living in groups when important resources (e.g., food and potential mates) are limited. Skilled field researchers working with various kinds of primate species have reported a substantial number of anecdotal cases of tactical deception, and Byrne and Whiten cite these in support of the social intelligence hypothesis. The social intelligence hypothesis proposes that group living in primates and other animals has favored social manipulation by adding to cognitive power through **natural selection**, and it has received support from a significant amount of empirical data, examples of which include the positive correlation between group size and **neocortex** ratio (i.e., the volume of neocortex relative to that of the other parts of brain) (e.g., Dunbar 1993, 1995) and superior performance of transitive inference in species with larger group size as compared to that of closely related counterparts with smaller group size (e.g., Bond et al. 2003). As such individuals living in large groups can infer from limited social interactions that if A is dominant to B, and B is dominant to C, then A must be dominant to C.

social intelligence hypothesis *See* social intelligence.

social learning (L. *socius*=companion and OE *lernen*=to gain knowledge) Mammalian development and certainly modern human development is very much dependent on learning that is influenced by the actions of others who provide cues and signals that guide an observer's attention to specific behaviors (e.g., social relationships) or to objects (e.g., food). The learning that results from observation or interactions with others falls under the general category of social learning (Bonnie and Earley 2007, Zentall 2007), and it is likely that learning to make stone and other types of tools involves social learning. Social learning is different from (a) individual learning, which is learning achieved through trial and error, (b) the learning

that arises in isolation without the benefit of interacting with a conspecific or a model, and (c) instinctual behaviors. Using this broad definition, social learning is widespread in the animal kingdom. In fact, for mammals and birds, social learning has been shown to play a critical role in the development and maintenance of species-specific behaviors (e.g., the acceptance or avoidance of novel foods, mate choices, and predator-avoidance strategies). Among primates, social learning may require reasoning about other individuals, or even reasoning about one's own behavior. Examples of socially learned primate behaviors include specialized grooming, communicative signals, and tool-use techniques. These types of activities may require that an individual understand their own relationship to the demonstrator (e.g., for copying motor patterns), or understand the goal of the demonstrator's actions, both of which involve relatively sophisticated cognitive abilities that may be unique to the great apes, or perhaps only to modern humans. Determining what cognitive abilities are involved in the learning process has been the primary objective of social learning researchers for over a century, with a great amount of attention focused on nonhuman primates. **Imitation** represents a specific type of social learning, initially considered one of the few traits that animals had in common with modern humans, and many languages even have terms that involve the words "ape" or "monkey" to describe imitation (e.g., "aping" the professor). However, there is debate over whether or not monkeys, apes, or any animals other than modern humans are able to truly imitate, with a particular emphasis being placed on what the definition of imitation should be. Sometimes imitation can be confused with more subtle forms of social influence that lead to learning the same behaviors as others. For this reason, the literature on social learning distinguishes terms for the different ways in which learning can take place, such as social facilitation, contagion, stimulus enhancement, local enhancement, emulation, imitation, and **teaching**. *See also* imitation.

soil carbonates *See* paleosol.

Solo *See* Ngandong.

Solo Man This is the informal way Franz Weidenreich referred to the **Ngandong hominins**, and he entitled his unfinished monograph

about these remains the *Morphology of Solo Man* (Weidenreich 1951). *See also* Ngandong hominins.

solution cavities *See* limestone.

Solutré (Location 46°18'N, 4°42'E, department of Saône-et-Loire, approximately 10 km/6 miles west of Mâcon, France; etym. unknown) History and general description Located in the scree slope at the base of a limestone outcrop, this is the type site of the **Solutrean** technocomplex. It was first excavated in 1866 by Adrien Arcelin and Henri Testot-Ferry, and has been under occasional excavation since then, most recently by Jean Combier. The site preserves one of the best examples of a mass kill site from the **Upper Paleolithic**. Temporal span and how dated? **Biostratigraphy** and archeological correlation, as well as **radiocarbon dating**, suggest an age span of 30.4–12ka. Hominins found at site Four hominin skeletons (a female with a neonate, and two males) were recovered from the **Aurignacian** level in the 1920s, but no detailed study of these fossils has been made. A juvenile mandible from one of the less well-documented excavations was discovered in 2002 among the collections at the Field Museum of Natural History, Chicago, USA, and was thought to be from the Solutrean, but radiocarbon dating revealed that it was from a recent intrusive burial. Archeological evidence found at site Three main stratigraphic layers were uncovered, from youngest to oldest they are **Magdalenian**, **Solutrean**, **Gravettian**, **Aurignacian**, and **Mousterian**. The overwhelming numbers of horse bones have suggested that the Solutrean hunters were regularly using a natural *cul-de-sac* to trap and kill migrating herds of horses. Key references: Geology, dating, and paleoenvironment Combier and Montet-White 2002; Hominins Bossavy 1923, Pestle et al. 2006; Archeology Combier and Montet-White 2002.

Solutrean (etym. After the site of Solutré) An Upper Paleolithic technocomplex that dates to *c.* 21–17 ka or during the Last Glacial Maximum. It is characterized by large, flat, and thin leaf-shaped points and it is associated with an increased site density, greater prevalence of art (particularly parietal art like cave paintings and engravings), and the hunting of reindeer.

somatic cells (Gk *soma*=body) Cells of the body other than reproductive cells (**gametes**).

Somatic cells typically have a diploid complement of **chromosomes**. For example, the interstitial tissue of the testis is made up of diploid somatic cells, whereas the secondary spermatocytes or “spermatids” are haploid gametic cells, or **germ cells**.

somite (Gk *soma*=body) In development, somites are the first expression of the segmental organization of the body. They form from so-called “presomitic mesenchyme,” and to reflect that they lie on either side of the midline, or axis, of the developing body, these cells are referred to as paraxial (literally “either side” of the “axis”) mesenchyme. Somites then form **sclerotomes** and all but the first four or so of the sclerotomes contribute to the development of the vertebrae, intervertebral discs, and ribs. The first four sclerotomes contribute to the basicranium. Each vertebra is formed from the caudal half of its equivalent sclerotome, plus the cranial half of the sclerotome below it (e.g., the C4 vertebrae is formed from the caudal half of the C4 sclerotome and the cranial half the C5 sclerotome).

South African Museum (Iziko Museums of Cape Town)

The South African Museum (or SAM) was founded by the Governor of the Cape of Good Hope, Lord Charles Somerset, in 1825, and as such it is the country’s second oldest scientific institute. Dr Andrew Smith was appointed the first Director (Superintendent) of the SAM, which was originally housed in a flat at what was then the Public Library (now the Slave Lodge, or South African Cultural History Museum) located in Cape Town. Early collections focused primarily on minerals, shells, fish, reptiles, birds, mammals, and ethnographic material. Between 1825 and 1855 the collections became neglected and dispersed across a number of locations in Cape Town, and in 1855 the SAM was reconstituted by government notice, at which time the first Curator and Board of Trustees were appointed. A new building for the SAM and Library was opened in 1860, but the building was too small and plans were made for another new building, which was opened on April 6, 1897, and it is this building, with later additions including the adjacent Planetarium, that houses the current collections. On April 1, 1999, the SAM was amalgamated, along with a number of other museums and heritage sites, into the Southern Flagship Institution, which was subsequently renamed the Iziko Museums of Cape Town in July 2000. *Iziko* is an isiXhosa word meaning “hearth,” which in this context

symbolizes the importance of this institution as a central gathering place for South African heritage. The SAM is important from a paleoanthropological point of view for its collections that include the remains of early modern humans from coastal sites around the Western Cape of South Africa, and it also houses extensive archeological collections including artifacts and the skeletal remains of Holocene hunter-gatherers. These Holocene Khoesan collections are studied frequently by researchers interested in the emergence of the modern human phenotype. Hominin fossil collections **Klasies River**, **Fish Hoek** (Peers' Cave), **Blombos Cave**, and **Elandsfontein** (Saldanha, Hopefield). Contact department Archeology Department. Contact person Dr Sarah Wurz (e-mail swurz@iziko.org.za). Postal address Box 61, Cape Town 8000, South Africa. Website www.iziko.org.za/sam/index.html. Tel +27 (0)21 481 3800. Fax +27 (0)21 481 3993. E-mail info@iziko.org.za.

South Turkwel (Location 2°19'N, 36°04'E, Kenya; etym. named after a local major river) History and general description This site is between Lodwar and **Lothagam** on the west side of **Lake Turkana**. A minimum of 140 m of sediments are exposed; the lower sediments are predominantly **lacustrine** and the upper ones are mainly fluvial. Temporal span and how dated? **Tephrostratigraphy** suggests that the two tuffs in the section are a vitric tuff near the base that is the equivalent of a tuff within Lonyumun Member of the Nachukui Formation (West Turkana) and the **Koobi Fora Formation** (Allia Bay), and a lens of the Lokochot Tuff that has been dated at 3.58 Ma. Thus, the upper fluvial sediments are equivalent to the Kataboi Member of the Nachukui Formation in West Turkana and Member A of the **Shungura Formation**, and the lower lacustrine sequence is equivalent to the Lonyumun Member of the Nachukui and Koobi Fora Formations. Hominins found at site The two hominin fossils from South Turkwel are KNM-WT 22936, part of a right mandibular corpus, and KNM-WT 22944, an associated skeleton that includes a piece of weathered mandible and tooth crowns, four hand bones, and a proximal foot phalanx. These were surface finds in a part of the section where the Lokochot Tuff is not exposed. A reasonable age for the two hominin fossils is the age of the Lokochot Tuff (i.e., 3.58 Ma) with a minimum age of *c.*3.2 Ma. Morphologically the two hominin specimens are consistent

with an attribution to *Australopithecus afarensis*, but the researchers who found them attribute them to *Australopithecus sp. indet.* Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Ward et al. 1999a; Hominins Ward et al. 1999a.

Southern Afar Rift System The term used for the southern part of the **Afar Rift System** (also known as the **Afar Depression**) (WoldeGabriel et al. 2000). This section of the **Ethiopian Rift System** includes the **Dikika study area**, **Gona study area**, **Hadar**, **Middle Awash study area**, and the **Woranso-Mille study area**.

Southern blotting (etym. Named after Sir Edwin Southern who devised and developed this technique) A method used to detect particular DNA sequences. Fragments of DNA are transferred from an electrophoretic gel to a filter membrane, and the fragments are subsequently detected by a **hybridization** assay using probes for specific nucleic acids.

Southern Oscillation Index (or SOI) This climate variable is the barometric pressure difference between Tahiti, in French Polynesia, and Darwin, in Northern Australia. It was first suggested and used by Sir Gilbert Walker. Along with **sea surface temperature** changes the SOI is a key indicator of the **El Niño Southern Oscillation**. In the **tropics** these pressure differences account for the anomalous longitudinal **Walker circulation** as opposed to the global average **Hadley circulation**. *See also* **El Niño Southern Oscillation**.

sp. indet. (etym. *sp. indet.* is an abbreviation of “indeterminate species”) When dealing with fragmentary specimens it is sometimes possible to identify the genus a specimen belongs to, but it may not be possible to be sure which species it belongs to. In that case the taxonomic allocation researchers should use is “*sp. indet.*” (e.g., the mandible **KNM-ER 1506** has been referred to *Homo sp. indet.*).

spatial packing hypothesis This hypothesis is an attempt to explain variation in the overall shape of the cranium in terms of physical interactions between the growth and development of the **brain**, the **chondrocranium**, and the **face**. It is based on the premise that the craniofacial complex consists of independent and partially independent **modules**

that interact as the cranium develops because they are physically adjacent or have developmental connections. In particular, the hypothesis holds that the growth of the brain relative to the growth of the basicranium is a major determinant of the **cranial base angle** and thus of the position of the face relative to the brain case. Thus, flexion of the basicranium enables an increase in brain size to be accommodated without any significant changes in its width and/or length. The model posits that interactions among the brain, chondrocranium, and face lead to correlated variation that results in integrated evolutionary change. In particular, the highly flexed **basicranium** of modern humans, which results in the face being underneath the anterior-most part of the brain case, evolved as a byproduct of the enlargement of the brain without elongation of the cranial base. The hypothesis has a long history (Virchow 1857, Bolk 1910, Weidenreich 1941a, Hofer 1960) but it was formulated most explicitly by Biegert (1957, 1963), and expanded upon with different degrees of formality by DuBrul and Laskin (1961), Vogel (1964), Gould (1977), and Enlow (1990). *See also* **basicranium**.

spear A weapon consisting of a long shaft and a sharp tip that can be thrust into, or thrown at, an animal. Many stone **points** recovered in the archaeological record are inferred to have been manufactured in order to be mounted onto a wooden shaft and to serve as the tips of spears, but sharpened wooden tips are also effective. Chance preservation of some wooden spears suggests that the latter types date to at least 400 ka (Thieme 1997).

specialist *See* **stenotopy**.

speciation In the most general sense, the process by which descendant **species** evolve from ancestral ones. More specifically, the term is often used to refer to the evolution of new species via a process of “splitting” off from a pre-existing species (i.e., **cladogenesis**). Speciation is often discussed in terms of the ecological and/or biogeographic factors that may have led to the evolution of new species and a terminology has been devised to distinguish among these various factors (e.g., **allopatric speciation**, **peripatric speciation**, **parapatric speciation**, **sympatric speciation**). Ultimately, however, although it is almost certainly true that at least some hominin species evolved as a result of cladogenesis, it is very difficult to assert with any confidence the precise type of specia-

tion involved with the emergence of any particular hominin taxon.

species (L. *specere*=to look; NB: *spectaculum*, *specimen*, and *spectio*, the source of “inspection,” come from the same verb. The connection with Gk *eidos*=form or idea, is a semantic and not an etymological one) Species is the next-to-least inclusive category in the Linnaean taxonomic system. There is disagreement about how species are recognized, and de Queiroz (2007) makes the point that there has been consistent confusion between how we *conceptualize* species and how in practice we *recognize* them (he refers to the latter process as “delimitation”). Andrew Smith (1994) usefully divides species concepts into process-related and pattern-related. The former emphasize the processes involved in the generation and maintenance of species, whereas the latter emphasize the methods used for recognizing them. The three main concepts in the process category are the **biological species concept** (or BSC), the **evolutionary species concept** (or ESC), and the **recognition species concept** (or RSC). The BSC definition given below is the one provided by Ernst Mayr in 1942, and subsequently modified by him in 1982. He suggested that species are “groups of interbreeding natural populations reproductively isolated from other such groups.” Note that this definition emphasizes isolation; it is a “relational” and not a “free-standing” definition. The ESC was an attempt by Simpson (1961) to add a temporal dimension to the BSC. Thus, he suggested that under the ESC a species is “an ancestral-descendant sequence of populations evolving separately from others and with its own evolutionary role and tendencies.” The third concept in this category, the RSC, instead of emphasizing reproductive isolation emphasizes the process that promotes interbreeding. Hugh Paterson (1985) suggested that under the RSC a species is “the most inclusive population of individual, biparental organisms which shares a common fertilization system.” In practice, species are recognized by one of three main pattern-based species concepts, the **phenetic species concept** (or PeSC), the **phylogenetic species concept** (or PySC), and the **monophyletic species concept** (or MSC). In the context of paleoanthropology, all are “morphospecies” concepts in that they each emphasize different aspects of an organism’s morphology. The PeSC as interpreted by Sokal and Crovello (1970) gives equal weight to *all* aspects of the phenotype, assembles a

matrix of these characters, and then uses multivariate analysis to detect clusters of individual specimens that share the same, or similar, phenotypes. Under the PySC introduced by Cracraft (1983) the emphasis is on those aspects of the phenotype that are diagnostic. According to Nixon and Wheeler (1990) in this scheme a species is “the smallest aggregation of populations diagnosable by a unique combination of character states.” Finally, under the MSC the morphological emphasis is narrower still, with species defined not on the basis of unique combinations of characters, but only on unique characters, or apomorphies. The problem with the MSC and is that it assumes the observer knows which characters are apomorphies. But one needs to do a cladistic analysis to determine which characters are apomorphic, and to perform a cladistic analysis you need to have **operational taxonomic units**, and to have these you need a **taxonomy**; the MSC has been criticized as the product of circular reasoning. de Queiroz (2007) includes a useful figure (*ibid*, Fig. 1, p. 882) in which he makes the point that the various properties researchers have suggested as criteria for recognizing species may arise at different stages in the complex process of speciation. In this way he reconciles the various suggestions for the species definitions he lists in his Table 1 (*ibid*, p. 880). In practice most researchers use one, or other, version of the PySC. They search for the smallest cluster of individual organisms that is “diagnosable” on the basis of the preserved morphology. Because in the hominin fossil record most of that morphology is craniodental, most diagnoses of early hominin taxa inevitably emphasize craniodental morphology. A useful review of the species concept with particular reference to paleoanthropology is provided by Holliday (2003).

species concept(s) *See* species.

species diversity An ecological diversity measurement that takes into account richness and evenness of species. *See also* **species evenness**; **species richness**.

species evenness An ecological diversity measurement that quantifies the evenness of the distribution of individuals across taxa.

species richness An ecological diversity measurement that refers to the number of species in a given community.

specific mate-recognition system *See* recognition species concept.

speciose A taxonomic hypothesis that emphasizes a larger rather than a smaller number of species. A researcher who favors speciose taxonomies is called a **splitter** (syn. **taxic**).

SPECMAP *See* orbital tuning.

specularite (L. *specere*=mirror) This variety of **hematite** is black or gray and it has a metallic luster. It has been found as an exotic material at sites such as **Twin Rivers, Zambia**. *See also* **hematite**.

speech (ME *speche*=speech) *See* spoken language.

speleothem (L. *speleon*=cave and *them*=deposit) The inclusive term for a range of rock types that are formed when water containing dissolved **calcium carbonate** reaches an air-filled cave. Within the cave, carbon dioxide de-gassing alters the water’s ability to retain minerals in solution, and over periods of tens of thousands of years its solutes precipitate and form **flowstones**, **stalactites**, and **stalagmites**; these are all forms of speleothem. Flowstones are formed when water flows on the floor or walls of a cave. They are generally horizontal, finely laminated layers of calcium carbonate that occur in sheets against walls or floor of the cave, or in thinner sheets between blocks of sediments. Stalactites are icicle-shaped mineral deposits that grow *down* from cave roofs, whereas stalagmites are conical mineral deposits fed from drip waters above that grow *up* from cave floors. *See also* **calcium carbonate**; **uranium-series dating**.

sphenomandibular ligament (Gk *sphen*=a wedge and *ooides*=shape) Fibrous ligament derived from the first branchial (Meckel’s) cartilage connecting the spine of the sphenoid to the lingula of the mandible. A line joining the inferior attachments of the two sphenomandibular ligaments is the axis around which depression/protrusion and elevation/retraction occur at the **temporomandibular joint**. *See also* **branchial arches**.

spheroid *See* Developed Oldowan.

splicing The process whereby **introns** are removed from messenger **RNA** to form a mature **transcript** containing either an unbroken **open reading frame** for **translation** into a **polypeptide** chain or a complete RNA sequence (e.g., for a transfer RNA, or ribosomal RNA molecule).

splitter (OD *spalten*=to divide) A label for researchers who favor dividing the fossil record into a larger number of exclusive taxa (i.e., with more stringent membership criteria) rather than a smaller number of more inclusive (i.e., with more relaxed membership criteria) taxa. Some researchers who are trying to reconstruct aspects of the biology of extinct taxa such as life history have suggested that splitting taxonomies is to be preferred because lumping taxonomies may “jumble characteristics from very different subgroups, producing chimeric life histories” (Smith et al. 1994, p. 181). Others claim splitting makes the hominin fossil record unnecessarily confusing.

spoken language (ME *speche*=speech and *language* from OF *langage* from L. *lingua*=tongue or speech) Spoken language, or speech, is a ubiquitous behavior among living modern human populations. It involves the use of a learned repertoire of sound units assembled in a distinctive sequence in rapid succession to convey information and meaning in an energetically efficient way. Among the advantages of spoken language are that the individuals involved in its transmission and reception need not be in visual contact with one another, and spoken language is an exceptionally efficient way of communicating with more than one person at a time. The “ingredients” of normal spoken language are a flow of exhaled air and a structure, normally the vocal cords, that is capable of vibration. The vocal cords break the emerging air into a series of separate emitted “puffs,” the fundamental frequency of which is determined by the length and the degree of tension of the vocal cords. Harmonic frequencies are added to the fundamental frequency as a result of changes in the shape and size (“gestural articulations”) of the various elements that make up the **supralaryngeal vocal tract**. Modern human languages use around 100 acoustically distinctive sound units, or **phonemes**. Phonemes are broken up into the consonants and vowels that make up syllables. Vowels involve phonation, whereas consonants involve the blocking and subsequently releasing the air flow. From within to without, the flow of

air can be obstructed at the glottis, the epiglottis, in the oropharynx, in the nasopharynx, in the nose, by the soft palate, by the tongue at various places along the hard palate, by the incisor teeth and by the lips (Ladefoged and Maddieson 1996). Subtle differences in the shape of the tongue can produce different formant frequencies and therefore different vowels. Compared with nonhuman primates modern human spoken language involves sound sequences that are an order of magnitude more rapid, and more than twice as long as those seen in nonhuman primates. The supralaryngeal vocal tract of modern humans is distinctive in that its two components – the horizontal one (SVT_H) and the vertical one (SVT_V) – are subequal (nearly equal) in length. In nonhuman primates and in other animals the SVT_H is usually longer than the SVT_V, and it is this 1:1 SVT_H/SVT_V ratio and the approximately 90° angle between the SVT_H and the SVT_V that makes it possible for modern humans to produce vowels such as [a], [i], and [u]. Researchers interested in language origins have been searching for a hard-tissue proxy for the shape and proportions of the supralaryngeal part of the vocal tract. They thought they had found it in the form of the **cranial base angle**, but Lieberman and McCarthy (1999) showed that flexion of the basicranium and laryngeal descent are not well enough related for the cranial base angle to be used a proxy for the height of SVT_V.

SPRP Acronym for the **Swartkrans Paleanthropological Research Project** (*which see*).

Spy (Location 50°28'21.64"N, 4°40'50.52"E, Belgium; etym. named after the nearby village of Spy) **History and general description** The Grotte de Spy (also known as the Bêche-aux-Roches cave) is a limestone cave about 15 km/9 miles east of Namur near the village of Spy. In 1885 Max Lohest and M. De Puydt discovered two hominin skeletons in the Grotte de Spy and they found **Late Pleistocene** fauna *in situ* low in the sequence of stratified terrace deposits in front of the cave entrance. The discoveries at Grotte de Spy were among the first attributed to *Homo neanderthalensis*, and even though they were subsequently transferred to *Homo spjensis* by Krause in 1909 their current taxonomic

allocation is to *H. neanderthalensis*. Hominins found at site The discoveries include two adult presumed male partial skeletons (Spy 1 and 2), two teeth, and a tibia of a juvenile (Spy 3). Between 2004 and 2006 researchers systematically reviewed the dispersed fauna from the cave and in doing so they identified 24 new Neanderthal fragments, six of which comprise part of the mandible and some of the mandibular dentition of a Neanderthal infant (the Spy VI child). Temporal span and how dated? **Radiocarbon dating** suggests the hominins are *c.*36 ka. Key references: Geology, dating, and paleoenvironment Semal et al. 2009; Hominins Fraipont and Lohest 1886, Holloway 1985b, Semal et al. 2009, Crevecoeur et al. 2010.

SST Acronym for **sea surface temperature** (*which see*).

Staatliches Museum für Naturkunde (or National Museum of Natural History) This museum was founded in 1791 in Stuttgart, Germany, and has some of the most important scientific biological collections in Europe. Hominin fossil collections **Reilingen calvaria**, **Steinheim 1**. Contact information Professor Dr Johanna Eder (e-mail eder.smns@naturkundemuseum-bw.de). Address Nordbahnhofstraße 177, 70191 Stuttgart, Germany. Website www.naturkundemuseum-bw.de/stuttgart/. Tel +49 (0)711 8936 115.

stabilizing selection A type of natural selection in which alleles that produce a divergence from the average phenotype are eliminated. For example, babies that are too small or too large have a lower probability of survival, so any alleles linked with those phenotypes will be removed. Stabilizing selection results in the reduction of genetic variation in a population (syn. normalizing selection).

stable isotope biogeochemistry The science that involves determining the **stable isotope** composition of biological, atmospheric, and geologic samples using isotope ratio mass spectrometers, and then interpreting the ecological, chemical, or geological processes driving stable isotope ratios in different substances such as plant or animal tissues. Stable isotope biogeochemistry is a systems science, in that it aims to determine how nutrients are cycled at scales ranging from the global down to an individual organism.

stable isotopes An **isotope** is one of two or more atomic forms of the same element that have the same atomic number, but different atomic masses (i.e., different numbers of neutrons). Unlike the isotopes that undergo decay such as the ones used in isotopic dating, the proportions of stable isotopes do not change with the passage of time. Instead their proportions are determined by processes such as photosynthesis (e.g., $^{13}\text{C}/^{12}\text{C}$), climatic variables, or diet ($^2\text{H}/^1\text{H}$, $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$). Thus, the stable isotope ratios in collagen recovered from fossils can be used for **diet reconstruction** and to reconstruct **paleoclimate**. Stable isotope ratios are frequently referred to using delta (or δ) notation, where the isotope ratio in a sample is measured relative to an international standard. When there is more of one of the two isotopes the system is said to be enriched with respect to that particular isotope, and when there is less of one of the two isotopes the system is said to be depleted with respect to that particular isotope. Combining data from two different stable isotope pairs is frequently more meaningful than only using one isotope system (e.g., Fuller et al. 2006 use both the $^{13}\text{C}/^{12}\text{C}$ and the $^{15}\text{N}/^{14}\text{N}$ systems to investigate the timing of weaning). In regions where prehistoric modern human populations had access to both marine foods and C_4 foods such as maize, which confound the use of $\delta^{13}\text{C}$ values, bone collagen $\delta^{15}\text{N}$ values can help identify dependence on marine foods (Schoeninger et al. 1990). Clementz and Koch (2001) also describe how $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values from tooth enamel can together discriminate among mammals feeding in purely terrestrial systems, animals feeding on a combination of terrestrial and near-shore (estuary) foods, and animals feeding on marine foods. Schwarcz and Schoeninger (1991), Schoeninger (1995), Koch (1998), McKechnie (2004), and Sponheimer et al. (2007) all provide useful reviews of the use of stable

isotopes. *See also* C₃ and C₄; **laser ablation stable isotope analysis**.

stable population If the age-specific fertility and mortality do not change across time for a group living in a particular region then the living age structure (proportions of individuals at each age) for that group will remain unchanged. Similarly, the age-at-death structure will not change. In the special case where fertility and mortality are equal the population will remain a constant size. While it would be difficult to assume that past populations followed unchanging fertility and mortality schedules for any appreciable amount of time, it is usually assumed that for short periods of time such an assumption may be reasonable. Further, even if past populations may not have had fixed fertility and mortality, any fluctuations are likely to “average out” over time. *See also* **stationary population**.

stage The **chronostratigraphic unit** equivalent of an age; not to be confused with **Oxygen Isotope Stages**.

Stage 3 project A multidisciplinary initiative to place the spatial and temporal distribution patterns of European Middle and Upper Paleolithic human sites within the context of **Oxygen Isotope Stage 3** (OIS 3) climate and landscape simulations (60–24 ka). The two major goals of the program were to determine (a) what the climate of Europe was like during OIS 3 and the extent to which the changes observed in the Greenland ice cores influenced the European landscape and its flora and fauna, and (b) in what way and to what degree *Homo neanderthalensis* and anatomically modern human populations may have been influenced by OIS 3 climate and environmental history. The Stage 3 project was conceived in 1995 by Nicholas J. Shackleton and Tjeerd H. van Andel of the Godwin Institute for Quaternary Research at the University of Cambridge and launched in 1996 at the Godwin Conference on Oxygen Isotope Stage 3. It concluded in 2003 with the publication of a major integrative monograph, “Neanderthals and modern humans in the European landscape during the last glaciation” (van Andel, Tjeerd, and Davies, 2003, McDonald Institute for Archeological Research, Cambridge). At its peak, the project had 34 members including Quaternary geologists, paleoclimatologists, paleo-

ceanographers, archeologists, paleoanthropologists, and human physiologists. Innovative at the time, modeling of climate and vegetation at a resolution of 60 km²/23 square miles across Europe was done at the Earth Systems Research Center of Pennsylvania State University by Eric Barron and David Pollard. One major achievement of the Stage 3 project was the documentation of two instances of major environmental stress resulting in most part from high-frequency **Dansgaard–Oeschger cycles**, one in OIS 4 and the other around 30 ka BP, a time of major mammalian extinction, including the demise of the Neanderthals. The Stage 3 climate and plant-cover simulations and the faunal and archeological databases of published data through 2000 are freely available at <https://www.esc.cam.ac.uk/research/research-groups/oistage3>.

Standardized African Site Enumeration System (or SASES) This system of naming sites was developed in the 1960s as a way of recording the location of African archeological sites. Its creator, the American archeologist Charles Nelson, adapted the method from Charles Borden’s (1954) system of site classification for Canada, where it is still employed. Nelson’s article was first published in a bulletin of nomenclature of the **Pan-African Congress on Prehistory and Quaternary Studies** in 1971 (Nelson 1971). Since this report is hard to find, the Society of Africanist Archaeologists reprinted it in *Nyame Akuma*, their research bulletin (Nelson 1993). The SASES divides the African continent into squares that measure 6° of longitude or latitude; these are identified by capital letters. Then each square is subdivided into units that correspond to 15′ of longitude or latitude; these are assigned lower-case letters. If there is more than one site in a square, the sites are assigned an Arabic numeral based on the order in which they were recorded. For example, the SASES designation of the **KBS** site at **Koobi Fora**, east of Lake Turkana in northern Kenya, is FxJj-1. The first two letters represent the latitude, the second two the longitude, and the Arabic numeral tells the user that this was the first site recorded at that location. Although the SASES was designed for the whole

of the African continent, the system has only been regularly adopted in Kenya and in parts of southern Ethiopia (e.g., in the **Lower Omo Basin**), but starting in 1988 the SASES was adopted by the Department of Antiquities in Tanzania.

stapes (L. *stapes*=stirrup) *See* **auditory ossicles**; **branchial arches**; **middle ear**.

starch grains (ME *starche*=substance used to stiffen cloth, from *sterchen*=to stiffen, from OE *stercan*) One of several kinds of **plant microfossils** (the others are **phytoliths** and **pollen**), starch grains are the energy storage bodies of plants. If they can be identified precisely enough they have the potential to provide, depending on the context, information about the plants that were present in the environment or about the **diet** of individuals and groups. Starch grains consist of alternating amorphous and crystalline layers of two kinds of long-chain carbohydrate, amylose, and amylopectin. Their shapes and sizes are usually unique to plant higher taxa, and sometimes down to the level of genus and species. Within the same taxon the morphology of starch grains may differ among the plant organ (e.g., fruit, seed, leaf) that produced them. The morphologically most diagnostic forms of starch grains are found within the areas of the plant that are designed for long-term energy storage (e.g., seeds, fruits, and **underground storage organs**) and this is also where starch grains are most abundant. Starch grains are best preserved in protected archeological environments, and have been recovered from stone tools, ceramics, and dental calculus. Cooking and other types of food processing causes predictable damage to starch grains, and thus the presence of such damage can be used as evidence that food has been subject to cooking or to other types of food processing. Torrence and Barton (2006) review the archeological uses of starch grains and provide several examples of their utility.

Starosel'e (Location 44°44'N, 33°53'E, Ukraine; etym. named after the nearby village) History and general description This site in a box canyon near the village of Starosel'e, an eastern suburb of Bachchisaraj in the Crimea, was excavated from 1952 to 1956 by A. Formozov, who found a thick **Middle Paleolithic** deposit and the burial of a young child. The taxonomic status and primary context of this individual was highly debated, with

some researchers suggesting it has a mixture of *Homo sapiens* and *Homo neanderthalensis* traits, while others suggesting it is a later intrusive *H. sapiens* burial. Excavations in 1993–5 by a American-Ukrainian team recovered two other burials in the same level, and both are unquestionably modern, supporting the interpretation that all three skeletons are intrusive burials from the 18thC. Temporal span and how dated? AMS radiocarbon, uranium-series, and electron spin resonance spectroscopy dating have provided a range of dates for the site, with the oldest layers dating to *c.*80 ka, and the youngest to *c.*40 ka, although the excavators note that all of the layers show mixing and the exact dates are therefore questionable. Hominins found at site Three intrusive 18thC burials, and a few fragmentary remains. Archeological evidence found at site Four main cultural horizons have been reported in the new excavations, all of which contain a local variant of the **Mousterian**. Use-wear and residue analysis of the stone tools shows that the inhabitants were regularly processing plants and animals. A study of the fauna suggests that the inhabitants were engaging in both directed hunting and opportunistic scavenging. Key references: Geology, dating, and paleoenvironment Marks et al. 1997, Formozov 1958; Hominins Marks et al. 1997, Formozov 1958; Archeology Marks et al. 1997, Burke 2000, Hardy et al. 2001.

Starosele *See* Starosel'e.

stasis (Gk *stasis*=standstill) Randomly directed change is constantly occurring within living **species**, but the term stasis is used for a period of time (it could be the temporal span of a species) during which there is no evidence of any directional change (i.e., trend) in morphology. For example, there are very few temporal trends evident within the time span of *Paranthropus boisei sensu stricto* (Wood et al. 1994) or within the time span of *Australopithecus afarensis* (Lockwood et al. 2000). Thus, the lack of any significant trend between the first and last appearance dates of those taxa would be examples of stasis within the hominin fossil record. *See also* **punctuated equilibrium**.

Station Amont *See* La Quina.

Station Aval *See* La Quina.

stationary population A special case of a **stable population** in which the crude birth and

crude death rates are equal. As the intrinsic growth rate (r) is equal to the **crude birth rate** (b) minus the **crude death rate** (d), a stationary population has a growth rate of zero. Consequently, a stationary population remains the same size through time. It is often assumed in paleodemographic analyses that the samples being analyzed came from stationary populations. If the growth rate is known for a population then the **life table** or hazards analysis can be adjusted for the known growth rate. On the other hand, if the population was not stationary, but one assumes that it was, this leads to estimation errors. Sattenspiel and Harpending (1983) proved that for nonstationary populations the inverse of the mean age at death was a better estimator of the crude birth rate than of the crude death rate.

stature (L. *statura*=height) A linear measure of standing height. Stature varies within and between populations and has been used in modern humans as an indicator of diet, environmental stress, and gene flow. Stature is also one of several ways of summarizing the overall size of an individual hominin and it has been used as a scaling factor. Standing height has increased over the course of hominin evolution. Initial estimates of stature in *Ardipithecus ramidus* place its stature between 1.17 and 1.24 m (Lovejoy et al. 2009d) and A.L. 288-1, the most complete *Australopithecus afarensis* skeleton recovered, has an estimated stature of 1.05 m (Schmid 1983). In contrast, estimations for KNM-ER 15000 (the Nariokotome *Homo erectus* skeleton) suggest a maximum stature of 1.60 m for this individual (Ruff 2007); there is no evidence of modern human-like statures prior to *Homo erectus*. Among modern humans, mean stature varies among populations and to varying degrees between males and females within populations. Mean statures for modern human adult populations range between 1.3 m and 1.8 m (Eveleth and Tanner 1976). Stature is known to have increased over the 20thC so that average heights in the USA (1999–2002) are 1.62 m for women and 1.76 m for men (Ogden et al 2004). Increases in mean stature that have been documented among modern human populations are examples of a **secular trend**. For example, mean statures of adult males in populations in Oaxaca, Mexico, have increased on average by 3 cm during the latter half of the 20thC (Malina et al. 2004). When only skeletal elements are available, stature is most commonly estimated from linear dimensions of

long bones, but it is important to note that all stature estimates (like all mathematical predictions based on regression analysis), especially those for fossil hominins for which there are no reference populations, are subject to varying amounts of error, and therefore may not be accurate. *See also* **stature estimation**.

stature estimation (L. *statura*=height) Stature is usually estimated by relating skeletal dimensions, usually the lengths of the long bones of the lower limb, to living stature. Early attempts to predict stature from a section of the skeleton (e.g., Dwight 1894) were limited by small sample sizes and limited population samples. Most standard contemporary methods of stature estimation regress the lengths of the femur, the tibia, or both bones against known statures to yield predictive equations for that reference sample. Bayesian methods also have their advocates and Hens et al. (2000) review the merits of various methods for estimating the stature of fossil hominins. Relatively few modern human reference samples exist for which both living stature and directly observed limb-bone lengths are available and obviously there are no directly relevant reference samples that can be used to estimate the stature of extinct hominin taxa. As in all estimations, it is statistically conservative to match the sample to be estimated with a reference sample whose range encompasses the expected range of the test sample. Estimating beyond the range of the sample from which the formulae were developed introduces unknown amounts of error, in part because a small error in the estimate of a regression slope becomes magnified the farther a predicted stature is from the mean of the reference population. Skeletal elements that contribute a greater amount to total stature (e.g., the femur versus the talus) will yield smaller estimation errors and therefore more accurate predictions of stature, but stature estimations from long bones assume that lengths of the skeletal elements are proportionally similar to total stature in the reference and estimated samples (Auerbach and Ruff 2010). This has far-reaching implications for stature estimations of extinct hominins, many of which had overall body and internal limb proportions that differ from those of modern humans. A family of stature-estimation methods, collectively known as anatomical techniques, created by Georges Fully in the 1950s (Fully 1956) and revised by Raxter and colleagues (Raxter et al. 2006) circumvents these limitations. In anatomical stature

estimation methods the constituent skeletal elements that directly comprise stature [i.e., the length of the lower limb (including tarsal height), the length of the vertebral column, and the height of the cranium] are measured and added together. Corrections are needed because (a) some dimensions overlap (e.g., the medial malleolus and trochlea of the talus), (b) there are “gaps” (e.g., between the first sacral element and the femoral head), and (c) no account is taken of soft tissues. Fully’s original correction was discrete, but the correction developed by Raxter et al. is continuous and based on regression analyses. An advantage of the anatomical technique for stature estimation is that it does not incorporate assumptions about body proportions and it is not dependent on specific reference samples for its calculation (assuming the correction factors employed are universal among populations). However, the technique requires nearly complete skeletons, and although the dimensions of some missing elements may be estimated, these increase the potential error of resulting stature estimates. Few early hominin associated skeletons are complete enough to justify the use of anatomical techniques but they have been used to estimate the stature of the A.L. 288-1 *Australopithecus afarensis* associated skeleton (Schmid 1983). Stature estimation of juveniles has received much less attention (Ruff 2007).

STD Abbreviation of Saitune Dora and the prefix used for fossils recovered from that site. *See Saitune Dora.*

Steinheim (Location 48°58’N, 9°17’E, Germany; etym. named after nearby town of Steinheim an der Murr) History and general description The gravel deposits along the river Murr had been known to contain fossils for quite some time before the discovery of a hominin cranium in 1933. There are four principal layers of deposit, the Older Mammoth Gravels, the Straight-Tusked Elephant Gravels, the Main Mammoth Gravels, and the Younger Mammoth Gravels. The Steinheim cranium was found in the Straight-Tusked Elephant Gravels. Temporal span and how dated? Biostratigraphy suggests that the Straight-Tusked Elephant Gravels are from the penultimate interglacial (i.e., the European Riss-Würm, which is equivalent to Oxygen Isotope Stage 7). Hominins found at site Only one hominin specimen, Steinheim 1, is known from the site. The location of the cranium is known, for its finder, Karl Sigrüst,

did not collect the fragments, instead he waited for F. Berckhemer to excavate them. The cranium is lightly built, and because of this it has been widely interpreted as belonging to a female. Archeological evidence found at site N/A. Key references: Geology, dating, and paleoenvironment Adam 1954a, 1954b, Howell 1960; Hominins Howell 1960; Archeology N/A.

Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*225 ka. Developmental age Young adult. Presumed sex Female. Brief anatomical description Distorted cranium, missing much of the left temporal and maxilla. Announcement Berckhemer 1933. Initial description Berkhemer 1934. Photographs/line drawings and metrical data Berckhemer 1934, Weinert 1936. Detailed anatomical description No monograph exists, but Weinert (1936) and Howell (1960) provide some details. Initial taxonomic allocation *Homo steinheimensis*. Taxonomic revisions *Homo heidelbergensis* Campbell (1964). Current conventional taxonomic allocation *H. heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance Due to its combination of archaic and modern features and plastic deformation, the Steinheim cranium has proved to be somewhat difficult to classify, and it was one of the specimens in the informal category known as the pre-Neanderthals. Location of original Staatliches Museum für Naturkunde, Stuttgart, Germany.

stem group (OE *stemma* = supporting stalk) A term introduced by Jefferies (1979) for a clade (or total group) minus its crown group. For example, for hominins it would be the hominin clade minus the *Homo sapiens/Homo neanderthalensis* subclade.

stenotope (Gk *steno* = narrow and *typos* = place) Refers to a species adapted to a restricted or narrow range of environmental conditions, or to a narrow ecological niche (e.g., an ant-eater). *See also* stenotopy (syn. specialist).

stenotopic Refers to a species adapted to a restricted or narrow range of environmental

conditions, or to a narrow ecological niche (e.g., an ant-eater). It is also used to refer to morphology interpreted as being part of a stenotopic adaptation (e.g., the tongue of an ant-eater). *See stenotopy.*

stenotopy (Gk *steno* = narrow and *topos* = place) The condition of being ecologically specialized. A stenotopic (or specialist) species is one that can use or consume only a narrow range of ecological resources, and that can live in only a limited set of habitats. The term was introduced to paleoanthropology by Elisabeth Vrba (e.g., Vrba 1980, 1985a, 1985b, 1988, 1992) in a series of hypotheses seeking to explain how environmental change influences evolutionary patterns in the fossil record. Several recent studies (Teaford and Ungar 2000, Wood and Strait 2004, Scott et al. 2005, Sponheimer et al. 2005) have inferred that most early hominin species were not ecological specialists, but rather were generalists, particularly with respect to diet. *See also effect hypothesis; eurytopy; habitat theory hypothesis; turnover-pulse hypothesis.*

stenotypic *See stenotopy.*

Sterkfontein (Location 25°58'08"S, 27°45'21"E, South Africa; etym. Afrikaans for a "strong spring" or "source of water" referring to the underground spring and lake in the cave complex) History and general description Sterkfontein is the umbrella term for a system of breccia-filled caves [e.g., Extension site, Jakovec Cavern, Silberberg Grotto, Tourist Cave(s), Type site, etc.] formed from solution cavities within pre-Cambrian dolomite in the Blauwbank valley near Krugersdorp, Gauteng Province, South Africa. The caves at Sterkfontein had been explored for gold in the 1880s, but they were later mined for lime by Hans Paul Thomasset in, or shortly before, 1895, and it was in that year that fossil bones from Sterkfontein were sent to the British Museum. Shortly thereafter the lease on the mine at Sterkfontein was taken over by Guglielmo Martinaglia, and it was he who exposed what are now known as the Tourist Cave(s). In the 1920s the Glencairn Lime Company was mining lime from the caves, and one of its employees was George Barlow, who had worked for a time at the Taungs mine. In the wake of the Taungs discovery, fossils from Sterkfontein, including the skull of a large baboon, were sent to Raymond

Dart, but he thought the fossil baboon was so similar to extant baboons that the Sterkfontein cave was unlikely to contain a hominin as primitive as *Australopithecus africanus*. By the 1930s Sterkfontein was being exploited for bat guano, and in 1936 one of Dart's students, Trevor Jones, visited Cooper's hardware store in Krugersdorp and persuaded the owner to let him borrow some of the fossils from the display advertising the Sterkfontein guano. A week or so later, Jones visited Sterkfontein where George Barlow was selling fossils from a table. Jones reports that Barlow gave him 43 specimens, mostly baboon skulls and endocranial casts. Jones took them back to Witwatersrand University Department of Anatomy, where he showed them to his teachers, including Raymond Dart. Later another of Jones' teachers, Gerrit Schepers, and a fellow student, William Harding Le Riche, went once again to Sterkfontein and were given a baboon mandible by Barlow. They reported this to Robert Broom, who wasted no time in going to see Jones' collection in the Department of Anatomy. During Broom's first visit to Sterkfontein in August 1936 he asked George Barlow to tell him, Broom, if he ever saw any Taung-like fossils. A week later, Barlow showed Broom the first Sterkfontein hominin, TM 1511. Later that month Broom assigned it to *Australopithecus transvaalensis*, but 2 years later he transferred that species to a new genus, *Plesianthropus*. In the early 1960s the Sterkfontein site was donated to the University of the Witwatersrand and research at the site has been carried on by first Alun Hughes then by Ron Clarke who is still working at the site. The classical description of the geology of the infill at Sterkfontein is based on interpretations set out in Partridge (1978, 2000) and Partridge and Watt (1991). These recognize six Members (1–6) and they have been summarized in the reviews of Martini et al. (2003) and Reynolds et al. (2007). Pickering and Kramers (2010) present a different interpretation that focuses on sedimentary facies and which also attempts to relate the geology of Sterkfontein to events recorded in nearby caves. More details of the history of the site are given in Tobias (1973a). Hominins found at site Most hominins recovered from Sterkfontein have come from Member 4 and the majority of these have been assigned to *Au. africanus*. Some researchers think that the Member 4 hominins sample more than one taxon,

but opinions are divided about which specimens are exotic, and what any second taxon should be called. Other taxa possibly represented in the Sterkfontein hominin fossil record are *Homo* sp. and *Paranthropus robustus* from Member 5A, and the remains of an archaic hominin *Australopithecus* sp. *indet.* from Member 4 breccia exposed in the main cave (e.g., Sts 71, Stw 252, Stw 505) and from Member 2 breccia exposed in the Silberberg Grotto (e.g., Stw 573) and in the Jakovec Cavern. Clark (2008) describes this latter hominin as a “*Paranthropus*-like species of *Australopithecus*” (*ibid.*, p. 448), but he suggests that among the features that distinguish this species from *Paranthropus* are its “large canines and incisors” (*ibid.*, p. 448). The hominins collected by Broom and John Robinson at the so-called “type site” were given Sts and TM catalogue designations and those collected by John Robinson at the “extension site” excavation in 1957–8 were given SE prefixes. Hominins recovered between 1966 and 1996 through the efforts of Alun Hughes, Ron Clarke, and Phillip Tobias were given a Stw catalogue designation. Archeological evidence found at site Archeological evidence includes stone artifacts (Oldowan from Member 5; Acheulean from the Extension site; MSA from the Lincoln Cave) and digging sticks fashioned from bone (Member 5). Temporal span and how dated? Biostratigraphy, magnetostratigraphy, and cosmogenic nuclide dating have provided approximate dates for the main fossil-bearing strata: Member 2 is *c.*4 Ma (Partridge et al. 2003), but others claim its age is *c.*2.8–2.6 Ma based on uranium-lead dating of the deposits (Pickering and Kramers 2010); Member 3 is not yet excavated or dated; Member 4 was interpreted to be between 2.6 and 3.0 Ma but Pickering and Kramers (2010) suggest it lies between 2.6 and 2.0 Ma. Partridge has divided Member 4 into four beds, A–D. Lockwood and Tobias (1999) report that most *Au. africanus* fossils come from Beds B–D, with Bed 4B the most prolific of the beds; Member 5 is *c.*1.4–1.9 Ma. Key references: Geology, dating, and paleoenvironment Tobias and Hughes 1969, Partridge 1978, 2000, 2005, Partridge and Watt 1991, Schwarz et al. 1994, Martini et al. 2003, Partridge et al. 2003, Herries et al. 2009, Pickering and Kramers 2010; Hominins Hughes and Tobias 1977, Clarke 1998, 1999, 2002, 2008, Lockwood 1999, Lockwood and Tobias 1999, 2002, Moggi-Cecchi et al. 2006, Partridge et al. 2003,

Toussaint et al. 2003; Archeology Kuman and Clarke 2000, Kuman and Field 2009.

Sterkfontein Formation (etym. Afrikaans for a “strong spring” or “source of water” referring to the underground spring and lake in the cave complex where the type section is located) General description The Sterkfontein Formation was established by Partridge (1978). He divided the breccias in the Sterkfontein cave into six members, the oldest and deepest being Member 1. The breccia that contains most of the *Australopithecus africanus* fossils, and which was referred to as the Lower Breccia by Robinson (1962), was termed Member 4, Robinson’s stone tool-bearing Middle Breccia became Member 5, and his Upper Breccia became Member 6. Members 1, 2, and 3 (Members 2 and 3 are fossiliferous) have been identified in the Silberberg Grotto, which is connected to the Tourist Cave. This classical description of the geology of the infill at Sterkfontein is summarized in the reviews of Martini et al. (2003) and Reynolds et al. (2007). Pickering and Kramers (2010) present a different interpretation that focuses on sedimentary facies, on uranium-lead dating of the flowstones and which also attempts to relate the geology of Sterkfontein to events recorded in nearby caves. Sites where the formation is exposed Sterkfontein. Geological age Perhaps more than 4 Ma to maybe less than 1 Ma, but the ages suggested by Pickering and Kramers (2010) make it unlikely that any of the presently explored fossil-bearing breccias are more than 3 Ma. Most significant hominin specimens recovered from the formation Most of the hypodigm of *Au. africanus* from Member 4, and important individual fossils such as Stw 53, Stw 573, and the collection of fossils from the Jakovec Cavern; Key references: Geology and dating Robinson 1962, Tobias and Hughes 1969, Partridge 1978, 2000, 2005, Partridge and Watt 1991, Clarke 1994, 1998, 2006, 2008, Schwarz et al. 1994, Kuman and Clarke 2000, Martini et al. 2003, Partridge et al. 2003, Herries et al. 2009, 2010, Pickering and Kramers 2010; Hominins Broom 1936, Hughes and Tobias 1977; Archeology Kuman 1994.

Sterkfontein Research Unit In 1999 the responsibility for research at Sterkfontein was transferred from the Palaeo-Anthropology Research Unit in the Witwatersrand University Department of Anatomy to a new entity, the

Sterkfontein Research Unit, with Phillip Sambung-macan as the Director and Ron Clarke the Deputy Director.

Stetten *See* Vögelherd.

stimulus enhancement A type of **enhancement** effect that is associated with a suite of cognitively primitive attention and motivation mechanisms that affect **learning**. Specifically, stimulus enhancement describes learning in situations where the presence of a conspecific directs an observer's attention to a particular object (such as a fruit or a tool) that the conspecific is interacting with (Spence 1937). This type of enhancement is seen in mammals and birds alike, and may result in behavior-matching, which resembles **imitation** learning.

stone cache hypothesis A hypothesis that suggests **Oldowan** sites were processing areas where artifacts and **manuports** were deposited at various points in the foraging range of hominins. These caches were either established consciously or they developed as an unconscious byproduct of hominin discard behavior, and then they became secondary sources of raw material. According to this view, sites served not as home bases, but as recurrently visited stockpiles of stone (Potts 1988, 1991).

STR Acronym for short tandem repeat. *See* **short tandem repeat**; **microsatellite**.

strain Strain, or ϵ , is a measure of the relative change in length that an object undergoes in response to an applied load, and it is technically defined as the difference between the loaded and the unloaded (i.e., the original) length relative to the original length of a structure ($\epsilon = \Delta L / L$). Because strain is expressed as a change in length divided by the original length, it is a dimensionless quantity. Any change in length is usually very small, so strain is normally expressed as micro-strain ($\mu\epsilon$), indicating a change in length on the order of a thousandth of the original length. Experimental evidence has shown that during normal activities (e.g., running, biting hard objects, etc.) most mammalian bones experience a peak of about 2000–3000 $\mu\epsilon$ (which indicates a 0.2–0.3% change in length). Mammalian bones typically break at around 6000 $\mu\epsilon$, indicating that most bones are overbuilt relative to their peak normal strains; thus they have a substantial safety factor of

between 2 and 3 (Rubin and Lanyon 1984). Some amount of dynamic strain is required for normal bone growth, but excessive strains can result in bone modeling and **bone remodeling**.

strain gage A device consisting of a very fine metal grid, or foil, or semiconductor material, which measures **strain**. Lord Kelvin reported in 1856 that metallic conductors change their electrical resistance when subjected to mechanical strain (e.g., when they are stretched). Strain gages take advantage of this property by calibrating the changes in resistance against known strains, allowing users to measure very small strains (changes in length) that occur when loads are applied to stiff materials like bone or metal. The most common strain gages consist of a small piece of metal foil supported by a flexible backing. These simple gages measure the strain that occurs within the plane it occupies and in the longitudinal direction of the piece of metal foil; a single-element gage thus has just a single foil and it can only measure strain in that plane. Studies of bone strain, in which the gage is attached directly to the bone surface, typically use rosette strain gages. These consist of three elements at 45° to each other and this configuration makes it possible to calculate the strain in all directions within the plane of the gage, and to determine the directions in which the maximum and minimum principal strain lie. Multiple gages around the circumference of a long bone can be used to calculate (using certain assumptions) the strain distribution throughout the bone's cross-section. Strain gages in **force plates** are also used to measure strains, and these strain measurements are used to calculate forces. Strain studies are important for validating models based on **finite element analysis**. William (Bill) Hylander, a pioneer of *in vivo* strain studies, found that when macaques and baboons chew strain in the brow ridge was much lower than in the zygomatic arch or in the mandible (Hylander et al. 1991). These results provided compelling evidence that refutes the hypothesis that brow ridge development in higher primates, including fossil hominins, is structurally related to countering stresses resulting from biting and chewing (*see* **chewing cycle**).

strain gauge *See* strain gage.

Stránská Skála (Location 49°11'N, 16°40'E, Czech Republic; etym. named after a small hill outside of Brno) [History and general description](#)

This open-air site, roughly 7 km/4 miles east of **Brno-Bohunice**, also preserved artifacts of the **Bohunician** transitional lithic industry. It was excavated in the 1980s and 1990s. Temporal span and how dated? **Radiocarbon dating** provided a range of 41–34.5 ka for the Bohunician contexts and 33–30 ka for the **Aurignacian** contexts. Hominins found at site None. Archeological evidence found at site Stone tools documenting the early **Upper Paleolithic**. Key References: Geology, dating, and paleoenvironment Svoboda 2003, 2006; Archeology Svoboda 2003, 2006.

strata (Gk *stratos* = to cover or spread) More than one layer of **sedimentary rock**.

stratigraphic criterion A controversial criterion for deciding which state of a **character** is **primitive** and which is **derived**. When employing the stratigraphic criterion, one examines the distribution of the states of the character in the fossil record. The state that occurs in the oldest deposit is the one that is deemed to be primitive. *See also* **cladistic analysis**.

stratigraphy (Gk *stratos* = to cover or spread and *graphos* = to draw or write) The study of sedimentary rocks, especially their formation, composition, sequence, and correlation. It also refers to the work of identifying and tracing layers of **sedimentary rock**. The “stratigraphy” of a site is the formal description of the sequence of strata found at that site.

stratum (Gk *stratos* = to cover or spread) A single layer of **sedimentary rock**.

strength In material science the strength of a material (e.g., bone, enamel) is its ability to withstand an applied stress without failure. There are two common types of failure: yielding and fracture. Yielding, which is defined by the material’s yield strength, occurs when the material undergoes macroscopic permanent deformation. A material with an applied stress value less than the yield strength of the material will not be permanently deformed upon unloading. Fracture is defined by the ultimate strength of the material, which is the largest absolute value of applied stress the material can withstand without fully fracturing. Since yielding occurs at an applied stress less than the applied stress that produces full fracture, the yield strength

of a material is always less than its ultimate strength. The type of loading (e.g., tensile, compressive, or shear) also influences the likelihood of failure, and therefore there are corresponding types of material strength (e.g., ultimate tensile strength, ultimate compressive strength, and ultimate shear strength).

stress Stress is a measure of the intensity of the internal forces within a loaded object that is assumed to behave as a continuum. Stress, which is expressed in units of force per unit area, correlates with the failure of many materials. Stress is specific to the hypothetical planes upon which it acts. If the stress acts perpendicular to a plane, it is called a normal stress component; a negative normal stress implies a compressive stress and a positive normal stress implies the normal stress is tensile. Stress that acts tangential to a plane is called a shear stress component. At a given material point there are up to six nonzero components of stress (i.e., three normal stresses corresponding to directions of the three orthogonal coordinate axes and three shear stresses corresponding to shear existing in three orthogonal planes of the coordinate axes). It turns out that at any point in the material there always exists an orientation of three orthogonal planes such that they only have normal stresses acting upon them. These three normal stresses are called principal stresses and provide the largest absolute value of normal stress that can exist on any plane at that point. Similarly, there is another orientation of the three orthogonal planes that maximizes shear stress, resulting in the maximum value of shear stress that can exist on any given plane at that point. Shear stresses tend to distort the material without changing the volume of the material, whereas normal stresses tend to elongate or compress the material in the directions in which they act. If the three principal stresses at a material point all have the same negative (positive) value, then the material at this point is in a state of pure hydrostatic compression (tension). In such a state shear does not exist on any plane at this point and therefore there is no distortion of the material. For ductile materials distortion is found to correlate closely to yielding and fracture, and von Mises stress (also called equivalent stress) measures this material distortion. Unlike the other measures of stress, von Mises stress is not associated with a particular orientation. Instead, it is a scalar

function of the stress components and is directly proportional to the square root of the energy of distortion at a given material point. The location of maximum distortion energy (i.e., maximum von Mises stress) is deemed most likely to yield or fracture. Since no distortion exists at a material point of pure hydrostatic compression or tension, the value of von Mises stress at such a point is zero.

strewn-field (OE *streowian* = to scatter) The area of the Earth's surface covered by a particular tektite shower. *See also* **tektites**.

striae of Retzius (L. *stria* = a furrow-like phenomenon described by Anders Retzius in 1837) **Long-period incremental lines** in **enamel** described by Anders Retzius of Lund in 1836–7 (see reviews in Boyde 1990 and Risnes 1990) that represent the position of the developing enamel front at successive points in time. They are manifest on the lateral surface of teeth as **perikymata** (Preiswerk 1895) or **imbrication lines** (Pickerill 1913). Although the cause of striae of Retzius is not known, they result from a regular slowing of enamel matrix secretion that keeps an intrinsic consistent temporal rhythm (see reviews in Risnes 1998, Dean 2000, Smith 2006b). One hypothesis is that they result from two **circadian** rhythms, one 24 hour and the other *c.*27 hour, that interact to give a “beat” every 7 or 8 days, but this hypothesis is untested and some suggest it is oversimplistic. The temporal repeat interval of striae of Retzius, known as their **periodicity**, is assessed by counting the number of daily **cross-striations** between consecutive striae. A long-period incremental marking analogous to striae of Retzius exists in **dentine** (called **Andersen lines**). Previous studies have examined aspects of striae of Retzius curvature, length, and the angle of intersection between the striae of Retzius and the **enamel-dentine junction** in an attempt (e.g., Beynon and Wood 1986, Grine and Martin 1988; Dean and Shellis 1998) to discriminate among primate taxa. In reflected light striae look blue but in transmitted light they look brown (hence the original description of “brown striae” by Anders Retzius) (syn. brown striae, Retzius' lines). *See also* **enamel development**.

striae parietalis (L. *striae* = scores or grooves and *parietalis* = wall) Descriptive term introduced by Phillip Tobias to describe fine ridges and

grooves on the external, or ectocranial, surface of the parietal bones that run postero-superiorly away from the border with the squamous part of the temporal bone. This distinctive morphology is probably related to the unusual degree of overlap at the temporoparietal suture and among hominins it is apparently a derived trait confined to *Paranthropus boisei* and *Paranthropus aethiopicus*.

striate cortex (L. *striatus* = furrowed, striped, ridged and *cortex* = husk, shell) The striate cortex, also known as the primary visual cortex, V1, and **Brodman's area 17**, is located at the posterior, or caudal, pole of the **occipital lobe** of the **cerebral hemisphere** of the brain. Most of it is on the medial aspect of the occipital lobe and much of it is buried within the walls of the **calcarine sulcus**. The name striate derives from the prominent “striped” appearance of the stria of Gennari in layer IVB (which is made up of myelinated axons) of primates and because of this distinctive myelination pattern the striate cortex is readily seen in sections of the brain, even with the naked eye. The striate cortex in each hemisphere receives inputs from the ipsilateral (i.e., the same side) **lateral geniculate nucleus** and contains a complete retinotopic map of the contralateral (i.e., the opposite side) visual field, with anthropoid primates having a magnified representation of the central portion of the visual field. Neurons in the striate cortex are tuned to relatively simple features of color and spatial frequency and information from the striate cortex is transmitted via two main pathways: the ventral and the dorsal visual streams. The ventral visual stream encompasses parts of the **temporal lobe** and contains areas that are specialized for the recognition of form and object identification. The dorsal visual stream encompasses parts of the **parietal lobe** and contains areas that are specialized for the processing of motion information, the representation of object locations, and the coordination of visually guided movements of the eyes and arms. The volume of the striate cortex in modern humans is considerably smaller than that predicted by the observed **allometry** for a generalized primate of the same brain size. This relative reduction of primary visual cortex in modern humans has been argued to reflect a reorganization of cortical area allocation, with a greater proportion of neocortical tissue devoted to the adjacent **posterior parietal cortex**. In addition, reorganization of the striate cortex in modern humans has also been

demonstrated at the histological level, with a unique distribution of apical dendrite bundles and interneurons in layer IVA. Because layer IVA of the striate cortex receives inputs from the motion-sensitive magnocellular (i.e., large-celled) layers of the **lateral geniculate nucleus**, this suggests that there have been modifications of the modern human brain's ability to process motion information, possibly in relation to tracking the movement of lips during the perception of **spoken language**.

striatum (aka corpus striatum) Refers to the entity made up of the caudate nucleus and the putamen, which are some of the largest subcortical (i.e., beneath the **cerebral cortex**) components of the **forebrain**. The caudate nucleus and putamen are anatomically distinct in primates (they are separated by the internal capsule) but they are fused in other mammalian taxa. The name striatum derives from the striated appearance of these **basal ganglia** nuclei in sections of unstained brain tissue because of the axon fiber bundles that traverse it. The striatum receives inputs from the cerebral cortex and sends outputs to other basal ganglia nuclei. In addition, the striatum receives substantial dopaminergic innervation from the substantia nigra pars compacta. Because of its central role in motor and cognitive circuits of the basal ganglia, the striatum has been implicated in modern human **language** function. Notably, the striatum shows volumetric reduction and under-activation in patients with loss-of-function mutations to the *FOXP2* gene. In addition, the medium spiny neurons of the striatum in mice with a “humanized” version of the *FOXP2* gene display a greater extent of dendritic branching.

stride *See walking cycle.*

strike Refers, in structural geology, to a bearing 90° from the direction of **dip**. In areas where the nature of the rock outcrop is determined by the intersection of the dip with the topography, strike can be a useful descriptor of the direction of the grain of the landscape and will define a direction in which strata of equivalent age may be encountered. For example, when surveying in the field, researchers will often try to control their fossil collections temporally by following along the strike of dipping beds.

striking platform A morphologically distinctive part of a stone artifact. It is the place on the

core that is struck during the act of **percussion** (freehand or otherwise) to remove a **flake**.

Stringer, Christopher Brian (1947–) Chris Stringer, who was born in East Ham, London, England, became interested in human evolution as a boy visiting what was then called the British Museum (Natural History) in London. He entered University College London where he was exposed to the research of physical anthropologist Don Brothwell and anatomist Michael Day. Stringer completed his BSc in anthropology in 1969 and after working briefly part-time at the British Museum (Natural History) he began his graduate studies at the University of Bristol where he worked with Jonathan Musgrave, who studied *Homo neanderthalensis*. At a time when Loring Brace was advocating a Neanderthal ancestry for modern humans and Henri Vallois was supporting the **pre-sapiens theory** (which held that *H. neanderthalensis* was not the ancestor of modern humans) Stringer examined Neanderthal crania from collections across Europe and used **multivariate analysis** to judge the degree of similarity or difference between Neanderthals and early modern humans. The results of his studies convinced Stringer that the anatomical differences separating Neanderthals and *Homo sapiens* indicated that Neanderthals had *not* evolved into modern humans. Therefore, Stringer concluded, the Neanderthals must have been replaced by populations of early *H. sapiens* that had migrated into Europe. While working on his graduate research Stringer had an opportunity to work with Michael Day on two partial skulls found at **Omo-Kibish**, Ethiopia, in 1967. Stringer completed his PhD at the University of Bristol in 1974 and by this time (in 1973) he had been appointed as research fellow at the British Museum (Natural History). In 1977 Stringer was appointed senior scientific officer at the museum, and he was appointed principal scientific officer in 1987. During this period Stringer continued to study Neanderthal specimens from Europe and the Middle East and to work on the problem of the origin of modern humans. He became a supporter of a version of the **out-of-Africa hypothesis** of modern human origins, variants of which were separately formulated by the German anthropologist Günter Bräuer, and by the South African archeologist Peter Beaumont. During the late 1970s Bräuer had argued that anatomically modern humans had originally evolved in Africa, and

then had migrated to populate Europe (where there was modest interbreeding with Neanderthals). Stringer opposed the **multiregional hypothesis** formulated and expanded by Milford Wolpoff in the early 1980s and 1990s. Alan Thorne and Wolpoff argued that *Homo erectus* migrated from Africa to populate Asia and parts of Europe, and that it was these regional populations of *H. erectus* that had evolved into *Homo sapiens*. Stringer could see that the results of the **mitochondrial DNA** studies of Allan Wilson and his colleagues were consistent with the out-of-Africa hypothesis, and together with his colleague Peter Andrews he published an influential article in *Science* in 1988 entitled “Genetic and fossil evidence for the origin of modern humans. “It summarized the molecular and fossil evidence that supported a recent migration of *H. sapiens* out of Africa that then replaced existing populations of hominins throughout Europe and Asia. During the 1980s Stringer collaborated with a number of colleagues in studies, some of which involved establishing new dates for specimens from the Near East that were consistent with the hypothesis that Neanderthals had been replaced by populations of anatomically modern humans. Stringer summarized his views on Neanderthals in *In Search of the Neanderthals* (1993), written with Clive Gamble of the University of London. In 1996 Stringer, in collaboration with Robin McKie, published *African Exodus* where they present the fossil, archeological, and genetic evidence that supports the out-of-Africa hypothesis. Stringer has served as head of the Human Origins Programme at the Natural History Museum, London, first between 1990 and 1993, and later from 1999 to the present (as of 2010). Since 2001 Stringer has also been the director of the **Ancient Human Occupation of Britain Project** (or AHOB project). This Leverhulme Trust-funded project brought together archeologists, paleontologists, and geologists from various institutions to investigate the early occupation of the British Isles and the environmental conditions at the time the first humans arrived in Britain. The discovery of the so-called “Boxgrove Man” (considered to be a specimen of *Homo heidelbergensis*) in West Sussex in 1993 had been the earliest evidence of hominins in Britain, but researchers with the Ancient Human Occupation of Britain Project have since re-examined evidence of a hominin settlement found at Westbury-sub-Mendip in Somerset in the 1980s, and they found evidence of worked flints *in situ* at **Pakefield** in East Anglia. Pakefield is likely to be at least from **Oxygen**

Isotope Stage 17 (>680 ka), thus providing, along with evidence from **Happisburgh**, the earliest definite evidence so far of human occupation north of the Alps (Parfitt et al. 2005, 2010).

stromatolite A laminated sedimentary structure formed by the activity of a bacterial and blue-green algal community. The community mediates the precipitation of calcite and this calcite, together with additional trapped sedimentary particles, results in a spheroidal or columnar structure that can reach up to a meter in diameter. Stromatolites are rare today, and presumably require highly specific environments that both foster their growth and exclude the grazing and burrowing organisms that would otherwise destroy them. The **Koobi Fora Formation** has extensive beds of stromatolites in its early Pleistocene lake margin facies.

strontium/calcium ratios This system of **stable isotopes** (abbreviated Sr/Ca) is used for **diet reconstruction**. **Herbivores** discriminate against dietary strontium, so their bones and tooth enamel have lower Sr/Ca ratios than the plants they consume. The **carnivores** that consume those herbivores also discriminate against dietary strontium, so their bones and tooth enamel have lower Sr/Ca ratios than the herbivores they consume. But leaves of broad-leaved plants have less Sr than grass, so grazing herbivores have a higher Sr/Ca ratio than browsing herbivores. Dietary items such as insects and **underground storage organs** are particularly rich in strontium, but grazers and insectivores are also rich in barium (Ba), so relatively high Ba/Ca ratios should discriminate between high Sr/Ca ratios due to grazing or insectivory from high Sr/Ca ratios due to the consumption of, say, underground storage organs. Enamel **apatite** is the most suitable material for Sr/Ca analysis. **Bone** apatite can be used, but the chemical changes that occur during the process of fossilization (i.e., effects associated with **diagenesis**) are more of a problem with respect to bone than they are with enamel. The method can be applied throughout hominin fossil record. Sponheimer et al. (2005) provides more details. *See also* **stable isotope biogeochemistry**.

structural paradigm *See* structure–function relationship.

structure *See* population structure.

structure–function relationship The relationship between the structure of an object or body part and its function; function is usually inferred from an analysis of structure. It is relatively easy to infer function from structure when a trait seen in an extinct taxon is also seen in the same context in an extant taxon in which structure–function relationships can be observed directly. Inferring function is much more difficult when the trait is found only in one or more extinct taxa. Rudwick (1964) suggested the trait should be compared with structures that are well suited to their function. For example, a pestle and mortar is well suited to fracturing relatively small pieces of brittle material, so Rudwick (*ibid*) would consider a pestle and mortar to be a “structural paradigm” for that particular function. The fossil trait (e.g., the shape of postcanine tooth crowns) is then compared to the various relevant structural paradigms, and its function is taken to be the same as the structural paradigm it most closely resembles.

Sts Prefix used for fossil hominins recovered from the **Sterkfontein** cave site, Blaauwbank Valley, Gauteng, South Africa between 1947 and 1949.

Sts 5 Site **Sterkfontein**. Locality Type site. Surface/in situ *In situ*. Date of discovery April 18, 1947. Finders Robert **Broom** and John **Robinson**. Horizon N/A. Bed N/A. Member Member 4. Formation **Sterkfontein Formation**. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but see a new U–Pb age of *c.*2.0 Ma (Pickering and Kramers 2010). Developmental age Subadult; the third molar roots are still open (Thackeray et al. 2002a). Presumed sex As its informal name “Mrs Ples” implies, Robert Broom considered Sts 5 to be a female. However, as part of a comprehensive analysis of *Australopithecus africanus* crania Lockwood (1999) judged the sex of Sts 5 to be “indeterminate” and Thackeray et al. (2002a) and Gommery and Thackeray (2006) suggest there are reasons to think that it might be a subadult male and not a female. Brief anatomical description A well-preserved subadult cranium that lacks all the tooth crowns, some of the alveolar process, and some detailed cranial base morphology. A wafer-thin layer of the surface bone of the cranial vault is preserved on five blocks of breccia (Sts 5 i–v)

removed at the time of discovery (Potze and Thackeray 2010), and after 25 cycles of consolidation and careful etching with acetic acid it is possible to see on blocks Sts 5 i and iii temporal lines that are approximately 10 mm from bregma. Endocranial volume 485 cm³ (Conroy et al. 1998). Announcement Broom 1947. Initial description, photographs/line drawings, and metrical data Broom, Robinson and Schepers 1950. Detailed anatomical description None. Initial taxonomic allocation *Plesianthropus transvaalensis*. Taxonomic revisions Post WWII there was a growing consensus that a separate genus and species for Sts 5 and its ilk was unjustified and *Plesianthropus transvaalensis* was formally incorporated into *Australopithecus africanus* by Robinson (1954). Current conventional taxonomic allocation *Au. africanus*. Significance Although not the type specimen of *Au. africanus* (which is TM 1511), Sts 5 has come to represent the modal cranial morphology of *Au. africanus*. This is unfortunate because it is one of the more **prognathic**, if not the most prognathic, specimen in the *Au. africanus* hypodigm. It was found 0.4 m above and 1.9 m northeast of **Sts 14** and Thackeray et al. (2002b) and Thackeray and Klover (2004) have raised the possibility that Sts 5 and Sts 14 may belong to the same individual. Location of original **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), Northern Flagship Institution, Pretoria, South Africa.

Sts 14 Site **Sterkfontein**. Locality Type site. Surface/in situ *In situ*. Date of discovery August 1, 1947. Finders Robert **Broom** and John **Robinson**. Horizon N/A. Bed N/A. Member 4. Formation **Sterkfontein Formation**. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U–Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Subadult. Presumed sex Gommery and Thackeray (2006) conclude that the morphology of the anterior inferior iliac spine suggests that both Sts 14 and **Stw 431** are males. Brief anatomical description Seven thoracic, six lumbar, and two sacral vertebrae, plus fragments of other vertebrae, rib fragments, both pelvic bones, and parts of the left femur and tibia. The pelvic bones and the femur have suffered significant plastic deformation. Announcement Broom and Robinson 1950. Initial description, photographs, and metrical data

Broom, Robison and Schepers 1950. Detailed anatomical description None. Initial taxonomic allocation *Plesianthropus transvaalensis*. Taxonomic revisions Post WWII there was a growing consensus that a separate genus and species for Sts 14 and its ilk was unjustified and *Pl. transvaalensis* was sunk into *Australopithecus africanus* (e.g., Robison 1954, Le Gros Clark 1955). Current conventional taxonomic allocation *Au. africanus*. Significance For a long time this was the most complete early hominin associated skeleton and although substantially affected by plastic deformation it was the only source of information about the femoro-pelvic morphology of *Au. africanus*. Lovejoy (1979) reconstructed the Sts 14 pelvis to resemble the A.L. 288-1 pelvis, but Schmid (1983) preferred a reconstruction that was narrower with a more posteriorly tilted sacrum. The most recent attempt at a reconstruction by Berge and Goularas (2010) uses virtual reconstruction techniques, and they interpret the shape of the pelvis as consistent with a modern-human type of rotational birth mechanism; this runs counter to the conclusions of Tague and Lovejoy (1986). This fossil was found 0.4 m below and 1.9 m southwest of Sts 5 and Thackeray et al. (2002b) and Thackeray and Klover (2004) have raised the possibility that Sts 14 and Sts 5 may belong to the same individual. Location of original **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), Northern Flagship Institution, Pretoria, South Africa.

Sts 19 Site Sterkfontein. Locality Type site. Surface/in situ *In situ*. Date of discovery October 1947. Finders Robert Broom and John Robison. Unit N/A. Horizon N/A. Bed/member Member 4. Formation Sterkfontein Formation. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Most of the basicranium of an individual that some researchers link with Sts 58. Announcement Broom et al. 1950. Initial description Broom et al. 1950. Photographs/line drawings and metrical data It is illustrated as “Skull No. 8” in Broom et al. (1950, pp. 27–33), Dean and Wood (1982), and Kimbel et al. (2004). Detailed anatomical description N/A. Initial taxonomic allocation *Plesianthropus transvaalensis*. Taxonomic revisions *Australopithecus africanus*

(Robison 1954), *Homo* (Kimbel and Rak 1993, Kimbel et al. 2004). Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance In their initial description of this cranium Broom et al. (1950) noted that “the whole glenoid region is essentially similar to that of man,” and “the whole occipital fossa is almost human” (*ibid*, p. 30), and that “the manner in which the cerebellum has come to be shifted forward and below the cerebral occiput is most striking” such that the “general arrangement is the same as that found in the human brain, especially in *Homo sapiens*” (*ibid*, p. 102). Others have also noted the ways in which the cranial base of Sts 19 is more *Homo*-like than the cranial bases of other *Au. africanus* crania from Sterkfontein and Makapansgat (Clarke 1977, Kimbel and White 1988b, Kimbel et al. 2004), but although Dean and Wood (1982) refer to it as “the most *Homo*-like of the (*Au. africanus*) sample” they concluded that the morphology of Sts 19 is consistent with intra-specific variation in *Au. africanus* (*ibid*, p. 171), and Spoor (1993) concluded that both the bony labyrinth and the endocranial aspect of the basicranium give no grounds for the exclusion of Sts 19 from *Au. africanus* as represented by the adult crania Sts 5 and MLD 37/38 (*ibid*, p. 129). Location of original **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), Northern Flagship Institution, Pretoria, South Africa.

Sts 71 Site Sterkfontein. Locality Type site. Surface/in situ *In situ*. Date of discovery November 1947. Finders Robert Broom and John Robison. Unit N/A. Horizon N/A. Bed/member Member 4. Formation Sterkfontein Formation. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Lockwood (1999) suggests that it is a female. Brief anatomical description A damaged calvaria that preserves much of the right side of the face. Announcement Broom et al. 1950. Initial description Broom et al. 1950. Photographs/line drawings and metrical data Lockwood 1999. Detailed anatomical description N/A. Initial taxonomic allocation *Plesianthropus transvaalensis*. Taxonomic revisions *Australopithecus africanus* (Robison 1954). Current conventional taxonomic

allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance The relatively prognathic Sts 5 is often illustrated in reviews of *Au. africanus*, but one should remember that other specimens that make up the cranial hypodigm of *A. africanus*, such as Sts 71, have faces that are more orthognathic. Location of original **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), Northern Flagship Institution, Pretoria, South Africa.

Stw 53 Site Sterkfontein. Locality From south of the Extension Site/West Pit, and 3 m south of the locality in Sterkfontein where in 1956–8 Bob Brain and John Robinson recovered stone tools (but see Bed/member below). Surface/in situ *In situ*. Date of discovery Between June and August, 1976. Finders Alun Hughes and Phillip Tobias. Unit N/A. Horizon N/A. Bed/member The specimen was initially linked with Member 5, Unit A by Partridge, but Clark (1994) claims that it derives from Member 4. Kuman and Clarke (2000) suggest it is late Member 4/early Member 5 breccia and Clarke (2008) suggests that it came from a hanging remnant of the Member 4 breccia largely on the observation that the decalcified breccia that derives from the erosion “swallow hole” from which the cranium was extracted is devoid of artifacts. However, the cranium itself has been observed to exhibit stone-tool cutmarks on the right zygomatic bone (Pickering et al. 2000), rendering this rationale for stratigraphic attribution less than secure. Formation **Sterkfontein Formation**. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 2.0–1.5 Ma, but Pickering et al. (2000) suggest it may be as old as 2.4 Ma and U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Unknown. Brief anatomical description Most of the remains belonging to this skull belong to the cranium. These include the right frontal and parts of the parietals of both sides, the midline of the occipital, important parts of the basicranium including the basioccipital, temporal and sphenoid, much of the face, much of the palate, and the right postcanine teeth. The mandibular remains are restricted to a fragment of the right ramus that includes the mandibular notch and the coronoid process. Announcement and initial description Hughes and Tobias 1977. Photographs/line drawings and metrical data

Hughes and Tobias 1977, Curnoe and Tobias 2006. Detailed anatomical description Curnoe and Tobias 2006, but see Clarke (2008) for a critique of their reconstruction. Initial taxonomic allocation *Homo* aff. *habilis*. Taxonomic revisions *Homo habilis* (Tobias 1991b), *Homo sp. nov.* Grine et al. (1996), *Australopithecus africanus* (Kuman and Clarke 2000), holotype of *Homo gautengensis* (Curnoe 2010). Current conventional taxonomic allocation *H. habilis*. Informal taxonomic category Pre-modern *Homo*. Significance If Stw 53 is part of the southern African hypodigm of *H. habilis* as Curnoe and Tobias (2006) suggest (but see the conclusions of Grine et al. 1996), then it would have substantial biogeographic significance, and it would encourage those who claim to see dental evidence of that taxon at Sterkfontein, and at other sites such as **Drimolen**. Curnoe and Tobias (2006) make the point that the initial attempt to restore Stw 53 by Hughes and Tobias (1977) has been followed by two reconstructions, one by Clarke (1985b) and one by Curnoe and Tobias (2006). The latter claim that the two reconstructions differ in important details (*ibid*, pp. 43–4), including a larger (but unreported) endocranial volume in the latter reconstruction. Clarke (2008) interprets the history of reconstructing Stw 53 very differently and is adamant that the Curnoe and Tobias (2006) reconstruction is not valid and “does not reflect the original form of the cranium” (*ibid*, p. 447); he takes the view that Stw 53 is an unexceptional example of a male *Au. africanus*. The cutmarks reported on the right maxilla are interpreted by Pickering et al. (2000) as being “the earliest unambiguous evidence that hominids disarticulated the remains of one another” (*ibid*, p. 579). Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Stw 151 Site Sterkfontein. Locality All but one of the more than 40 fragments were found in a single solution pocket in square Aa/49 (the exception was found in X/49) between 1 and 2.2 m below datum. Surface/in situ *In situ*. Date of discovery April/May 1983. Finders Alun Hughes and team. Unit/horizon N/A. Bed/member “late Member 4 breccia deposit” (Moggi-Cecchi et al. 1998, p. 426). Formation **Sterkfontein Formation**. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age

Juvenile *c.*5.2–5.3 year. Presumed sex Unknown. Brief anatomical description Initially the fragments were given separate specimen numbers (Stw 151–178), but Jacopo Moggi-Cecchi suggested that all but three of the specimens (Stw 162, left scapula fragment, Stw 164, fragment of an adult cranial vault, and Stw 169, a worn left I²) likely came from the same immature individual that is now referred to as Stw 151. The cranium is represented by parts of the temporals, the occipital, and the palate; the only evidence of the mandible is part of the right side of the body and the right ramus. However, most of the dentition is preserved including the upper right deciduous molars, all of the lower deciduous molars and the crowns of at least one of each of the permanent teeth. The left stapes is also preserved. Announcement The specimen is mentioned in Smith (1986). Initial description Moggi-Cecchi et al. 1998. Photographs/line drawings and metrical data Moggi-Cecchi et al. 1998, Spoor 1993, Moggi-Cecchi and Collard 2002. Detailed anatomical description Moggi-Cecchi et al. 1998, Moggi-Cecchi and Collard 2002. Initial taxonomic allocation *Australopithecus africanus*. Taxonomic revisions Moggi-Cecchi et al. (1998) point to the many ways, both metrical and non-metrical, Stw 151 resembles *Au. africanus*, but they also suggest that its relatively narrow upper and lower permanent molar crowns and the entoglenoid process are *Homo*-like and in relation to the bony labyrinth Spoor (1993) suggested that “it is feasible that Stw 158 [Stw 151] is affiliated with a more derived form of hominid than *A. africanus*” (*ibid*, p. 131). Curnoe (2010) lists it as one of the paratypes of *Homo gautengensis*. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance Stw 151 is “the most complete set of jaws and teeth of an early hominid child since the Taung child” (Moggi-Cecchi et al. 1998, p. 425), and the same authors suggest that Stw 151 “may represent a hominid more derived towards an early *Homo* condition than the rest of the *A. africanus* sample from Member 4” (*ibid*, p. 425). Thus, Stw 151 is one of the specimens from Sterkfontein that some researchers think may represent a second, more *Homo*-like, taxon. Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Stw 252 Site Sterkfontein. Locality N/A. Surface/in situ *In situ*. Date of discovery June

1984. Finders Alun Hughes and Phillip Tobias. Unit/horizon N/A. Bed/member Decalcified “talus cone” of Member 4. Formation Sterkfontein Formation. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Lockwood (1999) suggests that it is a female. Brief anatomical description Clarke (1988) has made a reconstruction of this cranium that preserves the upper dentition, the anterior part of the palate, part of the face and frontal bone, the left parietal, and part of the occipital. Announcement Broom et al. 1950. Initial description, photographs/line drawings, metrical data, and detailed anatomical description Clarke 1988. Initial taxonomic allocation *Australopithecus africanus*. Taxonomic revisions Clarke (1988) has suggested that Stw 252 (plus Sts 36 and 71) represents a second, more postcanine megadont, taxon from Sterkfontein, Member 4. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance Clarke (1988, 2008) has suggested that Stw 252 is part of the male sample of a second *Paranthropus*-like *Australopithecus* taxon in Member 4 at Sterkfontein. Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Stw 431 Site Sterkfontein. Locality Grid Squares 45–6. Surface/in situ *In situ*. Date of discovery February 9 to March 23, 1987. Finders Alun Hughes, S. Sekowe, M. Makgothoko, and J. Kibii. Unit Bed 4B. Horizon “Several meters below the Members 4/5 junction” and “well above the junction between Members 3 and 4” (Lockwood and Tobias 1999, p. 638–9). Bed/member Member 4. Formation Sterkfontein Formation. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Male. Brief anatomical description Stw 431 comprises 48 postcranial fragments of an associated skeleton that includes the right humerus, ulna, and radius that articulate, the vertebral column from mid-thoracic to the sacrum, and the right sacro-iliac joint. Several isolated teeth, a vault fragment, a left first metacarpal, and a possible

right metatarsal may also belong to the same individual. Announcement, initial description, photographs/line drawings, and metrical data Toussaint et al. 2003. Detailed anatomical description Toussaint et al. 2003, Kibii and Clarke 2003. Initial taxonomic allocation *Australopithecus africanus*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance This is the third associated skeleton from this part of the Sterkfontein cave and it formed part of the evidence that McHenry and Berger (1998) put forward to support their contention that there are significant differences in the limb proportions of *Au. africanus* and *Australopithecus afarensis*. Location of original School of Anatomical Sciences, the University of the Witwatersrand, Johannesburg, South Africa.

Stw 505 Site Sterkfontein. Locality Grid Square H/42. Surface/in situ *In situ*. Date of discovery 1989. Finders Alun Hughes and Phillip Tobias. Unit Bed 4B. Horizon “Several meters below the Members 4/5 junction” and “well above the junction between Members 3 and 4” (Lockwood and Tobias 1999, p. 638–9). Bed/member Member 4. Formation Sterkfontein Formation. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously 3.0–2.6 Ma, but U-Pb dating suggests an age of *c.*2.6–2.0 Ma (Pickering and Kramers 2010). Developmental age Adult. Presumed sex Lockwood (1999) suggests that it is a male. Brief anatomical description Stw 505a comprises most of the face and the left half of the cranial vault, the left anterior cranial fossa, and part of the right middle cranial fossa; Stw 505b comprises most of the petrous and tympanic parts of the right temporal Announcement Clarke 1988. Initial description, photographs/line drawings, and metrical data Lockwood and Tobias 1999. Detailed anatomical description Lockwood and Tobias 1999. Initial taxonomic allocation *Australopithecus africanus*. Taxonomic revisions Clarke (1988, 1994) has suggested that Stw 505 is part of the hypodigm of a second hominin taxon in Member 4 at Sterkfontein. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance Clarke (1988, 1994, 2008) has suggested that Stw 505 (plus Sts 1, 36, 71, and Stw 183, 252, 384, 498) is part of a sample of a second

Paranthropus-like *Australopithecus* taxon in Member 4 at Sterkfontein, but Lockwood and Tobias’ (1999) detailed analysis suggest that Stw 505 can be accommodated within a range of variation for *Au. africanus* that is reasonable for a single taxon. Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Stw 573 Site Sterkfontein. Locality N/A. Surface/in situ The first and second tranche of bones belonging to this associated skeleton were recovered from Dumps 18 and 20, but the bulk of the skeleton of Stw 573, the *in situ* part, was discovered embedded in flowstone at the western end of the Silberberg Grotto. Date of discovery The initial recognition of four bones from the left foot of an early hominin took place in 1994. More bones of the left foot were recognized in May 1997, along with the distal ends of what were assumed to be the fibula and tibia of the left leg, and a right distal tibia. In June 1997 it became clear that there was a good chance that the rest of the skeleton was still *in situ* in the Silberberg Grotto. A few rib fragments were exposed between 1997 and 2002, but in 2002 Ron Clarke and his colleagues found a substantial parts of the pelvis and evidence of the vertebral column (Clarke 2002), and since then all of the skeleton of a single hominin individual (apart from some foot bones) has been located (Clarke 2008). Finders Clarke recognized the initial four bones as hominin, and it was also Clarke who recognized the additional foot and lower leg bones in boxes of bones marked “D18 (i.e., Dump 18)” and “D20 Cercopithecoids.” However, the first signs of what proved to be the bulk of the skeleton of Stw 573, the *in situ* part, was discovered by Stephan Mostsumi and Nkwane Molefe when Ron Clarke gave them the distal ends of the left tibia and fibula and asked them to search the walls of the Grotto to look for the exposed, matching, proximal surfaces of the broken leg bones. Unit Found embedded in flowstone on a talus slope at the western end of the Silberberg Grotto. Horizon N/A. Bed/member Member 2. Formation Sterkfontein Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Previously estimated to be *c.*2.6–3 Ma, but recent U-Pb ages suggest an age for the associated flowstone of *c.*2.2 Ma (Walker et al. 2006, Pickering and Kramers 2010). Developmental age Adult. Presumed sex Unknown.

Brief anatomical description Clarke has reported the discovery of the left lower limb (Clarke and Tobias 1995, Clarke 1998), the skull (Clarke 1998), the left arm and hand (Clarke 1999), the pelvis and part of the axial skeleton (Clarke 2002), and all but some of the foot bones of a hominin (Clarke 2008). **Announcement and initial description** Clarke and Tobias 1995. **Photographs/line drawings and metrical data** Some photographs, but no metrical data, in Clarke and Tobias (1995) and in Clarke (1998, 1999, 2002, 2008). **Detailed anatomical description** N/A. **Initial taxonomic allocation** *Australopithecus* sp. **Taxonomic revisions** N/A. **Current conventional taxonomic allocation** *Australopithecus* sp. **Informal taxonomic category** Archaic hominin. **Significance** Potentially the most complete early hominin skeleton, and certainly the best-preserved archaic hominin from southern Africa. Clarke (2008) claims that Stw 573 is part of the hypodigm (along with Sts 1, 36, 71, Stw 183, 252, 384, 498, 505) of a second *Paranthropus*-like *Australopithecus* taxon in Member 4 at Sterkfontein. **Location of original** School of Anatomical Sciences, the University of the Witwatersrand, Johannesburg, South Africa.

StW, Stw/H, StW/H Various abbreviations of “Sterkfontein Witwatersrand” and “Sterkfontein Witwatersrand Hominin” that are used as prefixes for fossil hominins recovered after 1949 from the Sterkfontein cave site, Blaauwbank Valley, Gauteng, South Africa.

stylopod (L. *stylus* = stem and Gk *pod* = foot) The proximal of the three compartments of a tetrapod limb. The proximal compartment (i.e., the upper arm or the thigh) is called the stylopod, the intermediate one (i.e., the forearm or the lower leg) is called the **zeugopod**, and the distal one (i.e., the hand or the foot) is called the **autopod**.

Subalyuk [Location 48°00'N, 20°30'E, Hungary; etym. Hu. Suba-lyuk = Suba's (a local landowner) cave) **History and general description** This cave near Cserépfalu village, in the Bükk Mountains, was excavated in 1932. **Temporal span and how dated?** **Biostratigraphy** suggests **Oxygen Isotope Stage** 5a–c. **Hominins found at site** Subalyuk 1 consists of a partial adult mandible that includes the symphysis, part of the left ramus, the dentition from the right P₃ to the left canine, the

left P₄ to the M₃. There are also isolated right molars, as well as postcranial fragments. Subalyuk 2 consists of a partial cranium of a child, including the right di¹–dm², left dc–dm¹, isolated left dm², and the crowns of four adult incisors and both first permanent molars. **Archeological evidence found at site** Late **Mousterian**. **Key references:** **Geology, dating, and paleoenvironment** Kadic 1940, Vértes 1964; **Hominins** Thoma 1963, Vlček 1970, Smith 1982; **Archeology** Bartucz et al. 1940, Mester 1990.

subarachnoid space (L. *sub* = below) The space between the arachnoid mater (the middle of the three meningeal layers) and the underlying pia mater (the innermost of the three meningeal layers) that is the most intimate covering of the surface of the brain, brain stem, and spinal cord. In adult modern humans the subarachnoid space contains approximately 150 cm³ of **cerebrospinal fluid**. The fluid-filled intracranial part of the subarachnoid space makes a major contribution to the difference between the volume of the brain and the brain stem and the volume of the endocranial cavity. *See also* **cerebrospinal fluid; meninges**.

subchron (Gk *kronos* = time) This term is an abbreviation of the term “polarity subchronozone,” which refers to a relatively short period of consistent geomagnetic polarity. Subchrons are subdivisions of **chrons**, and they (like chrons) are numbered (NB: the magnetic direction of a subchron is identified by a lower-case ‘n’ for normal and ‘r’ for reversed; thus the first reversed subchron in the normal chron 3An is 3A.1r). Numbered subchrons have replaced the named events (e.g., Jaramillo, Olduvai, etc.) that were used in the older geomagnetic polarity time scales. *See also* **geomagnetic dating; geomagnetic polarity time scale**.

subdivision *See* population structure.

subdural space (L. *sub* = below) The space between the dura mater (the outermost of the three meningeal layers) and the underlying arachnoid mater (the middle of the three meningeal layers). It contains the thin-walled cerebral veins that drain venous blood from the brain tissue to the endocranial venous sinuses. It makes a minor contribution to the difference between the volume

of the brain and the brain stem and the volume of the **endocranial cavity**. *See also* **dural venous sinuses**; **meninges**.

subjective synonym *See* synonym.

subnasal prognathism *See* prognathism.

subspheroid *See* Developed Oldowan.

substitution (L. *substituere* = in place of) Used in genetics to refer to one allele replacing another or in molecular evolution to refer to a single nucleotide or base change in DNA. *See also* **mutation**; **single nucleotide polymorphism**.

suid Informal term for taxa within the family Suidae (syn. pig, swine). *See* **Suidae**.

Suidae (L. *sus* = swine) The formal name for the mammalian family that includes the pigs. Pigs are omnivorous **artiodactyls**, with simple non-ruminating stomachs, that first appear in the fossil record in the Oligocene of Asia, but successive adaptive radiations are important elements of later African faunas. In the main they are large-bodied, although the smallest highly endangered modern species *Sus (Porcula) salvania* can be as small as 10 kg. In addition to the ubiquitous domestic pig, *Sus scrofa*, the suid family contains many wild species, including the three indigenous extant African wild hogs, *Phacochoerus aethiopicus*, the warthog, *Hylochoerus meinertzagani*, the giant forest hog, and *Potamochoerus porcus*, the bush pig. While paleoanthropologists are interested in all members of the ecological communities in which hominins evolved, there at least two reasons why the Suidae have a special bearing on human evolution. First, the Suidae underwent an **adaptive radiation** during the **Pliocene** and **Pleistocene** of Africa. This radiation is characterized by relatively rapid speciation, resulting in the evolution of taxa with a larger body size than the ancestral forms and with taller tooth crowns (i.e., hypsodonty). The speed at which this radiation occurred has made the Suidae a useful biochronological tool for dating hominin sites (e.g., **Koobi Fora**, **Sterkfontein**, etc.). Second, because they are found alongside hominins at fossil sites it is assumed that they are ecologically similar to hominins (i.e., large-bodied, terrestrial, omnivores). Thus, their evolutionary history provides a useful comparative heuristic device for examining our own evolution.

sulcus (L. *sulcus* = furrow) A deep furrow within an organ. Most named sulci are in the parts of the central nervous system, such as the gray matter of the **cerebral cortex**, that are thrown into folds. In the central nervous system the crest of a fold is called a **gyrus** and the deepest part of a fold is a sulcus. *See also* **calcarine sulcus**; **central sulcus**; **lunate sulcus**.

sulcus supratoralis *See* supratoral sulcus.

Sunda (etym. In Hindu lore, variants of the word Sunda were used as names by ancient creatures. “Sunda,” “ni-Sunda,” and “Upa-Sunda” were the names of giants, or “Daityas,” mentioned in the Upanishads. They fought with the gods because of their jealousy with their human half-brothers). Blavatsky suggests that Daitya was the name of an island-continent said to have been inhabited by giants such as Sunda during the time of Atlantis. The term “Great Asiatic Bank” had been introduced by Earl(e) in 1845 to refer to the “south-eastern extreme” of the Asiatic landmass that extends “to within 50 miles of Celebes.” In their 1919 summary of the Dutch Siboga Expedition, Molengraaff and Weber suggest that Great Asiatic Bank be replaced by the term “Sunda Shelf.” The term Sunda is now used to refer to both the Sunda Shelf (or Sundaland) and to the Sunda Islands. Sundaland is the name given to the part of the continental landmass that includes mainland Southeast Asia and the Greater Sunda Islands. The Sunda Islands are divided into the Greater (Borneo, Sumatra, Java) and the Lesser (Lombok, Sumbawa, Flores, Sumba, Timor) Sunda Islands; the former are part of the continental landmass, but the latter are not. During particularly cold periods when substantial volumes of water were locked up in ice accumulations at high latitudes, sea levels would have fallen low enough for much of Sundaland to have been one continuous landmass. However, the water channels between the Greater and Lesser Sunda Islands, and between Timor and the smaller Lesser Sunda Islands (i.e., Flores, Sumba, etc.), are deep, as is the channel between Timor and **Sahul** (i.e., Greater Australasia). *See also* **Sahul**.

Sunda Islands *See* Sunda.

Sunda Shelf *See* Sunda.

Sundaland *See* Sunda.

Sunghir *See* Sungir.

Sungir (Location 56°08'N, 40°24'E, near the city of Vladimir, Russia; etym. unknown) History and general description Excavations of this very large, open-air Upper Paleolithic site were first conducted by Otto Bader in the 1950s and have been continued by the Russian Archaeological Society. The site is notable for its elaborate multiple burials, with grave goods including thousands of beads, jewelry, and pendants. Temporal span and how dated? Radiocarbon dates suggest a range of 20–28 ka. Hominins found at site Five individuals, including at two adolescents buried head to head, were recovered. Archeological evidence found at site Upper Paleolithic artifacts attributed to the “Eastern Gravettian,” house structures, hearths, storage pits, and tool-production evidence. Key references: Geology, dating, and paleoenvironment Kuzmin et al 2004; Hominins Kuzmin et al 2004, Alexeeva et al. 2000; Archeology Alexeeva et al. 2000.

superciliary arch (L. *cilium* = eyelid and *supercilium* = eyebrow. The term “ciliary” refers to anything – i.e., lids, muscles, nerves, vessels – that pertains to the eye) The superciliary arch is a bilateral unitary bony arch that runs laterally and superiorly from the medial end of the superior orbital margin in some pre-modern *Homo* crania, and in most *Homo sapiens* crania. In such specimens the supraorbital region takes the form of a composite structure, made up of the superciliary arch medially and the supraorbital trigon laterally.

superciliary eminence *See* superciliary arch.

superior nuchal line A roughened line on the occipital bone that is produced by the attachment of the fascia that covers one of the biggest nuchal muscles, the semispinalis capitis. If the muscle and the fascia are well developed the line may take the form of a crest of bone called the nuchal crest.

supernumerary tooth (L. *super* = above and *numerus* = number) When the number of teeth exceeds the typical, or modal, number for that tooth class in each quadrant of a jaw (e.g., for Catarrhines, including hominoids, incisors = 2,

canine = 1, deciduous molars = 2, premolars = 2, molars = 3). Supernumerary teeth may resemble neighboring teeth, or show less morphological complexity (crown and/or roots) than the other teeth in the respective tooth class. Mouse mutants have demonstrated that supernumerary teeth are associated with genetic disturbance of developmental pathways, especially those initiated by SHH (Sonic hedgehog), FGFs (fibroblast growth factors), and BMPs (bone morphogenic proteins) (reviewed in D’Souza and Klein 2007). Alternate hypotheses exist for how these mutations ultimately lead to the development of supernumerary teeth. Supernumerary teeth may be associated with the splitting of normal tooth germs during development (reviewed in Schwartz 1984, Miles and Grigson 1990) or they may be the product of continued proliferation of cells in the dental lamina (Ackermann et al. 2006, D’Souza and Klein 2007). There are many documented cases of fourth molars among hominoid primates (e.g., Schwartz 1984, Ackermann and Bishop 2009), and in mammals supernumerary teeth are found in higher frequency in hybrids (Goodwin 1998, Ackermann et al. 2006), and may relate to the breakdown of normal genetic regulation in these individuals (Kangas et al. 2004).

superposition, law of (L. *super* = above) Principle, or law, that within a sequence of strata the strata at the top are younger than those at the bottom.

supination (L. *supinum* = lying on its back) In the forelimb, supination refers to the action involved in returning the forearm from the pronated position (i.e., with the palm of the hand facing backwards or downwards) to the supine position (i.e., with the palm of the hand facing forwards or upwards). In the hindlimb, supination refers to the action of moving the foot from the out-turned, pronated, position (i.e., with the sole of the foot facing outwards), to one in which the sole is maximally in-turned (i.e., with the sole of the foot facing inwards). *See also* anatomical position; foot movements.

suprainiac fossa (L. *supra* = above, and *inion* = which is a midline bony landmark that represents the superior attachment of the ligamentum nuchae) A trait consisting of a small depression, or fossa, above the inion. It has been proposed as an autapomorphy

of *Homo neanderthalensis* (Hublin 1978), but others have suggested that its expression is not restricted to that taxon and that it is also seen in fossil crania belonging to *Homo sapiens* (e.g., Trinkaus 2004). Balzeau and Rougier (2010) investigated the detailed morphology of the trait as it is expressed in Neanderthal crania (e.g., Gibraltar 1, Spy 1, etc.), and they compared it to the suprainiac fossae in *H. sapiens* crania (e.g., Afalou Bou-Rhummel and Taforalt). These authors showed that what appears superficially to be the same phenotypic trait shows detailed differences in the two taxa. In *H. neanderthalensis* the depression is due to loss of the **diploë** between the inner and outer tables of the cranial vault, whereas in *H. sapiens* the depression is due to a thinning of the outer table. This latter phenomenon has been referred to as a “**supranuchal fossa**” (Sládek 2000, Caspari 2005).

supralaryngeal vocal tract (L. *supra* = above) The part of the vocal tract above the vocal folds. The supralaryngeal part of the vocal tract (or SVT) comprises all of the structures between the vocal folds and the lips [i.e., the “aditus” (the part of the laryngeal cavity between the vocal folds and the opening into the pharynx), the oropharynx, and the mouth, made up of the oral cavity proper and the vestibule]. From within to without, it is divided into a vertical (or SVT_V) and a horizontal (or SVT_H) component. In modern humans these components are at right angles to each other and they are subequal (nearly equal) in length. This geometry is one of the reasons modern humans can make such a wide range of sound units, or **phonemes**, especially the vowels [a], [i], and [u]. *See also* spoken language.

supramarginal gyrus (Gk *gyros* = ring, circle) The supramarginal gyrus of the cerebral cortex corresponds to **Brodman’s area 40**, which is part of the inferior parietal cortex. The supramarginal gyrus curves around the posterior end of the **lateral sulcus**. The cortex of the supramarginal gyrus is involved in spatial orientation, the phonological and articulatory processing of words, the memory of meaningful gestures, and the sequence of actions of the upper limb. Because of these associations, the supramarginal gyrus, like the **angular gyrus**, has been implicated in the neural basis of tool production and tool use.

supramastoid crest (L. *supra* = above, Gk *mastos* = breast, *oeides* = shape, and L. *crista* = crest)

If the posterior-most fibers of the temporalis muscle are especially well developed, then the edge of that muscle attachment in the region of the mastoid may be raised up to form a supramastoid crest. The supramastoid crest and the **mastoid crest** are usually well developed in *Paranthropus*, and are usually separated by a **supramastoid sulcus**.

supramastoid sulcus *See* mastoid crest; mastoid process.

supranuchal fossa (L. *supra* = above and ME *nucha* = nape, or back, of the neck) The term supranuchal fossa has been used to describe a depression in the midline of the occipital bone in *Homo sapiens* crania that is due to a thinning of the outer table (Sládek 2000, Caspari 2005). *See also* suprainiac fossa.

supraorbital bar (L. *supra* = above and *orbis* = wheel or hoop) The name given to a strut of bone that extends across the frontal bone, above the orbits and the nose, in taxa that manifest substantial postorbital constriction, or postorbital narrowing (e.g., chimpanzees, *Australopithecus afarensis*). The postorbital constriction means that the supraorbital bar is effectively separated from the rest of the cranial vault. A supraorbital bar has a midline, or glabellar, component and two lateral components. In megadont archaic hominin crania such as OH 5 the glabellar component projects ahead of the lateral components.

supraorbital height index The index introduced by Wilfrid Le Gros Clark (1950) to describe the relationship between the cranial vault and the upper part of the face. The index, which is taken away from the sagittal plane, refers to the ratio between the height of the calotte above the upper margin of the orbit (FB) and the total height of the **calvaria** above the Frankfurt Horizontal (AB), multiplied by 100. The higher the cranial vault the higher the ratio (e.g., in modern humans the average is about 70 and in *Pan* it is about 50).

supraorbital region (L. *supra* = above and *orbis* = wheel or hoop) The supraorbital region refers to the region of the cranial vault that is situated above the superior orbital margins.

supraorbital torus (L. *supra* = above, *orbis* = wheel or hoop, and *torus* = bulge) Name given to a

relatively straight and continuous morphological feature, essentially a bar of bone, that extends across the frontal bone above the orbits and the nose. It has a midline, or glabellar, component and two lateral components. The central portion encloses the frontal sinus. In taxa that manifest substantial postorbital constriction, or postorbital narrowing (e.g., chimpanzees, *Australopithecus afarensis*) such that the supraorbital region is effectively separated from the rest of the cranial vault, the analogous structure is referred to as a **supraorbital bar**.

supraorbital trigone (L. *supra* = above, *orbis* = wheel or hoop, and *trigonum* = triangle) Name given to the lateral of the two components of the compound structure that forms the supraorbital margin in most *Homo sapiens* crania.

supratoral sulcus In *Homo erectus* crania there is often a hollowed area in the midline between lambda and inion, and in his description of the Zhoukoudian crania Franz Weidenreich (1943, p. 39) introduced the term *sulcus supratoralis*, or supratoral sulcus, to describe it.

survivorship The probability that an individual will live until a specified age. Note that if the survivorship at age 45 years is 0.4 then this simply indicates that at birth an individual will have a 40:60 chance of surviving until age 45 years, but could die at any age past 45 if they survive to that age. Also note that the starting point for survivorship need not be at birth, but can instead refer to any point in an individual's **life history**. For example, adult survivorships could be defined as starting at age 20 years, whereas fetal survivorship could be defined as starting at conception. The survivorship curve across age is determined by the **hazard rate** of death. Because life histories vary so greatly between modern humans and the extant apes, survivorship is one of the most intensively studied variables in **paleodemography**.

survivorship analysis A formal method for studying the "time to failure," which in **paleodemography** is typically death. Survivorship analysis usually assumes a particular form for the hazard of death and then estimates the parameters that fully describe **mortality**. Although paleodemographic data are typically too sparse for an in-

depth survivorship analysis, survivorship models can sometimes be simplified and applied even to paleoanthropological samples. Survivorship analysis produces estimates of the parameter or parameters describing a hazard function, which gives the **hazard rate** at every age ($h(t)$). Survivorship can then be found from the hazard function by exponentiating the negative integral, which gives: $S(t) = \exp \left[- \int_0^t h(y) dy \right]$ (Wood et al. 1992). The probability density function for age at death is then the product of survivorship and the hazard.

susceptibility The state of being at risk from a disease or condition. It is the probability that an individual will suffer from a condition because of environmental exposure (such as the infective agent of an infectious disease or exposure to a chemical) or from a condition that is influenced by both genotype and environment (i.e., genetic susceptibility to a disease such as type II diabetes or malaria). Scenarios for human evolution seldom take into account the possibility that disease may have played an important role in our evolution.

suture (L. *sutura* = a seam) A fibrous joint between two bones of the cranial vault. The fibrous tissue in these joints gradually disappears as the bone fuse together.

Svaty Prokop (Location 50°05'N, 14°20'E, Czech Republic; etym. Czech "Saint Procopius" = name of the valley in which it is found) History and general description Cave site southwest of Prague in the middle of the Svaty Prokop valley. Hominin remains found with Pleistocene fauna and lithic artifacts were initially thought to be Upper Paleolithic in age, but they have been recently redated and they have an age that is post-Paleolithic. Temporal span and how dated? Radiocarbon dating on the human bones provided two dates, 4–5 ka BP and 1.8 ka BP, showing that these remains are Holocene intrusions. Hominins found at site Occipital bone and femoral head attributed to *Homo sapiens*. Archeological evidence found at site Middle Paleolithic stone tools and a bone industry were found at the site, but they are not associated with the hominin remains. Key references: Geology, dating, and paleoenvironment Svoboda et al. 2004; Hominins Vlček 1971, Churchill and Smith 2000.

Švédův stůl *See* Ochoz.

Svitavka (Location 50°05'N, 14°20'E, Czech Republic; etym. named after the valley in which it is located) History and general description Skeletal fragments discovered during geological surveying in 1962 were initially thought to be Upper Paleolithic in age, but they were recently related to the Middle Ages. Temporal span and how dated? Radiocarbon dating of the fragments has provided a recent date. Hominins found at site A partial skeleton assigned to *Homo sapiens*. Archeological evidence found at site Some lithic artifacts. Key references: Geology, dating, and paleoenvironment Svoboda et al. 2002; Hominins Vlček 1971.

SVT Acronym for the supralaryngeal part of the vocal tract. *See* **supralaryngeal vocal tract**.

SVT_H Acronym for the supralaryngeal part of the vocal tract, horizontal component. *See* **supralaryngeal vocal tract**.

SVT_V Acronym for the supralaryngeal part of the vocal tract, vertical component. *See* **supralaryngeal vocal tract**.

swallowing (OE *swillian* = to wash out from Ge. *swelgan*) Swallowing is the act of moving a bolus of food or a volume of liquid from the mouth through the oropharynx and the laryngopharynx to the esophagus. Muscles help swallowing by changing the shape of the oral cavity, elevating the larynx, and by closing the oropharynx behind the food or liquid. Swallowing is aided by gravity, but it can take place against it. During swallowing striated muscle sphincters contract by reflex to close off the nose and the larynx to prevent the entry of food and liquid. The initial phase of swallowing involving striated muscles can be initiated voluntarily, but once the food or liquid is in the oropharynx swallowing becomes involuntary. Swallowing during normal eating and drinking is an unconscious reflex activity. You do not have to make a conscious decision to swallow; you swallow automatically when receptors in the mouth judge the food to be ready, or before you take another mouthful. In modern humans the soft palate closes off the nasopharynx, whereas in nonhuman primates with an unflexed cranial base the soft palate meets the epiglottis, effectively seal-

ing off the mouth from the airway so animals can swallow and breathe at the same time. Researchers have made several, but as yet unsuccessful, attempts to work out when in human evolution this switch from the nonhuman primate-type to the modern human-type arrangement took place. Modern human infants have a relatively unflexed cranial base and newborn babies and neonates have the nonhuman relationship in which the soft palate meets with the epiglottis. This allows them to breathe and suckle at the same time, and this explains why babies and adults with blocked noses due to upper respiratory tract infections have to stop feeding to take a breath. *See also* **pharynx**.

Swanscombe (Location 51°26'44.12"N, 0°17'56.80"E, England; etym. the site is within the boundary of the village of Swanscombe, Kent) History and general description The site, called **Barnfield Pit**, is a gravel pit in the 100-ft (30-m) terrace just inland from the south bank of the estuary of the river Thames. The site was known for its **Clactonian** stone artifacts recovered *in situ* from the middle gravel beds. A single hominin calvaria (**Swanscombe 1**) is represented by three cranial vault fragments. The occipital and left parietal were found by Alvan Marston (a dentist from Clapham, south London) in 1935 and 1936, and the right parietal was found by John Wymer and A. Gibson in 1955. The remains were originally allocated to 'archaic' *Homo sapiens*, then to *Homo sapiens protosapiens*, and then to *Homo sapiens steinheimensis*. The current conventional taxonomic allocation is to *Homo neanderthalensis*. Temporal span and how dated? The fauna from the site is consistent with the interglacial that preceded the Anglian glaciation (i.e., **Oxygen Isotope Stage 11**, c.400 ka). Hominins found at site Hominin adult calvaria represented by the occipital and both parietals. Archeological evidence found at site Excavations led by John d'Arcy Waechter between 1968 and 1972 yielded predominantly **Acheulean** handaxes. Key references: Geology, dating, and paleoenvironment Stringer and Hublin 1999; Hominins Marston 1936, Montandon 1943, Wymer 1955, Weiner and Campbell 1964, Stringer and Hublin 1999; Archeology Hawkes et al. 1938, Wymer 1964, Waechter 1971.

Swanscombe 1 Site Swanscombe. Locality N/A. Surface/in situ *In situ*. Date of discovery

June–October 29, 1935 (occipital), March 15, 1936 (left parietal), July 30, 1955 (right parietal). Finders Alvan Marston (1935–6) and John Wymer and A. Gibson (1955). Unit/horizon Near the base of the Upper Middle Gravels. Bed/member 100-ft Thames terrace. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*400 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Almost complete occipital, well-preserved left parietal, and less well-preserved right parietal. Endocranial volume *c.*1325 cm³ (Olivier and Tissier 1975). Announcement Marston 1936, Wymer 1955. Initial description Le Gros Clark 1938, Morant 1938. Photographs/line drawings and metrical data Ovey 1964. Detailed anatomical description Ovey 1964. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions *Homo sapiens protosapiens* (Montandon 1943), *Homo sapiens steinheimensis* (Weiner and Campbell 1964). Current conventional taxonomic allocation *Homo neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The Swanscombe calvaria is one of a group of specimens (others include the hominins from Reilingen, the Sima de los Huesos, and Steinheim) referred to *H. neanderthalensis*. Researchers who interpret *H. neanderthalensis* as an evolving lineage would interpret the Swanscombe 1 calvaria as an example of “Stage 2,” a stage that has also been referred to as the “pre-Neanderthal” (e.g., Dean et al. 1998) stage. Location of original Natural History Museum, London, UK.

Swanscombe skull See Swanscombe 1.

Swartkrans (Location 25°58'08"S, 27°45'21"E, South Africa; etym. Afrikaans for “black hillside,” so-called because the rocks are stained black by manganese) History and general description The cave had been mined for lime in the 1930s, but the first paleontological exploration of the Swartkrans breccias was instigated by Robert Broom and John Robinson in 1948. This initial exploration, partly funded by the University of California’s Africa Expedition, began in November 1948 and ran until November 1949. The first hominins, SK 2–SK 6, were recovered in November 1948, from what was called at the time called “pink breccia,” and they were assigned to *Paranthropus crassidens* (Broom 1949); *P. crassidens* is now recognized by all authorities as a subjective junior synonym of

Paranthropus robustus. Broom and Robinson excavated together at Swartkrans until Broom’s death in 1951, and Robinson continued for 2 years after that. C.K. (Bob) Brain reopened scientific exploration of the caves in 1965 and spent the first 7 years sorting through the breccia dumps the lime miners had left behind. In 1973 he began clearing the surface of the site of all remaining rubble, and starting in 1979 he conducted *in situ* excavations and these lasted until 1986. Since 1965 Brain was responsible for the research at the cave and for the interpretation of the discoveries; research at Swartkrans is now under the joint direction of Brain and Travis Pickering. The Swartkrans breccias were initially formally designated as the **Swartkrans Formation** (Butzer 1976b), with two Members (1 and 2), but researchers now recognize five Members (1–5). Member 1 (the old “pink breccia”) is the most extensive and is divided into the “Hanging Remnant” (HR) and the “lower bank” (LB) components. Most of the Swartkrans *P. robustus* hypodigm comes from Member 1, but both Member 2 (this includes the old “brown breccia”) and Member 3 also contain fossil evidence of *P. robustus*. There are two newly recognized sedimentary units, the Talus Cone Deposit (TCD) and the Lower Bank East Extension. The former contains *P. robustus* fossils and the latter, which is presently the lowest sedimentary unit in the cave, is equivalent to the “lower bank” of Member 1. Temporal span Approximate dates of the main fossil-bearing strata: Members 1–3 are *c.*1.8–1.0 Ma. A recent review suggests that “the currently best accepted dating of Members 1–3 relies on biostratigraphy, which, on balance, places each unit between *c.* 1.8–1.0 Ma. Parsing of the bovid and equid data leads some (e.g., Vrba 1985, Churcher and Watson 1993) to assign dates more specifically, with Member 1 at 1.7 Ma, Member 2 at 1.5 Ma, and Member 3 at 1.0 Ma” (Sutton et al. 2009, p. 689). Direct uranium-lead dating of the flowstone layers above and below the Hanging Remnant and Lower Bank deposits gives an age of 2.25–1.8 Ma for Member 1 (Pickering et al. 2010). Member 4 is Middle Stone Age (*c.*<100 ka); Member 5 is *c.*11 ka. How dated? Biostratigraphy, with some recent ages from uranium-series dating, electron spin resonance spectroscopy dating, and radiocarbon dating. Hominins found at site More than 400 hominin fossil specimens, probably representing fewer than 150 individuals, have been recovered

from dumps of Swartkrans breccia, or have been found *in situ* in the cave. In April 1949 a mandible **SK 15** was recovered from a pocket of “brown breccia” and was assigned to a second hominin, *Telanthropus capensis* (Broom and Robinson 1949c). Subsequent excavation has shown that all the Broom/Robinson hominin fossils come from what is now referred to as the “hanging remnant.” In addition small numbers of fossils assigned to *Homo* sp. have been recovered from Members 1 and 2, and some researchers have suggested that one, or more, hominin postcranial fossils from Member 3 may belong to *Homo*. *Homo* remains make up about 5% of the hominins in Member 1, and some 20% of the hominins in Member 2. In addition to SK 15 these presumed *Homo* fossils include the composite cranium, **SK 847**, the mandible fragment, **SK 45**, and several isolated teeth. Archeological evidence found at site Stone artifacts, including cores and choppers resembling the **Developed Oldowan** from East Africa, have been recovered from Members 1–3, as have bones that appear to have been used as **digging sticks**. Assemblages from Member 1 (Lower Bank) and Members 2 and 3 have been interpreted as evidence for systematic butchery by early hominins, and it has been suggested that burned bone recovered in substantial quantities from Member 3 is evidence of the deliberate use of fire. Key references: Geology, dating, and paleoenvironment Curnoe et al. 2001, Brain 2004, Herries et al. 2009, Sutton et al. 2009, Pickering et al. 2010; Hominins Robinson 1956, Grine 2004, Susman 2004, Sutton et al. 2009; Archeology Clark 2004, Backwell and d’Errico 2004b, Pickering et al. 2008, Sutton et al. 2009.

Swartkrans I *See Swartkrans.*

Swartkrans II (Location 25° 58’ 08” S, 27° 45’ 21” E, South Africa; etym. Afrikaans for “black hillside,” so-called because the rocks are stained black by manganese) A set of breccia outcrops a short distance northeast of the Swartkrans Main Site excavation. The outcrops were exposed by miners early in the 20thC and C.K. (Bob) **Brain** collected a few samples in the late 1950s. The deposit was mapped, a grid was constructed, and systematic excavations began in 2005. *See also Swartkrans.*

Swartkrans Formation The Swartkrans breccias were formally designated as the Swartkrans Formation (Butzer 1976b). Researchers now recognize five members (1–5). *See also Swartkrans.*

Swartkrans Main Site *See Swartkrans.*

Swartkrans Paleoanthropological Research Project (or SPRP) Initiated in 2005, this is the umbrella organization for the latest phase of research at Swartkrans. It is co-directed by Travis Pickering and C.K. (Bob) **Brain**. Other members include Morris Sutton (site supervisor and artifacts), Jason Heaton (nonhominin primate paleontology), Ron **Clarke** (hominin paleontology), and Kathleen Kuman (artifacts). The SPRP is currently focusing on excavations in (a) an artifact-rich **Middle Stone Age** (or MSA) deposit in the northeastern portion of the site and (b) in two deposits of early **Pleistocene** age that underlie the MSA unit, including the newly recognized and fossiliferous Talus Cone Deposit, and an eastward extension of the well-known Lower Bank deposit of Swartkrans Member 1. Other current SPRP excavations include (a) the reopening of Member 3, a depositional unit from which abundant burned bones – claimed to be the earliest evidence of hominin-controlled fire at *c.*1.0 Ma – have been previously recovered, and (b) the systematic excavation of Member 5, the site’s most recent surviving depositional unit (*c.*11 ka), with a well-preserved fauna inferred to have been accumulated primarily by leopards and that is dominated by the fossils of the extinct springbok *Antidorcas bondi*.

Swedish China Research Committee In 1924/5 Carl Wiman and Otto Zdansky had found what they interpreted to be a hominin tooth in the collection from what was then called Choukoutien (now called **Zhoukoudian**) and this prompted them to suggest that a tooth found in 1921 might also belonged to a hominin and not to an ape. Johan **Andersson** learned of Wiman and Zdansky’s conclusions by letter in 1926 and with support from the Swedish industrialist Axel Lagrelius the Swedish China Research Committee was established to fund and organize paleontological exploration in China, especially at Choukoutien. *See also Homo erectus; Zhoukoudian.*

swine Informal term to describe the taxa within the family Suidae (syn. pig, suid). *See Suidae.*

swing phase *See walking cycle.*

Sylvian fissure *See lateral fissure.*

symbol One of three categories of possible signs used by communication systems to refer to things in the world (icons and indexes are the others) (Deacon 1997). Icons are signs that encode meaning in a transparent fashion; photographs of individuals, maps, and animal sounds are examples of iconic signs because they bear a direct relationship to the things they refer to (i.e., the referent). Indexes are signs that are causally related to the things they refer to; weathervanes index the direction of wind and speedometers index driving speed. Scents are also indexical, in that they are causally related to a particular individual or category of animal. According to Deacon (1997), symbols are arbitrarily related to their referent, but the relationship between a given symbol and its referent is derived by an explicit and learned social convention. This definition of symbol differs from standard definitions that emphasize the arbitrary relationship between a sign and a given referent. In addition to being arbitrary, symbols are generative, since they are composed of indexes, icons, and other symbols, and they are part of a “system of conventional relationships” (Deacon 1997, p. 71), or social conventions. Deacon has argued that modern human brains are uniquely specialized for creating and manipulating symbols. As such, while indexical and iconic signs are common in animal communication systems, symbols are not. Archeologists have emphasized the use of symbols (e.g., the curation of **ochre** presumably to use to color the skin or as a non-utilitarian object; McBrearty 2001) as an important element of what makes the behavior of modern humans different from that of early hominins. *See also* **word**; **symbolic**.

symbolic (L. *symbolus* = a token or sign) An adjective that describes anything that serves to effectively reference a socially shared idea, object, concept, or phenomenon. The presence of symbolic behavior (and its apparent absence from some hominin populations) is a central component of many debates on the origin of modern human behavior (e.g., Henshilwood and Marean 2003). Among extant populations symbolism takes many forms, including material representations as well as social performances such as dance, myth, folklore, song, gesture, and speech. Archeologists are necessarily most concerned with symbolic material culture because it alone is preserved in the archeological record. An object, image, or other item of material culture is not inherently symbolic, but

rather its symbolic nature is socially ascribed or constructed. It is through collective agreement on the meaning of the symbol that it comes to be symbolic and the symbol itself may or may not bear a direct resemblance to that which it symbolizes. This renders interpretation of symbolism in the archeological record difficult, as we lack anyone to inform us of the cultural context necessary to interpret such items. Wedding rings provide a good example. Populations living in the USA, Canada, and the UK (for example) recognize that a person wearing a ring on the fourth finger of the left hand is probably married. However, from the perspective of the archeologist, there is nothing about the physical characteristics of (most) wedding rings that would link them to marriage; rather, it is the understanding of their meaning shared by members of a culture or community that lend them significance. Early artifacts (e.g., pierced shells from **Grotte des Pigeons**) that may have served as pendants may carry similarly complex meanings that present unique archeological challenges in their interpretation.

sympatric (Gk *sym* from *sumbion* = to live together and *patris* = fatherland) Two organisms with significantly overlapping geographic ranges. It is possible that several hominin species (e.g., *Paranthropus boisei* and *Homo habilis*) were sympatric, although co-occurrence in the fossil record does not necessarily imply the animals lived at the precisely the same time or in precisely the same place. There are very few examples of sympatric speciation (the genetic divergence of populations that remain geographically associated) in animals; it is likely to be a much more common mechanism of speciation in plants. *See also* **syneecology**; **taphonomy**.

sympatric speciation A mode of **speciation** in which new **species** are formed when two or more populations within a single species diverge ecologically within the same geographic range. The ecological divergence results in disruptive selection that drives the populations apart anatomically and/or behaviorally, resulting eventually in genetic divergence and reproductive isolation between the groups. There is a considerable debate within evolutionary biology as to how frequently sympatric speciation occurs, if at all.

sympatry The state when two or more organisms are **sympatric** (*which see*).

symphyse *See joint; symphysis.*

symphysis (Gk *sym* from *sumbion* = to live together and *phyein* = to grow) A midline **secondary cartilaginous joint** such as that between the bodies of the right and left sides of the developing **mandible** and between the paired pubic components of the pelvic bones. Pl. symphyse. *See also joint.*

symplesiomorphic *See symplesiomorphy.*

symplesiomorphy (Gk *sym* from *sumbion* = to live together, *plesios* = near to, and *morph* = form) A term used in cladistics to refer to the primitive condition of a character (i.e., the character state of the **hypothetical common ancestor** of a **clade**, or of the **outgroup**). For example, a small canine crown is probably a symplesiomorphy, or symple-siomorphic, for the **hominin** clade, and a slender mandibular corpus is probably a symplesiomorphy for the *Homo* clade (syn. plesiomorphy).

synapomorphy (Gk *syn* from *sumbion* = to live together, *apo* = different from, and *morph* = form) A term used in cladistics for a character state that is neither symplesiomorphic (primitive or shared by many taxa) nor autapomorphic (confined to one taxon; *see autapomorphy*). Synapomorphies are character states shared by at least two taxa. For example, extreme postcanine **megadontia** is probably a synapomorphy of *Paranthropus boisei* and *Paranthropus aethiopicus*. Extreme postcanine megadontia is also seen in *Australopithecus garhi*, but it may be a homoplasy in that taxon and not a synapomorphy shared with the two aforementioned *Paranthropus* taxa. (syn. apomorphy).

synapse (Gk *syn* from *sumbion* = to live together and *haptein* = to fasten) The places on the cell surface of a **neuron** where the neuron touches its target cell. A neuron can form a synapse with another neuron, with a gland, or with a muscle. Synapses, depending upon the kind of impulse conveyed, can be divided into two categories, electrical and chemical. At electrical synapses, ion channels connect the cytoplasm of the presynaptic (sending) and postsynaptic (receiving) cells. At chemical synapses, there is no cytoplasmic continuity between the cells, and the neurons are separated by a synaptic cleft. In a chemical synapse it is through the synaptic cleft that **neurotransmitters** pass from the presy-

naptic axon terminal to the postsynaptic receptor membrane.

synchondroses *See joint.*

synchronic (Gk *sunchronos* = contemporaneous) Term implying that events took place together, or fossils are of the same age. But “together” and the “same” are being used in the sense of geological time, so the events could be hundreds or thousands of years apart, and the organisms represented by the fossils could have been living at times that were hundreds or thousands of years apart.

synchrotron A machine that sends accelerated particles (electrons) through a cyclical course determined by magnetic fields. When the electrons are deviated by the magnets, synchrotron light is emitted, which can range from radio frequencies to high-energy X-rays. Synchrotron X-rays have properties (e.g., high flux, monochromaticity, parallel beam geometry, spatial coherence, etc.) that are superior to laboratory or medical **computed tomography**. *See also synchrotron radiation micro-computed tomography.*

synchrotron radiation micro-computed tomography A **synchrotron** imaging technique (abbreviated SR- μ CT) that facilitates submicron imaging and phase-contrast techniques, which reveal structures invisible with conventional **computed tomography** (or CT). The small size and focused high energy of the source beam means that, compared to CT, micro-computed tomography can deliver an advantageous signal-to-noise ratio on even highly mineralized bone and tooth samples (Mazurier et al. 2006). Propagation phase-contrast techniques reveal interfaces within structures, including microscopic variations in the prismatic structure of enamel and the tubular structure of dentine. It has enabled researchers to image the incremental development of intact teeth (Tafforeau and Smith 2008), reveal the fine details of **enamel-dentine junction** in heavily mineralized fossil teeth (Smith et al. 2009), and determine the age at death in juvenile fossil hominins from dental microstructure (Smith et al. 2007).

syncline (Gk *syn* = together or with and *klinein* = to slope) In structural geology a syncline is a type of fold where the youngest rocks occupy the center of the structure and the rocks become progressively

older towards the margins. The simplest form of syncline is a symmetrical U-shaped fold (open upwards). Such folds are important in geological and paleontological fieldwork, as they will determine the direction in which successively older or younger strata are encountered and will cause a repetition of the **outcrop** pattern on either side of the fold's axis.

syndesmoses *See* joint.

synecology (Gk *syn* = together, *auto* = self, and *logos* = knowledge) The branch of **ecology** concerned with the interactions of communities of organisms. There is great potential for synecological studies in paleoanthropology, as hominins lived in evolving ecological communities. Some hominins may have interacted or lived alongside other hominin species. At **Koobi Fora**, for example, as many as four **contemporaneous** hominin species have been identified: *Homo ergaster*, *Homo habilis*, *Homo rudolfensis*, and *Paranthropus boisei*. Although co-occurrence in the fossil record does not necessarily imply that the animals lived at precisely the same time or in precisely the same place, the fact that these species are found together in the same geological unit and in the same region suggests they may well have been **sympatric**. Although several arboreal primate species live in mixed-species groups, analogy with modern terrestrial primates suggest that sympatric hominins may have avoided competition by having (a) different home ranges, (b) exploiting different foodstuffs, or (c) by interacting only where their ranges met (Elton 2006). *See also* **community ecology**; **taphonomy**.

synonym (Gk *sun* = with and *onuma* = name) Any available formal name that denotes the same **taxon** as any other formal name. The earliest ("prior") available name is the **senior synonym**; any other name denoting the same taxon is a **junior synonym**. For example, the names *Paranthropus robustus* Broom, 1938 and *Paranthropus crassidens* Broom, 1949 are considered to denote the same taxon, so are deemed to be synonyms, but *P. robustus* has 11 years' priority, so it is the senior synonym, and *P. crassidens* is a junior synonym. Franz Weidenreich (1940) suggested that the species included in *Pithecanthropus* are actually better regarded as species of *Homo*, so *Pithecanthropus* is a junior synonym of *Homo*, the genus name that has priority.

If it is someone's opinion that two or more named taxa actually denote the same taxon, they are subjective synonyms. Occasionally, however, two or more taxa are established on the same type specimen: and then the names given to them are called objective synonyms. For example, when *Anthropopithecus erectus* Dubois, 1893 was described, with the Trinil calotte as its type specimen, several other scientists felt themselves at liberty, for whatever reason, to give their own names to the taxon denoted by this specimen (e.g., *Homo javanensis primigenius* Houz , 1896, *Homo pithecanthropus* Manouvrier, 1896, *Hylobates giganteus* Bumuller, 1899, *Pithecanthropus duboisii* Morselli, 1901, *Hylobates gigas* Krause, 1909, and *Homo trinilis* Alsberg, 1922); they are all examples of objective synonyms. A **synonymy** is the condition that exists when more than one name has been given to the same taxon.

synonymous mutation (Gk *sun* = with and *onuma* = name) A point mutation (i.e., change in one **nucleotide**) in a coding sequence that does not result in a change in the amino acid sequence of a protein. Such changes are typically neutral. For example, if the DNA sequence CTA changes to CTG, because of the redundancy in the genetic code it still codes for the same amino acid, aspartic acid (syn. silent mutation).

synonymous substitution *See* synonymous mutation.

synonymy (Gk *synonymos* = the same meaning) More than one Linnaean name given to the same taxon. Also used for a list, in chronological order, of the names previously used for a taxon (i.e., a list of synonyms for that taxon). The earliest available name (also known as the **senior synonym**) has priority; any names for the taxon other than the earliest available name are called **junior synonyms**. Thus *Australopithecus africanus* is the senior synonym for the taxon for which **Taung 1** is the **holotype**. *Plesianthropus transvaalensis* is one of several junior synonyms of *Au. africanus*; it is an available taxon name, but because it is not the senior synonym it is not a valid name.

syntactic rules *See* syntax.

syntax Order and structure of language (as a grammar). Language is not just about using signs (e.g., sounds or gestures) with specific meanings to

refer to things in the world. Languages are also characterized by syntax (Chomsky 2007). That is, all languages have grammars that orders and structures signs in a sentence or sequence of sounds. Consider the phrases *the boy hit the girl* versus *the girl hit the boy*. While the words in each sentence are identical, their meaning is radically different; what governs this shift in meaning is syntax. Since Chomsky (1977) stressed the centrality of syntax to modern human communication and language, many language scientists (e.g., Hauser et al. 2002, Pinker 1994) have noted the absence of syntax in nonhuman communication. However, Hauser and colleagues (e.g., Fitch and Hauser 2004) have argued that while some aspects of grammar may be present in nonhuman animals, modern humans are unique in their ability to engage in recursive syntactic processing. In one study Fitch and Hauser (2004) demonstrated that whereas cotton-top tamarins (*Saguinus oedipus*) could recognize violations to a simple grammar of the form AB, AB (i.e., [AB]ⁿ), they could not recognize violations to a hierarchical grammar of the form AAA, BBB (i.e., [AⁿBⁿ]) where the number of the first sound (e.g., A) constrains the number of the following sound (e.g. B). College students, however, given this same task, quickly mastered these two syntactic rules and performed equally well in both. These results have been widely interpreted to mean that there are cognitive constraints that limit syntactic processing in nonhuman primates. These constraints may explain the universality of modern human languages and the failure of the various ape language projects (Terrace 1979). *See also recursion.*

synteny (Gk *syn* = along with and *tainia* = band, thus “on the same ribbon”) A term used to describe **loci** on the same **chromosome**. These loci are not necessarily linked; their probability of linkage is based on the physical distance between them. Shared synteny between species refers to the preserved order of genes on a chromosome; it can be lost because of translocations or inversions.

syntype (Gk *syn* = together and *typos* = image) If a **holotype** was not designated at the time of the original description of a taxon then one of the “syntypes” (i.e., all the specimens known to the authors at the time of the initial publication) can subsequently be designated as the **lectotype**. For example, when the taxon *Pithecanthropus*

rudolfensis was introduced by Alexeev, he did not formally designate a holotype. Subsequently **KNM-ER 1470**, one of the syntypes of the original taxon, was formally designated as the lectotype of *Homo rudolfensis*.

system The **chronostratigraphic unit** equivalent of a **period**; periods are subdivided into **series**.

systematic biology The part of biology that focuses on the principles and practice of **systematics** as applied to animals. *See also systematics.*

systematics (Gk *systema* = a whole made of several parts) Systematics is an inclusive term that subsumes all of the activities involved in the study of the diversity and origins of living and extinct organisms. Thus systematics includes (a) **identification** (i.e., identifying individual living, or fossil, organisms, and assembling them into groups), (b) **classification** (i.e., the formalization of those groups as taxa, giving formal names to the taxa, allocating the taxa to taxonomic categories, and then assembling the taxonomic categories into a hierarchical scheme), and (c) **phylogeny reconstruction** (i.e., generating hypotheses about the branching pattern of the tree of life). **Taxonomy** is the study of the principles and theory of classification. **Nomenclature**, which combines the principles used in the allocation of formal names to taxa and the rules (e.g., **priority**, **synonymy**, etc.) governing how those names may be used, is a subcomponent of classification, and thus of taxonomy.

Szeleta (Location 28°06'N, 20°37'E, Hungary) History and general description This cave site overlooks the town of Lillafüred in the Bükk mountains. It was first excavated in 1906–13 and then again in the 1920s, 1940s, and 1960s. It is the type site for the **Szeletian** transitional lithic industry, which appears between the **Middle Paleolithic** and **Aurignacian** deposits at the site. Temporal span and how dated? Early **radiocarbon dating** suggested an age of more than 40 ka (uncalibrated) for the early Szeletian layers. However, newer radiocarbon dates point to an age of 30–20 ka (uncalibrated) for this layer. Hominins found at site None. Archaeological evidence found at site The site preserves Middle Paleolithic, Szeletian, Aurignacian, and **Gravettian** layers.

The Szeletian is an early **Upper Paleolithic** transitional technocomplex that is problematically associated with early migrations of modern humans. Key references: Geology, dating, and paleoenvironment Adams and Ringer 2004; Archeology Vértes 1968, Adams and Ringer 2004.

Szeletian (etym. Named after the site of *Szeleta*) An eastern European technocomplex that is one of several so-called transitional lithic industries (e.g., **Châtelperronian**), which appear in the late **Middle Paleolithic** or early **Upper Paleolithic** across

Europe, and show aspects of both lithic traditions. These transitional technocomplexes are put forward as evidence of either a pre-Aurignacian expansion of modern humans into Europe, or the acquisition of advanced, so-called “modern human behaviors” by *Homo neanderthalensis*. Few fossils are associated with the Szeletian; one tooth found at *Dzeravá Skála* has been identified as belonging to *Homo sapiens*, but its stratigraphic context is questioned and therefore it cannot be taken as evidence that the Szeletian was associated with, and certainly not only with, modern humans.

T

t test A statistical test used to determine whether the mean of a **sample** of measurements differs significantly from some hypothetical value (often zero), or whether the means of two different samples of measurements differ significantly from each other (e.g., whether mean cranial capacity size differs significantly between a sample of modern humans and a sample of Neanderthals). For a two-sample *t* test, two versions of the test exist in which the variances within the two samples are assumed to be either equal or unequal. A paired *t* test determines whether two sets of observations on the same sample differ significantly from each other (for example, whether mean endocranial volume is significantly different than mean brain volume within a sample of modern human cadavers). All *t* tests assume that data are normally distributed; if not, a **nonparametric statistical test** such as the **Mann–Whitney U test** or the **Wilcoxon ranked sign test** should be used.

Tabarin (Location 00°75'N, 35°86'E, Kenya; etym. the name for the area in the local Tugen language) History and general description Tabarin is a locality within the lowest part of the **Chemeron Formation** within the Tugen Hills sequence to the west of Lake Baringo, Kenya. The Kaparaina Basalt at the base of Tabarin separates the Chemeron and **Lukeino Formations**. It has produced abundant fossil fauna and one hominin, **KNM-TH 13150**, a partial adult hominin mandible discovered by Kiptalam Cheboi in 1984 while he was working with Baringo Paleontological Research Project. At the time of its discovery, KNM-TH 13150 was suggested to be the oldest known hominin and it may prove to belong to *Ardipithecus ramidus*. Temporal span and how dated? Single-crystal **argon-argon dating** have given a median age of 5.31 ± 0.03 Ma for the ignimbrite and the associated basal air-fall tuff that are in the lowest part of the Tabarin section. This evidence suggests a temporal span for the Chemeron succession at the site from about 5.3 Ma

to 3.8 Ma, with KNM-TH 13150 being *c.*4.42 Ma based on the dating methods above plus **magnetostratigraphy** and a calculated sedimentation rate of 23 cm/ka. Hominins found at site KNM-TH 13150. Archeology found at site None. Key references: Geology, dating, and paleoenvironment Hill 1985, 1994, 1999, 2002, Deino et al. 2002, Hill and Ward 1988; Hominins Hill 1985, 1994, 1999, Hill and Ward 1988, Ferguson 1989, Ward and Hill 1987, Wood 1999, Deino et al. 2002; Archeology None.

Tabon Cave (Location 9°16'N, 117°58'E, Palawan Island, The Philippines; etym. the name refers to the Tabon bird, *Megapodius cumingii*, that sheltered in the caves and deposited the guano layers) History and general description The site is located at an altitude of about 35 m on the Lipuun point, facing the small town of Quezon of the western coast of Palawan Island, some 100 km/62 miles south of Puerto Princesa. It is part of the so-called Tabon caves complex, which was explored for its archeological potential in the 1960s by Robert B. Fox, at the time chief of the Anthropology Division of the National Museum of the Philippines. Archeological surveys and excavations were made of more than 20 caves, fissures, and rock-shelters in the karstic massif of Lipuun, one of them having yielded the famous (late Neolithic or early Metal age) secondary burial Manunggul Jar, figuring a boat. Temporal span and how dated? The stratigraphy of the cave is complex and somewhat disturbed, especially by the activities involved with the secondary burial jars, the activity of birds, as well as the usual bioturbation. Recent work carried out at the site since 2000 under the authority of the National Museum of the Philippines has shown from uranium-lead dating of **speleothems** that the cave is more than 0.45 Ma and **uranium-series dating** suggests the fossil hominin remains are between *c.*15 and 50 ka. Recent **radiocarbon dating** of *in situ* charcoals from an occupation layer in the upper part of the stratigraphy confirms the presence

of hominins in the cave *c.*34 ka. Hominins found at site Fox's excavations in Tabun Cave yielded, beyond numerous Neolithic modern human remains (found as jar burials on the surface layers), several hominin fossils, including a quite complete *Homo sapiens* frontal bone. Two fragmentary mandibles were also found, one of them, quite mineralized, being especially robust for and anatomically modern human. Further excavations by the National Museum of the Philippines yielded more hominin cranial and postcranial remains, including a fragmentary tibia. Archeological evidence found at site Lithic implements (mostly flakes) considered by Fox to be associated with the anatomically modern human fossils were found in a layer dated in the 1960s by radiocarbon dating to be *c.*22 ka. The Upper Pleistocene age attributed to the hominin remains makes Tabun one of the few Southeast Asian island sites that document early colonization by modern humans. In the case of Tabun this probably involved crossing the quite narrow sea straits that would have separated Palawan from the Borneo Islands during glacial periods of low sea level. Location of originals The National Museum of the Philippines, Manila, The Philippines. Key references: Geology, dating, and paleoenvironment Fox 1970, Bellwood 1997; Hominins and archeology Bellwood 1997, Dizon et al. 2002, Detroit et al. 2004.

Tabun (Location 32°40'N, 35°57'E, Israel; etym. Ar. مغارة *mugharet*=cave, and تنور *tabun*=oven) History and general description Tabun is one of the three sites on the western slope of Mount Carmel excavated by Dorothy Garrod between 1928 and 1934. Garrod defined several levels, with Level C containing the most of the hominin remains. Subsequently Arthur Jelinek supervised work from 1967 to 1972 that sought to refine and revise Garrod's stratigraphic system and to better understand the chronological relationship among the sites of Mount Carmel, but no further hominin remains were recovered. Temporal span and how dated? Garrod originally dated Level C to *c.*40 ka. The most recent electron spin resonance spectroscopy dating gives a date of *c.*104 ka for Level B and *c.*208 ka for Level E. Hominins found at site The remains of up to 14 individuals have been recovered from Levels E, C, and B. A fragmentary skeleton and a dissociated mandible from Level C (**Tabun 1** and **Tabun 2**) are the most iconic. McCown and Keith saw these as belonging to the same pre-modern population as those from **Skhul**, but more recent interpretations emphasize

their affinities with *Homo neanderthalensis*. A number of teeth that were thought to have come from Level A have recently been re-examined and dated. They most closely correspond in morphology and preservation with remains from Level B. Archeological evidence found at site Many Levantine **Mousterian** and **Levallois** artifacts have been recovered. Because of the long and presumably continuous record at Tabun, and in the absence of absolute dating, other archeological sites have been dated based on how their stone tool assemblages matched those from the various levels at Tabun. Key references: Geology, dating, and paleoenvironment Garrod and Bate 1937, Jelinek 1982, Grün et al. 1991, Schwarcz et al. 1998, Grün and Stringer 2000; Hominins McCown and Keith 1939, Trinkaus 1995, Quam and Smith 1998, Stefan and Trinkaus 1998, Coppa et al. 2005; Archeology Garrod and Bate 1937.

Tabun 1 Site **Tabun**. Locality West sector of the terrace. Surface/in situ *In situ*. Date of discovery 1932. Finders Team led by **Dorothy Garrod**. Unit Level C, but Garrod noted that it "lay so near the surface of [Layer] C that the question must arise whether it does not represent a burial from Layer B" (Garrod and Bate 1937), an idea supported by Bar-Yosef and Callander (1999). Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Grün and Stringer (2000) place the remains at *c.*122 ka. Developmental age Adult. Presumed sex Female. Brief anatomical description Fragmentary cranium and skeleton; the cranium includes all teeth except for upper right M³. Announcement Garrod 1934. Initial description McCown 1936. Photographs/line drawings and metrical data McCown 1958. Detailed anatomical description McCown and Keith 1939. Initial taxonomic allocation *Palaeoanthropus palestinus* McCown and Keith, 1939. Taxonomic revisions Howell (1958) compared the specimens to the **Krapina** remains, implying that they belong to *Homo neanderthalensis*. While this is the generally accepted view, some (Arensburg and Belfer-Cohen 1998) disagree. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The Tabun 1 skeleton helped confirm the presence of *H. neanderthalensis* in the Near East. Location of original Natural History Museum, London, UK.

Tabun 2 Site Tabun. Locality East sector of the terrace. Surface/in situ *In situ*. Date of discovery 1932–4. Finders Team led by Dorothy Garrod. Unit Level C. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Level C. Nearest underlying dated horizon Level C. Geological age *c.*122 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description A mandible that includes all lower teeth except the left I₁. Announcement Garrod 1934. Initial description McCown 1936. Photographs/line drawings and metrical data McCown 1958. Detailed anatomical description McCown and Keith 1939. Initial taxonomic allocation *Palaeoanthropus palestinus* McCown and Keith, 1939. Taxonomic revisions Howell (1958) compares both Tabun specimens to those from Krapina, implying that they belong to *Homo neanderthalensis*. Stefan and Trinkaus (1998) also conclude that *H. neanderthalensis* is the most sensible assignment for Tabun 2, but Quam and Smith (1998) note some more modern human-like features, particularly in the mandibular symphysis. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance Like Tabun 1, the Tabun 2 mandible points to the Tabun material being *H. neanderthalensis*. Location of original Rockefeller Museum, Jerusalem, Israel.

Taenia *See taeniid tapeworms.*

taeniid tapeworms Flatworms belonging to the class Cestoda. In their adult form they are parasitic in carnivorous mammals, and they are debilitating because they predispose the host to chronic anemia. The life history of these cestodes involves an intermediate and a definitive host. Intermediate hosts ingest eggs that then develop into larvae. These larvae are destroyed by cooking, but if modern humans ingest undercooked meat or offal from an infected intermediate host, then the ingested larvae mature into adults, and these adults lodge in the gut, and produce the eggs which are found in human feces, thus completing the cestode life cycle. Modern humans are the definitive host for three different species of taeniid tapeworms, *Taenia saginata*, *Taenia asiatica*, and *Taenia solium*. Domesticated cattle are the intermediate hosts for *T. saginata*, whereas domestic swine are the intermediate hosts for *T. asiatica* and *T. solium*. For a long time it was assumed that

modern humans had acquired their taeniid parasites when cattle and swine were domesticated, but evidence from molecular biology suggests that cattle and swine acquired their infestations from modern humans, not the other way round (Hoberg et al. 2001). Moreover, the results of a phylogenetic analysis suggest that the three taeniid tapeworms that infest modern humans belong to two different subclades. Their relationship takes the form (*T. solium* (*T. saginata*, *T. asiatica*)), which suggests that there were at least two, and probably three, separate episodes of infestation. Furthermore, the same analyses suggest that the definitive hosts of the immediate precursors of modern human taeniid tapeworms were carnivores (canids, felids, or hyaenids) and their intermediate hosts were bovids. The results also suggest that the host-switching occurred in sub-Saharan Africa prior to the domestication of ungulates, and that it most likely occurred when early hominins were interacting with carnivores in the quest for meat. As Hoberg et al. (2001) state at the conclusion of their article “this work highlights the utility of parasitological data in elucidating the history and behaviour of human ancestors” (*ibid.*, p. 786).

Taforalt (Location 34°48'38''N, 2°24'30''W, southwest of Berkane and northwest of Oujda, Morocco) History and general description Also referred to as the Taforalt Caves or the Grotte des Pigeons, the site is a large, east-facing cave situated in a limestone cliff, 40 km/25 miles inland and approximately 720 m above sea level in the Atlas Mountains of eastern Morocco. The cave, which was first reported in 1908, was test excavated by Ruhlmann during the 1940s and extensively dug by Roche during the 1950s and the late 1960s. Since 2003 the site has been under excavation by a joint British/Moroccan team (Bouzzougar et al. 2007). Temporal span *c.*95,000–12,000 years BP. How dated Most recently using AMS radiocarbon dating on eight charcoal samples from Epipaleolithic deposits, optically stimulated luminescence dating on 15 sediment samples, thermoluminescence dating on five burnt lithics from the Middle Paleolithic deposits, and uranium series dating on two samples of the flowstone which underlies the Middle Paleolithic layers (Bouzzougar et al. 2007). One of the two burial zones has been radiocarbon dated from a single sample to 11,900 years BP. (Lubell et al. 1992). Hominins found at site

About 180 hominin individuals have been recovered from two burial zones or “cemeteries” at the site. Burials are sometimes marked with grave goods such as the horn cores or entire cranium of a Barbary sheep; around 100 individuals are subadult (Humphrey and Bocaege 2008, Lubell 2001, Ferembach et al. 1962). Dental evulsion of one or most often both maxillary central incisors is seen on all the adult skeletons; evidence of post-evulsion bone formation indicates the tooth removal occurred during life. This was a common practice of the Iberomaurusian culture and evidence of it is found at numerous contemporary sites in the region (Humphrey and Bocaege 2008). Archeological evidence found at site Artifact assemblages from different parts of Taforalt Cave have been assigned to the **Middle Stone Age/Middle Paleolithic** Aterian tool industry, known for its tanged points, and to the Epipaleolithic Iberomaurusian industry. The Aterian deposits contain numerous superimposed hearths, pedunculate points, and bifacially worked foliates. The recently discovered perforated Nassarius gibbosulus shells are an early example of human production of goods for personal adornment; these are broadly comparable in age and form to the shell beads found at Blombos Cave in South Africa (Bouzzougar et al. 2007). The Iberomaurusian deposits feature cutmarked and modified bones from Barbary sheep, ostrich eggshells, many Aterian microlithic points, and large numbers of burnt land snail shells. Key references: Geology, dating, and paleoenvironment Bouzzougar et al. 2007, Lubell et al. 1992; Hominins Humphrey and Bocaege 2008, Lubell 2001, Ferembach et al. 1962; Archeology Bouzzougar et al. 2007, Lubell 2001, Lubell et al. 1992. *See also* **Grotte des Pigeons**.

Tagliente (Location 45°35'N, 11°00'E, Italy; etym. It. sharp or pointed) History and general description Rock-shelter at the base of Mt. Tregano just north of Verona, with a long stratigraphic sequence. Excavations began in 1964 under F. Zorzi, and continued on-and-off under different leaders for the next 35 years. Temporal span and how dated? Biostratigraphy suggests the earliest levels date to the Early Würm. Radiocarbon dating on the **Upper Paleolithic** levels provide dates in the range of 13,430±180 to 12,040±170 years BP. Hominins found at site Levels 36 and 37, which are part of the **Middle Paleolithic** sequences, yielded two deciduous

teeth: a right dm² (Tagliente 3) and upper right dc (Tagliente 4). The Upper Paleolithic levels yielded an incomplete mandible (Tagliente 1) and the fragmentary skeleton of a young adult burial (Tagliente 2). Archeological evidence found at site The **Mousterian** sequences contain primarily scrapers and Levallois flakes. The ungulates in the faunal assemblage from these levels bear evidence of human modification. The Upper Paleolithic levels are notable for their stratigraphically secure examples of art. Two engravings of bison were recovered from levels 13a and 10, and the stone block covering the young adult burial is emblazoned with a lion. Key references: Geology, dating, and paleoenvironment Bartolomei et al. 1982; Hominins Corrain 1966, Bartolomei 1974; Archeology: Mussi 2001, Fiore et al 2004.

Talgai (Location 28°01'S, 151°51'E, Australia; etym. named after a local outpost) History and general description Talgai 1 is a cranium of a young male recovered by workmen from the wall of Dalrymple Creek southwest of Brisbane in 1886. The cranium was encrusted with carbonate and derived from a reddish-brown clay stratum. Temporal span and how dated? Late Pleistocene, on the basis of dates from radiocarbon dating on carbonate and organic soil associated with the cranium that are 11,650 and 12,400 years BP, respectively. Hominin found at site The vault of the Talgai 1 cranium was crushed and distorted upon recovery. Its robusticity and long, retreating, frontal resemble the morphology seen in the **Kow Swamp** and **Cohuna** group, suggesting to some researchers continuity with Javan *Homo erectus*. Others claim, and this is now the consensus view, that there are no demonstrable differences between Talgai and modern Australian Aboriginals and that the apparent similarities to Kow Swamp frontal morphologies are due to post-mortem deformation. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Gill 1978; Hominins Macintosh 1967, Brown 1987.

talon (L. *talus*=heel) The distal (hence heel) component of a maxillary (upper) postcanine tooth crown in the dental terminology devised by Osborn (1892). In hominin maxillary molars it comprises the **hypocone**, which is on the distolingual aspect of the **trigon**, plus any accessory cups or cusps associated with the hypocone.

talonid (L. *talus*=heel) The distal (hence heel) component of a mandibular (lower, hence the post-fix “-id”) postcanine tooth crown in the dental terminology devised by Osborn (1892). In hominin lower molars it comprises the **hypoconid** on the buccal aspect, the **entoconid** on the lingual aspect, together with a **hypoconulid** (if present) and any C6s. Modern human lower premolars do not normally have a talonid. Premolars with a well-developed talonid (e.g., *Paranthropus boisei*) are referred to as “**molarized**” or “**molariform**.” See also **molarized**.

talonid basin See **posterior fovea**.

talus cone (OF *talus*=the sloping sides of an earthwork) When soil washed into openings in the roofs of caves reaches the floor of the cave it forms a cone-shaped heap of debris. Some of the material newly washed into the cave adds to the height of the talus cone, but the remainder runs down the sides of the cone so that its base is ever increasing in size. There is evidence of talus cones in the southern African early hominin cave sites (e.g., **Silberberg Grotto**, **Sterkfontein**; **Swartkrans**), and they are one of the reasons why some of the sediments in these caves violate the law of **superposition**.

tandem repeat array See **tandemly repeated sequences**.

tandem repeats See **tandemly repeated sequences**.

tandemly repeated sequences (L. *tandem*=one after the other) An inclusive term for DNA sequences, two or more bases long, that are repeated and adjacent. Tandemly repeated sequences include **microsatellites**, **minisatellites**, **variable number of tandem repeats**, and **satellite DNA**.

tang (etym. ME of Scandinavian origin, similar to the Norse *tangi*, or point of land) The narrow elongated region at the base of a **point**, or point-like stone tool that is designed to facilitate hafting. The tang projects downward from the base of the piece, resembling the vertical segment of the letter “T.” Tangs are most often seen on arrowheads, and tanged points are one element considered diagnostic of **Aterian** sites in North Africa.

Tangi Talo One of the sites in the exposures of the Early and Middle **Pleistocene Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Tangier See **Mugharet el ‘Aliya**.

Tangshan Huludong (汤山葫芦洞)(Location 32°03′24.94″N, 119°02′40.41″E, eastern China; etym. named after the local town and the karst cave) **History and general description** The Tangshan locality, which is approximately 80 km/50 miles east of **Hexian**, across the Yangtze River, consists of the **karst** cave site of Huludong (Hulu Cave). It is just west of the town of Tangshan, some 23 km/14 miles east of Nanjing City, Jiangsu Province. The fossil hominins discovered in 1993 are collectively known as “**Nanjing Man**.” **Temporal span and how dated?** High-precision **thermal ionization mass spectrometry uranium-series dating** of the overlying **stalagmite** and **flowstone** provides a minimum age of 500 ka, and a possible age of 580 ka, for the hominin fossils. Further comparison with the **SPECMAP** deep-sea oxygen isotopic record suggests that deposition of the crania likely occurred during **Oxygen Isotope Stage 16**, a *c.*620 ka cold stage. This agrees with the biostratigraphy, which noted that the Tangshan fauna is composed of cold-adapted mammals typical of **Zhoukoudian Locality 1**. **Hominins found at site** Skull 1 (or Hulu 1), which belonged to a young adult female, consists of a partial **cranium** with well-preserved (and highly protruding) nasal bones, a fairly complete left upper and mid-face, and a large antemortem lesion (caused by either trauma or burning) that covers most of an otherwise complete frontal bone. Skull 2, which belonged to an older adult male, consists of a distorted calotte (a partial frontal, both parietals, a partial left temporal, and a partial occipital). There is also an isolated right M² (initially thought to be an M³). **Archeological evidence found at site** None. **Repository** Nanjing Municipal Museum, Nanjing. **Key references:** **Geology, dating, and paleoenvironment** Zhou et al. 1999, Zhao et al. 2001, Wu et al. 2002; **Hominins** Wu and Poirier 1995, Brown 2001, Wu et al. 2002, Liu et al. 2005, Shang and Trinkaus 2008.

tapeworms See **taeniid tapeworms**.

taphonomy (Gk *taphos*=grave and L. *nomos*=law) Russian paleontologist I.A. Efremov coined

the term taphonomy, which refers to the branch of science that investigates the factors involved in the death, decay, preservation, and **fossilization** of organisms. In other words, taphonomy is the study of the transition of organic materials from the biosphere to being part of the geological record. Taphonomy is obviously important to paleontologists but it is also of critical importance to archeologists who focus on the organic component of the archeological record (e.g., zooarcheologists, paleoethnobotanists). For a long time it was assumed that bones found at a fossil site were an unbiased sample of the animals living at that place many thousands, or even millions, of years ago. Only relatively recently have scientists taken an interest in the range of processes that convert a once living community into its fossil record. Taphonomy includes the consideration of why some organisms are more likely to fossilize than others (also called **differential preservation**, or differential survivorship). For example, animals that go to water-holes to drink and to the lakeshore to graze are vulnerable to predators, and in both places their bones are likely to be protected by sediments deposited by streams and rising lake levels. These two factors increase the likelihood that such animals are more likely to become part of the fossil record than animals that live away from sources of standing water in more arid habitats. Therefore, just because the remains of mammals adapted to more arid habitats are few and far between in the fossil record does not mean these animals were few and far between in the mammalian paleocommunity sampled by that fossil record. In zooarcheological contexts, taphonomy encompasses all the processes involved from the death of an animal (e.g., its butchery, transport, and discard, to the deposition, preservation, recovery, and analysis of that animal in the form of faunal remains). By understanding the factors that bias the fossil record, allowance can be made for those biases when researchers try and reconstruct the structure of a fossil paleocommunity or when they use the archeological record to interpret hominin behavioral patterns. Some general biases are well known. In general, bones with more dense cortical bone (e.g., the **mandible**) survive better than bones that are mostly made up of more fragile **cancellous bone** (e.g., vertebrae). Small animals tend to be systematically under-represented and large ones over-represented in the mammalian fossil record (Soligo and Andrews 2005). However, size

is not the sole determinant in all groups, for objects such as vole teeth that are small but which are also dense and durable are well represented in the fossil record. *See also differential preservation; carcass transport strategy; carcass acquisition strategy.*

Tapiridae The perissodactyl family that comprise the tapirs. Fossil tapirs are found at archeological sites in southeast Asia, particularly in Malaysia. *See Perissodactyla.*

Taramsa 1 Site Taramsa Hill. Locality N/A. Surface/in situ *In situ.* Date of discovery 1994. Finders Vermeersch and colleagues. Unit N/A. Horizon Activity Phase (or AP) III. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon AP IV (56.2 ± 5.5 ka). Nearest underlying dated horizon AP II (102.5 ± 7.5 ka). Geological age Optically stimulated **luminescence dating** (or OSL) provides mean ages for AP III of 55.3 ± 3.7 ka and sand above the burial has an OSL age of 68.6 ± 8 ka; Van Peer et al. (2010) discount an OSL age of 24.3 ± 2.1 ka from sandy fill inside the cranium. Developmental age Immature: dental evidence suggests an age at death of $c.8-10$ years. Presumed sex Unknown. Brief anatomical description The rounded forehead and occipital, the absence of a supraorbital torus, and the slenderness of the long bones of the associated skeleton are all features of anatomically modern humans. Many detailed morphological features recall the robust Epipaleolithic populations of North Africa and the early anatomically modern humans from sites in the Levant. Initial taxonomic allocation *Homo sapiens*. Announcement Vermeersch et al. 1998. Initial description Vermeersch et al. 1998. Photographs/line drawings and metrical data Vermeersch et al. 1998, Van Peer et al. 2010. Detailed anatomical description Van Peer et al. 2010. Location of original National Museum of Egyptian Civilization, Cairo, Egypt.

Taramsa Hill (Location $26^{\circ}6'N$, $32^{\circ}42'E$, Egypt; etym. named after a nearby hill) History and general description Taramsa Hill, near Qena, is an isolated landform that has been excavated by the Belgian Middle Egypt Prehistoric Project since 1989. The numerous pits and trenches suggest the site was used for the systematic quarrying of chert cobbles during the entire northeast African **Middle Stone Age**. Temporal span There are six major

activity phases (or APs) at the site that span the period the Middle to the Upper Pleistocene (i.e., from $<207 \pm 52.7$ to 33.2 ± 2.6 ka) based on optically stimulated **luminescence dating** (or OSL) on the sandy pit fills and one accelerator mass spectrometry date on charcoal. **Archeological evidence found at site** AP I ($>117 \pm 10.5$ ka) is a **Lupemban**-type non-Levallois production system (i.e., blades and lanceolate foliate tools). The lithic assemblage of AP II (117 ± 10.5 – 102.5 ± 7.5 ka) is a production system based on **Levallois** cores and is part of Nubian Complex *sensu lato*, but the assemblages of AP III whose average OSL age is 78.5 ± 5.6 ka can be assigned to the Nubian Complex *sensu stricto*. The average of the OSL ages for AP IV is 56.2 ± 5.5 and this large **Upper Paleolithic** lithic assemblage is Taramsan. The AP V technology is similar to the older Safahan industry in terms of its efficiency features and morphological aspects; this phase has covered up the AP IV debris. The Upper Paleolithic technology of AP VI dates to between 45,348 and 40,711 years BP in calibrated radiocarbon years and an OSL date of 33.2 ± 2.6 ka; bifacial tools of the Nazlet Khater axe type in the western part of the AP VI exploitation pit were probably used for extraction. **Hominins associated with the site** The skeleton of a child was found on a 10 cm layer of AP III extraction debris. Key references: **Geology, dating, and paleoenvironment** Vermeersch et al. 1997, Van Peer et al. 2010; **Archeology** Vermeersch et al. 1997, Van Peer et al. 2010; **Hominins** Vermeersch et al. 1998, Van Peer et al. 2010.

Tata (Location $47^{\circ}39'N$, $18^{\circ}19'E$, Hungary; etym. named after the nearby city) **History and general description** An open-air site in a travertine deposit excavated by L. Vertes in 1958–9. It contains an unusually advanced **Middle Paleolithic** stone tool industry, with artifacts that have been used as evidence for Neanderthal symbolic behavior. **Temporal span and how dated?** **Radiocarbon dating** and uranium-thorium dating provide dates between 116 ± 1.6 and 70 ± 2 ka, or roughly **Oxygen Isotope Stage 5**. **Hominins found at site** None. **Archeological evidence found at site** The stone tools from this site represent a microlithic **Mousterian** industry. The artifact that is most often used as evidence of symbolic behavior is a polished oval plaque carved from a mammoth molar lamella and incised at right angles to a natural crack to make a “cross.” Key references: **Geology, dating, and paleoenvironment** Schwarzc

and Skoflek 1982; **Archeology** Vertes et al. 1964, Marshack 1990.

Tategahana (Location $36^{\circ}49'N$, $138^{\circ}12'E$, Nagano Prefecture, Japan) **History and general description** An open-air site on the shoreline of Nojiriko (*ko* is “lake” in Japanese), which is located outside Nagano City on the western side of Honshu Island. During a period of low water level, a *Palaeoloxodon naumanni* (Naumann’s elephant) molar was discovered by a local resident in 1949, but it was not reported until 1958. Excavations began at Tategahana site in 1962 and to date there have been 16 seasons of fieldwork, some of which have encouraged the participation of amateurs. The Tategahana site can be divided into five geologic units: J-retsū Formation, Upper Nojiriko Member (three sublevels), Middle Nojiriko Member, Lower Nojiriko Member (three sublevels), and the Kannoki Formation. The majority of the artifacts and faunal remains are derived from the Upper, Middle, and Lower Nojiriko Member levels. The Tategahana faunal assemblage is one of the few examples in Japan (Hanaizumi is another) where Paleolithic artifacts and vertebrate fauna have been found in direct association; acidic soil conditions mean that bone preservation in Pleistocene open-air sites in Japan is generally poor. **Temporal span and how dated?** The presence of extinct megafauna (e.g., *Palaeoloxodon*, *Sinomegaceros*) indicates a Pleistocene age for the locality and uncalibrated **radiocarbon dating** of the first four stratigraphic levels has indicated a chronological range between 49 and 8 ka, with the majority of the materials thought to date to between 49 and 11 ka. The basal Kannoki Formation is estimated to date to between 70 and 50 ka. **Hominins found at site** None reported. **Archeological evidence found at site** Cultural modification of some of the *Palaeoloxodon* and *Sinomegaceros* bones indicates Tategahana was probably a megafaunal kill-butchery site. Three clusters of modified megafauna, scrapers, knives, and points manufactured from flakes of elephant bone and stone artifacts are interpreted to be butchery areas and in one such cluster located in the Middle Nojiriko Member, a fractured *Palaeoloxodon* rib has a stone flake deeply embedded in it. **Repository** Nojiriko Museum, Nagano, Japan. Key references: **Geology, dating, and paleoenvironment** Sawada et al. 1992, Nojiriko Excavation Research Group 1994, Kondo et al. 2001, 2007; **Hominins** N/A; **Archeology** Kondo et al. 2001, 2007, Ono 2001, Norton et al. 2010a.

Taubach (Location 50°57'N, 11°23'E, Germany; etym. named after local village) History and general description This **travertine** quarry is located 5 km/3 miles southeast of Weimar, in eastern Germany. Human remains, lithics, and fauna were recovered in the 19thC during the course of quarrying. Temporal span and how dated? **Biostratigraphic** correlation suggests a date of **Oxygen Isotope Stage 5e** (c.122 ka). Hominins found at site Two hominin teeth were recovered: Taubach 1, a left M₁, and Taubach 2, a left m₁. Archeological evidence found at site A **Middle Paleolithic** microlithic industry named Taubachian after the site. Several faunal remains were also recovered, including mammoth, rhinoceros, and other large mammals. Key references: Geology, dating, and paleoenvironment Street et al. 2006; Archeology Schäfer 1981; Hominins Gieseler 1971.

Taung (Location 27°32'S, 24°48'E, South Africa; etym. Taung is derived from two words from the language of the Tswana: *tau*=lion and *ng*=place of; therefore it means “the place of the lion.” The site was formerly called Taungs) History and general description The site consists of an outcrop of Thabaseek **tufa** 9.6 km/6 miles southwest of the village of Buxton, in the Northern Cape Province. At the beginning of the 20thC it was being mined commercially by the Northern Lime Company as the Buxton Limeworks. Solution cavities filled with pink breccia occur within the lime-rich tufa and fossil **baboons** were first noted in one of these breccia-filled cavities in 1919. Raymond **Dart**, the Professor of Anatomy at the University of the Witwatersrand, learned about the presence of fossil baboons at Taung in the middle of 1924. E.G. Izod, a director of Rand Mines Limited, had visited Taung in the late summer of 1924 and had brought back to Johannesburg a fossil cranium the mine manager had kept in his office as a souvenir. Izod's son, who was a student at the University of the Witwatersrand, showed it to his fellow students, among whom was Josephine Salmons, one of Dart's students. She borrowed the cranium to show to her Professor, and Dart recognized it as a fossil baboon. Dart then asked R.B. (Robert) Young, Professor of Geology at the University of the Witwatersrand, to use his connections with the Northern Lime Company to make sure that if any similar crania and skulls were to be found that

they should be saved and shipped to Dart. Young promised to do this when he visited Taung, which he was scheduled to do in November 1924. Shortly before Young's arrival at Taung, the quarry-master, de Bruyn, noticed the front of a skull in the rubble after a blast, but the skull looked different from the now familiar baboons. de Bruyn gave the specimen to the mine manager, A.E. Spiers, who showed it to Young. There are conflicting accounts about whether Young brought the skull to Johannesburg and delivered it personally to Dart (with the boxes containing the other fossils following by rail), or whether Young made arrangements for the new fossil, together with more fossil baboon skulls, to be sent by rail to Dart. The former is the more likely, and it is reasonably certain that Young and the unusual skull arrived at Dart's house in Melrose, Johannesburg, on November 28. Dart recognized that the specimen was the skull of an infant, and after cleaning it he also concluded that it was not a baboon skull, but that it was the skull of a hitherto unknown man-like ape. Dart made what has become known as the “Taung child” the type specimen of a new genus and species, *Australopithecus africanus* (Dart 1925). No formal investigations were made at the find site, but in 1925 Ales Hrdlicka excavated fossil baboons from an adjacent cave, and between 1947 and 1950 Frank Peabody undertook excavations there. Jeff McKee, Phillip Tobias, and Michel Toussaint (in 1988 and 1989) worked at Taung between 1988 and 1993. They recovered fauna from breccia that is very likely the same as that adhering to the Taung child's skull and found it to be comparable to the fauna from Mb 4 at **Sterkfontein**. Temporal span and how dated? **Biostratigraphy** points to an age for Taung of c.2.6–2.8 Ma. Hominins found at site The only hominin recovered from the site, **Taung 1**, is the holotype of *Australopithecus africanus*. Berger and Clarke (1995) have suggested that the Taung child was taken to the cave by a large **raptor**, citing the otherwise unusual areas of damage in the orbit, and Berger and McGraw (2007) report similar damage to monkey crania taken by raptors in the Tai Forest, Ivory Coast. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment McKee 1993, McKee and Tobias 1994, Partridge 2000; Hominins Dart 1925, 1926, Falk 1980, 1983, Holloway 1981b, 1984, Dean and Wood 1984, Falk and Clarke 2007.

Taung 1 Site Taung. Locality Unknown. Surface/in situ Recovered from pink calcified sand that formed part of what was described as the “solidified floor” (Dart 1926, p. 319) of the cave illustrated in that publication (*ibid*, p. 319). Date of discovery 1924. Finder A miner, probably M. de Bruyn, but the breccia fragment that included Taung 1 was selected to be sent to Johannesburg by Professor R.D. Young. Unit/horizon Pink calcified sand. Bed/member Member 1. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.6–2.8 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description A mostly undistorted skull of a juvenile hominin. It preserves most of the right half of a natural **endocast**, the face, the upper jaw, part of the cranial base, and the mandible. The natural endocast preserves some endocranial morphology in exquisite detail, but frustratingly the area where the **lunate sulcus** is most likely located is poorly preserved (see below). The dentition of Taung 1 includes the maxillary and mandibular permanent molars, all of the deciduous teeth on at least one side, and the germs of the deciduous premolars, canines, and incisors. Dart (1926, p. 319) reported the breccia also contained “fragments of the distal ends of the forearm bones and of the phalanges,” but he also wrote that “these proved too fragmentary and too friable to develop” (*ibid*). Announcement and initial description Dart 1925. Photographs/line drawings and metrical data Dart 1925, 1934. Detailed anatomical description Dart (1934) provides the closest there is to a detailed description. It focuses on the dentition and includes excellent plain radiographs with exquisite images of the germs of the permanent teeth. Endocranial volume 382 cm³ (estimated to be equivalent to an adult value of 406 cm³) (Falk and Clarke 2007). Initial taxonomic allocation *Australopithecus africanus*. Taxonomic revisions Partridge (1973) used geomorphological principles to investigate the timing of the opening of the southern African hominin cave sites, and suggested that the cave where Taung 1 was found may have opened as recently as 1 Ma. Tobias (1973b, p. 82) responded to these proposals by proposing the hypothesis that because the Taung site may be “>1.0 m.y., and probably about 2.0 m.y. more recent than the latest of the other African fossils assigned to *A. africanus*” then the Taung child may represent “a member of *A. robust-*

tus” (*ibid*, p. 82). However, a raft of studies (e.g., Grine 1985, Wood and Dean 1986, McNulty et al. 2006) have since demonstrated that the morphology of Taung 1 is consistent with it belonging to the same hominin taxon as that sampled at **Sterkfontein** and **Makapansgat**. Current conventional taxonomic allocation *Au. africanus*. Informal taxonomic category Archaic hominin. Significance The Taung 1 cranium is still iconic for many reasons. It was the first evidence of an early hominin to be recovered from Africa, it is the **holotype** of *Au. africanus*, it was the first hominin skull to be imaged using **computed tomography** (Conroy and Vannier 1987), and its natural endocast has been the focus of one of the longest-running disputes in paleoanthropology, namely the placement of the lunate sulcus. Whereas Ralph **Holloway** (e.g., Holloway 1984) is convinced the lunate sulcus is situated in a posterior, more modern human-like, position, Dean Falk (e.g., Falk 1989) is just as strongly convinced the lunate sulcus is in a more anterior, extant great ape-like, location. Berger and Clarke (1995) suggested the Taung child was taken to the cave by a large **raptor**, citing the otherwise unusual areas of damage in the orbit, and Berger and McGraw (2007) report similar damage to monkey crania taken by raptors in the Tai Forest, Ivory Coast. Location of original School of Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa. *See also* **Taung; lunate sulcus**.

Taungs *See* Taung.

taurodont (Gk *tauros*=bull and *dont*=teeth) Molar teeth that have tall **pulp chambers** relative to the distance between the roof of the pulp chamber and the tip of the longest root. In other words, the bi- or trifurcation of multirooted teeth occurs further from the cervical margin of the tooth and the common root trunk makes up a greater proportion of total root length. High incidences of taurodontism are claimed for the molars of *Homo neanderthalensis* and for African populations, although the degree of wear and age of the individual also influences this condition (Constant and Grine 2001). Quantified using a “Taurodont Index” (Keene 1966) (ant. **cynodont**). *See also* **pulp; pulp chamber**.

taurodontism The state of having taurodont teeth. *See* **taurodont**.

Tautavel Cave *See* Caune de l'Arago.

taxa Pl. of **taxon** (*which see*).

taxic (Gk *taxis*=arrangement) A term used by Eldredge (1979) for one of the two main theoretical components of evolutionary theory. He suggested that in order to be comprehensive all evolutionary theories must have at least two theoretical components. One theoretical component is concerned with explaining how evolutionary change occurs, be it at the level of the genome or the phenotype. He refers to this as the transformational component, or approach. The second theoretical component is concerned with how species originate and thus it implicitly acknowledges that species exist. He refers to this as the taxic approach. Eldredge (1979) suggested that overdominance of one or other of these emphases makes for "poor" science. He argues that whereas the taxic approach has to acknowledge the transformational approach, the converse is not always the case, claiming that some paleontologists have effectively abandoned the search for the equivalent of extant species in the fossil record. He cited George Gaylord Simpson's (1951) concept of an "evolutionary" species as an example of this tendency. A contemporary example is paleontologists who are more concerned with the recognition and identification of lineages in the fossil record than they are with the recognition and identification of species. *See also* **species**.

taxon (Gk *taxis*=to arrange, or 'put in order') A group recognized at any level, or category, in the Linnaean hierarchy. So, the tribe **Hominini**, the genus *Paranthropus*, and the species *Paranthropus boisei* are all examples of a taxon. Pl. taxa.

taxonomy (Gk *taxis*=arrange, or "put in order") The principles involved in assembling individual organisms into groups, the formalization of those groups as **taxa**, giving formal names to the taxa, allocating the taxa to taxonomic categories, and then assembling the taxonomic categories into a hierarchical **classification**. The term is also sometimes used to refer to the taxonomic hypothesis that results when Linnaean taxonomic principles are applied to a particular group of organisms; many researchers would refer to this as a hominin classification, but some refer

to it as a hominin taxonomy. It is common for reference to be made to "alpha taxonomy," but very seldom do you read, or hear, any reference to "beta" or "gamma" taxonomy. Mayr et al. (1953) is one of the few sources that define these terms [e.g., these terms do not appear in the index of George Gaylord Simpson's (1960) *Principles of Animal Taxonomy*]. Mayr et al. (1953) suggests that "the taxonomy of a given group, therefore, passes through several stages...informally referred to as alpha, beta, and **gamma taxonomy**" (*ibid*, p. 19). **Alpha taxonomy** results in species being "characterized and named," **beta taxonomy** involves arranging species in "a natural system of lesser and higher categories," and gamma taxonomy to the "analysis of intraspecific variation and to evolutionary studies" (*ibid*, p. 19). *See also* **alpha taxonomy**.

Tchadanthropus uxoris Coppens, 1965. Unavailable (proposed conditionally)
See Coppens, Yves (1934-).

TD Abbreviation of Trinchera Dolina and the prefix used for the fossils recovered from the **Gran Dolina** at Atapuerca, Spain.

TD6 One of the lithostratigraphic levels within the Gran Dolina, a site that is part of the sediment-filled cave system called the **Trinchera del Ferrocarril**, which itself is within the Sierra de Atapuerca, a series of eroded limestone hills 14 km/8.5 miles east of Burgos in northern Spain. The TD6 level includes the **Aurora stratum**. *See also* **Gran Dolina**; **lithostratigraphy**.

TDS Abbreviation for Trinchera Dolina Sondeo Sur, the name given to the focus of the excavations at **Gran Dolina**, in Atapuerca, Spain, carried out between 1993 and 1999.

teaching Caro and Hauser (1992) have proposed a working definition for teaching that takes into consideration empirical work and an appreciation of evolutionary theory. Thus, "An individual actor A can be said to teach if it modifies its behavior only in the presence of a naive observer, B, at some cost or at least without obtaining an immediate benefit for itself. A's behavior thereby encourages or punishes B's behavior, or provides B with experience, or sets an example for B. As a result, B acquires knowledge or learns

a skill earlier in life or more rapidly or efficiently than it might otherwise do, or that it would not learn at all" (*ibid*, p. 153). An important feature of Caro and Hauser's conceptualization of teaching is that teachers must incur a cost to their own productivity, and may even encourage or discourage the observer. According to this influential paper, teaching need not require an explicit understanding of another's mind or knowledge, a feature that may be unique to the forms of teaching practiced by modern humans. Teaching by nonhuman animals is not limited to a specific taxonomic group, nor is it only seen in mammals or primates. The most convincing examples of teaching come from animals that breed cooperatively (e.g., ants, pied babblers, and meerkats). Meerkats, for example, take turns monitoring for predators while others forage for food; and in some cases, a group member will present young offspring with prey that is partially maimed in order to provide them with direct hunting experience. By doing this, a meerkat may lose the prey if the offspring are not successful in killing it, making this behavior a costly act for the teacher. However, it is clear that modern human teaching differs from the teaching observed among cooperative breeders such as meerkats. Csibra and Gergely (2009) have recently argued that modern human teaching is marked by the evolution of a unique communicative system that evolved to facilitate the exchange of information from one individual to another. This "natural pedagogy" facilitates the social learning of cognitively opaque cultural information that would be difficult to learn by observational learning alone. They argue that modern human infants have been shaped by natural selection to become attuned to a variety of communicative cues emitted by adults, allowing infants to learn rapidly and make specific as well as accurate generalizations from these cues.

technostratigraphy In archeology, using the recovered lithic technology (e.g. **Mousterian**, **Oldowan**) to provide a relative or correlated date for a layer or site.

teeth (OE *toth*=tooth) In each quadrant of the upper and lower jaw there are normally five deciduous teeth [mandible: di_1 , di_2 , dc , dm_1 , dm_2 (or dp_1 and dp_2); maxilla: di^1 , di^2 , dc , dm^1 , dm^2 (or dp^1 and dp^2)] and eight permanent teeth [mandible: I_1 , I_2 , C , P_3 , P_4 , M_1 , M_2 , M_3 ; maxilla:

I^1 , I^2 , C , P^3 , P^4 , M^1 , M^2 , M^3]. Note that, because anthropoids retain only the distal two of the four premolars seen in primitive mammals, the two retained premolars are numbered P_3 and P_4 . See also **deciduous dentition**; **permanent dentition**.

tektites (Gk *tektos*=molten) Approximately spherical natural glass rocks, usually black or olive-green, ranging up to a few centimeters in size. Showers of tektites are formed when large meteorites hit the Earth's surface. The area of the Earth's surface a particular tektite shower covers is called its strewn-field.

telanthropoid (Gk *tele*=distant, *anthropos*=human being, and *oides*=form) A term used to suggest a specimen is *Telanthropus*-like. For instance, one of the three mandibles from **Tighenif 1** is substantially larger than the other two, and Briggs (1968) suggested that whereas it belonged to a "paranthropoid" group, he assigned the smaller Tighenif 1-2 mandibles to a "telanthropoid" group.

Telanthropus (Gk *tele*=distant and *anthropos*=human being) Genus established by Robert **Broom** and John **Robinson** in 1949 to accommodate the new species they established to accommodate **SK 15**, an adult mandible recovered at **Swartkrans** from "brown breccia" now referred to as being from Member 2. Robinson (1961) formally sank the taxon into *Homo*. Type species *Telanthropus capensis* **Broom and Robinson, 1949**. See *Telanthropus capensis*.

Telanthropus capensis Broom and Robinson, 1949 (Gk *tele*=distant, *anthropos*=human being, and *cape*=reference to land that includes the Cape of Good Hope) Hominin species established by Robert **Broom** and John **Robinson** in 1949 to accommodate **SK 15**, an adult mandible recovered at **Swartkrans** from brown breccia now referred to as being from Member 2. They considered **SK 15** to be "somewhat allied to Heidelberg man" (Broom and Robinson 1949, p. 322) and "intermediate between *P. crassidens* and *Homo*" (*ibid*, p. 323). Robinson (1961) transferred the mandible to *Homo erectus* and *T. capensis* is now widely regarded as a **junior synonym** of *Homo erectus* (e.g., Howell 1978, p. 198). Note that, if transferred to the genus *Homo*, the name *capensis* is a

junior **homonym** of *Homo capensis* Broom, 1918 (type specimen: the Boskop calvaria, usually assigned to *Homo sapiens*), so *Homo capensis* is not an available **Linnaean binomial** for the Swartkrans mandible. First discovery and holotype SK 15 (1949). Main site Swartkrans, southern Africa.

teleconid A term introduced by Vanderbroek (1961, 1967) for what more commonly used schemes of cusp nomenclature refer to as the **hypoconid**. *See* **hypoconid**.

telencephalon *See* **forebrain**.

telocentric *See* **chromosome**.

Témara A city in Morocco. The name has been used in the literature to refer to two different cave sites: Smugglers' Cave and El Harhoura. *See* **Smugglers' Cave**; **El Harhoura**.

temperate (L. *temperatus*=restrained or regulated) The term for the regions (and the organisms occupying that region) between the Tropic of Cancer (approximately 23°N) and the northern polar circle, and between the Tropic of Capricorn (approximately 23°S) and the southern polar circle (i.e., between latitude 23° and 66° both north and south). The sun is never directly overhead in temperate regions. Compared to the **tropical** region its biodiversity is lower (this is known as Rapoport's rule). Very few contemporary primates live in temperate regions, although in the past, when the Earth's climate was warmer, the latitudinal range of primates was greater. Although living baboons are found below the Tropic of Capricorn in southern Africa, macaques are the only living nonhuman primates to have radiated extensively into temperate zones. Anatomically modern humans and their recent extinct relatives used cultural and behavioral adaptations to exploit temperate regions, and extant modern humans have extended their range even further, into the Antarctic and Arctic circles.

temperate deciduous forest (Latin *deciduus*=falling off) A biome that consists of trees, both in the upper and lower canopy, that lose their leaves simultaneously and may remain bare for several months. These forests are found in latitudes between 35 and 60°N, are in highly seasonal climates and have a

mean annual rainfall of between 500–1500 mm per year and average monthly temperatures of 0–20°C. Most animals in these forests have unique behavioral and physiological adaptations to cope with the extreme fluctuations in climatic variables. Once covering large areas of Europe, Asia, and South and North America, temperate deciduous forests are now largely confined to eastern North America, eastern Australia, central Europe, Japan, and eastern China.

tempo (L. *tempus*=time) When tempo is used in connection with evolution it refers to the time it takes for evolution to occur (i.e., the rate at which evolution occurs). The other main variable is the **mode**, or the pattern, of evolution. George Gaylord Simpson's *Tempo and Mode in Evolution* (1944) helped push evolutionary biologists in the direction of recognizing these two critical components of the evolutionary process.

temporal lobe One of the four main subdivisions of the cerebral cortex of each cerebral hemisphere. It is located ventral to (i.e., beneath) the Sylvian fissure in both hemispheres. The temporal lobe houses the primary auditory cortex, which is located along the posterior part of its superior surface. Other parts, or areas, within the temporal lobe are involved in language, higher-order auditory processing, and the processing of visual information important for object perception and recognition. The medial part of the temporal lobe contains the hippocampus and the amygdala.

temporalis *See* **mastication, muscles of**.

temporomandibular joint (or **TMJ**) (L. *tempus*=time. The temple of the forehead that overlies the temporal bone is the first area to show grey hairs, signifying the passage of time) A modified synovial joint between the condyle of the mandible and the mandibular fossa and articular tubercle of the temporal bone. The bones are covered with white fibrocartilage not yellow hyaline cartilage. A meniscus partly divides the joint cavity into superior and inferior compartments. Gliding mostly occurs in the upper compartment and rotation in the lower. *See also* **cartilage**.

tentorium cerebelli (L. *tentorium*=a tent and *cerebelli*=diminutive of cerebrum, also called the "small brain") A fold of the fibrous, or meningeal, layer of the **dura mater** that covers the

cerebellum. It transmits the brain stem, but otherwise separates the posterior cranial fossa from the rest of the cranial cavity. *See also* **endocranial cavity**.

tephra (Gk *tephra*=ash) A collective term for rock fragments that have been ejected explosively from a volcanic source (i.e., **pyroclastic** material) that forms unconsolidated (i.e., loosely bonded) deposits. As Lowe and Hunt (2001) note, strictly speaking tephra is singular and is used as a collective with singular verb forms, although appending an “s” to form the plural “tephras” may serve to reduce ambiguity. Tephra range in size from fine ash (particles of approximately 0.063 mm) to larger “bombs” greater than 64 mm in size (Scmid 1981). A consolidated (i.e., firm or hardened) tephra deposit is called a **tuff**.

tephrochronology (Gk *tephra*=ash and *kronos*=time) The use of dated **tuffs** to provide a regional chronology.

tephrostratigraphy (Gk *tephra*=ash, *stratos*=to cover or spread, and *graphos*=to draw or write) The use of chemically or lithologically distinctive tuffs to correlate strata from one **locality** to another, or from one **site** to another.

Terminologia Anatomica *See* anatomical terminology.

termites Eusocial insects in the order Isoptera, termites are an important source of protein and lipids for some chimpanzee communities (Bogart and Pruettz 2008). The extractive foraging techniques that have been observed involve the use of sticks or grass, sometimes extensively modified, to remove termites from the mounds that are conspicuous and often abundant features of many African landscapes (McGrew 1992). Females chimpanzees are said to be up to three times more likely to spend time fishing for termites than males (McGrew 1979) and there is evidence that chimpanzee termite consumption increases in open environments (e.g., Mt. Assirik and Fongoli; see McGrew 1983; Bogart and Pruettz 2008). Potential evidence for the consumption of termites by early hominins came in the form of use-wear patterns observed on bone tools from the sites **Swartkrans** and **Drimolen** in South Africa (Backwell and d’Errico 2001, 2008). Use was made of **actualistic**

studies to show that microscopic wear on the bone tools resembled the fine and highly oriented wear seen when experimental bone tools were used to dig termite mounds. Other potential support for termite consumption comes from evidence for the consumption of ¹³C-rich **C₄ foods** by australopiths (Sponheimer et al. 2005, van der Merwe. 2008). Many termites, including the mound-building termites belonging to the genus *Macrotermes*, a favorite of many chimpanzee populations (McGrew 1992), consume C₄ vegetation. The diets of *Macrotermes* are subject to considerable variation and their carbon isotope compositions tend to track the relative abundance of C₃ and C₄ vegetation in their habitats (Schoorman 2006). Thus, they (and many other termite taxa) tend towards mixed C₃/C₄ consumption in wooded savanna environments (Sponheimer et al. 2005). Consequently, it is unlikely that termite consumption could account for the high proportion (roughly 80%) of C₄ foods consumed by some australopiths (van der Merwe et al. 2008). Harvester termites of the genera *Trinervitermes* and *Hodotermes* do consume principally C₄ vegetation and in theory their consumption could explain the C₄ signal of australopiths, but because they do not all build conspicuous nests they would be unlikely targets for foraging hominins (Sponheimer et al. 2005) and large-bodied insect dietary specialists are rare among mammals.

Ternifine The old name for the site of **Tighenif** (or Tighennif). *See* **Tighenif**.

Terra Amata (Location 43°41’51”N, 7°17’20”E, France; etym. It. for beloved land) History and general description This site was located on an ancient beach, about 20 m above current sea level, on Mount Boron in Nice, France. It was discovered and excavated during construction in 1966; today a museum stands on the site (Musée de paléontologie humaine de Terra-Amata, or Museum of Human Paleontology of Terra Amata). Henry de Lumley, who excavated the site, claims that the site preserves evidence of early use of shelters and fires, in a closely constrained series of living floors. Paolo Villa has argued that many of the stones de Lumley suggested were the outline of shelters were instead deposited by soil creep or other natural forces. She also noted that artifacts found in different “living floors” actually refit, implying a significant amount of vertical displacement. Temporal span and how dated?

Thermoluminescence dating of flint has suggested an age of 380 ka, but Villa argues for an age of *c.*230 ka. Hominins found at site None. Archeological evidence found at site Stones in circular arrangements centered around patches of dark sediment, that de Lumley interpreted as huts surrounding fire pits, and a variety of **Acheulean** stone tools. Coprolites were found in a few layers, and these preserved plant remains that suggested a seasonal occupation of the site. Key references: Geology, dating, and paleoenvironment Wintle and Aitken 1977, Villa 1983, de Lumley 2007; Hominins N/A; Archeology Villa 1983, de Lumley 2007.

terrestrial (L. *terrestris*=earthly) Animals that live on the ground. The vast majority of primates are dependent on trees for living, sleeping and foraging, but some nonetheless spend a significant proportion of their time on the ground. Terrestrial primates tend to be relatively large and have more robust limb bones than do arboreal primates, although there are several exceptions to these trends. The most terrestrial living nonhuman primate is *Theropithecus gelada*, but many other taxa, including ring-tailed lemurs, common baboons, patas monkeys, vervets, mandrills, rhesus macaques, and gorillas also spend a significant amount of time on the ground. Extinct terrestrial primates include *Victoriapithecus*, *Gigantopithecus*, and **hominins**. Terrestriality is an important adaptation in areas where tree cover is broken, which could partially explain why hominins eventually became habitually terrestrial. Terrestrial primates often have relatively large **home ranges** and **day ranges**. Increased susceptibility to **predation** is an important cost of terrestriality and terrestrial primates therefore tend to live in relatively large groups and may seek refuge from predators in trees, which are often used as sleeping sites. Terrestrial and bipedal locomotion are usually treated synonymously in debates about early hominins, but Kevin Hunt (1996) has argued that bipedalism might have been selected in part as a postural rather than a locomotor adaptation. *See also* **seed-eating hypothesis**; **postural feeding hypothesis**.

terrestriality (L. *terrestris*=earthly) The tendency to live partially, or wholly, on the ground. *See* **terrestrial**.

Terry (Robert J.) Collection Taxon *Homo sapiens*. History Collection of modern human

skeletons assembled by Robert J. Terry (1871–1966). The Terry Collection comprises the remains of citizens predominantly from the St Louis, Missouri, region of the USA collected between 1917 and 1966. Two experiences prompted Terry to make an anatomical skeletal collection: his time as a student of George S. Huntington and the year he spent in Edinburgh where he studied under Sir William Turner. Terry became the Professor of Anatomy at the Missouri Medical College (which later became the Washington University Medical School) and began to collect skeletal remains from the cadavers starting in 1898. The Washington University Collection was actually the third attempt by Terry to establish a collection of modern human cadavers with detailed supporting documentation; one previous start became mixed by inaccurate curation, and the other was destroyed in a fire. Terry retired in 1941 but the collection continued to accumulate under the direction of Mildred Trotter. Trotter's initial title was "Coursemaster of Human Anatomy" but she became a full Professor of Anatomy in 1946; it was Trotter who changed the name of the Washington University Collection to the Robert J. Terry Collection. More than 80% of the collection was assembled by the time Trotter took over but at the time of her succession the collection was dominated by aged males. Trotter's main contribution was to increase the numbers of females and younger individuals. Around the time of her retirement Trotter began negotiations with T. Dale Stewart with a view to transferring the collection to the Department of Anthropology at the **National Museum of Natural History, Smithsonian Institution** (or NMNH). The transfer took place in 1967, the year Trotter retired, and the collection is now part of the permanent collection of modern human skeletons at the NMNH. The Robert J. Terry Collection comprises 1728 individuals, 1608 of which have morgue-identified ages and 68% (1182) of which have accompanying anthropometric data. Curator/contact David Hunt (e-mail hunt@d@si.edu). Postal address Department of Anthropology, National Museum of Natural History, PO Box 37012, Smithsonian Institution, Washington DC 20013-7012, USA. Website <http://anthropology.si.edu/cm/terry.htm>. Relevant references Hunt and Albanese 2005. *See also* **Huntington (George S.) collection**.

Tertiary (L. *tertius*=the third in a series) A unit of geological time (i.e., a **geochronologic unit**). Although the Tertiary is no longer recognized as

a formal geochronologic or chronostratigraphic unit, many still use the term to refer to the pre-**Pleistocene** part of the **Cenozoic** era. The term is a remnant of the old classification of geologic **strata** (and time) into four units: Primary, Secondary, Tertiary, and **Quaternary**. The decision was made to split up the Tertiary into the Paleogene and **Neogene** periods in order for the Cenozoic era to more closely match the duration of the Mesozoic and Paleozoic eras.

tertiary dentine *See* dentine.

Teshik-Tash [Location approximately 38°17'24"N, 67°02'46"E, Baisan Tau Mountains, near Pas-Machai (Pas-Machay), 18 km/11 miles from Baisun (Boysun), Uzbekistan; etym. Uzbek stone with an opening] History and general description In 1938, A. Okladnikov discovered a skeleton of a juvenile *Homo neanderthalensis* in this cave site. The skeleton was surrounded by five pairs of goat horns, which the discoverer and others have interpreted to be evidence of intentional burial with symbolic behavior. This interpretation is questioned by others who argue that the fossil was damaged by carnivores and may not have been buried, and that goat remains are common throughout the site and therefore may not be intentionally associated with the skeleton. The site is also one of the easternmost Neanderthal inhabitations. Temporal span and how dated? Based on the archeology, fauna, and fossil hominin remains, it has been assigned to the **Middle Paleolithic**. Hominins found at site The remains of a juvenile, possibly 8–11 years old. Most of the skeleton was poorly preserved, but the skull and mandible, although fragmentary, were sufficiently preserved to be reconstructed. Genetic analysis of the **mitochondrial DNA** from the left femur confirms that this specimen is a Neanderthal. Archeological evidence found at site Okladnikov recovered five layers "with remains of ancient culture," at least one of which has been attributed to the **Mousterian**. Key references: Geology, dating, and paleoenvironment Hrdlička 1939, Movius 1953; Hominins Hrdlička 1939, Krause et al. 2007, Movius 1953; Archeology Hrdlička 1939, Movius 1953.

TEX86 An abbreviation of "tetraether index of 86 carbon atoms," which refers to a relatively new paleoclimate index that is based upon the abundance ratio of a group of organic molecules all of which have 86 carbons. These molecules are

produced by members of the Archaea, a major group of prokaryotes, and they are found in marine and lake sediments. Because their molecular structure varies with temperature they can be used as a **proxy** for **sea surface temperature** (or SST) and thus they can be used in **paleoclimate** reconstruction. For example a c.60 ka-long record from Lake Tanganyika implies that lake surface temperature dropped by more than 4°C during the **Last Glacial Maximum** (Tierney et al. 2008).

thalamus (Gk *thalamus*=inner chamber or bedroom) Part of the **diencephalon**, one of the two major components of the **forebrain** (the **cerebral hemispheres** are the other). It is a bilateral subcortical structure consisting of a set of nuclei and it is situated superior to the hypothalamus. The thalamus has many functions, including synthesizing and relaying incoming sensory information from lower processing centers to the cerebral cortex from all the sensory modalities except for olfaction. It is also thought to regulate levels of awareness and emotional aspects of sensory experience through a wide variety of effects on the cerebral cortex. Some evidence suggests that the nuclei in the thalamus, with interconnections with the **limbic system** in the brain, have undergone disproportionate enlargement in modern humans in comparison with the apes (Armstrong 1980).

The High Cave *See* Mugharet el 'Aliya.

The L.S.B. Leakey Foundation *See* L.S.B. Leakey Foundation.

theory of mind The ability to attribute perceptions, knowledge, intentions, goals, and beliefs to oneself and others. The term was first used by Premack and Woodruff (1978) in their pioneering paper, "Does the chimpanzee have a theory of mind?" Their studies generated considerable excitement and controversy and stimulated research into the "mindreading" skills of both modern human children and nonhuman primates. Theory of mind tests may be divided into two categories: tests of true beliefs and tests of false beliefs. Tests of true beliefs assess second-order intentionality; that is, an individual's ability to attribute beliefs, intentions, goals, etc. to another individual. Tests of false beliefs assess third-order intentionality, which involves beliefs about (second-order) beliefs.

In a classic study assessing true beliefs in modern human children and chimpanzees, Povinelli and Eddy (1996) had participants gesture to one of two experimenters: one who was blindfolded (and could not see) or another who wore a bandana over their forehead (and could see). In this study, “seeing” represents a psychological property that we infer from shared experiences. I look at you and you look at me, so I see you and you see me. Seeing, in this case, is a true belief because my psychological state matches your own. However, such is not the case in false beliefs (e.g., lies), where what you believe is not the same as what others believe. In a classic false-belief study, Wimmer and Perner (1983) used the “Sally-Anne” task to assess when children understand that others may have “false beliefs” or beliefs that differ from their own. In this task, a child sees a puppet, Sally, hiding candy in a basket while a second puppet, Anne, watches. Anne then leaves the room, but while she is away Sally retrieves the candy and moves it to another location in a box instead of its original hiding place in the basket. Anne reappears and the child is asked: “Where will Anne look for the candy?” Three-year olds typically say that Anne will look for the candy in the box, where they know the candy is *now*; that is, they fail to attribute a different (false) belief to Anne. However, 4-year olds typically answer that Anne will look for the candy in the basket, which is where Anne saw the candy placed before she left the room. At the moment there is no consensus as to whether or not nonhuman primates understand either true beliefs or false beliefs. Some authors have argued that chimpanzees (Hare et al. 2000, Hare et al. 2001) and rhesus monkeys (Flombaum and Santos 2005) understand true beliefs such as “seeing” and “hearing.” Another study has argued that whereas chimpanzees understand true beliefs, they do not understand false beliefs (Krachun et al. 2009). From this, one may infer that reasoning about true beliefs is a more primitive cognitive trait, whereas reasoning about false beliefs is a more derived trait and likely appeared later in hominin evolution. However, one must assess these claims cautiously. Povinelli and colleagues (Povinelli and Vonk 2004, Penn and Povinelli 2007), for example, have argued that true belief tasks cannot discriminate between an understanding of mental states and an understanding of behavioral states, because to understand mind you have to understand behavior (e.g., eyes are necessary for “seeing”). Consequently, it is possible to reason about a person’s behavior without

necessarily being able to reason about their mental states. If this is true, then an individual who makes inferences about minds (and behavior) and one who makes inferences about behaviors (but not minds) will respond similarly in true belief tasks. *See also intentionality.*

thermal ionization mass spectrometry

thermoluminescence dating *See luminescence dating.*

Theropithecus Geoffroy, 1843 (Gk *ther*=wild beast and *pithekos*=ape) **Background** A genus of Old World monkey with only one extant species, the highly terrestrial *Theropithecus gelada*, whose habitat is presently restricted to the Ethiopian highlands. The modern *T. gelada* is unusual among primates in having a diet restricted to grass. *Theropithecus* was identified in the fossil record as a distinct genus by Andrews (1916), who assigned the species we now know as *Theropithecus oswaldi* to *Simopithecus*. This classification was revised when *Simopithecus* was made a junior synonym of *Theropithecus* (Jolly 1972). Six fossil species of *Theropithecus* are currently recognized: *T. oswaldi*, *T. darti*, *T. atlanticus*, *T. brumpti*, *T. baringensis*, and *T. quadratiostris*, but some authors recognize fewer taxa (e.g., Frost and Delson 2002 classify *T. atlanticus* and *T. darti* in *T. oswaldi*). **Relevance for human evolution** Although *Theropithecus* is only distantly related to the hominin clade it is relevant to hominin evolution because (a) the genus apparently underwent an adaptive radiation in the Plio-Pleistocene (i.e., at much the same time as the hominin clade), (b) at most African early hominin sites *Theropithecus* is usually the most closely related primate to be found along with the hominin fossils, (c) of this any success at reconstructing the habitats of fossil theropithecids might help in the reconstruction of early hominin habitats, and (d) the unique status of fossil *Theropithecus* as large-bodied, open habitat primates led to their use as an analogue for hominin behavioural evolution (e.g., the **seed-eating hypothesis**; Jolly 1970). Many of the features that distinguish *Theropithecus* from other **papionins**, including its high-crowned molars and opposable digits, are related to a diet of grass and seeds. However, palaeobiological studies indicate that fossil theropithecid diets might have included a broader

range of food items, including leaves and fruits (Teaford 1993, Benefit 1999, Codron et al. 2005). The one extant species, *T. gelada*, is highly terrestrial, and it is likely that some extinct members of the genus, particularly *T. oswaldi*, also preferred an open woodland or a grassland habitat (Elton 2002), although *T. brumpti* has been interpreted as preferring closed, forested habitats (Krentz 1993, Ciochon 1993, Elton 2000, Jablonski et al. 2002). *T. oswaldi* is also notable because some populations exhibited a marked increase in body size, with the largest individuals weighing as much as 60 kg (Delson et al. 2000). There were two partially contemporaneous *Theropithecus* lineages in the **Turkana Basin** during the Plio-Pleistocene, one leading to *T. oswaldi* and the other to *T. brumpti* (Leakey 1993). In line with their apparently different habitat preferences, *T. oswaldi* and *T. brumpti* also had different adaptive strategies (Teaford 1993, Krentz 1993, Elton 2002, Jablonski et al. 2002). As well as dispersing from East Africa into southern Africa on at least two occasions, *Theropithecus* also colonized north Africa and parts of Eurasia (Pickford 1993). By 0.5 Ma, *Theropithecus* had all but disappeared in Africa, and the only extant member of the genus, *T. gelada*, is found in isolated populations in the highlands of Ethiopia and Eritrea. See also **seed-eating hypothesis**.

Thomas Quarry (Location 33°34'N, 07°42'W, Morocco; etym. Thomas is the name of the family who rented the land for quarrying) History and general description One of several sites discovered as a result of sandstone quarrying activities that began in 1907 during harbor construction near Casablanca, Morocco. R. Neuville and A. Ruhlmann noted it in their 1941 survey of the sequence of Miocene to Holocene sea-level transgressions and regressions on the Atlantic coast and Pierre Biberson visited it during the 1950–60s and referred to it briefly in his 1961 synthesis. Detailed stratigraphic studies began in 1985 and modern controlled excavations, which began in 1988, were undertaken by a joint French-Moroccan research team led by Jean-Paul Raynal and Fatima-Zohra Sbihi-Alaouied. Since 1978 further research has been undertaken by a joint Moroccan–French research team led by Jean-Paul Reynal. The Thomas Quarry site was initially divided into three quarries: I, II, and III. Caves in Thomas Quarry I and Thomas Quarry III have

yielded hominin remains, but the Thomas III (also known as Oulad Hamida 1) cave has subsequently been destroyed. In 1969 P. Beriro discovered a mandible in a cave of Thomas I, and in 1972 skull fragments were discovered in Thomas Quarry III. Between 1994 and 2005 Raynal's excavations recovered four hominin teeth in the GH cave of Thomas Quarry I. In May 2008 a complete mandible was discovered in the same level and in May of the following year a further mandible belonging to a young individual was recovered. Along with the fossils from Salé and Sidi Abderrahman, the Thomas Quarry fossils represent a distinctive north African group that falls somewhere between *Homo erectus* and *Homo sapiens*. Temporal span and how dated? Lithostratigraphy suggests an upper age range of 700–600 ka for these sediments based on data from the Rhinoceros cave (GDR) at Oulad Hamida 1 Quarry (former Thomas Quarry III); its electron spin resonance age lies between 400 and 700 ka and its macrofauna, microfauna, and lithic artifacts are broadly similar. The smaller size of the micromammal fossils at GH (i.e., *Eliomys* and *Meriones*) as well as the morphology of the *Ellobius* fist mandibular molar, suggests an age earlier than the GDR cave, and probably younger than Tighenif. This latter range is consistent with optically stimulated luminescence dating estimates between 470 and 360 ka reported for the hominin layer of GH and with a direct laser ablation inductively coupled plasma mass spectrometry date of c.500 ka for a hominin premolar. Hominins found at site Several remains attributed to *Homo* have been discovered. These include the 1969 finds from Thomas Quarry I: a left mandibular ramus with four teeth; the 1972 finds from Thomas Quarry III: several calotte fragments and a left partial maxilla, and a well-preserved mandible; and the recent finds from Thomas Quarry I: several isolated teeth, a complete mandible and several other unpublished fragments. Archeological evidence found at site The lithic artifacts from Thomas Quarry include **Acheulean handaxes, cleavers, cores, flakes**, and other lithic debris associated with a modest faunal assemblage. thoracic cage, comparative anatomy and evolution The thoracic cage consists of the ribs and the thoracic vertebrae to which they are attached,

along with the sternum and costal cartilages. These structures provide protection for the thoracic contents, most notably the heart and lungs. The thoracic skeleton also anchors the proximal muscles of the upper limb, the muscles that move the head and neck, and those that support the walls of the abdomen; internally the thoracic cage anchors much of the diaphragm. Except for the caudalmost two ribs, each of the other ribs articulate with the vertebral column at two synovial joints; the head with one, or two, vertebral bodies at the costovertebral joints and the tubercle with with the vertebral transverse process of the same (or the lower of the two) vertebrae at the costotransverse joint. In modern humans the ventral ends of the first six ribs articulate with the sternum via independent costal cartilages and ventrally ribs 7–10 share a joint costal cartilage; the caudal two ribs do not articulate with the sternum, nor do they have costotransverse articulations. The thoracic cage must move when an animal breathes to allow expansion of the lungs. All the details of this motion within the thoracic cage are incompletely understood, but during respiration the anterior ends of especially the upper ribs move cranially with a “pump-handle” motion, while the shafts of the lower ribs tend to be elevated in a “bucket-handle” motion. The zygapophyseal facets are almost planar and coronally oriented, so the thoracic vertebral column is also capable of rotation, flexion-extension, and lateral flexion (Kapandji 1974). The overall shape of the thoracic cage differs among groups of primates in ways that reflect locomotor adaptation. The most significant differences are those between most monkeys and the apes. Monkeys, which stand and move in pronograde posture both in the trees and on the ground, have ventrally facing shoulder joints (Preuschoft et al. 2010, Schultz 1961). The thoracic cage is mediolaterally narrow and dorsoventrally deep, and the scapula sits in a parasagittal plane so that the glenohumeral (shoulder) joint is oriented normal (perpendicular) to the direction of load in this posture. The muscles that run between the thoracic cage and scapula are also in roughly parasagittal planes, so their contraction moves the limb primarily in flexion and extension. In contrast, the thoracic cage of extant apes is mediolaterally broader, thus shifting the scapulae into a more coronal plane and changing the orientation of the glenohumeral joint so that it is more laterally facing (Schultz 1961). The thoracohumeral musculature, most notably latissimus dorsi, is also more mediolaterally oriented, making it more effective at adducting the humerus, which is how an

animal pulls itself up from hanging beneath a support (Ward 1993). Related to this morphology, the ribs of apes, especially the cranial ribs, are more tightly curved than those of monkeys (Kagaya et al. 2008, 2009); ape ribs are also more declined from dorsal to ventral. Modern humans also differ from great apes in the form of the thoracic cage. Extant great apes have thoracic cages that are narrow at the top and wide at the bottom, and the long lower ribs sit adjacent to the iliac crest due to their elongated pelvis and short, stiff lumbar spines; monkeys, gibbons and modern humans have longer lumbar regions, and their lower rib cage dimensions do not have to match the pelvis as tightly. Modern humans resemble gibbons in having a barrel-shaped thoracic cage, whereas that of great apes is aptly described as cone-shaped (Schmid 1991). Modern humans also have their thoracic vertebral column invaginated into the rib cage, so that the neck of the rib and thoracic vertebral transverse processes flare dorsally relative to the vertebral body, before swinging laterally and anteriorly (Jellema et al. 1993). Early *Homo* appears to have a thoracic cage most like that of modern humans (Jellema et al. 1993). The thoracic cage of *Homo neanderthalensis* is similar overall to modern humans, but it is barrel-shaped (i.e., it is expanded both anteriorly and laterally), reflecting their overall stocky, presumably cold-adapted, body form (Trinkaus 1983). The initial reconstruction of the thoracic cage of *Australopithecus* suggested it was cone-shaped, like that of apes (Schmid 1991), but the new *Australopithecus afarensis* skeleton at Korsi Dora in the Woranso-Mille study area, Ethiopia (KSD-VP-1/1), has a nearly complete second rib that is clearly unlike that of apes but instead is similar in curvature to those of modern humans and recent pre-modern *Homo* (Haile-Selassie et al. 2010a). Other *Au. afarensis* thoracic vertebrae reflect a modern human-like pattern and *Australopithecus sediba* also appears to have had a modern human-like thoracic cage. Another feature of the *Australopithecus* thoracic cage that is unlike that of great apes is the first rib. The head of their first rib of modern humans articulates with the vertebral body of the first thoracic vertebrae, whereas that of great apes sits more cranially, articulating in two distinct facets with the caudal margin of the last cervical and cranial margin of the first thoracic vertebrae. The head of its first rib of *Au. afarensis* has only one facet, which points to it having a lower position of the first rib on the vertebral column, like that of modern humans (Ohman 1986). The cross-section of the ribs of *Au. afarensis* is

rounder, and thus more chimp-like, compared to that those of modern humans. But this may not be a reliable indication of an ape-like thoracic cage, for the cross-sectional profile of gorilla ribs is modern human-like; rib cross-sectional shape is apparently not a reliable predictor of the overall shape of the thoracic cage. It is most likely that the thoracic cage of *Australopithecus* was broad cranially, like that of modern humans. This calls into question reconstructions of a large ape-like gut made under the assumption of a caudally flaring, cone-shaped rib cage, that would have contrasted with a more modern human-like smaller gut; reconstructing gut size from fossil evidence is necessarily highly speculative. *See also expensive tissue hypothesis; scapula, evolution in hominins; KSD-VP-1/1; lumbar vertebral column.*

three-dimensional morphometrics *See* geometric morphometrics; morphology.

Tighenif (Location 35°30'N, 0°20'E, Algeria; etym. named after a nearby plain) History and general description The site is a commercial sandpit 17 km/10 miles southeast of Mascara, Algeria, in the foothills of the Atlas Mountains. Fossils were reported in the 1880s, but in 1931 Camille Arambourg realized the sediments exposed in the sandpit were laid down in the basin of an ancient paleolake. In 1954 he arranged for water to be pumped from the sandpit and he was able to excavate the deeper sediments. Temporal span and how dated? Biostratigraphy points to a Middle Pleistocene age. Hominins found at site Arambourg and Hoffstetter unearthed three hominin mandibles (Tighenif 1–3) and a parietal fragment (Tighenif 4). Although Arambourg noted the new mandibles were “very closely related to the Asiatic *Pithecanthropus* and *Sinanthropus*” and that “some features (are) reminiscent of the australopithecines, *Telanthropus* particularly” (Arambourg 1955, p. 195), he concluded that the fossils “cannot be identified exactly with either *Pithecanthropus* or *Sinanthropus* or *Telanthropus*” so he “assigned to them the provisional name, *Atlanthropus mauritanicus*” (*ibid.*, p. 195). Arambourg’s paper was published in the same year as the first edition of Wilfrid Le Gros Clark’s *The Fossil Evidence for Human Evolution*, but in the second, 1964, edition, when discussing the fossil record for *Homo erectus*, Le Gros Clark concludes his discussion of the remains from what is now

called Tighenif that “there can be little doubt . . . that these remains do belong to the same species (i.e., to *H. erectus*)” (Le Gros Clark 1964, p. 112). The most detailed taxonomic assessment of the Tighenif mandibles was that of Mounier et al. (2009), and their conclusion was that all the mandibles should be assigned to *Homo heidelbergensis*, even though they noted that one of the mandibles, Tighenif 2, had “an incipient modern-human-like chin” (*ibid.*, p. 243). One of the three mandibles (Tighenif 1) is substantially larger than the other two, and Briggs (1968) suggested that it belonged to a “paranthropoid” group, whereas he assigned Tighenif 1–2 to a “telanthropoid” group. Archaeological evidence found at site Handaxes. Key references: Geology, dating, and paleoenvironment Arambourg and Hoffstetter 1955, Howell 1960 (pp. 208–9); Hominins Arambourg 1954, 1955, Howell 1960 (pp. 212–16); Archeology Arambourg and Hoffstetter 1954.

Tighenif 1 Site Tighenif. Locality N/A. Surface/in situ *In situ*. Date of discovery 1954. Finders Camille Arambourg and R. Hoffstetter. Unit Sandpit. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*780 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Large mandible lacking most of left and right rami, but preserving the left P₁–M₃ and right P₁–M₃ and fragmentary left I₂ and right I₂. Announcement Arambourg and Hoffstetter 1954. Initial description Arambourg 1954. Photographs/line drawings and metrical data Rightmire 1990. Detailed anatomical description Hublin 2001, Rightmire 1990. Initial taxonomic allocation *Atlanthropus mauritanicus* Arambourg, 1955. Taxonomic revisions *Homo erectus* (Le Gros Clark 1964). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Thus far the oldest hominin discovered in north Africa. Location of original Laboratoire de Paléontologie, Muséum National d’Histoire Naturelle, Paris, France.

TILLMIAP Acronym for the International Louis Leakey Memorial Institute for African Pre-history. *See* Leakey, Louis Seymour Bazett (1903–72).

time-averaging Substantial phenotypic change may have occurred during the time covered by many of the fossil collections researchers hypothesize may sample a single species. This increases the variance of the “time-averaged” sample, and may invalidate attempts to use museum collections of extant taxa, which are inevitably accumulated over a much shorter period of time than paleontological samples, as comparative analogues for testing whether a fossil sample subsumes more than one taxon.

time scale Framework for assigning ages to geological deposits or to events in the geological record. For example, the **astronomical time scale** is based on Earth/sun orbital systems and the **geomagnetic polarity time scale** uses calibrated changes in the direction of the Earth’s magnetic field.

time units The IUPAC-IUGS Task Group (2006-016-1-200) urge that the SI unit “a” be used for both ages and time spans, where a is the abbreviated form of *annum*. The correct SI usage of units must follow algebraic rules, such as the distributive law: 100–90 Ma=(100–90) Ma =10 Ma, and so on (Bureau International des

Poids et Mesures 2006). Similarly, half-lives should be expressed in ka (thousands), Ma (millions), or Ga (billions), and rates and decay constants in (ka)⁻¹, (Ma)⁻¹, or (Ga)⁻¹. The IUPAC-IUGS Task Group discourage the use of “y,” “yr,” “yrs” along with any combination of “k,” “K,” “m,” “M,” etc. All ages of fossil material or associated deposits should be quoted with their full error margins. *See also* a.

timing (L. *tempus*=time) *See* heterochrony; tempo.

TL *See* luminescence dating.

TM Abbreviation of Transvaal Museum and the prefix used for fossils recovered from the **Sterkfontein** Type site between 1936 and 1938, and from **Kromdraai** between 1938 and 1955. The abbreviation is also used as a prefix for fossils recovered from **Toros-Menalla**, **Chad Basin**, Ethiopia. *See also* Kromdraai; Toros-Menalla.

TM 1511 Site Sterkfontein. Locality Type site. Surface/in situ *In situ*. Date of discovery August 17, 1936. Finder Robert Broom. Unit N/A. Horizon N/A. Bed/member Member 4. Formation Sterkfontein Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.* 2.6–3.0 Ma. Developmental age Young adult. Presumed sex Male. Brief anatomical description Cranium with palate (including right P₄–M₂, and left P₃–M₂), right side of the face and occipital region, and an isolated right M₃. Announcement Broom 1936a. Initial description Broom 1936a, 1936b. Photographs/line drawings and metrical data Broom and Schepers 1946. Detailed anatomical description Broom and Schepers 1946. Initial taxonomic allocation *Plesianthropus tranvaalensis*. Taxonomic revisions *Australopithecus africanus* (Robinson 1954). Current conventional taxonomic allocation *Australopithecus africanus*. Informal taxonomic category Archaic hominin. Significance The **holotype** of *Plesianthropus tranvaalensis*. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa. *See also* Sterkfontein; *Australopithecus africanus*.

TM 1517 Site Kromdraai. Locality Kromdraai B. Surface/in situ This specimen was removed from the breccia deposit by a schoolboy, Gert Terblanche, who then showed Robert Broom where he had found it at Kromdraai. Date of discovery June 8, 1938. Finder Gert Terblanche. Unit N/A. Horizon N/A. Bed/member Member 3. Formation Kromdraai Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description An associated skeleton, made up of a skull, isolated teeth, the distal end of the right humerus, the proximal end of the right ulna, hand bones, a right talus, and other foot bones. The cranium of the skull is crushed, and the face, palate (with the left P³–M²), and the cranial base are the better-preserved regions. The right side of the mandibular corpus (with the right P₃–M₃) is damaged anteriorly. Announcement and initial description Broom 1938a, b. Photographs/line drawings, metrical data, and detailed anatomical description Gregory and Hellman 1939, Robinson 1956 (teeth), Broom and Schepers 1946 (skull), Broom 1942 (hand), Broom 1943 (foot). Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions None specific to this specimen. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance The holotype of *P. robustus* and one of the few associated skeletons of that taxon. The talus and the arm bones have featured in attempts to reconstruct *Paranthropus* limb morphology. Location of original Ditsong National Museum of Natural History (formerly the Transvaal Museum), Northern Flagship Institution, Pretoria, South Africa. *See also* Kromdraai; *Paranthropus robustus*.

TM 266-01-060-1 Site Toros-Menalla. Locality TM 266. Surface/in situ Surface. Date of discovery 2001. Finder Djimdoumbaye Ahounta. Unit Anthracotheriid Unit. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*7 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description A nearly complete cranium with, on the right, the I² alveolus, distal part of the canine crown, P³–P⁴ roots, and fragmentary M¹–M² crowns, and on the left, the I² alveolus, C–P⁴ roots, and fragmentary M¹–M³ crowns. Announcement Brunet et al. 2002. Initial

published description Brunet et al. 2002. Photographs/line drawings and metrical data Zollikofer et al. 2005. Detailed anatomical description Zollikofer et al. 2005. Initial taxonomic allocation *Sahelanthropus tchadensis*. Taxonomic revisions White et al. 2009 suggest that *Sahelanthropus* may be a junior synonym of *Ardipithecus*. Current conventional taxonomic allocation *S. tchadensis*. Informal taxonomic category Possible primitive hominin. Significance Holotype of *S. tchadensis*. The authors believe that despite primitive features the cranium belongs to a primitive hominin and not to a panin because of its small, apically worn canines and the intermediate thickness of the post-canine enamel. It was virtually reconstructed by Zollikofer et al. (2005), who claimed that the reconstructed morphology of the cranial base demonstrated that *S. tchadensis* is bipedal. A further, phenetic, analysis of 3D landmark data obtained from the virtually reconstructed cranium by Guy et al. (2005) concluded that while the reconstructed cranium shared some basicranial features with archaic hominins (e.g., “long, flat [or horizontally orientated] nuchal plane,” “shortened occipital,” and “anteriorly-positioned foramen magnum”; *ibid*, p. 18838), other features on other regions of the cranium (e.g., the face) were either primitive or unique among hominins. Location of original Département de Conservation des Collections, Centre National d’Appui à la Recherche (CNAR), Ndjame’na, Chad.

TMJ *See* temporomandibular joint.

Toba super-eruption The Youngest Toba Tuff (YTT) is evidence of a volcanic eruption that occurred 74,000 years ago in Indonesia. This is one of Earth’s largest known volcanic events and the largest eruption in the last 2 million years (Rose and Chesner 1990). It was two orders of magnitude larger in erupted mass than the largest known historic eruption in Tambora, Indonesia. The YTT involved the eruption of a minimum of 2800 km³ of magma, of which at least 800 km³ was transported in atmospheric ash plumes that blanketed an area from the South China Sea to the Arabian Sea (*ibid*). Its impact on Earth’s atmosphere and climate (Robock et al. 2009) and on local and animal populations remains a matter of contention (Ambrose 1998, Oppenheimer 2002). The Indian subcontinent contains extensive YTT deposits (Jones 2007). Pollen and carbon isotope studies have suggested that the Toba eruption

caused climatic cooling and prolonged deforestation in South Asia, leading to severe impacts on mammalian communities (Williams et al. 2009). The causative link between the YTT, global cooling, deforestation in India, and genetic bottlenecks and extinctions in mammals has been questioned (Haslam and Petraglia 2010). At **Jwalapuram**, in the Jurreru River Valley of southern India, Middle Paleolithic artifact assemblages have been found before and after the YTT, indicating that hominins survived the eruption (Petraglia et al. 2007, Haslam et al. 2010).

Tobias, Phillip Vallentine (1925–) Phillip V. Tobias was born in Durban, in the former Natal province in South Africa. In the first volume of his autobiography, *Into the Past* (2005), Tobias claims the premature death, at age 21, of his sister Val from inherited diabetes, and visits to the Durban Natural History Museum to see the Campbell Collection of southern African vertebrates and an exhibit of artifacts from KwaZulu-Natal during his teenage years, were the reasons for his subsequent scientific interest in genetics, zoology, and archeology. Tobias entered the University of the Witwatersrand, in Johannesburg, and completed a BSc in physiology and histology and embryology in 1946, and earned an honors BSc in histology in 1947. It was as an undergraduate student at Wits that Tobias first met Raymond **Dart**, who not only taught anatomy at the medical school, but was also famous for his recognition of *Australopithecus africanus*. In 1945 Tobias and some of his fellow students organized a student expedition to the **Makapansgat** Limeworks. They located and recovered evidence of fossil **baboons**, and this led to an intensive exploration of the site by Dart and colleagues over the next several decades, which produced new fossil remains of what were later referred to *Au. africanus*. After this initial experience in paleontology Tobias was soon exploring other hominin sites such as **Sterkfontein** and **Kromdraai**, and the former site came to be the focus of much of Tobias' field efforts in later years. After completing his undergraduate science studies Tobias continued his medical course at Wits, where he conducted research in genetics. He completed his medical degree in 1950 (but never practiced clinical medicine) and his PhD in 1953, with a dissertation on *Chromosomes, Sex-Cells, and Evolution in the Gerbil*. In 1951 Tobias was invited to join the French

Panhard-Capricorn Expedition, led by French explorer François Balsan, which collected anthropological and anthropometric data on the San Bushmen of the Kalahari Desert. This experience drew Tobias further into physical anthropology and this interest was further strengthened when in 1955 he was awarded a Nuffield Dominion Senior Travelling Fellowship and left for Cambridge University in England to conduct postdoctoral research on biometrics in physical anthropology. He used this opportunity to examine the hominin fossils curated in the British Museum (Natural History) in London as well as at the **Musée de l'Homme** (Museum of Man), the **Muséum National d'Histoire Naturelle** (National Museum of Natural History), and the **Institut de Paléontologie Humaine** (Institute of Human Paleontology) in Paris. It was at the latter institution that he spent time with Henri **Vallois** and Camille **Arambourg**. By the end of his time in England and Europe Tobias was turning away from a career in genetics and toward a career in paleoanthropology, and he spent 1956 in the USA as a Rockefeller Traveling Scholar. He spent half of 1956 visiting various US universities and institutions, including the University of Chicago and the University of Michigan, studying physical anthropology, human genetics, and dental anatomy. Tobias returned to South Africa in late 1956 and during 1957–8 he worked with an interdisciplinary team of researchers conducting studies of the Tonga of Northern Rhodesia (now Zambia). In 1959, shortly after Raymond Dart's retirement from the Chair of Anatomy, Tobias was appointed Professor of Anatomy and Head of the Department of Anatomy at the University of the Witwatersrand, a position he held until 1990. Tobias was drawn even further into paleoanthropology in 1959 when Louis and Mary **Leakey** invited him to undertake the detailed study of the recently discovered *Zinjanthropus boisei* cranium (OH 5) found at **Olduvai Gorge** in Tanzania. This led to Tobias's long-standing collaboration with Louis and Mary Leakey, which included his collaboration with the British anatomist John **Napier**, to describe and name the fossils discovered by Louis and Mary Leakey at Olduvai that were referred to *Homo habilis*. Detailed monographic treatments of OH 5 and of the cranial remains attributed to *H. habilis* were published in the Cambridge University Press series on Olduvai Gorge. The first of these, *Olduvai Gorge* volume 2, *The Cranium and Maxillary Dentition of*

Australopithecus (Zinjanthropus) boisei, was published in 1967, and the second, *Olduvai Gorge* volume 4, *The Skulls, Endocasts and Teeth of Homo habilis*, was published in 1991. For much of Tobias' career in paleoanthropology he was concerned in one way or another with the excavations at Sterkfontein in South Africa. Robert **Broom** and John **Robinson** conducted excavations there from 1947 until Broom's death in 1951, and throughout the 1950s Robinson continued to work periodically at Sterkfontein. The Sterkfontein site became the property of the University of the Witwatersrand in 1958 and Tobias initiated extensive excavations of the site that have continued ever since. Assisted by Alun Hughes, who had worked closely with Raymond Dart at Makapansgat, and later by paleontologist Ronald **Clarke**, who had worked with Louis and Mary Leakey as a research assistant/conservator, Tobias and his team amassed a substantial collection of animal fossils and hominin remains, as well as data on the paleoecology of the site. By the early 1990s Tobias' team had collected over 500 hominin fossils, most of which belonged to *Au. africanus*, but there were some fossils that Hughes and Tobias suggested belong to an early variety of *Homo* (e.g., **Stw 53**) while Clarke argued that some other specimens belong to *Paranthropus robustus*. Tobias was appointed Honorary Professor of Palaeoanthropology at the **Bernard Price Institute for Palaeontological Research** at the University of the Witwatersrand in 1977, and he served as director of the university's **Palaeo-Anthropology Research Unit** (or **PARU**). Tobias retired as head of the Department of Anatomy in 1990 but he continued as the director of the **Sterkfontein Research Unit**. In 1994 Ronald Clarke discovered four australopithecine foot bones in a box of fossils that had originally been collected in 1977. Tobias and Clarke published an account of the fossils (**Stw 573**), nicknamed "Little Foot," and subsequent excavations have recovered much of the skeleton, which has tentatively been dated to *c.*3 Ma. Tobias was elected a Fellow of the Royal Society of South Africa in 1951 and served as its president from 1970 to 1972. He was involved in the establishment of the **Institute for the Study of Man in Africa** and he became its first president in 1961. In 1987, Tobias was named a foreign associate of the US National Academy of Sciences. The Royal Anthropological Institute of Great Britain and Ireland elected him an Honorary Fellow in 1989 and he was elected a Fellow of the Royal Society of London in 1996.

toe-off See **push-off**.

ToM See **theory of mind**.

Tomes, Sir Charles Sissmore (1846–1928) The eldest son of Sir John Tomes, Charles Tomes read (i.e., studied) natural science at Christ Church, Oxford, and then medicine at the Middlesex Hospital Medical School, London, before practicing as a dental surgeon. He published a series of important papers on the structure of **dentine** and the enamel organ and he edited the last four editions of his father's book, *Tomes's Dental Surgery*. He was author of a *Manual of Dental Anatomy, Human and Comparative*, which reached its sixth edition in 1904. Charles Tomes' name has been given to a root form variant most commonly seen in mandibular first premolars. See also **Tomes' root**.

Tomes, Sir John (1815–95) The son of a West Country farmer, he was apprenticed to an apothecary before studying dental surgery at King's College, London, and medicine at the Middlesex Hospital Medical School, also in London. Inspired by lectures given by Richard Owen he presented a paper to the Royal Society aged 23, "On the structure of teeth," unaware that others in Europe had already described identical histological structures. Tomes' name is associated with Tomes' fibers (the cell processes of an **odontoblast** contained within the dentine tubules), the Tomes' process at the secretory end of an **ameloblast**, and the granular layer of Tomes, an incompletely mineralized layer of **dentine** close to the root surface.

Tomes' process The eponymous name of the process at the secretory end of an ameloblast. The process was described by Sir John Tomes. See also **ameloblast**; **Tomes, Sir John**.

Tomes' root This term refers to a distinctive root form variant that is most commonly seen in mandibular first premolars. It consists of a mesiolingual groove in the mandibular first premolar root that may deepen to a "C-shaped" cleft when seen in cross-section. Occasionally it may be deep enough to divide the apical portion of the root into a distinct mesio-buccal rootlet. Sir Charles **Tomes** drew attention to this root form, thus his name (and not that of his father Sir John **Tomes**) is commemorated in this eponymous term. See also **Sir Charles Tomes**.

tool (OE *tool*=to “prepare for use”) Any material object (modified or unmodified) used to accomplish a task. Evidence from **Gona**, in Ethiopia, and dated to *c.*2.55 Ma, consisting of **flakes** and the **cores** from which they were struck, currently marks the beginnings of the archeological record, but if the cut-marks from **Dikika study area** (*c.*3.39 Ma) are anthropogenic then they would mark the first use of stone flakes, manufactured or natural, as tools. The **Gona first appearance datum** almost certainly underestimates the onset of habitual tool use, but because evidence of scattered unmodified stones or perishable items of the sort used by other primates is difficult to detect (Panger et al. 2002) we may never know when habitual tool use began.

tool-use hypothesis This hypothesis is one of several purporting to explain the origin of upright posture and bipedal locomotion within the hominin clade. It derives originally from no less of an authority than Charles Darwin, who proposed it in *The Descent of Man, and Selection in Relation to Sex* (1871). The basic premise of the tool-use hypothesis is that the advantage of **bipedalism** is that it frees the hands from locomotion, thereby allowing them to be used for tool use, which in turn stimulates the evolution of many other derived characteristics of later hominins. The hypothesis remained salient throughout much of the mid-20thC (e.g., Bartholomew and Birdsell 1953) and reached its height of influence in the writings of Sherwood Washburn. Washburn (e.g., Washburn 1960) proposed a sophisticated system of selective feedback mechanisms in which bipedalism allowed and/or was caused by tool use, which in turn favored canine reduction, hunting, and the evolution of a large brain. Brain enlargement and the concomitant increase in intelligence led to the evolution of ever more sophisticated tools, which re-energized the feedback loop (i.e., better tools led to enhanced bipedalism and a larger brain, etc.). Ultimately, increased brain size and hunting behavior led to language and complex human social behavior. The tool-use hypothesis is compelling and logical, and was influential in paleoanthropology, to the point that fossils of an extinct ape then known as *Ramapithecus* that possessed small canines were thought to be bipedal hominins (see review in Pilbeam 1978) despite the then lack of postcranial evidence for this taxon. Subsequently it was suggested the fossils in question were females of an ape genus (*Sivapithecus*) now thought

by most workers to be closely related to the modern orangutan (Pilbeam 1982, Andrews and Cronin 1982; but see Pilbeam et al. 1990). The ultimate demise of the tool-use hypothesis was brought about by the application of **radiometric dating** techniques (e.g., Leakey et al. 1961, Dalrymple and Lanphere 1969) and new fossil discoveries (e.g., Johanson and White 1979), which between them demonstrated that the earliest possible fossil hominins (*c.*6–7 Ma) and inferred bipedal locomotion (Richmond and Jungers 2008) substantially pre-dated the earliest archeologically visible stone tools (*c.*2.6 Ma) by several millions of years. *See also* **artifacts**; **bipedalism**.

tooth crypt *See* **alveolus**.

tooth emergence *See* **eruption**.

tooth eruption *See* **eruption**.

tooth formation Process of crown and root development that begins with soft tissue differentiation inside crypts in jaws, and ends with apical closure of the root(s). It is often categorized as discrete categories or stages that may be assessed from dental radiographs (reviewed in Hillson 1996). *See also* **enamel development**; **dentine development**; **eruption**.

tooth germ Tooth germ refers to the immature tooth bud within the mandible or maxilla that is undergoing **tooth formation**. At the earliest stages tooth germs are small and comprise only soft tissues, but as mineralization begins tooth germs are found in fully grown crypts in the jaws. Because they are so fragile, the very early mineralizing stages of tooth germs are relatively rare in the hominin fossil record. *See also* **enamel development**; **dentine development**.

tooth marks *See* **carnivore ravaging**; **cutmarks**.

tooth material An attempt by researchers to combine the size of several teeth as the unit of analysis of tooth size. Howes (1954) introduced the term tooth material to refer to the sum of the mesiodistal lengths of the maxillary and mandibular incisors, canines, premolars, and first molars. Advances in methods for image capture and in analytical methods are enabling researchers to investigate the absolute and relative sizes of the component cusps of multicuspid tooth crowns, and

for taxonomic purposes these studies are beginning to replace more simplistic assessments of overall tooth size.

tooth nomenclature *See* teeth.

tooth size When researchers write and talk about hominin tooth size, unless they specify to the contrary, they are almost certainly referring to the maximum size of the tooth crown as reflected in its horizontal dimensions. For the incisors and canines this is usually the part of the tooth crown closest to the occlusal plane, and for the postcanine teeth the size of the junction at the junction between the crown and the root. Tooth crown size can be expressed in terms of one or more linear dimensions or as an area measurement, and this can be in two or three dimensions. When a single linear dimension is used as a proxy for tooth size it is almost always the mesiodistal length of the crown (e.g., premolar and molar chords, see below), but mesiodistal measurements need to take into account loss of enamel due to the **interproximal wear** that occurs between adjacent teeth when they move against each other during **chewing**. The area of a tooth crown can be computed by multiplying the mesiodistal and labio- or buccolingual dimensions of the crown. This works well when the shape of the crown is close to being a rectangle, but it is unacceptably inaccurate when the outline of the crown is irregular. Crown area can also be measured from occlusal photographs, but care must be taken to orient the crown in the way the technique prescribes. Researchers often combine the size of several teeth as units of analysis. Examples include the chord lengths of rows of morphologically or functionally similar teeth (e.g., incisor, premolar, and molar row lengths), and even more inclusive units, such as Howes' (1954) global measure of **tooth material** (i.e., the sum of the mesiodistal lengths of the maxillary and mandibular incisors, canines, premolars, and first molars), or the combination of the maxillary or mandibular incisors and canine as the **anterior teeth**, and the combination of the maxillary or mandibular premolars and molars as the **posterior teeth**, or **postcanine teeth** (e.g., Curnoe and Tobias 2006). Advances in methods for image capture that allow for 3D measurements, as well as advances in analytical methods, are enabling researchers to investigate the absolute and relative sizes of the component cusps of multicusp tooth

crowns, and for taxonomic purposes these studies are beginning to replace more simplistic assessments of overall tooth size. For the great apes, possible primitive hominins, and early hominins the operative measure of canine size is the height of the crown.

tooth wear Wear involves the worn object losing some of its volume, and the process of tooth wear (the loss of enamel volume, and then later the loss of dentine volume) begins as soon as a tooth loses its gingival covering and is exposed in the mouth. Most research on tooth wear in hominins is concentrated on the wear that occurs on the functional or occlusal surface of a tooth (so-called **occlusal wear**), but wear also takes place on the non-occlusal surfaces of the teeth (due to the action of acid) and between tooth crowns (called approximal or **interproximal wear**) when adjacent teeth move slightly against each other in the mouth during the process of **chewing**. Occlusal wear is often divided into the wear that occurs between the occlusal surfaces of teeth (tooth-tooth wear is also called attrition), the wear that occurs between teeth and food (tooth-food wear is also called abrasion), and the wear that results from chemical erosion. However, these processes can also interact in a complex fashion. Occlusal tooth wear that can be seen with the naked eye is called gross wear, dental macrowear, or dental mesowear, while tooth wear that needs a microscope to see it is called **dental microwear**. Observations about gross dental wear focus on the development of **wear facets**, including measurements of their size and orientation. Dental microwear focuses on the size, number, and orientation of microscopic scratches, pits, etc. on the enamel, or on overall complexity and **isotropy** of the enamel surface. Dental macrowear is a measure of the abrasiveness of the diet in the long term, whereas dental microwear indicates whether the food ingested in the days or weeks before death contained hard or abrasive material. Such abrasive material can be either intrinsic to the ingested foods (e.g., **phytoliths**) or extrinsic to the foods (e.g., adherent sand grains). Dental microwear can also detect evidence for softer or tougher foods (e.g., polished or finely pitted surfaces). If any striations or scratches have a predominant orientation, this can be used to reconstruct the direction of the jaw movement(s) that generated the microwear. When occlusal dental macrowear is examined at the level of the whole

dentition, researchers have assessed it by examining the shape of the occlusal wear plane. The occlusal wear plane is rarely perfectly flat. In fact, the pitch (i.e., the transverse orientation) of the occlusal wear plane is not the same along the tooth row, for wear is normally greater on the lingual side of the maxillary teeth in the anterior part of the postcanine tooth row, with the posterior part of the tooth row either showing less emphasis on the lingual side or more wear on the buccal side (the so-called Curve of Spee). Tobias (1980b) suggested that this twist in the pitch of the occlusal wear plane was not seen in hominins until the emergence of *Homo*, but Richards and Brown (1986) suggest that the twisting nature of the occlusal wear plane has no taxonomic value. Dental microwear studies were revolutionized when precision molding materials were introduced, enabling positive molds of whole teeth to be examined with a scanning electron microscope (Walker et al. 1978). Fred Grine, Peter Ungar, and Mark Teaford have been in the vanguard of applying dental microwear analysis to fossil hominins (e.g., Ungar et al. 2006) and in the process they have helped develop new analytical methods (e.g., dental microwear texture analysis; see Scott et al. 2005). Enamel volume can also be lost when substantial-sized chips of surface enamel are removed when teeth are used intentionally, or unintentionally, to bite on hard objects. *See also enamel chipping.*

topographic (Gk *topos* = a place and *graphein* = to write) Topography refers to a detailed description of a place or region, usually in the form of a map. Topographic representation in the brain refers to the manner in which parts of the body are represented in a region of the brain. The brain's topographic representations of sensory systems, except olfaction, are due to the orderly preservation of information regarding the adjacency of peripheral sensory receptor arrays along the various stages of neural processing. For example, the spatial distribution of retinal photoreceptors is represented accurately in the lateral geniculate nucleus and the primary **visual cortex**. Similarly, the hair cells in the organ of Corti are tuned to different frequencies depending on their location along the basilar membrane of the cochlea, and the brain's representation of "tonotopy" is actually a topographic representation of the hair cells in the cochlea. The cortical representation of body parts may be magnified relative to their original size.

For example, the somatosensory representation of the bill of the platypus in its **neocortex** is greatly enlarged and certain acoustic frequencies are magnified in the auditory cortex of echolocating bats. Among primates, when the body surface is mapped onto the somatosensory cortex, the lips, hands, and the genitalia are "overrepresented," so the resulting map, or "homunculus," looks bizarre. Similarly, the visual cortex representation of the central visual field is highly magnified in haplorrhine primates in association with the presence of a retinal fovea.

Toros-Menalla (Location 16°14'–15'N, 17°28'–30'E, Chad; etym. Toros-Menalla is the name given by paleontologists to a region about 150 km/90 miles long in the western end of the **Chad Basin**, also known as the Djurab Desert) History and general description Toros-Menalla is a fossiliferous area in the Chad Basin of Northern Chad that was explored by the **Mission Paléoanthropologique Franco-Tchadienne** (French-Chadian Paleoanthropological Mission, or MPFT) beginning in 2001. Three fossiliferous localities within Toros-Menalla, TM 247, TM 266, and TM 292, have yielded hominin remains. All three localities are within the **Anthracotheriid Unit** (or AU) and are located within an area of 0.73 km²/0.3 square miles. Temporal span and how dated? Biostratigraphy suggests that the fauna associated with the possible hominins is older than fossils from **Lukeino**, Kenya (*c.* 6 Ma), and more closely resembles material from the Nawata Formation at **Lothagam**, Kenya, which is radioisotopically dated to 5.2–7.4 Ma, so the TM 266 fauna can be tentatively dated to between 6 and 7 Ma. The results of ¹⁰Be/⁹Be **cosmogenic nuclide dating** of 28 samples from the AU point to the age of the AU being between 7.2 and 6.8 Ma. Hominins found at site In 2001 D. Ahounta recovered **TM 266-01-060-1**, a nearly complete cranium that became the **holotype** of *Sahelanthropus tchadensis*. The paratypes were a symphyseal fragment with incisor and canine alveoli (TM 266-01-060-2), a right M³ (TM 266-01-447), and a right I¹ (TM 266-01-448) recovered in 2001, and the right side of a mandible (TM 266-02-154-1) and a right c (TM 266-02-154-2) recovered in 2002. Three additional specimens, a right P³ (TM 266-01-462) from TM 266, a fragment of the right side of a mandibular corpus (TM 247-01-02) from TM 247, and a mandibular fragment (TM 292-02-01) from TM 292, were reported in Brunet et al. (2005). All these specimens have been attributed to *S. tchadensis*. It is understood there are also unpublished postcranial remains from

the AU. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Vignaud et al. 2002, Lebetard et al. 2008; Hominins Brunet et al. 2002, 2005, Zollikofer et al. 2005, Guy et al. 2005; Archeology N/A.

torque *See* **petalia**.

Torralba (Location 41°08'19"N, 2°29'51"W, Spain; etym. named after the nearby town, Torralba del Moral) History and general description This site lies along the Masegar River, and it, along with the nearby site of **Ambrona**, was originally excavated by Clark **Howell** and Les Freeman in the early 1960s. They believed both sites to be contemporaneous, and presented their finding of many faunal remains, particularly from elephants, and a quantity of stone tools, as the earliest evidence of hunting. Furthermore, Freeman argued that at Torralba there were associations between the types of tools and the types of bones recovered, suggesting specialization in tool use. Later researchers, including Lewis **Binford** and Richard Klein, argued that the faunal profiles from these sites suggested scavenging, not hunting. The most recent analysis by Santonja and Pérez-González has shown that, first, Ambrona is significantly older than Torralba, and second, there is a mix of natural and hominin components to both sites with so little evidence of interaction between the hominins and the fauna that it is impossible to say anything more than some butchery occurred at the site. Temporal span and how dated? Based on the uranium-series date of a nearby river terrace, Torralba is thought to be more than 240 ka. Hominins found at site None. Archeological evidence found at site A large number of animal bones, mostly elephants, and stone tools. Torralba also has at least two pieces of elephant bones that have been intentionally flaked and shaped into points; these are among the oldest evidence of flaked bone tools. Key references: Geology, dating, and paleoenvironment Villa et al. 2005, Freeman 1994, Howell et al. 1963; Hominins N/A; Archeology Villa et al. 2005, Freeman 1994, Howell et al. 1963.

torus (L. *torus* = bulge) An area of projecting bone with a rounded profile (e.g., the occipital and frontal tori on the **cranium** and the transverse tori on the **mandible**).

total fertility rate (or TFR) The sum of the **fertility rate** (age-specific or ASFR) across the

female reproductive years. If the ASFRs are given by yearly age intervals, then the TFR is the simple sum of all the ASFR values. If the ASFR values are given across broader age intervals, then each ASFR value must be multiplied by the width of its respective age interval. This is the case because ASFR values are given per year of life, and a woman who has, for example, lived to her 25th birthday will have spent 5 years in the 20–25-year-old age interval for which the ${}_5f_{20}$ fertility rate applies. Ultimately, the TFR represents the total number of births a woman can be expected to experience during her lifespan. The TFR makes the assumption that a woman will survive to the cessation of ovulation at menopause, but it makes no assumption about the mortality of her offspring. The TFR also does not specify the sex ratio of a woman's offspring, and as such the TFR is less useful than the **gross reproductive rate** (or GRR) in making statements about population growth. In the case where the sex ratio of a woman's births is 1:1 the GRR is equal to half of the TFR.

total group (L. *totus* = whole) A term introduced by Jefferies (1979) for a **clade** or monophyletic group that includes all of the taxa more closely related to a living **taxon** in that clade than they are to any other living taxon. For example, the **hominin** and **panin** clades are both total groups. All the taxa in the former group are more closely related to *Homo sapiens* than they are to any other living taxon, and all the taxa in the latter group are more closely related to *Pan troglodytes* and *Pan paniscus* than they are to any other living taxon. A total group is made up of a **crown group** (equivalent to the "group" of Willi Hennig; Hennig 1981) plus the **stem group**. *See also* **clade**; **crown group**; **stem group**.

total morphological pattern This term (and the concept associated with it) was introduced by Wilfrid **Le Gros Clark**. He first used the term in a letter to *Nature* written in response to Solly Zuckerman (1950). Zuckerman had reiterated the claim made by Ashton and Zuckerman (1950) that they had successfully used dental morphometric methods to demonstrate that the australopith dentition was ape-like and not modern human-like as claimed by **Dart** and **Broom**, and supported by Le Gros Clark. Le Gros Clark (1950) wrote that "it is open to serious question whether the major dimensions and indices of individual teeth can by themselves provide adequate information on which

to base statements regarding affinities of primitive hominids and anthropoid apes” (*ibid*, pp. 893–4). He suggested that the new fossil evidence then recently reported by Broom and others “has now made it possible to take a comprehensive view of the *total morphological pattern* presented by the dentition” (*ibid*, p. 894). He went on to report that “according to my own comparative studies based on more than four hundred ape skulls, the **Australopithecine** dentition displays certain hominid features which severally find no precise parallel in any of the known apes (recent or extinct), and others which may very occasionally be found singly if diligently sought in a large series. But conclusions regarding the hominid nature of the dentition must ultimately be based on the total pattern determined by all these features in a particular combination” (*ibid*, p. 894). Just in case the reader had failed to get the point he continues “So far as I am aware no similar combination of *all* these hominid features together has been found in the dentition of any of the anthropoid apes” (*ibid*, p. 894). In an earlier paper about evolutionary parallelism Le Gros Clark (1936) warns that “the systematic position of the animal can only be established by a complete anatomical survey, and the systematist is liable to fall into serious error if he confines his attention to one part of the body only” (*ibid*, p. 4). This suggests the concept of the total morphological pattern, but Le Gros Clark did not use the term in this earlier paper. *See also* Wilfrid Le Gros Clark.

total person-years to be lived in an age interval The total number of years (based on the **radix**) lived in an age interval and all older age intervals, represented in a **life table** as T_x or ${}_nT_x$. The calculation is very closely related to **person-years lived in an age interval** (L_x). T_0 is just the sum of L_x across all age intervals; T_1 is the same sum but without L_0 . It is simplest to think of T_x as a backward-running cumulative sum, where the addition starts at the bottom (oldest age interval) of the life table.

“Toumaï” (etym. Toumaï means “hope of life” in the Goran language) According to Michel Brunet this was informal name given by “the highest Chadian authorities” to a hominin cranium recovered in 2001 by the **Mission Paléoanthropologique Franco-Tchadienne** (French-Chadian Paleanthropological Mission, or MPFT) at a site

called **Toros-Menalla**. Brunet and his colleagues assigned the specimen **TM 266-01-060-1** to a new genus and species, *Sahelanthropus tchadensis*.

TPS Acronym for thin-plate spline interpolation. *See* transformation **grids**.

Tpt Acronym for the temporal parietal transition area. *See* **Wernicke’s area**.

trabecular bone *See* **bone**.

trace element A chemical (e.g., aluminum, zinc) that is only required in small, or “trace,” amounts in the diet for normal function. Trace elements are not nutrients, but they may be essential for nutrients to be effective.

trace fossil (L. *tractus*=a track and *fossile*=something that is dug up) Trace fossils (also called **ichnofossils**) make up a small, but important, fraction of the fossil evidence for human evolution. They provide direct evidence that an organism has been at a particular place at a particular time, but no remnant of the organism itself, either in the form of hard (i.e., bones and teeth) or soft (i.e., skin, muscle, etc.) tissues, is preserved. There are two categories of hominin trace fossils. In the first, sediments have functioned like casting material, and they have retained details of the surface of soft-tissues long after any evidence of the individual has disappeared. Examples include footprints (*see* **Laetoli hominin footprints**; **Koobi Fora hominin footprints**), which preserve the impression of a soft tissue, the skin of the foot, and natural **endocranial casts** that faithfully reproduce the inner (i.e., endocranial) surface of the brain case of the hominins preserved. The second, much smaller category of trace fossils, comprises fossilized solid excreta in the form as **coprolites** (i.e., fossilized feces).

trachyte (Gk *trachys*=rough) A family of fine-grained volcanic rocks, mostly rich in phenocrysts of alkali feldspar and other minerals, with the former often aligned approximately parallel to the direction of lava flow. The proportions of silica, sodium, and potassium can be used to define trachyte and other lava types, with trachyte having SiO₂ abundances of approximately 57–72% and a total alkali (Na₂O+K₂O) abundance of approximately 9–15% (Le Bas et al. 1986). Where

available, trachyte is used for artifact production, as in the production of blades at archeological sites in the **Kapthurin Formation** in the Tugen Hills of Kenya.

trade-off A mutually exclusive interaction between two **life history** traits (i.e., traits that concern growth, maintenance, and/or reproduction). For each pair, you can have the benefit of one, or the benefit of the other, but you cannot have the benefit of both. Examples of trade-offs include those that occur between the following pairs of variables: extended life span versus early reproduction; egg number versus egg size; reproductive effort versus energy storage, etc.

tragelaphine See **Tragelaphini**.

Tragelaphini (Gk *tragos*=male goat and *elaphus*=deer) The antelope tribe (family **Bovidae**) comprising the genus *Tragelaphus*, kudu, and allies. Aside from one kudu from Arabia, this tribe, which arose in the late Miocene, is exclusively African. Their horn cores have keels and they are generally large bodied. Many tend to be found in relatively dry habitats, with the main exception of the Bongo, *Tragelaphus euryceros*, which is a large forest antelope.

tragulid The informal name for the **artiodactyl** family comprising the chevrotains and their allies, whose members are found at some hominin sites. See also **Artiodactyla**.

Tragulidae One of the **artiodactyl** families. Its members, which include the chevrotains and their allies, are found at some hominin sites. See also **Artiodactyla**.

trait (L. *tractus*=drawing. It refers to the distinctive pencil or brush strokes in a drawing or painting) Any measurable feature or non-metrical component of the **phenotype** (e.g., the characters used in a **phylogenetic analysis** are referred to as traits, as are the features used in a species diagnosis). See also **non-metrical trait**.

transcript (L. *transcribere*=to copy) The RNA that is formed when the information in a DNA template is transcribed into RNA. See also **transcription**.

transcription (L. *trans*=across and *scribere*=to write, thus to transcribe is to “write across”, or to copy) The process whereby the information encoded by DNA is transferred (or copied) into messenger RNA (or mRNA): the RNA product of this process is called a transcript. The information encoded in mRNA then takes part in a second process, called **translation**, to form a polypeptide chain. In the case of other types of RNA (e.g., transfer RNA and ribosomal RNA, etc.) the RNA molecule is not translated into polypeptides; instead, it functions as an enzyme or it becomes associated with proteins and performs specific functions within the cell. The process is facilitated by an enzyme called RNA polymerase. The process of DNA transcription is initiated or regulated by **proteins** called **transcription factors** (e.g., in modern humans the *FOXP2* gene codes for the **FOXP2** protein, which is a transcription factor that influences a number of target genes involved with the cognitive and the motor aspects of language).

transcription factor A protein complex that initiates or regulates the process of **DNA transcription** (e.g., in modern humans the *FOXP2* gene codes for the **FOXP2**^{human} protein which influences a number of target genes involved with the cognitive and the motor aspects of language). Transcription factors may bind directly to the **promoter** or other regulatory regions of genes to influence transcription, or they may bind to other transcription factors to affect their activity. The process mediated by transcription factors is one of many ways **gene expression** is controlled.

transcriptome All of the messenger RNA molecules present in one, or more, cells. It includes all of the transcripts produced by genes that are expressed at a particular time.

transduction (L. *transduce*=transfer) The transfer of energy from one form or state to another (e.g., photons to electrical impulses in the retina; motion to electrical impulses in the semicircular canals and the organ of Corti).

transfer RNA A type of RNA molecule (abbreviated tRNA) that has a 3'-terminal site for an **amino acid** attachment and a three-base “anticodon” sequence. The tRNA “transfers” (hence its name) an amino acid (specified by the

anticodon) to the site of messenger RNA (or mRNA) **translation** (the **ribosome**) so that it can be added to the growing polypeptide chain. The anticodon sequence is complementary to that of the mRNA **codon**.

transformation grid (L. *transformāre*=to change shape, and grid is a back-formation of gridiron, which is of obscure origin, perhaps from *gredire* which likely derives from OF *gredil*=griddle plus ME *ire*=iron) A device for visualizing shape differences between two objects whereby one (the reference shape) is typically mapped onto a 2D square grid and the other (the target shape) is represented as a warping of that grid to fit its corresponding features. In some representations the reference configuration is mapped onto the transformed grid rather than shown separately, or eliminated altogether since its shape can be intuited from the deformation of the square grid cells. Artist Albrecht Dürer (1471–1528) employed hand-drawn transformation grids to study variations in modern human form that arose through differences in perspective (Dürer 1557). It was D’Arcy Thompson (1860–1948), however, who more generally established the biological application of transformation grids as a mechanism to depict shape differences between organisms (Thompson 1917). Despite the apparent simplicity of this style of representation, it was another seven decades before an appropriate mathematical foundation was attached to Thompsonian transformation grids, through the apparatus associated with thin-plate splines (Bookstein 1991). The use of thin-plate splines in landmark-based geometric morphometrics has popularized transformation grids in modern anthropological and biological research. Here, differences between two sets of corresponding (presumably homologous) landmarks are visualized by warping the square grid of one set to fit the differences in the second set, with the spline function smoothly interpolating the spaces between landmarks through bending and stretching of the grid lines. Visually, the warped lines provide an intuitive and appealing model of how the target shape differs from the reference. Mathematically, however, the bending and stretching of the 2D mesh in a thin-plate spline is actually computed as vertical displacement of the target’s landmarks above and below the plane of the reference configuration. Thus, the visual interpretation of grid lines bending within a flat surface actually

derives from topographic undulations of a once-flat surface (this is the “thin plate” of thin-plate splines) warped through a new set of points offset from this plane. Whereas transformation grids can be applied to 3D data as well, trying to meaningfully visualize deformations using stacks and depths of grid cubes is nearly impossible. For 3D visualizations, authors typically rely on a single 2D grid characterizing a plane of anatomical interest, multiple stacked grids sampling the volume in increments, or video representation of a 2D grid passing through the entire volume with corresponding shape differences animated by changes to its gridlines. *See also* **thin-plate spline interpolation**; **geometric morphometrics**; **landmark**; **warp**.

transgenic mice *See* **knockout**.

transgression (L. *transgress*=to step across) When a body of water (lake or sea) increases in volume and enlarges to cover, or transgress, the landscape (ant. **regression**).

translation (L. *translatus*=to carry across) **Cell biology** The process whereby a polypeptide chain is created from a messenger RNA (mRNA) template. During this process, which occurs in the cytoplasm, the mRNA is bound by a **ribosome** that catalyzes the transfer of amino acids from **transfer RNA** (tRNA) molecules to the gradually elongating polypeptide chain. **Behavior** The term also used in connection with communication, which has three components: (a) encoding, (b) transmission, and (c) decoding, or translation.

translocation (L. *trans*=to move across and *locus*=place, so to move from one place to another) The transfer of a section of one **chromosome** to another, usually nonhomologous, chromosome. Translocations are common in cancer cells. In reproductive cells, three types of translocation are possible: reciprocal translocation, non-reciprocal translocation, and **Robertsonian translocation**. A reciprocal (or balanced) translocation is the exchange of the equivalent portions of two nonhomologous chromosomes. Such exchanges are also referred to as balanced translocations because the normal diploid chromosome complement is still present (though rearranged). Individuals with reciprocal translocations are normal (unless the breakpoint is in the middle of a gene

that affects the phenotype), but they have a 50% chance of having a normal child and a 50% chance of either having a child with a genetic condition or a miscarriage (depending on the amount and location of the genetic material involved). If the affected chromosomes are not “balanced” during production of the gamete, the latter may not have a complete haploid complement of some chromosomal regions and some regions may be present in diploid number resulting in a zygote that has monosomy for part of the genome and trisomy for another part (these are referred to as “unbalanced” translocations). Unbalanced translocations also occur when the initial translocation is non-reciprocal (causing an “unbalanced non-reciprocal translocation”). In this case, one segment of a chromosome attaches to another chromosome while the rest is lost. A Robertsonian translocation (also known as Robertsonian, or centric, fusion) is a chromosomal rearrangement where two nonhomologous acrocentric chromosomes (chromosomes where the centromere is located near one end of the chromosome) break at the centromere and the long arms join together to form one chromosome. The short arms are also fused to form a new chromosome. The short arms often do not contain essential genes, and this new chromosome is usually lost after a few rounds of mitosis. Thus, a person with a Robertsonian translocation only has 45 chromosomes but may be phenotypically normal. In modern humans, the acrocentric chromosomes commonly involved in Robertsonian translocations are chromosomes 13, 14, 15, 21, and 22. Individuals with Robertsonian translocations involving chromosomes 21 and 14 (or 15) run a greater risk of having children with Down syndrome because of an unbalanced trisomy 21. Over time, translocations can result in loss of shared **synteny** on chromosomes between species. A Robertsonian translocation may have been responsible for producing the modern human chromosome 2 from two ape chromosomes (Yunis and Prakash 1982). *See also* **chromosome**; **chromosome number**.

transmutation *See* Lamarckism.

transposition (L. *trans*=to move across and *poser*=to place, so to move from one place to another) The transfer of a segment of genetic material from one location to another. There are two basic methods of transposition. Retrotransposition involves **DNA transcription** into messenger **RNA**, the messenger RNA is then reverse transcribed into DNA, and finally, the DNA is

inserted back into the genome in a new location. DNA transposition involves the excision of a segment of DNA from the genome and then this is reinserted at a new location. *See also* **transposon**.

transposon DNA segments that are capable of undergoing **transposition**. They are also known as **mobile genetic elements** or jumping genes. *See also* **transposition**.

Transvaal Museum The institution now called the **Ditsong National Museum of Natural History**, but formerly known as the Transvaal Museum, was founded in December 1892 and was originally the Staatsmuseum (“State Museum” in Afrikaans) of the Zuid-Afrikaansche Republiek (South African Republic). The idea of establishing the museum originated with Willem Johannes Leyds, the Secretary of State of the republic, and the museum was originally housed in the Raadsaal (Parliament House) in Pretoria. The museum’s collections consisted primarily of zoological, botanical, geological, and paleontological specimens as well as ethnographic artifacts of the indigenous population and historical artifacts from the early European occupation of South Africa. Jan Willem Bowdewyn Gunning, a zoologist, served as the first director of the Staatsmuseum from 1897 to 1912 during a difficult time in its history. Construction of a new building to house the museum’s collections began in 1899 but later that year the Anglo Boer War began and after the victory of the British the new museum opened (in 1900) and was renamed the Transvaal Museum in 1901. The museum moved to its current location on Paul Kruger Street in 1912, although the natural history collections were not relocated to the new buildings until 1925. The Transvaal Museum became an important center of paleoanthropological research during the 1930s when the Scottish-born paleontologist Robert **Broom** became curator of paleontology at the museum. Between 1936 and his death in 1951 Broom conducted excavations at **Sterkfontein**, **Kromdraai**, and **Swartkrans** that led to the discovery of the numerous **australopith** and animal fossils and some artifacts, now housed at the museum. John **Robinson** and C.K. (Bob) **Brain** continued the tradition of paleoanthropological research at the Transvaal Museum after Broom’s death and expanded the museum’s collection of australopith fossils and archeological artifacts, and Francis Thackeray continued that tradition. In 1999, the Transvaal Museum was amalgamated with

the Pretoria-based National Cultural History Museum (also called the African Window) and the South African National Museum for Military History (situated in Johannesburg) to form the Northern Flagship Institution. On the May 28, 2010, its name was changed to the Ditsong National Museum of Natural History. Hominin fossil collections Sterkfontein (the material collected by Broom and Robinson from Members 4 and 5 between 1936 and 1958; the material collected by Clarke, Hughes, and Tobias since 1966 from Members 2–6 is curated by the School of Anatomical Sciences, University of the Witwatersrand), Swartkrans, Kromdraai, Cooper's Cave. Contact department Vertebrate Department. Contact person Stephany Potze (e-mail potze@nfi.museum). Postal address Paul Kruger Street, PO Box 413, Pretoria 0001, South Africa. Website Under reconstruction. Tel +27 12 322 7632. Fax +27 12 322 7939.

transverse arch A mediolaterally oriented arch in the midfoot formed by the cuneiform, cuboid, and metatarsal bases. It is present in the foot of modern humans as well as nonhuman primates. All the heads of the metatarsal are weight-bearing so there is no distal transverse arch. However, because the bases of the metatarsals are not in the same plane, there is a transverse arch in the midfoot. The arch is also evident where the hindfoot articulates with the midfoot at the calcaneocuboid joint and at the joint between the navicular and the cuneiforms. The transverse arch is actively supported by the adductor hallucis, fibularis longus, and tibialis posterior. Loss of the transverse arch results in a splayfoot (pes transversoplanus).

transverse buttress A crest-like structure that in *Pan* and *Gorilla* runs from above the infra-orbital foramen to blend inferiorly with the canine eminence.

transverse crest *See* epicrista.

transverse isotropy In materials science, a material whose properties (such as stiffness) are similar within a cross-sectional plane but which are different from those along an axis orthogonal (i.e., at right angles) to that plane. Some bones (e.g., portions of long bones like the femoral shaft) exhibit material properties that approximate transverse isotropy.

transverse ridge *See* distal trigon crest.

transverse-sigmoid system A variant of the intracranial venous system. In most modern humans the veins draining the deep structures of the brain drain as the deep cerebral veins into the left transverse sinus, and the superior sagittal sinus drains into the right transverse sinus. Each transverse sinus drains into a sigmoid sinus, which runs inferiorly in a sigmoid-shaped groove from the lateral end of the transverse sinus to the superior jugular bulb, which marks the beginning of the internal jugular vein. This pattern of dural venous sinuses is known as the transverse-sigmoid system, and individuals (e.g., KGA 10–525) with transverse and sigmoid venous sinuses on both sides are said to show transverse-sigmoid system dominance. In just a few percent of modern humans and in some chimpanzees and gorillas the venous blood from the brain takes a different route (Kimbel 1984). Instead of draining into the transverse sinuses, the deep cerebral veins and the superior sagittal sinus drain into an enlarged midline occipital sinus, which courses from the cruciate eminence towards the foramen magnum in a midline groove. The occipital sinus drains into uni-, or bilateral, marginal sinuses, which run(s) around the margin(s) of the posterior quadrants of the foramen magnum to drain into the superior jugular bulb and/or the vertebral venous plexuses. This is known as the occipito-marginal system of intracranial venous sinuses, and individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., OH 5) are said to show occipito-marginal system dominance. Some individuals (e.g., A.L. 333-45 and KNM-ER 23000) have a mix of the two systems, with a transverse-sigmoid system of venous sinuses on one side, and an occipito-marginal system of venous sinuses on the other, and a few individuals (e.g., Taung 1) have been reported to show coexistence of the two systems on the same side (Tobias and Falk 1988). *See also* cranial venous drainage.

transverse sinus One of the dural venous sinuses that belong to the intracranial venous system. In most modern humans the right and left transverse sinuses receive venous blood from, respectively, the superior sagittal sinus and the straight sinus (the latter drains venous blood from the deep cerebral veins), and they drain into the

sigmoid sinuses. This **transverse-sigmoid system** of venous sinuses is the dominant system for intracranial venous drainage in modern humans. *See also* **cranial venous drainage**.

transverse tori *See* **mandible**.

travertine *See* **calcium carbonate**.

tree In systematics, a tree is a diagram that depicts the descent relationships among a group of taxa. The term tree is used interchangeably with the term **cladogram** (syn. cladogram).

tree ring dating *See* **radiocarbon dating**.

tree topology (Gk *topos*=a place and *logos*=word) The branching pattern of a phylogenetic tree or **cladogram**.

tribe The category in the Linnaean hierarchy between a **genus** and a **family**. It is the category that some researchers prefer for the *Pan* and *Homo* clades. There is no formal definition of a tribe.

tribosphenic (Gk *tribein*=to rub and *sphen*=wedge) The name given to the triangular configuration of the three main cusps that forms the basic structure of the upper and lower postcanine tooth crowns. Hence the etymology “wedge-shaped structures that rub together.” *See also* **cusp morphology**.

trigon (Gk *trigonon*=triangle) The basic triangular three-cusped (or triconodont) structure of a maxillary (upper) postcanine tooth crown in the dental terminology devised by Osborn (1892). The three cusps are the **protocone** at the apex of the triangle on the lingual aspect, and the **paracone** mesially and the **metacone** distally on the buccal aspect.

trigon basin The term used by Szalay (1969) and Hershkovitz (1971) for the area others refer to as the **central fovea**. *See* **central fovea (maxillary)**.

trigon crest A term used by Robinson (1956) for an **enamel** structure on a maxillary molar tooth crown that others call the **distal trigon crest**. *See* **distal trigon crest**.

trigonid (Gk *trigonon*=triangle) The basic triangular three-cusped (or triconodont) structure of a mandibular (lower) postcanine tooth crown in the dental terminology devised by Osborn (1892). The three cusps are the **protoconid** at the apex of the triangle on the buccal aspect, and the **paraconid** mesially (this cusp has been lost in all higher primates including hominins) and the **metaconid** distally on the lingual aspect.

trigonid basin The term used by Szalay (1969) and Hershkovitz (1971) for the area others refer to as the **anterior fovea (mandibular)**. *See* **anterior fovea (mandibular)**.

trigonid crest Term used by Robinson (1956) for an **enamel** structure on a mandibular molar tooth crown that others call the **distal trigonid crest**. *See* **distal trigonid crest**.

trigonum frontale *See* **frontal trigon**.

Trinchera del Ferrocarril One of several sediment-filled cave systems in the Sierra de Atapuerca, 14 km/9 miles east of Burgos in northern Spain. The fossiliferous cave/fissure complexes within this system include the sites of **Galería**, **Gran Dolina**, and **Sima del Elefante**. *See also* **Atapuerca**; **Galería**; **Gran Dolina**; **Sima del Elefante**.

Trinchera Dolina *See* **Gran Dolina**.

Trinil (Location 7°22'S, 11°34'E, Indonesia; etym. named after a local village) **History and general description** The type site of *Pithecanthropus erectus* (now referred to as *Homo erectus*) takes its name from the nearby village of Trinil in East Java, and is the best known of all the hominin-bearing sites in Indonesia. The Dutchman Eugène Dubois excavated the site from 1891 to 1894, and after he returned to Europe in 1895 his assistants Sergeants Kriele and De Winter continued systematic excavations until 1900. Subsequent field projects at Trinil were conducted by Selenka (1906–8) and by a joint Indonesian–Japanese team from 1976 to 1977. Hundreds of vertebrate fossils (including mammals, crocodiles, and turtles) were excavated, and the faunal collection is housed in the **Rijksmuseum van Natuurlijke Historie**, Leiden, The Netherlands. These fossils are known as the **Trinil H.K. Fauna** (H.K. is an

abbreviation of *Hauptknochenschicht* meaning “main bone layer” in German). A recently completed ecomorphological study of this fauna concluded that the paleoenvironment of Trinil was characterized by open savannas, densely covered river valleys, and upland forests. The site is an exposure of river-formed deposits on the banks of the Solo River and it is derived from the Trinil Beds of the **Bapang Formation** (formerly Kabuh), which overlies the **Sangiran Formation** (formerly Pucangan). Temporal span and how dated? Initially dated by the **potassium-argon dating** method to 500 ka, most scholars now date the hominin fossil-bearing sediments to between 700 ka and 1 Ma. Hominins found at site Nine hominin specimens (Trinil 1–9), attributed today to *H. erectus*, were recovered by Dubois and his collectors between 1891 and 1900. These specimens include Trinil 1, the third molar found in September 1891, the **calotte** designated **Trinil 2** found in October 1891 and assigned the **holotype** of *Pithecanthropus erectus*, and a femur, **Trinil 3** (found in August 1892), that was presumed to be associated with the calotte. It was the latter that led Dubois to conclude that the individual walked bipedally. Trinil 4 and 5 are isolated teeth (a left M² and P₃, respectively) found in 1897. Much later in time Dubois’ attention was drawn to four femoral fragments known as the **Trinil femora** (a proximal femur designated Trinil 6 and pieces of the femoral shaft numbered Trinil 7–9) that were also assigned to *P. erectus* (Dubois 1932). Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Selenka and Blanckenhorn 1911, von Koenigswald 1964, Pope 1983, Weinand 2005; Hominins Dubois 1893, 1894, 1924, 1932.

Trinil 2 Site **Trinil**. Locality N/A. Surface/in situ *In situ*. Date of discovery October 1891. Finder N/A. Unit N/A. Horizon N/A. Bed/member Trinil Beds. Formation **Bapang Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*700 ka to 1 Ma. Developmental age Adult. Presumed sex Unknown, but its small size suggest it might be female. Brief anatomical description Calotte made up of most of the frontal, the occipital squame, and both parietals. Announcement Dubois 1892. Initial description Dubois 1894, 1924a. Photographs/line drawings and metrical data Dubois 1924b. Detailed anatomi-

cal description N/A. Initial taxonomic allocation *Anthropopithecus erectus*. Taxonomic revisions *Pithecanthropus erectus* (Dubois 1894), *Homo erectus* (Weidenreich 1940). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The first good evidence for an early hominin outside of Europe and the **holotype** of *Homo erectus*. Location of original **Rijksmuseum van Natuurlijke Historie**, Leiden, The Netherlands.

Trinil 3 Site **Trinil**. Locality N/A. Surface/in situ *In situ*. Date of discovery August 1892. Finder N/A. Unit/horizon N/A. Bed/member Trinil Beds. Formation **Bapang Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*700 ka to 1 Ma. Developmental age Adult. Presumed sex Unknown, but the small size of the head led Kennedy (1983) to suggest that the femur “is that of a female” (*ibid*, p. 607). Brief anatomical description The specimen comprises a complete adult hominin left femur. An irregular bony excrescence that extends from the posteromedial surface of the proximal one third of the femoral shaft is most likely due to the formation of woven bone within a traumatically induced hematoma (i.e., myositis ossificans) in the adductor muscle compartment (Day and Molleson 1973). Other than that the specimen is free of significant pathology. Announcement Dubois 1893. Initial description Dubois 1926a. Photographs/line drawings and metrical data Dubois 1926a, Day and Molleson 1973. Detailed anatomical description Dubois 1926a. Initial taxonomic allocation *Anthropopithecus erectus* (Dubois 1893). Taxonomic revisions *Pithecanthropus erectus* (Dubois 1894), *Homo erectus* (Weidenreich 1940). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The resemblance between Trinil 3 and the femora of upright-walking modern humans was the reason Dubois used the species name he did for this taxon, but doubts have been expressed about whether Trinil 3 is contemporary with the type specimen of *H. erectus* (Day and Molleson 1973). Location of original **Rijksmuseum van Natuurlijke Historie**, Leiden, The Netherlands.

Trinil fauna The inclusive name given by Ralph von Koenigswald for the fauna found at Trinil and at Trinil-aged sites elsewhere in Java. Not to be confused with the more exclusive **Trinil H.K. fauna**, a term introduced by de Vos and

Sondaar (1982) for the fauna found in the same horizon as **Trinil 2**, the type specimen of *Homo erectus*.

Trinil femora The relatively complete and well-preserved **Trinil 3** femur (also referred to as “Femur I”) was recovered in August 1892. It was the first of five hominin femora from **Trinil** recognized by Eugène **Dubois**. The remaining four hominin femora (i.e., Femora II–V) consist of one specimen that preserves the damaged proximal end (the greater trochanter is missing) and the shaft (Femur II), two substantial mid-shaft fragments (Femurs III and IV), and one shorter fragment from the mid-shaft region (Femur V). The four femora were excavated in 1900, but Dubois did not recognize them as hominins until 1932, exactly 40 years after the recovery of **Trinil 3** (Dubois 1932). Three years later a sixth femur (Femur VI in Dubois’ scheme) was recognized by Dubois as belonging to *Pithecanthropus erectus* (Dubois 1935). Its exact provenance is uncertain, but Dubois wrote that it is “certainly not from Trinil but from another part of the Kendeng region,” and he suggested there is “some probability that this fossil was found at **Kedung Brubus**” (*ibid.*, p. 3). However, when Day and Molleson (1973) examined all of the Trinil femora (i.e., Femora I–VI) in detail (using radiography and microscopy) they concluded that Femur VI “is not hominine, hominid or even primate” (*ibid.*, p. 151). Doubts have been expressed about whether the femoral remains from Trinil are the same age as the calotte and the teeth (Day and Molleson 1973). Kennedy (1983) addressed the traditional morphometric affinities of the Trinil femora in a multivariate analysis and her conclusion was that “although the Trinil femora demonstrate a few characters, particularly in the lower shaft, similar to those in *Homo erectus*, their overall pattern unequivocally allies them with the sapient comparative group” (*ibid.*, p. 614). See also **Trinil**; **Trinil 3**; **Kedung Brubus**.

Trinil H.K. fauna (etym. Combination of the name of the site, **Trinil**, and *Hauptknochenschicht* (Ge. for “main bone layer”)) The name given by de Vos and Sondaar (1982) to the fauna found in the same horizon as **Trinil 2**, the type specimen of *Homo erectus*. The Trinil H.K. fauna is not to be confused with the more inclusive **Trinil fauna**,

a term introduced by Ralph von **Koenigswald** for the fauna found at Trinil, and at Trinil-aged sites elsewhere in Java.

trinucleotide repeat See **microsatellite**.

triplet codon See **genetic code**.

trisomy The presence of three copies of a particular **chromosome** in a cell rather than the normal diploid number (i.e., two). In modern humans, the only trisomies in which the individuals survive to adulthood are trisomy 21 (Down syndrome) and trisomy X (triple X syndrome).

tRNA Abbreviation of **transfer RNA** (*which see*).

trophic (Gk *trephein*=to nourish) A term which refers to anything having to do with the activities that promote nutrition. Any behaviors involved with the acquisition and the processing of food are examples of trophic behavior.

trophic level (Gk *trephein*=to nourish) The position an organism occupies in a food chain. The sun is the ultimate source of the vast majority of the energy that enters the Earth’s food chain. Primary producers, typically photosynthetic plants, use sunlight as their energy source. **Herbivores** obtain their energy by consuming live plants, and **carnivores**, called primary consumers, obtain their energy by eating herbivores. Ultimately insects and micro-organisms degrade the carcasses of carnivores, and whatever energy is left becomes dead biomass. Substantial amounts of energy and/or biomass are lost at each stage of the food chain as (a) waste (e.g., feces and urine) and the energy expended on waste excretion, (b) energy used for locomotion, mastication, etc., and (c) energy consumed to heat and cool the body (especially by warm-blooded creatures). It is unlikely that any member of the hominin clade was either an obligate herbivore or an obligate carnivore; they were most likely **eclectic feeders** (e.g., omnivores).

tropical (Gk *tropikos*=pertaining to the solstice) The term for the region (and the organisms occupying that region) between the Tropics of Cancer (approximately 23° latitude in the northern hemisphere) and Capricorn (approximately 23° latitude in the southern hemisphere) where at

some point in the year the sun is directly overhead. Day length in the tropics is less variable than in **temperate** regions, and climate tends to be determined by rainfall rather than temperature. The tropics have high levels of biodiversity, with the latitudinal range of each species generally being less than in the species found in temperate areas (known as Rapoport's rule). Primates are primarily a tropical order, and the hominin clade almost certainly emerged in the tropics.

tropical dry forest A biome located within the tropical (between 23°N and 23°S) and subtropical (between 20° and 40° of latitude in both hemispheres) regions. Tropical dry forests are characterized by long periods of drought during which the abundant deciduous trees drop their leaves. The length of the dry period depends on latitude, with sites further from the equator having longer dry periods. During the dry periods, trees and shrubs drop their leaves to conserve water, and leaf flushing resumes with the start of the rainy season. Dry forests have trees that are shorter and simpler in structure than those in rain forests. The dry forests of Africa, Central and South America, and those of tropical islands, have a diverse wildlife, although not as highly diverse as tropical rain forests. African tropical dry forests tend to have a greater diversity of mammals than most rain forests in Central and South America.

tropical rain forest A biome restricted mostly to the equatorial zone between latitudes 23°N and 23°S and which is primarily defined by climate and quantity of rainfall. Tropical rain forests have climates in which the mean temperature of the coldest month is at least 18°C and every month has at least 100 mm of rainfall, although short dry periods lasting a few days to a few weeks may exist. Overall, they are the least seasonal of all forest biomes. Some sources define tropical rain forests as those forests with a minimum annual rainfall of 1750–2000 mm of rainfall and located within the above equatorial zone. Tropical forests with several consecutive dry months (less than 60 mm rainfall) are referred to as tropical monsoon or seasonal forests. Both tropical rain forests and tropical monsoon forests are categorized under the inclusive term tropical moist forests. Tropical rain forests occur in all three tropical land areas (Americas, Africa, and Indo-Malaysia). The neotropical rain forests of the Americas are the most extensive, covering about half of the global total rain

forests (4×10^4 km²), followed by Indo-Malaysia (2.5×10^4 km²), followed by Africa (1.8×10^4 km²), but these numbers are in decline because of deforestation. Tropical rain forests have the highest net primary productivity of any forest biome, with approximately 9000 kilocalories per m² per year; to put this into perspective, woodland biomes have an average net primary productivity of 3000 kilocalories per m² per year (Archibold 1995). This translates into tropical rain forests containing approximately 80% of the world's biodiversity, thus they are a critical reserve for global biodiversity. Most African tropical rain forests experience wet and dry seasons, although the number may vary depending on their location; dryer seasons tend to be associated with lower fruit production, a preferred resource for many arboreal primates. During these lean periods, primates may switch to abundant, low-quality food items that tend to be more mechanically challenging. It is these **fallback food** items that have been suggested to have played an important role in the evolution of primate craniodental and digestive morphology.

Trotter, Mildred See Terry (Robert J.) Collection.

true chin A mental protuberance separated from the alveolar process of the mandible by a hollowed area called an *incurvatio mandibulae*. See also mandible.

true fossils (OE *trīewe* = steadfast, characterized by good faith and L. *fossile* = something that is dug up) True fossils are remnants of the organism itself, in the form of either hard (i.e., bones and teeth) or soft (i.e., skin, muscle, etc.) tissues. True hard-tissue fossils (i.e., bones and teeth) make up the vast majority of the fossil evidence for human evolution.

Tswaing Impact Crater (also known as the Pretoria Salt Pan) A lake formed in the meteor impact crater at Tswaing, South Africa. The site preserves a sedimentary record of paleoclimate for subtropical southern Africa stretching back 200 ka (Partridge et al. 1997). **Proxy** records indicate that summer rainfall amounts varied with the amount of summer **insolation** in the southern hemisphere paced by the timing of orbital **precession**. See also closed basin lakes.

tuber See underground storage organ; belowground food resources.

tubercle A small rounded projection on a bone (e.g., scaphoid tubercle) or tooth. *See also* **tuberculum**.

tuberculum (L. *tuberculum*=a small rounded projection, diminutive of L. *tuber*=lump) An **accessory cusp** on a tooth crown.

tuberculum anomalus A term used by Georg Carabelli (1842) for the distinctive feature he described on the mesiolingual face of a maxillary molar tooth crown. *See* **Carabelli(s) trait**.

tuberculum intermedium A term introduced by Gustav Schwalbe for a distinct **accessory cusp** located on the lingual edge of a mandibular molar crown between the **metaconid** and the **entoconid**. Some authors refer to weaker expressions of this feature as a **metaconulid** and others as a **postmetaconulid**, but Grine (1984) has reported examples of the possible co-occurrence of a **tuberculum intermedium** and a **postmetaconulid** (syn. C7, entostylid, lingual accessory cusp, median lingual accessory cusp, metaconulid, **metastylid**, postmetaconulid, **preentoconid**, seventh cusp). *See also* **postmetaconulid**.

tuberculum paramolare *See* **paramolar tubercle**; **protostylid**.

tuberculum sextum (L. *tuberculum*=a small rounded projection and *sextus*=sixth) One or more **accessory cusps** in the distal part of a mandibular molar crown between the **entoconid** and the **hypoconulid** (syn. C6, cusp 6, sixth cusp, postentoconulid).

tufa (OIt *tufo*=volcanic ash) A variety of **speleothem**, a tufa is a sedimentary rock predominantly composed of **calcium carbonate** made up of sediments deposited from water percolating through a porous rock in a spring or a lake. The **Taung** cave was formed as a solution cavity within a flow made up of tufa. *See also* **calcium carbonate**; **speleothem**.

tuff (OIt *tufo*=volcanic ash) A rock made of small-sized (approximately <4 mm) volcanic debris, often in the form of an ash. Most fragments contain enough glass crystals to enable their age to be determined using the **argon-argon dating** or **potassium-argon dating** methods (e.g., **KBS Tuff** in the **Koobi Fora Formation**).

tuffaceous Any sediment that has a significant **tephra** (or **tuff**) component (e.g., reworked volcanic ash deposits). *See also* **tephra**; **tuff**.

Tuinplaas (Location 25°00'S, 28°36'E, in Limpopo Province, South Africa; etym. Afrikaans for "Garden City," the name of a nearby town) **History and general description** The site is a quarry, in which a human skeleton was found, approximately 130 km/80 miles north of Pretoria. **Temporal span and how dated?** It was originally thought to be associated with **Middle Stone Age** artifacts, but it has since been directly dated by **uranium-series dating** to between 11.0±0.7 and 20±3 ka (i.e., it is within the time span of the **Late Stone Age**). **Hominins found at site** **Tuinplaas 1**, a fragmentary skull and postcranial skeleton. **Archeological evidence found at site** MSA (Pietersburg) artifacts. **Key references:** **Geology, dating, and paleoenvironment** Lang 1929, Wells 1959, Pike et al. 2004; **Hominins** Broom 1929, Schepers 1941, Toerien and Hughes 1955, Hughes 1990; **Archeology** van Riet Lowe 1929, Mason 1962.

Tuinplaas 1 **Site** **Tuinplaas**. **Locality** N/A. **Surface/in situ** *In situ*. **Date of discovery** 1929. **Finders** C.J. Swierstra and H. Lang. **Unit** N/A. **Horizon** N/A. **Bed/member** Lateritic deposit atop calcareous **tufa** in the Tuinplaas Quarry. **Formation** N/A. **Group** N/A. **Nearest overlying /underlying dated horizon** N/A. **Geological age** **Late Pleistocene**. **Developmental age**. **Adult**. **Presumed sex** Male, based on overall size. **Brief anatomical description** A large, fragmentary cranium, plus a mandible with a weakly modeled chin and many postcranial fragments, including portions of most of the major long bones. **Announcement** Lang 1929. **Initial description** Broom 1929. **Photographs/line drawings and metrical data** Schepers 1941, Hughes 1990. **Detailed anatomical description** Schepers 1941, Toerien and Hughes 1955, Hughes 1990. **Initial taxonomic allocation** *Homo sapiens*. **Taxonomic revisions** N/A. **Current conventional taxonomic allocation** *H. sapiens*. **Informal taxonomic category** Anatomically modern human. **Significance** Although it does not derive from the **Middle Stone Age**, Tuinplaas 1 is nonetheless a rare specimen of terminal Pleistocene *H. sapiens* from southern Africa. **Location of original** **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), Northern Flagship Institution, Pretoria, South Africa.

turbinates *See conchae.*

Turkana Basin A hydrological and sedimentary basin located in northern Kenya and southern Ethiopia. The Turkana Basin, which is part of the **East African Rift System**, comprises several structural elements. Portions of the southern part of the basin integrate components of a transverse Mesozoic rift system, the Anza Rift, while the more northerly parts reflect a series of half-graben developed on the flank of the modern rift trend. The basin today is a closed system; the Omo, Turkwell, and Kerio Rivers drain into Lake Turkana and there is no outlet. However, in the geological past at times the basin has been an open system, with connections to both the Nile River and the Indian Ocean. The Turkana Basin is well known for its extensive fossils sites and the many vertebrate fossils that have been recovered. The oldest fossiliferous sediments, which extend back to the Mesozoic (<100 Ma) when dinosaurs were numerous, are found in the Labur Hills to the north west of the modern lake. Late Oligocene, and earliest Miocene outcrops are found to the west of Lake Turkana at Nakwai and Losodok, and early Miocene sites are found at Kalodirr, Moruorot, and Loncherangan on the western shores and at Buluk and Kajong (Mwiti) to the east. The lake basin is best known for its Pliocene and early Pleistocene record of human evolution and much of the fieldwork in Kenya and in Ethiopia over the last 40–50 years has been focused on sediments of this age. The Turkana Basin developed as an integrated sedimentary basin in the Early Pliocene (*c.*4.2 Ma). For much of ensuing times, the ancestral Omo River occupied most of the basin and extensive fluvial deposits accumulated, hosting much of the vertebrate fossil record the basin is well known for (e.g., the **Omo Group** deposits, particularly the **Koobi Fora**, **Nachukui**, and **Shungura** Formations). Tectonic and climatic developments fostered lake phases in the basin, as increased subsidence created room and the strengthened monsoonal rains supplied the necessary water. Present-day Lake Turkana has a stratigraphic record reaching back 200,000 years in the **Turkana Group** strata, during which time it has shifted between a freshwater mega-lake linked to the Nile and the current closed-basin alkaline water body seen today. Outcrops of the Late Pleistocene are known in the Omo Valley (the Kibish Formation) and they are also found on the

western shores of the modern lake (at Eliye Springs), where they are less extensive. Numerous Holocene sites are present in the Lake Turkana Basin, but to date these have not been worked as extensively as those of the Cenozoic, although interest is increasing and currently several field teams have begun to survey these more recent outcrops. *See also Omo Group; Turkana Group.*

“Turkana boy” *See* KNM-WT 15000.

Turkana Group The younger of the two inclusive stratigraphic sequences (the older one is known as the **Omo Group**) exposed on the **Lower Omo Basin** (also called the Lower Omo Valley). It consists of the Bume Formation, **Kibish Formation**, and Errum Formation.

turnover-pulse hypothesis One of several hypotheses proposed by Elisabeth Vrba that seek to explain how environmental change influences evolutionary patterns in the fossil record. In the absence of environmental change, species should experience evolutionary **stasis**. Sudden, large-scale environmental change should be associated with a “pulse” or concentration of extinction and speciation events within a relatively narrow time range. The turnover-pulse hypothesis (Vrba 1985a) states that most of the turnover within lineages (i.e., the extinction of old species and the appearance of new ones) is driven by environmental change, and that if environmental changes are strong enough to induce turnover within one **lineage** then they should be strong enough to induce turnover in other lineages. Vrba suggested that stenotopic (i.e., specialist) species are more affected by environmental change than eurytopic (i.e., generalist) species, so she predicted there will be a temporal ordering of extinction and speciation effects, with **stenotopes** being affected first and **eurytopes** later. With respect to paleoanthropology, she (Vrba 1985b, 1988, 1995) stated that as African habitats became cooler and dryer at *c.*2.5 Ma, the diversification of mammal lineages, including hominins, which also occurred around that time may be a manifestation of a turnover pulse. She furthermore suggested that evidence of this pulse can be found in the fossil record of bovids (i.e., antelopes and their close relatives), but a detailed investigation of fossil mammals from the Turkana Basin (Behrensmeyer et al. 1997) failed to find conclusive evidence of such a pulse at the

predicted time. A caveat, however, is that the presence of a permanent water source (the Omo river) in the **Turkana Basin** may have buffered the species living there from the effects of environmental change. *See also* **effect hypothesis; habitat theory hypothesis; punctuated equilibrium.**

Turolian *See* **European mammal neogene; biochronology.**

Turubong (Location 36°30'16"N, 127°32'15"E, North Chungchong Province, South Korea; etym. named after the nearby Turubong Hill) History and general description Turubong is a cave complex located on Turubong Hill in the central part of South Korea. The caves were discovered in the 1970s during mining for limestone. The primary localities are Turubong Cave No. 2, No. 9, Saegul, Chonyogul, and Hungsugul. The importance of the Turubong localities is the presence of a purported burial of a child in Hungsugul and the argument that Turubong Cave No. 2 is evidence of an **osteodontokeratic**-type culture. Temporal span and how dated? Recent **AMS radiocarbon dating** suggests Hungsugul may be recent in age, possibly early **Holocene**, but the presence of *Crocuta ultima*, *Hyaena* sp., and *Coelodonta antiquitatis* in the Turubong Cave No. 2 faunal assemblage suggests it may date to the **Late Pleistocene**. Hominins found at site The nearly complete skeleton of a c.5–6 year-old modern human child was excavated from Hungsugul. Archaeological evidence found at site There are few stone tools in the Turubong Cave localities, particularly Cave No. 2, and although the excavators have argued that some of the bones are evidence of an osteodontokeratic culture, they are almost certainly bones that have been modified by carnivores. Repository The Turubong materials are currently stored in the Chungbuk University Museum in Cheongju and the Yonsei University Museum in Seoul, both in South Korea. Key references: Geology, dating, and paleoenvironment Lee 1983, 1984, 1994, Sohn 1983, Park and Lee 1990, Park 1996, Norton 2000; Hominins Park and Lee 1990, Park 1992, Norton 2000, Norton and Jin 2009; Archeology Lee 1983, 1984, 1994, Kwon 1996, 1998, Norton 2000.

"Twiggy" Nickname given by Louis and Mary Leakey to the OH 24 cranium from **Olduvai Gorge**.(NB: "Twiggy," also known as Lesley Hornby, was the first "supermodel." She was

unusually "skinny" for a model and by 1968, when OH 24 was found, she was internationally known and had been on the covers of *Vogue* and *Tatler*).

Twin Rivers (Location 15°31'S, 28°11'E, eastern Zambia; etym. located between the Chikupi and Nangombi Rivers, also known as Twin Rivers Kopje) History and general description A hilltop site on a 52 m-high isolated outcrop of limestone, Twin Rivers consists of several exposed fissures filled with fossil fauna and artifact-bearing **speleothem-cemented breccia**. A series of excavations (Blocks A–G) were directed by Desmond Clark in the 1950s and by Lawrence Barham in the 1990s. The site represents the only well-dated stratified example of Lupemban (**Middle Stone Age**) assemblages, and contains a large amount of imported and worked potential pigments such as **specularite** and **hematite**. Temporal span and how dated? A, F, and G blocks have been radiometrically dated. **Thermal ionization mass spectrometry and uranium-series dating** estimates on speleothem suggests a **Middle Pleistocene** age range of 226–170 ka for A and F blocks prior to cave roof collapse. Based on **AMS radiocarbon dating** estimates on bone and **thermoluminescence dating** estimates on burnt quartz and calcite, G block was likely occupied during the **Late Pleistocene** to the **Holocene** (c.60 ka to the present). Hominins found at site One probable humeral shaft fragment. Archaeological evidence found at site Flake production from local raw materials (especially quartz) was from single, multiple, and radial cores (including prepared/Levallois examples). Retouched tools include some of the earliest known examples of backed pieces and Lupemban lanceolates and lanceolate fragments. The fauna is well preserved but highly fragmented; a hominin accumulation agent is possible, but not proven. The A block excavation yielded more than 180 pieces of possible pigments (e.g., hematite and specularite), including pieces with wear facets, striations, and incised surfaces, as well as a quartzite pestle with iron-oxide-stained worn surfaces. Key references: Geology, dating, and paleoenvironment Barham 2000; Hominins Barham 2000; Archeology Barham 2000; Clark and Brown 2001.

tympenic tube *See* **auditory tube.**

type (L. *typus*=image) A specimen to which the name of a taxon is irrevocably attached. If it is designated in the original description it is called the

holotype, but if it is designated subsequently it is called the **lectotype**. *See also type specimen.*

Type I error In statistics, this type of error occurs when a **null hypothesis** is rejected incorrectly (i.e., when a result is accepted as significant when it is actually *not* significant). For example, when the difference in cranial capacity between two samples is accepted as significant when it actually is not, or when two variables are thought to be significantly associated when there is not actually a significant relationship.

Type II error In statistics, this type of error occurs when a **null hypothesis** fails to be rejected incorrectly (i.e., when a result is judged to be non-significant when it actually *is* significant). For example, when the cranial capacities in two samples are thought to be equal when they are actually different, or when two variables are thought to be independent of each other when there is actually a significant relationship between them.

type locality The locality at which the **type specimen** of a species was collected.

type section The geological **section** specified in the first formal description of a **stratum**.

type site In archeology, a type site is considered to be the model of a particular technocomplex (La Madeleine is the type site for the Magdalenian). In geology, a type site is considered to be typical of a particular rock formation.

type species A species of a given genus that has been chosen (by the describer of the genus, or, failing that, by a subsequent reviser) to represent the genus. The generic name is thereafter irrevocably attached to the type species, just as a species name is irrevocably attached to its type specimen. *See also type.*

type specimen The specimen to which a species' name is irrevocably attached (e.g., Neanderthal 1 with *Homo neanderthalensis*; OH 7 with *Homo habilis*; Trinil 2 with *Homo erectus*). Whatever species the specimen belongs to, it carries its **Linnaean binomial** with it, and if its binomial has priority (i.e., it has the earliest publication date) then it provides

the name of the species. Thus, if someone decided that the type specimen of *H. neanderthalensis* was in fact a modern human, but that all other Neanderthals were still Neanderthals, then *H. neanderthalensis* would be sunk into *Homo sapiens* (*H. sapiens*, 1758 has priority over *H. neanderthalensis*, 1864), and the next available name for a presumed Neanderthal specimen would have to be substituted (the next name given to a Neanderthal specimen would appear to be *Homo neanderthalensis* var. *krapinensis* Gorjanovic-Kramberger, 1902, the type specimen being Krapina skull D, so the "Neanderthal" species with have to be called *Homo krapinensis*). If there had been no such name, a new name would have to be found for the Neanderthal **hypodigm** and a **lectotype** would need to be designated and attached to that new species binomial. But, if someone decided that the type specimen of *H. habilis* really belonged to *Homo rudolfensis*, but that all other members of the *H. habilis* hypodigm were still *H. habilis*, then *H. rudolfensis* would be sunk into *H. habilis* (*H. habilis*, 1964 has priority over *H. rudolfensis*, 1986), a new Linnaean binomial would have to be found for the "old" *H. habilis* hypodigm (minus the transferred type specimen) and in this case it is *Homo microcranous* Ferguson, 1995. If the type specimen (**holotype** or **lectotype**) is destroyed then a new type specimen, called a **neotype**, can be designated from one of the **syntypes**.

typological A typological definition of a species is one that allows for relatively little variation, for, by definition, all the individual members of the species would closely conform to the specifications set out in the definition. It is an outmoded (but alas still extant) way of thinking about species.

Tyto alba (Gk *tuto*=night owl and *L. alba*=white) The formal name for the common barn owl, a **predatory** bird found throughout the Old and New Worlds. This animal is significant in paleoanthropology because it is largely responsible for the preservation of **microfauna**, particularly **micro-mammals**, at paleoanthropological and paleontological sites, and these remains are important for the **biostratigraphy** and for the **paleoenvironmental reconstruction** of these sites. The common barn owl feeds on microfauna, principally small rodents of the Muridae and Cricetidae families, in addition to invertebrates.

U

U-series dating *See* uranium-series dating.

UA 31 Site Buia. Locality Uadi Aalad. Surface/in situ *In situ* (details in Ghinassi et al. 2009). Date of discovery December 1995. Finder Lorenzo Rook and team. Unit N/A. Horizon FL2a/FL2b, low-sinuosity fluvial channels sand. Bed/member N/A. Formation Alat Formation. Group Dandiero Group, Maebele Synthem. Nearest overlying dated horizon Upper part of the Alat Formation comprising sediments with reversed polarity, and correlated with the post-Jaramillo Matuyama Chron. Nearest underlying dated horizon Bukra Formation, sediments with reversed polarity correlated with the pre-Jaramillo Matuyama Chron. Geological age *c.*1 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description An almost complete cranium lacking part of the basicranium and the right side of the face. The vault is long, low, and narrow, and the occiput is angled; an angular torus is present. The supraorbital torus is thick and strongly projecting, and it is separated from the frontal squama by a sulcus. The maximum cranial breadth falls across the supramastoid crests, but the maximum biparietal breadth is higher on the vault than is usual in *Homo erectus*. The face displays marked subnasal prognathism. All of the tooth crowns are broken off, but the roots of right P³-M³ and left P⁴-M² are preserved. Endocranial capacity 950 cm³ (directly measured by teff seed; Macchiarelli et al. 2008). Announcement Abbate et al. 1998. Initial description Abbate et al. 1998, Macchiarelli et al. 2004. Photographs/line drawings and metrical data Abbate et al. 1998. Detailed anatomical description Macchiarelli et al. 2004. Initial taxonomic allocation *H. erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance In many ways the UA 31 cranium resembles *H. erectus* yet it lacks an occipital torus and it possesses some “progressive” features such as a high position of

maximum parietal breadth. Location of original Eritrea National Museum, Asmara, Eritrea.

UA 466 Site Buia. Locality Uadi Aalad. Surface/in situ Surface. Date of discovery 2003. Finder Luca Bondioli. Unit N/A. Horizon FL2a/FL2b, low-sinuosity fluvial channel sand. Bed/member N/A. Formation Alat Formation. Group Dandiero Group, Maebele Synthem. Nearest overlying dated horizon Upper part of the Alat Formation comprising sediments with reversed polarity that are correlated with the post-Jaramillo. Nearest underlying dated horizon Bukra Formation, sediments with reversed polarity correlated with the pre-Jaramillo Matuyama Chron. Geological age *c.*1 Ma. Developmental age Adult. Presumed sex Male, based on a very narrow subpubic angle and lack of ventral arc. Brief anatomical description A left pubic symphysis preserving the entire face of the symphysis and most of the bone medial to the obturator foramen. Announcement and initial description Bondioli et al. 2006. Photographs/line drawings and metrical data Bondioli et al. 2006. Detailed anatomical description Bondioli et al. 2006. Initial taxonomic allocation None. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The symphysis is tall relative to modern humans. If this fragment proves to be from *H. erectus* it would be the second pubic fragment belonging to that taxon. Location of original Eritrea National Museum, Asmara, Eritrea.

Uadi Aalad *See* Buia.

UB 335 Site ‘Ubeidiya. Locality Square E 78. Surface/in situ *In situ*. Date of discovery It was excavated in 1966, but it was not recognized as a hominin until much later. Finder Excavated by M. Stekelis and colleagues, but identified by M. Belmaker. Unit I-26a. Horizon “Shoreline deposit”. Bed/member Member FI. Formation ‘Ubeidiya Formation. Group N/A. Nearest

overlying dated horizon Yarkouk Basalt 0.79 Ma. Nearest underlying dated horizon Erg el Ahmar Formation 1.96–1.78 Ma. Geological age *c.*1.5–1.2 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Heavily worn right I₂ whose morphology matches that of UB 1700. Announcement Belmaker et al. 2002. Initial description Belmaker et al. 2002. Photographs/line drawings and metrical data Belmaker et al. 2002. Detailed anatomical description Belmaker et al. 2002. Initial taxonomic allocation *Homo sp. indet.* but “tentatively identified as *H. ergaster*” (*ibid.*, p. 53). Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance Until the recovery of the hominins from Dmanisi the hominins from ‘Ubeidiya constituted what little evidence there was of early hominins in the Caucasus/Near East. Location of original Department of Anatomy and Anthropology, Sackler Faculty of Medicine, Tel Aviv University, Israel.

‘Ubeidiya (Location 32°41’N, 35°33’E, Israel; etym. name of a nearby settlement) History and general description The site, just south of the sea of Galilee, is located on the western flank of the Jordanian Rift and is unusual because the strata are steeply tilted. It was systematically excavated between 1960 and 1974, and then for two shorter periods (1989–94, 1997–9) thereafter (see Belmaker et al. 2002 for more details of the personnel involved and the results of the three campaigns). The ‘Ubeidiya Formation comprises four members: from below they are the Li (Limnic Inferior), Fi (Fluviatile Inferior), Lu (Limnic Upper), and Fu (Fluviatile Upper). Each member represents a cycle of deposition, but it is not known how long these cycles lasted, nor how much time elapsed between the cycles. The strata within the members are numbered (1–<92 from below upwards) within each of the main trenches, but in all of the members, but particularly in the upper three members, the number of the same stratum differs from trench to trench. Temporal span and how dated? Biostratigraphic dating suggests a range of *c.*1.5–1.4 Ma (Martinez-Navarro et al. 2009), which is consistent with paleomagnetic studies indicating a sequence spanning *c.*1.53–1.2 Ma (Sagi 2005, Rink et al. 2007) for the Fi member. Hominins found at site Fragments of two parietals and one temporal (UB 1703-6), a left I₂ (UB 1700), and a right M³ (UB 1701) were assigned to *Homo sp.* by Tobias (1966a) and later to *cf. Homo*

erectus (Tchernov and Volokita 1986). However, these hominin remains are most likely intrusive. A right I₂ (UB 335) is the only *in situ* Lower Pleistocene hominin remain from the site (Belmaker et al 2002). Archeological evidence found at site Early **Acheulean** and later **Oldowan** tools are well known from the site, The assemblages most resemble the **Developed Oldowan B** and the Early Acheulean from **Olduvai Gorge**. While taphonomic evidence indicates some hominin involvements in carcass processing (Gaudzinski 2004), the majority of the faunal assemblage was probably a natural accumulation (Belmaker 2006). Key references: Geology, dating, and paleoenvironment Tchernov 1988; Hominins Tobias 1966a, Tchernov 1986, Belmaker et al. 2002; Archeology Martinez-Navarro et al. 2009, Bar-Yosef and Goren-Inbar 1993, Shea 1999.

Uluzzo (Location 40°09’23’’N, 17°57’38’’E, Puglia, Italy; etym. named after a nearby tower and inlet) History and general description A cluster of caves on the edge of the Bay of Uluzzo, on the Ionian coast of Puglia. They include Serra Ciocora, Grotta del Cavallo, Grotta di Uluzzo, and Riparo di Uluzzo. Grotta del Cavallo is the only one to have yielded hominin remains; three teeth. Some of the caves have a relatively advanced stone tool technology named the Uluzzian by Palma di Cesnola (1989). The Uluzzian, like the **Châtelperronian** from French sites, is considered a transitional technocomplex that is associated with late **Neanderthals**. Temporal span and how dated? Layer IV of Grotta de Cavallo was dated using **radiocarbon dating** to more than 31 ka. Hominins found at site Three molars (left M₂ from lower levels; left M¹ and right M² from the upper levels) were found in Grotta del Cavallo. Archeological evidence found at site A typical **Mousterian** industry is found in the lower layers of the caves on the Bay of Uluzzo, but the upper layers contain evidence of the Uluzzian industry. The caves are also notable for evidence of shellfish consumption. Key references: Geology, dating, and paleoenvironment Messeri and Palma di Cesnola 1976; Hominins Palma di Cesnola and Messeri 1967, Alciati et al. 2005; Archeology Palma di Cesnola 1989, Bietti 1997.

unbalanced translocation *See* translocation.

unbiased strategy *See* economic utility index.

uncalibrated radiocarbon age *See* radiocarbon dating.

unconformity A break in the stratigraphic record that may be due to a period of non-deposition or to a period of active erosion. When there is an angular difference in the amount and/or direction of dip in the rocks on either side of the stratigraphic break the term angular unconformity is used. When there is no such angular difference the terms **disconformity** or non-sequence are sometimes used. Such non-angular unconformities may be very difficult to spot within the stratigraphic record yet within a given sequence they can account for substantial amounts of time.

underdominance A type of natural selection in which homozygous genotypes are favored and heterozygotes have lower fitness.

underground storage organ (or USO) The belowground or below-water part of a plant that has been modified and enlarged to store energy and/or water, typically found in dry or frequently burned environments. Depending on what part of the plant has been modified, these storage bodies can be called tubers, corms, bulbs, or rhizomes. USOs can be cryptic and are sometimes deeply buried, and therefore difficult to acquire. Due to their high caloric value, USOs are an important food of modern-day and historic hunter-gatherer groups (e.g., the Hadza of Tanzania). Several researchers have suggested USOs may have played an important role in hominin evolutionary history, including as **fallback foods** for the megadont archaic hominins (Laden and Wrangham 2005). This is at least in part because many USOs use the C₄ photosynthetic pathway and their consumption by hominins could explain the elevated $\delta^{13}\text{C}$ levels seen in hominins such as *Paranthropus robustus* and *Australopithecus africanus* (Yeakel et al. 2007). Estimates of their mechanical properties reveal that certain rhizomes, corms, and tubers can be harder and/or tougher than foods eaten by extant great apes (Dominy et al. 2008); their consumption could therefore possibly explain the derived craniofacial morphology of *Paranthropus*. USOs have also been proposed as a key component that allowed the evolution of the modern human-like body plan and life history of *Homo erectus* (O'Connell et al. 1999) (syn. geophyte). *See also* belowground food resources; grandmother hypothesis.

UNESCO Cradle of Humankind World Heritage Site *See* Cradle of Humankind World Heritage Site.

ungual process *See* apical tuft.

ungual spines (L. *unguis*=claw and *spina* = thorn) The fingers of the primate hand each comprise three bones; the proximal, the intermediate and the distal phalanges. The small distal phalanx has a base, a shaft, and an apex. In higher primates the apex is rounded and takes the form of a bony excrescence called an **apical tuft**. The edges of this apical tuft extend more proximally than does its mid-part, and it these edges that are referred to as unguinal spines.

ungual tuberosity *See* apical tuft.

ungual tuft *See* apical tuft.

Ungulata (L. *ungulatus*=hoof, from *unguis*=nail) The formal term for the group of mammals that possesses at least one hoofed toe. The group contains common domesticates such as horses, sheep, goats, and cows, as well as their wild relatives contained within the orders **Perissodactyla** and **Artiodactyla**. Ungulates are generally large-bodied and relatively long-lived, and with a few exceptions they give birth to single live young. They are either vegetarians or omnivores (e.g., the **Suidae**). Recent genetic studies suggest that ungulates are a **polyphyletic group**; however, the use of the term to describe the ubiquitous hoofed animals remains a useful, even if cladistically inaccurate, shorthand.

ungulate (L. *ungulatus*=hoof, from *unguis* = nail) The informal term for the group of mammals that possesses hoofs. *See* **Ungulata**.

unifacial *See* uniaxially worked.

unifacially worked (L. *unus*=one) A term used in the analysis of stone tools that refers to a piece that is worked (i.e., shaped), on one surface, or face. It contrasts with a piece that is worked (i.e., shaped), on two surfaces, or faces; such pieces are said to be **bifacially worked**.

uniformitarianism A fundamental assumption of all sciences that posits the spatial and

temporal invariance of natural (materialistic) laws. The term was coined in 1832 by the geologist William Whewell when reviewing the second volume of Lyell's *Principles of Geology*. In the third volume of that work, Lyell effectively articulated the concept because he argued that natural law invariability was necessary to explain past geological changes. The concept has since been generalized to all sciences. Uniformitarianism is an example of inductive logic in that it assumes that modern processes operated in the past. It also asserts parsimony in that invoking different processes in the past is unnecessary (and it is simpler not to do so) as long as current processes provide sufficient explanations. A number of examples in human evolutionary studies can be cited where the concept of uniformitarianism is implicitly invoked (e.g., reconstructing the biomechanics of australopith chewing using data derived from observational and experimental studies of living species, dating tuffaceous rocks using the assumption that decay rates of potassium have been invariant through time, estimating body mass of past species using relationships between, for example, femoral head diameter and body mass deduced for living species, defining species in the fossil record using patterns of variation within and differences among living species, reconstructing aspects of paleoclimate, or diet, using the stable isotopic behavior of oxygen or carbon measured in living systems).

unit In geological terminology, a vaguely defined or user-defined interval of rock strata. Units are the basic components by which a stratigraphic sequence is described and measured in the field, in which case they are commonly bounded by natural breaks or discontinuities, but the scale of the chosen units is determined primarily by the field geologist according to the scale of analysis and type of investigation being undertaken.

University of California's Africa Expedition
See Swartkrans.

University of Pennsylvania Museum of Archaeology and Anthropology *See* Wenner-Gren Foundation for Anthropological Research.

University of the Witwatersrand site numbering system Zipfel and Berger (2009) set out a proposal for a numbering system to be

used by the University of the Witwatersrand for "Cenozoic fossil-bearing sites" (*ibid*, p. 77). The system allocates each site a "U.W." number beginning with the earliest site to be recorded (e.g., Taung type site is U.W. 1, Gladysvale is U.W. 3, Swartkrans is U.W. 22, and Malapa is U.W. 88). The recommendation is that within these U.W. numbered sites fossils should themselves be given numbers, so the first evidence of the MHI associated skeleton to be found, the right clavicle, is U.W. 88-1.

untranslated region The parts, or regions, of DNA or messenger RNA molecules that are not translated into protein.

Upper cave *See* Zhoukoudian Upper Cave.

Upper Paleolithic A term used to describe the stage of the European and Near Eastern Paleolithic that is defined by the use of Mode 4 stone tool technology including the use of blade and burin tools, and is characterized by an increase in number and variety of tool types made from stone and organic materials and the proliferation of artwork and symbolic behavior including personal ornaments (beads, jewelry), portable art (figurines), and parietal art (cave paintings and engravings). It first appears in eastern Europe around 40 ka (e.g., at Istállósk and Bacho Kiro) and spreads westward over the course of 5000–10,000 years and, depending on the area, it is replaced by Mode 5 microlithic technologies between 20 and 10 ka. It is usually linked with *Homo sapiens*, but some early Upper Paleolithic or so-called transitional technocomplexes, such as the Châtelperronian, were apparently created by *Homo neanderthalensis*. The equivalent term for African sites with similar technologies (but not necessarily similar ages) is Late Stone Age.

Upper Pubu *See* Bubing Basin.

upper scale The name sometimes used for the upper part (i.e., above the superior nuchal line) of the squamous part of the occipital bone (syn. occipital plane).

upstream The term upstream refers to any relative position in a DNA or RNA molecule that is toward the 5' end of that molecule.

UR 501 *See* HCRP UR 501.

uracil See RNA.

Uraha (Location 10°21'0.6"S, 34°09'23.3"E, Malawi; etym. named after the village of Uraha) History and general description In the 1920s F. Dixey discovered artifacts on the surface of Uraha Hill that were subsequently attributed to the **Middle Stone Age** (Clark et al. 1966). In 1963, Desmond Clark led a pioneering expedition to the Malawi Rift that collected various mammalian faunal remains, but no hominins. The older fossiliferous sediments around Uraha Hill were first recognized in Mawby (1970). The southernmost area of the **Chiwondo Beds**, including those at Uraha, were explored by the **Hominid Corridor Research Project** beginning in 1983. The main significance of the fossil assemblage is biogeographical, for it extends the range of the hominin taxon recovered from the site by more than 1000 km/620 miles to the south. Temporal span and how dated? Biostratigraphy suggests an age of *c.*2.5–2.3 Ma. Hominins found at site A well-preserved fragment of an adult hominin mandibular corpus, **HCRP UR 501** assigned to *Homo rudolfensis*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Betzler and Ring 1995, Kullmer 2008; Hominins Schrenk et al. 1993, Bromage et al. 1995; Archeology N/A.

uranium-series dating Principle The uranium-thorium ($^{230}\text{Th}/^{234}\text{U}$, U-Th) system is an isotopic dating method that measures the daughter products resulting from the decay of uranium (this is referred to as the “daughter deficiency” variety of uranium-series dating). It is widely used for dating Quaternary deposits and the hominins therein, but U-Th dating only extends back to *c.*0.5 Ma because by this time the ^{230}Th has decayed away; material older than this can be dated with uranium-lead dating ($^{206}\text{Pb}/^{238}\text{U}$, U-Pb). This technique is relatively new and it has only recently been used to provide direct radiometric ages for the southern African hominin-bearing caves deposits. Uranium-lead dating could prove as useful for dating southern African hominins as **argon-argon dating** has proved to be for dating East African hominins. The advantages of uranium-series dating are its precision (e.g., errors are typically 0.1–1% for U-Th and 1–10% for U-Pb) and its independence from ambient conditions such as temperature. Method Material for dating is prepared in a clean labora-

tory environment to isolate and concentrate the isotopes of interest, which are then measured using a mass spectrometer. Inductively coupled plasma mass spectrometry (ICP-MS) and **thermal ionization mass spectrometry** (TIMS) are sensitive new counting methods that are up to 10 times more precise than alpha counting. For very high-precision work TIMS is the best, although ICP-MS has the advantage of simpler sample preparation and a higher sample throughput. The relationship between uranium-series dating and ICP-MS is much the same as that of accelerator mass spectrometry (or AMS) to regular ^{14}C estimations. For U-Th, a single analysis of the U and Th isotopes can produce an age, whereas U-Pb dating requires multiple analyses to construct **isochrons** from which the age is calculated. Suitable material The most suitable materials for uranium-series dating are inorganic carbonates, both marine (coral) and terrestrial (stalagmites, **flowstones**, **tufa**). Organic material, such as fossil bone, teeth, and ostrich egg shell, can be dated by U-Th but these are open systems and the uptake or loss of uranium must be modeled. Simple “early-uptake” or “late-uptake” models can be employed but most bone and mollusc shell samples have a much more complex uranium-uptake history. Mollusc shells are notorious for giving misleadingly young ages. Time range $^{230}\text{Th}/^{234}\text{U} \geq 500$ ka and $^{206}\text{Pb}/^{238}\text{U} \geq 500$ ka–billions of years. U-Pb can be applied to material within the same time range as U-Th, but given the extra analysis and sample volume, this is seldom worth the effort. Problems The **speleothem** material best suited to uranium-series dating is often not directly associated with fossil hominins or archeological remains, thus it is important to have precise and accurate site stratigraphy. Methods for dealing with calcite contaminated with detritus (“dirty calcite”) and material with so-called open-system behavior, such as fossil bone and teeth, are still relatively experimental and currently ages have large error margins.

ursid The informal name for the **Ursidae** (bears), one of the **caniform** families whose members are found at some hominin sites. See also **Carnivora**.

Ursidae The family that includes bears and their close relatives. It is one of the **caniform** families whose members are found at some hominin sites. See also **Carnivora**.

use wear Polishes, pits, and striations on the surface of a stone, bone, or metal tool that are the result of the use of that tool. Archeologists are able to examine use wear and identify the tool motion and contact material. *See* **use-wear analysis**.

use-wear analysis The study of polishes, pits, fractures, and striations on the surface of a stone, bone, or metal tool to understand how the tool was used. The field of use-wear analysis began in the late 1950s with Sergei Semenov's publication of *Prehistoric Technology* (published in English in 1964), in which he documented the processes that caused wear on the surface of stone tools, and became popular throughout the late 1970s and 1980s. Questions about the accuracy and reliability of the method arose in the 1980s, and though several blind tests using both high-power (high magnification) and low-power (low-magnification) analysis have shown that the method is robust, although many researchers in the archeological community are still wary of use-wear analysis. After years of methodological improvements (e.g., Anderson-Gerfaud 1981, Plisson 1985), use-wear analyses are increasingly being used to answer questions about past life and behaviour (e.g., Clemente et al. 2008, Shea, 2006). Keeley (1980), Odell (2004), and Grace (1996), among others, provide summaries of use-wear analysis.

Usno Formation (etym. The name is taken from the Usno River that joins the Omo River just north of the exposures of the Usno Formation) General description The Usno Formation is a group of outcrops *c.*30 km/19 miles north of the northernmost extent of the **Shungura Formation**. They lie immediately to the west of the Omo River in southern Ethiopia, just south of where the Usno River joins it, and the exposures extend for *c.*7 km/4.3 miles from their most northeasterly extent to their southwestern limit.

The Usno Formation is equivalent to Member A and most of Member B of the **Shungura Formation**, and its total area (not all of which contains sediments) is only about 20% of the area occupied by the "Type area" of the Shungura Formation. The total thickness of the Usno Formation is approximately 175 m. Sites where the formation is exposed Hominins have been found in two localities, known as **Brown Sands** and **White Sands**, within the exposures of the Usno Formation. Fossils found in the two localities have been given the prefix "B" for Brown Sands or "W" for White Sands. Geological age The oldest sediments of the Usno Formation are *c.*3.6 Ma and the youngest *c.*2.7 Ma. Most significant hominin specimens recovered from the formation The only hominins recovered from the Usno Formation are isolated teeth. Few studies have addressed these teeth, but those that have suggest that they are similar to those from **Hadar** and elsewhere that have been assigned to *Australopithecus afarensis*. Key references: Geology, dating, and paleoenvironment Butzer and Thurber 1969, de Heinzelin and Haesaerts 1983b, Feibel et al. 1989; Hominins Howell 1969b, Howell and Coppens 1974, 1976.

USO Acronym for **underground storage organ** (*which see*).

Uto-Aztec premolar *See* **distosagittal ridge**.

U.W. system Abbreviation of **University of the Witwatersrand site numbering system** (*which see*).

UW88-1 *See* MH1.

UW88-2 *See* MH2.

V

V1 *See* striate cortex.

Vaal River *See* Rietputs Formation.

Vaal River Gravels *See* Rietputs Formation.

Valdegoba Cave (Location 42°32'30"N, 0°05'10"W, Spain; etym. unknown) History and general description Valdegoba Cave is 28 km/17 miles northwest of Burgos, in northern Spain, at the southern end of the Cantabrian Cordillera. Four excavations took place between 1987 through 1991 by a team led by Rolf Quam, during which eight stratigraphic levels were uncovered. Of the six areas of the cave excavated, only one area in the western interior section contained *in situ* remains. Temporal span and how dated? Biostratigraphy suggests that the oldest layers of the site are more than 350 ka, whereas uranium-series dating of level 7 gives a date of 73.2 ± 5 ka. Hominins founds at the site Five hominin specimens were recovered from levels 5, 6, and 8. Mandibular fragments from an adolescent individual, VB1, were recovered from level 8, but that level is disturbed. The other fragments, with more precise stratigraphic context, consist of deciduous teeth (VB2), a proximal phalanx (VB3), and two metatarsals (VB4 and 5). The material is presumed to belong to *Homo neanderthalensis*. Archeological evidence An abundant Middle Paleolithic industry is known from levels 4–8, produced from local quartzite and flint. The presence of numerous first-order flakes implies that tool production was carried out at the site. Faunal evidence suggests at least two possible climatic regimes. Key references: Geology, dating, and paleoenvironment, hominins, and archeology Quam et al. 2001.

valgus (L. *valgus* = bent out) Refers to a joint, or an angle within a bone (e.g., the neck-shaft angle of the femur), being “bent” so that the limb segment beyond the joint, or the shaft of a long

bone beyond the angulation, are inclined further away from the midline than normal. Thus, when children have knees that are abnormally close together, because the long axis of the lower leg appears to be inclined away from the midline, that “knock-kneed” deformity is called genu valgum. But because valgus (and its antonym varus) are terms that are often misunderstood (Fairbank and Fairbank 1984), their use should probably be avoided. *See also* varus.

valid (L. *validus* = strong) In relation to taxonomy a valid taxon name is the correct taxon name. Among what may be several available names for a taxon only one, called the senior synonym, is valid in the sense that it is the correct name according to the rules and recommendations of the International Code of Zoological Nomenclature. For example, *Australopithecus africanus* is the senior synonym for the taxon for which Taung 1 is the holotype. *Plesianthropus transvaalensis* is one of several junior synonyms of *Au. africanus*; it is an available taxon name, but because it is not the senior synonym it is not the valid name.

Vallesian *See* European mammal neogene; biochronology.

Vallois, Henri Victor (1889–1981) Henri Vallois, who was born in Nancy, France, studied medicine at the University of Montpellier where he defended his thesis about the primate knee in 1914. He then entered the University of Paris where he studied natural history and completed his degree in 1922. Vallois became Professor of Anatomy and Zoology in the Faculty of Medicine at the University of Toulouse in 1922 and soon began to conduct research in physical anthropology and hominin paleontology. He became a close associate of anatomist and anthropologist Raoul Anthony, director of the Laboratoire d'Anthropologie

(Laboratory of Anthropology) at the École Pratique des Hautes Études (Practical School of Higher Studies) in Paris and of physical anthropologist Léonce-Pierre Manouvrier, who had written on the *Pithecanthropus erectus* fossils discovered by Eugène Dubois, and on the *Homo neanderthalensis* fossils found at Spy in Belgium. Vallois succeeded Anthony as director of the Laboratoire d'Anthropologie in 1938, and in 1941 he joined the prestigious **Museum National d'Histoire Naturelle** (National Museum of Natural History) as Chaire d'ethnologie et d'anthropologie des hommes actuels et des hommes fossiles (Chair of Ethnology and Anthropology of Current and Fossil Humans). At the Museum Vallois became a colleague and close associate of paleontologist Marcellin Boule, who had conducted the influential study of the **La Chapelle-aux-Saints** Neanderthal fossils discovered in 1908. Vallois investigated a substantial number of Paleolithic fossil humans during his career. During the 1930s and 1940s he wrote extensively on the paleopathology of prehistoric humans and estimated their life span, and during the 1940s and 1950s he analyzed the Upper Paleolithic hominin skeleton found at Chancelade and the mandible found at **Montmaurin**. Vallois and Germaine Henri-Martin published an extensive account of the hominin fossils discovered at **Fontéchevade** in 1947 in *La grotte de Fontéchevade* (1957–8). Vallois is best known for his interpretation of *Homo neanderthalensis* and for his opposition to the idea that Neanderthals were the ancestors of anatomically modern humans. He published a paper in 1929 in the journal *L'Anthropologie* where he argued for a monophyletic origin of modern humans and he was a supporter of the **pre-sapiens hypothesis**, which argued that anatomically modern humans were geologically very old and therefore the other known species of fossil hominins were not direct ancestors of modern humans. The discovery of the Fontéchevade specimen prompted Vallois to address what he saw as the three basic competing views regarding human evolution: (a) that modern humans had evolved through a Neanderthal phase, (b) that modern humans had evolved from a pre-Neanderthal hominin that gave rise to two lineages, one leading to *Homo sapiens* and the other to the Neanderthals, and (c) the pre-sapiens hypothesis that used evidence of the apparently ancient, but relatively anatomically modern-looking skeletons, found at Swanscombe, Fontéchevade, and **Pitldown**, to argue for an even greater antiquity for modern humans. Vallois, who was heavily influenced by Marcellin Boule, became a co-author on the third edition (1946) of Boule's classic

Les hommes fossiles (Fossil Men), first published in 1921. Boule and Vallois published a fourth edition of the book in 1952. Vallois continued to support the pre-sapiens theory even after 1955 when Pitldown was conclusively exposed as a hoax. In addition to his research on human paleontology Vallois also studied modern human racial variation. In *Les races humaines (Human Races)* (1944) Vallois identified four major racial groups (White, Black, Yellow, Australoid), which he subdivided into 27 separate human races. Vallois succeeded Boule as director of the Institut de Paléontologie Humaine (Institute of Human Paleontology) and served in that position from 1942 to 1971. He served as director of the **Musée de l'Homme** (Museum of Man) from 1941 to 1945 and again from 1950 to 1960, and was president of the committee in charge of anthropology at the Centre National de la Recherche Scientifique (CNRS) from 1949 to 1966. He also served as the general secretary of the Société d'Anthropologie de Paris (Anthropological Society of Paris) from 1938 to 1969. Vallois was at one time or another also the editor of three prominent journals: *L'Anthropologie*, *Bulletins et Mémoires de la Société d'Anthropologie de Paris*, and the *Archives de l'Institut de Paléontologie Humaine*. Vallois also published several important works on European prehistory, an anthropometric study of the French in *Anthropologie de la population française* (1943), and in 1953, together with Harvard geologist Hallam Movius, he compiled the *Catalogue des hommes fossiles (Catalogue of Fossil Men)*. He also collaborated with Suzanne de Félice on an important study of the French Mesolithic titled *Les mésolithiques de France* (1977).

Van Wesele, Andreas See anatomical terminology.

Vandermeersch, Bernard (1937–) Bernard Vandermeersch was born in Wervicq in northern France. He studied zoology, geology, paleontology, and ethnology at the Sorbonne (Paris) and earned his 3rd Cycle Doctorate in 1963 under the direction of J. Piveteau. He was then hired as Assistant at the Laboratoire de Paléontologie des Vertébrés et Paléontologie of the University of Paris. He became Maître Assistant in 1964 and then full Professor at the University of Bordeaux I in 1983, a position he held until his retirement in 2001. After participating in various Paleolithic excavations, including those at **Arcy-sur-Cure**, **Regourdou**, **Petit-Puymoyen**, and **Rigabe**, Vandermeersch undertook his first field trip to Israel in 1964 and directed the excavation of

Qafzeh, initially by himself and then in collaboration with Ofer **Bar-Yosef**. He later co-directed excavations in Israel at **Kebara** and **Hayonim**. In France, he excavated the site of Marillac. He is best known for his studies of the exceptional series of Mousterian early modern humans of Qafzeh (Vandermeersch 1981). He established the clear association of modern humans and **Mousterian** assemblages *c.* 95–100 ka. This work was seminal for the hypothesis that Neanderthals were not the immediate ancestors of modern humans and later in the development of the **out-of-Africa hypothesis**. Another important achievement at Qafzeh was the discovery of the oldest modern human burials, and the recovery of evidence that pigments were being curated and shells were being deliberately perforated well before the beginning of the Upper Paleolithic (Bar-Yosef Mayer et al. 2009). In Europe, Vandermeersch focused his work on several Mousterian sites (Petit-Puymoyen, Marillac, Regourdou, and **Saint-Césaire**) and he has been involved in the description of many *Homo neanderthalensis* fossils. His involvement in the study of some of the earliest evidence of modern humans (at Qafzeh), as well as some of the most recent evidence of Neanderthals (at Saint-Césaire), promoted his interest in the relationships between the two groups as well as the question of the extinction of the Neanderthals (Lévêque and Vandermeersch 1980). The Saint-Césaire specimen was crucial to the demonstration that the **Châtelperronian** culture was produced by late Neanderthals and it prompted a re-examination of the significance of other assemblages underlying the **Aurignacian** in Europe. Besides his career at the University, Vandermeersch was also Directeur des Antiquités Préhistorique de Pointou-Charentes (director of prehistoric antiquities from Pointou-Charentes) from 1972 to 1984 and an active member of the Comité des Travaux Historiques et Scientifiques au Ministère de l'Éducation Nationale et de la Recherche (the Ministry of National Education and Research Committee on Historic and Scientific Work).

variability (*L. varius* = various) Refers to the tendency to exhibit **variation** (Wagner 1996). The terms variation and variability are often used interchangeably in the literature, but this is not strictly correct. Variability may be thought of as referring to how different a new observation from a population is likely to be compared to earlier observations, whereas variation refers to the amount of difference in an existing set of observations. Like solubility, variability is a dispositional

concept and refers not to the observation of variation but rather to the underlying property of having the potential to exhibit variation. This distinction is important in biology because the determinants of variability apply to the developmental or genetic architecture of a species (or the shared architecture of a larger taxonomic group) whereas variation is the result of the confluence of many factors in a particular population. Just as a solution is the result of the particular combination of the solvent, a physical environment, and a substance with a given solubility, variation is the result of the epigenetic variability characteristics of a species combined with a particular level of genetic **variance**. Variability cannot be observed directly, it can only be inferred from observations about variation in samples of the parent population. Halgrímsson (2002) argued that **integration**, **canalization**, and developmental stability are crucial developmental factors that contribute to determining variability, but, like variability, they are dispositional concepts that are not observed directly. Their influence can only be inferred (e.g., integration by observations about covariation, canalization by observations about variance, and developmental stability by studying fluctuating asymmetry). To illustrate the distinction between variation and variability, imagine you are interested in the integration of dental non-metrical traits because you suspect that the covariation among them is relevant to their evolution. You obtain observations about the correlations among the traits in two samples from the same species. Your samples differ, however, in that one sample consists of identical clones raised under identical environmental conditions, whereas the other sample manifests high genetic and environmental variance. When you calculate the respective correlations, you find that in the sample made up of clones, the correlations are extremely low, whereas they are high in the sample with high variance. In fact, in the absence of genetic and environmental variance, the correlations (or covariances) among the traits will be 0. However, in both of these samples, the underlying developmental architecture is the same. If you were to introduce genetic variation into the population of clones, that sample would also exhibit covariation just as it does in the non-clone population. In both cases, therefore, the tendency to exhibit covariation is the same while the observed covariation (or correlations) is radically different. Variability refers to the tendency for developmental systems to exhibit variation in the face of particular combinations of genetic and environmental variance.

variability selection A mode of **natural selection** (*see also* **directional selection**; **disruptive selection**; **stabilizing selection**) that is hypothesized (Potts 1998) to occur when environmental conditions are highly unstable (i.e., they are prone to both large- and small-scale unpredictable changes that may occur over geologically short periods of time). The variability selection hypothesis suggests that under such conditions **alleles** that confer behavioral flexibility would be favored over alleles that experience strong positive selection during a given climatic extreme (e.g., dry habitats) but negative selection during the opposite extreme (wet habitats). Many modern human adaptations (e.g., intelligence, language, manual dexterity, tool use) confer extraordinary behavioral flexibility and are likely to have evolved during the **Pleistocene** epoch, when oscillations in global climates increased in both amplitude and frequency. Thus, it is suggested that variability selection may explain the evolution of these traits, but while variability selection is an intuitively appealing hypothesis, it is not immediately apparent how it can be tested in the context of human evolution.

variable (L. *varius* = various) When used as a noun, the term variable refers to any trait, feature, characteristic, or property of interest, or symbol representing any of the above, that differs in some way among the members of a population and that can be measured, described, or categorized (e.g., the mesiodistal length of mandibular first molars, shape of the orbit, or type of mating system) in a sample of that population. The variables in a statistical study can be organized by their properties, including (a) continuous versus discrete, (b) nominal (also referred to as categorical), ordinal, interval, or ratio, (c) dependent versus independent, and/or (d) controlled, uncontrolled, and confounding. Variables can be computed (derived) from other variables. By definition, variables must be able to take on more than one value (e.g., more than one tooth crown length, more than one orbit shape, or more than one type of mating system); otherwise they are constants, not variables. Because variables can take on more than one value, sample statistics are typically used to describe the values for a set of observations of a variable for a sample drawn from a population (e.g., the mean, range, or standard deviation for continuous variables; frequencies for categorical variables, etc.). When used as an adjective, the term variable refers to how much observations within a sample differ from

each other. Compared to other samples of the same taxon, or a sample of a different taxon, a sample can be characterized as showing little, average, or substantial variation. *See also* **variability**.

variable number of tandem repeats (or VNTRs) Different numbers of **tandemly repeated sequences** at a location in the genome. Subcategories include satellite sequences, **minisatellites**, and **microsatellites**, but VNTRs usually refers to minisatellites.

variance (L. *varius* = various) A specific statistical quantity formulated by Ronald Fisher (1918) to express the variability (or dispersion) in a sample. To compute the variance, the deviation of each value from the sample mean is squared. The variance of the population is equal to the sum of these values (the “sum of squares”) divided by N , but extreme values tend to be underrepresented in samples. Because of this, the sample variance is a biased estimate of the population variance, but this is corrected by dividing the sample sum of squares by $N-1$ rather than N . The variance is also the mean of the squared deviations of the variable from their mean, and is also known as the “mean squared error.” The square root of the variance is the standard deviation.

variation (L. *varius* = various) Refers to the observation that the values for a **variable** or **trait** differ from each other among the individuals in a **sample**. The quality of being subject to variation is known as **variability**. Variation within a **population** can be estimated and quantified with sample statistics such as the standard deviation, variance, or range. A homogeneous sample exhibits little variation; a heterogeneous sample exhibits substantial amounts of variation. An emphasis on the study of variation is a key feature of evolutionary biology. *See also* **variability**.

varus (L. *varus* = bent or turned in.) The term varus refers to a joint, or an angle within a bone (e.g., the neck-shaft angle of the femur), being “bent” so that the limb segment beyond the joint, or the shaft of a long bone beyond the angulation, are inclined further towards the midline than is normal. In some children with an unusually obtuse (i.e., large) neck-shaft angle, such that the femur shaft is directed away from the midline, because the knees are so far apart the lower leg appears to

be inclined towards the midline. Thus, that deformity is called genu varum. But because varus (and its antonym **valgus**) are terms that are often misunderstood (Fairbank and Fairbank 1984) their use should probably be avoided. *See also valgus.*

vault *See* cranial vault.

vector Biology A vector refers to an organism that permits the transfer of a pathogen from reservoir to host. For example, *Anopheles* mosquitoes are the vectors that transfer the protozoan parasites of the genus *Plasmodium*, which cause malaria, from reservoir to host, including modern humans. Statistical analysis A vector is a sequence of numbers written out horizontally (a row vector) or vertically (a column vector). Vectors of length two or three (i.e., vectors containing two or three numbers) are often used to represent spatial position as *XY* or *XYZ* coordinates. In kinematics, vectors of length three are used to represent the *X*, *Y*, and *Z* components of velocity, acceleration, force, etc. In statistics, vectors are used to contain a series of observations (for example, 12 measurements of body mass would be represented as a vector of length 12, with each element in the vector corresponding to one measurement of mass). One or more of these vectors may then be manipulated to produce single values (such as the mean or standard deviation) of a **matrix** (e.g., **covariance matrix**, **distance matrix**, etc.).

VEK Acronym for Vivian Evelyn (Fuchs) korongo. A locality at Olduvai Gorge where artifacts were collected in 1931. Vivian Fuchs (or Bunny as he was always called) was a Cambridge colleague of Louis **Leakey** who joined Louis and Freda Leakey on the 1931 expedition to Olduvai to look at the geology and to check on the provenance of a hominin skeleton found by Hans Reck. In 1958 then Sir Vivian Fuchs made history when he successfully completed the first crossing of the Antarctic via the South Pole. In 1962 Margaret Cropper discovered the remains of a fragmented hominin calotte, **OH 12**. *See also Olduvai Gorge.*

Velika Pećina (Location 46°17'N, 16°02'E, Croatia; etym. the words mean “reflecting cave”) History and general description A cave site near Goranec on the Ravna Gora, northwest of Ivanec. Excavations were undertaken in 1948 and again from 1957 to 1979. Temporal span and how dated?

From the last interglacial to the **Holocene**. The results of **AMS radiocarbon dating** on the hominin frontal suggest these remains are Holocene (c.5 ka BP). Hominins found at site The frontal bone of *Homo sapiens* originally thought to be **Aurignacian**, but more recently it has been found to be Holocene. Archeological evidence found at site Artifacts described as **Mousterian**. Key references: Geology, dating, and paleoenvironment Smith et al. 1999, Karavanić 2007; Hominins Smith 1976a, 1984; Archeology Karavanić and Smith 1998, Karavanić 2007.

velocity curve A device used to study patterns of individual growth, with an advantage not provided by a distance curve. That is, it illustrates the growth dynamic over the course of ontogeny. The specific velocity of growth will vary according to measurement, age, and individual. Growth velocities of various parts and organ systems of the body have been shown to exhibit asynchrony. To calculate velocities, researchers employ a range of techniques, from logistic to shape invariant models. The particular method utilized will depend on the nature of the sample, the age range that is being examined, and the frequency of measurement. The overall pattern for modern human postnatal weight and length growth includes initial rapid decreases in growth velocity throughout the first three years of life, followed by a slowing and plateauing of growth rate through to the adolescent growth spurt. A “mid-growth spurt” may or may not occur between the childhood and juvenile stages of growth. The growth velocities experienced *in utero* surpass any seen in postnatal life. Calculations of arithmetic velocity curves using cross-sectional samples of nonhuman primate mass indicate a wide range of growth velocity patterns across taxa, which vary in conjunction with socioecological factors.

Venta Micena (Location 37°43'N, 2°23'W, Spain; etym. after a nearby town) History and general description This site, one of several in the **Orce region**, comprises an 80–120 cm-thick horizontal layer, which appears in outcrops for over 2.5 km/1.5 miles. Venta Micena has provided one of the best faunal records for the **Plio-Pleistocene** (Martínez-Navarro 2002) but in relation to paleoanthropology it is best known for the debate about the identification of one specimen, VM-0. Initially VM-0 was published as a hominin cranial vault fragment, making it the oldest hominin fossil in Europe (Gibert et al. 1983). But after the specimen was cleaned two of

the original team (Agustí and Moyá-Solá 1987) argued that it was not a hominin but part of equid skull and other researchers suggested it belonged to a “juvenile female of a large ruminant species” (Martínez-Navarro 2002). Nonetheless, until his death in 2007 Gibert maintained it was hominin (Gibert et al. 1998). Temporal span and how dated? Biostratigraphic correlation to other sites in the area that have been dated using **magnetostratigraphy** indicates an early Pleistocene age (i.e., younger than 1.78 Ma). Hominins found at site No confirmed hominin fossils. Archeological evidence found at site There are several apparent **manuports**, associated with bones fractured by blows (Gibert et al. 1987), which also have microstriations probably caused by defleshing (Gibert and Jiménez 1989). Key references: Geology, dating, and paleoenvironment Gibert et al. 1983, Martínez-Navarro 2002, Oms et al. 2000; Hominins Martínez-Navarro 2002, Gibert et al. 1983, 1998, Agustí and Moyá-Solá 1987; Archeology Gibert et al. 1987, Gibert and Jiménez 1989.

Venus figurines See Gravettian; Perigordian; Hohle Fels Venus.

vertebral number (L. *verter* = to turn) The count of vertebrae is recorded as the total for the whole vertebral column [i.e., cervical (Cx), thoracic (T), lumbar (L), sacral (S), and caudal (Ca)], usually written out as the modal numbers for each of the above five regions, in the order given above (e.g., 7, 13, 4, 6, 3 for *Pan troglodytes*), or as the modal number within just one of the five regions of the vertebral column [e.g., for *P. troglodytes* lumbar (L) = 4 (range 2–5)]. Total vertebral number is precisely related to original **somite** number. All but the most **rostral** (i.e., anterior) somites (i.e., the 4.5 incorporated into the cranium) give rise to **sclerotomes** and the sclerotomes give rise to vertebrae and ribs. Each vertebra receives a contribution from two sclerotomes, its own and the one **caudal** to it (e.g., the C4 vertebra is formed from the caudal part of the C4 sclerotome and the cranial part of the C5 sclerotome). Comparisons of developing chick and mouse along with **knock-out** and **knock-in** experiments show that among the many gene systems involved in the generation, specification, and determination of somites, the *Hox* system plays a major role. The timing and duration of *Hox* **gene expression** apparently controls the number of vertebrae within

each region. Regional modal numbers of vertebrae can be combined as species-specific vertebral formulae or patterns (e.g., 7, 12, 5, 5, 4 for *Homo sapiens*). Regional vertebral number varies within as well as between species, especially in hominoids; a within-species sequence of patterns ordered by frequency is called a vertebral profile. For example, there are approximately 40 patterns in reasonably sized samples of *Pan troglodytes* (e.g., 7, 12, 5, 7, 2) and *Pongo pygmaeus* and over 20 in *Homo sapiens*, *Gorilla gorilla*, and *Hylobates lar*. In addition to different patterns, the total number of vertebrae varies within species, usually with a range of 4 or 5. In hominoids, as in almost all mammals, cervical number is effectively invariant at 7, vertebral number varies within more caudal regions, and vertebral number variation tends to be greater the further caudally you go. Of both phylogenetic and functional interest are the total numbers of thoracic plus lumbar vertebrae (documenting trunk length and degree of fore- and hindlimb separation) and their relative contributions to trunk length. For *H. sapiens*, the dominant modal pattern for thoracic and lumbar vertebrae is 12:5, whereas in the African apes it is 13:4. *P. troglodytes* and *Pan paniscus* differ on average by one vertebra (somite), half of this difference falling within the trunk region; *P. troglodytes* averages 13.1 thoracic and 3.6 lumbar vertebrae, whereas *P. paniscus* averages 13.4 thoracic and 3.8 lumbar vertebrae. Reasonably complete vertebral columns are rare in the early hominin fossil record, and they are only seen in useful numbers in *Homo neanderthalensis*; its vertebral column resembles that of *H. sapiens*. There is no consensus about whether the one *Homo erectus* and two *Australopithecus africanus* individuals that preserve at least some evidence of the vertebral column had five, or six, lumbar vertebrae (Haeusler et al. 2002). Prior to c.3 Ma the hominin fossil record is mute about the organization of the vertebral column. See also **lumbar vertebral column**.

vertebrate (L. *vertebratus* = having joints) As a noun the term refers to animals with a backbone, or spinal column, that protects their spinal cord, and as an adjective it means having a backbone and the characteristics associated with this condition. Fossil vertebrates are often preserved at archeological sites and at paleontological sites relevant to the study of human evolution. They are studied to provide an environmental context for human evolution as well as giving additional

information on the age and taphonomic processes that affected the site. Vertebrate fossils can also provide insights into hominin behavior and ecology when they can be directly related to hominin activity by virtue of cutmarks, breakage patterns, or skeletal part representation that can only be attributed to human agency.

Vértesszöllős (Location 47°41'N, 18°20'E, Hungary; etym. the name of a nearby town) History and general description A **travertine** quarry 50 km/31 miles west of Budapest and 15 km/9 miles south of the Danube. Excavations began in 1964 and the Vértesszöllős 1 hominin remains were uncovered in 1965 during sieving of the sediments excavated in 1964 from lowest cultural horizon; Vértesszöllős 2 was excavated in 1965. Temporal span and how dated? Biostratigraphy suggests an Upper Biharian age, and uranium-series dating of the travertine suggests ages of >350 ka and 225–185 ± 25 ka BP; equivalent to **Oxygen Isotope Stages** 11–6. Hominins found at site Left lower dc, dm₂, and M (Vértesszöllős 1) and much of the squamous part of an adult occipital (Vértesszöllős 2). Archeological evidence found at site **Lower Paleolithic** small-sized pebble tool industry (described as the Buda industry). Key references: Geology, dating, and paleoenvironment Schwarcz 1982, Hennig et al. 1983, Schwarcz and Latham 1984, van der Muelen 1973; Archeology Kretzoi and Vértes 1965, Vértes 1965, Svoboda 1987; Hominins Kretzoi and Vértes 1965, Vértes 1965, Thoma 1967 and 1969.

Vértesszöllős 2 Site Vértesszöllős. Locality N/A. Surface/in situ Probably *in situ*. Date of discovery August 21, 1965. Finder Excavations under the direction of L. Vértes. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Oxygen Isotope Stages** 7–6. Developmental age Adult. Presumed sex Male. Brief anatomical description Much of the squamous part of an adult occipital bone. Announcement and initial description Vértes 1965. Photographs/line drawings and metrical data Thoma 1966, 1969. Detailed anatomical description Thoma 1969. Initial taxonomic allocation *Homo* (*erectus* or *sapiens*) *palaeohungaricus*. Taxonomic revisions *Homo incertae sedis* (Hublin 1978), *Homo heidelbergensis* (Stringer 1983). Current conventional taxonomic allocation *Homo neanderthalensis*.

Informal taxonomic category Pre-modern *Homo*. Significance The Vértesszöllős occipital is one of a group of specimens (others include the hominins from Reilingen, the Sima de los Huesos, Steinheim, and Swanscombe) that is referred to *H. neanderthalensis*. Researchers who interpret *H. neanderthalensis* as an evolving lineage would interpret the Vértesszöllős occipital as an example of “Stage 2” (or perhaps “Stage 1”) in this lineage. These stages are also referred to as pre-Neanderthal and “early pre-Neanderthal” (e.g., Dean et al. 1998), respectively (see **pre-Neanderthal hypothesis**). Location of original Magyar Nemzeti Múzeum, Budapest, Hungary.

vertical climbing hypothesis See arboreal climbing hypothesis.

Vesalius, Andreas See anatomical terminology.

Veternica (Location 45°51'N, 15°53'E, Croatia) History and general description Excavations at this cave site near Gornji Stenjevec, 9 km/5.5 miles west of Zagreb, started in 1951 and lasted until 1971. Temporal span and how dated? Conventional **radio-carbon dating** and **biostratigraphy** suggest the site includes artifacts from the last interglacial to the **Holocene**. Hominins found at site A calotte belonging to *Homo sapiens* is considered to be an intrusive Mesolithic burial. Archeological evidence found at site **Mousterian**. Key references: Geology, dating, and paleoenvironment Smith 1977, Karvanić 2007; Hominins Churchill and Smith 2000; Archeology Karvanić 2007.

vicariance (L. *vicarius* = a substitute, from *vicis* = to change) Refers to the subdivision of a population or species range that results in two descendant populations separated by a biogeographic barrier. Vicariance may lead to **speciation** or extinction in one or more of the descendant populations. Vicariance is caused by fragmentation of the environment, either because a geographic barrier has developed, such as an enlarged river or a recently formed mountain chain, or because of a change in climate. The study of the role played by vicariance events in evolution is called vicariance biogeography. See also **allopatry**; **vicariance biogeography**.

vicariance biogeography (L. *vicarius* = a substitute, from *vicis* = to change, and Gk *bios* = life,

geo = earth, and *graphein* = to write) A mode of biogeographic analysis that uses **cladistic** methods to determine whether or not **vicariance** best explains the distributions of closely related taxa within multiple clades. The principle underlying the method is that because a single ecological/geological change might be expected to affect several different clades in similar ways, vicariance due to environmental or geophysical factors is more parsimonious than dispersal as an explanation of the same geographic distribution applying to several taxa. For in such circumstances in the absence of evidence for vicariance, researchers must invoke multiple independent dispersal events to explain the distribution of taxa.

vicariance event *See* vicariance.

victoriapithecoid An informal term for the Victoriapithecidae, an extinct family of Old World monkeys. *See also* Victoriapithecidae.

Victoriapithecidae (Gk *pithekos* = ape and Victoria from the East African Lake named after Queen Victoria) This extinct family of Old World monkeys is the **sister taxon** of the family **Cercopithecidae**; the two families comprise the superfamily **Cercopithecoidea**. The earliest known **victoriapithecoids** are *Prohylobates* (*c.*19–15 Ma) known from sites in North and East Africa and *Victoriapithecus* (*c.*19–12.5 Ma) known from the sites of Maboko and Fort Ternan in East Africa. Victoriapithecids and cercopithecids share a number of derived features, including the absence of a maxillary sinus, bilophodont lower molars, and ischial callosities (Benefit and McCrossin 2002). Compared to cercopithecids, victoriapithecids have a relatively lower neurocranium, a steeper and more linear facial profile, and taller orbits.

Viking Fund In 1941 Axel Wenner-Gren established the Viking Fund, Inc. (which he endowed with US\$2 million of Electrolux stock) as a means of supporting anthropology. Ten years later, in 1951, the name of the fund was changed to the Wenner-Gren Foundation for Anthropological Research, Inc. *See also* **Wenner-Gren Foundation for Anthropological Research**.

Viking Fund Medal This was introduced in 1946 by the Viking Fund but was then taken over by the **Wenner-Gren Foundation for Anthropological Research**. Medals were awarded annually

until 1961 and five awards have been made since that time. Leading paleoanthropologists who have received the medal include Franz **Weidenreich** (1946), Adolph Schultz (1948), William Gregory (1949), Hallam Movius (1949), William Straus (1952), T. Dale Stewart (1953), William **Howells** (1954), Wilfrid **LeGros Clark** (1955), Raymond **Dart** (1957), Henri Vallois (1958), Sherwood **Washburn** (1960), and Louis **Leakey** (1961). *See also* **Viking Fund**; **Wenner-Gren Foundation for Anthropological Research**.

Viking Fund Publications in Anthropology *See* **Wenner-Gren Foundation for Anthropological Research**; **Burg Wartenstein International Symposium Program**.

Viking Summer Seminars in Physical Anthropology In 1946 the **Viking Fund** introduced the Viking Summer Seminars in Physical Anthropology program. Under the leadership of Sherwood **Washburn** these seminars ran annually from 1946 to 1951, and then there was gap until the last one in 1953. The meetings helped introduce genetics and evolutionary theory to biological anthropology, and this in large measure helped determine the course of the modern subdiscipline of human origins research. Human evolution was a central theme in the summer seminars and Wilfrid **Le Gros Clark**, Raymond **Dart**, Kenneth **Oakley**, John **Robinson**, Ralph von **Koenigswald**, and Franz **Weidenreich** were among those who participated. *See also* **Viking Fund**; **Wenner-Gren Foundation for Anthropological Research**.

Villafranchian *See* European mammal neogene; biochronology.

Vindija (Location 46°17'N, 16°6'E, Croatia) History and general description A rock-shelter on the southwest side of Križnjak Peak, near Ravna Gora. The existence of the site was first noted in 1878, and excavations were conducted from 1928 to 1958 and again from 1974 to 1986. Temporal span and how dated? Uranium-series dates on the lower-level deposits are consistent with an age of *c.*114 ka BP. The hominin G3–G1 layers have been dated by a variety of methods: G3, **amino acid racemization** *c.*42 ka BP, U-Th *c.*41 ka BP, **AMS radiocarbon** >42 ka radiocarbon years BP; G1, conventional ¹⁴C on cave bear

bone (18 ka ± 400 radiocarbon years BP, AMS ¹⁴C on cave bear bone 33 ka ± 400 to 46 ka ± 2000 radiocarbon years BP, direct ultrafiltration AMS ¹⁴C on hominin bone c.32.5 ka radiocarbon years BP. Hominins found at site More than 60 hominin specimens associated with **Mousterian** artefacts and identified as *Homo neanderthalensis* (levels G3 and G1). Specimen Vi-80 (33.16) from level G3 has yielded extremely well-preserved **mitochondrial DNA** and nuclear DNA; the 45 specimens associated with Epigravettian artefacts are identified as *Homo sapiens*. Archaeological evidence found at site The artefacts are Late Mousterian or Mousterian in levels G3 and G2. The stratigraphic integrity of the G1 assemblage is disputed: it preserves Mousterian as well as some **Aurignacian**-like stone and bone tools, but some argue that the latter are intrusive from higher levels. Geology and dating Ahern et al. 2004, Higham et al. 2006, Karavanić 2007; Hominins Wolpoff et al. 1981, Smith et al. 1985, Ahern et al. 2004, Green et al. 2006, 2008; Archaeology Karavanić and Smith 1998, Karavanić 2007. Significance The Neanderthal fossil remains from levels G1 and G3 have consistently been argued to show cranial features [e.g., reduced facial (especially nasal and alveolar process) size, reduced supraorbital tori (including greater mid-orbital thinning), more vertical mandibular symphyses and an incipient mentum osseum] that set them apart from most other Neanderthals. Originally these were interpreted as evidence of an ancestral relationship between Neanderthals and early modern Europeans (Wolpoff et al. 1981, Smith and Ranyard 1980, Smith 1984), but others suggested the differences may be due to the unusually high proportion of subadult and generally small individuals in the Vindija sample, but apparently the Vindija people are of average body size for Neandertals (Trinkaus and Smith 1995). More recently, it has been claimed that the Vindija fossils sample a population that is an admixture of Neanderthals and early modern human populations entering Europe (Smith et al. 2005, Cartmill and Smith 2009).

virulence Refers to the ability of a pathogen to cause disease.

viscerocranium (L. *viscus* = organ and Gk *kranion* = brain case) More or less equivalent to the **face**, this is the part of the **cranium** that covers the anterior aspect of the **brain**. One scheme for subdividing the cranium draws a distinction between

the **neurocranium** and the viscerocranium. The viscerocranium develops from a combination of the frontonasal process and the first pharyngeal arch; all of its components include cells that derive from the **neural crest**.

Visogliano (Location 13°38'53"N, 45°43'29"E, Italy; etym. named after the nearby town) History and general description This rock-shelter in north-east Italy, near Trieste, was first explored in the early 1970s and excavations have continued off and on to the present day. **Paleolithic** sequences that contain some of the oldest hominin remains in Europe have been found in two distinct areas at the site: a rock-shelter (Unit A) and a nearby, chronologically older, breccia (Unit B). Temporal span and how dated? **Electron spin resonance spectroscopy dating** and **uranium-series dating** suggest that Unit B is c.350–500 ka; Unit A is slightly younger. Hominins found at site Six hominin specimens have been recovered from the site: Unit A yielded Visogliano 3, 4, 5, and 6, whereas Unit B yielded Visogliano 1 and 2. The specimens consist of isolated dental material, except for Visogliano 2, which is a fragmentary mandible. The remains have been assessed as showing characteristics of both *Homo erectus* and archaic *Homo heidelbergensis*. Archaeological evidence found at site The upper layers in the rock-shelter have a flake-based tool technology similar to the Tayacian. The lower rock-shelter layers and the breccia have a variant of the **Acheulean** known as the “Italian Pebble Culture” that includes a high percentage of **choppers** and chopping tools but few **handaxes**. Key references: Geology, dating, and paleoenvironment Falguères et al. 2008; Hominins Cattani et al. 1991, Abbazzi et al. 2000; Archaeology Cattani et al. 1991, Abbazzi et al. 2000.

visor See facial visor.

visual cortex See striate cortex.

vitric tuff (L. *vitrium* = glass) A deposit of **pyroclastic** material erupted from a volcano, in which the majority of the particles are of the non-crystalline glass form of ash. Vitric tuffs are central to the geochemical correlation of individual volcanic eruptions, and their correlation potential has been used to relate the products of the same eruption in volcanic-rich deposits (e.g., the **Omo Group** of

the **Turkana Basin**). A distinctive “geochemical fingerprint” is preserved in vitric tuffs because the glass phase of the ash is not constrained by the rigid chemical formulae of the mineral phases; thus glass preserves a unique subsample of magma chemistry at the time of an eruption.

Viverridae The family that includes civets and their close relatives is one of the carnivore families whose members are found at some hominin sites. *See also* **Carnivora**.

viverrids Informal name for the **Viverridae** (civets and their relatives), one of the carnivore families whose members are found at some hominin sites. *See also* **Carnivora**.

VNTR Acronym for **variable number of tandem repeats** (*which see*).

vocal (L. *vocalis* = voice) A sound that has to be made by an organism (aka vocalization). A beaten drum makes a sound, but it is not a vocal sound. *See also* **language**; **speech**.

vocal imitation *See* **imitation**.

Vogel River Series *See* **Laetoli**.

Vögelherd Location 48°33'31N, 10°11'37E, Germany; etym. Ge. *vögel* = birds, *herd* = hearth or oven) **History and general description** This cave site along the Lone River is located roughly 1 km/0.6 miles north of Stetten ob Lonetal, just upstream of **Höhlenstein-Stadel**. The site was excavated in the 1930s by G. Riek, who found several layers of archaeological material and some human fossils. The anatomically modern human remains were thought to have been found in an **Aurignacian** context, therefore making them some of the oldest in Europe, but direct dating has suggested a more recent date. The site is best known for several ivory and bone sculptures from the Aurignacian levels, mostly of animals, including a horse, a mammoth, and a feline. **Temporal span and how dated?** The site contains layers ranging from the **Middle Pleistocene** to historic period based on stratigraphic analysis. The hominin remains were directly dated using **AMS radiocarbon dating** to 3.9–5 ka (uncalibrated), indicating that they are intrusive. **Hominins found at site** Several numbered human remains attributed

to *Homo sapiens* were recovered: Vögelherd 1 (Stetten 1), an incomplete cranium, partial mandible, two lumbar vertebrae; Vögelherd 2 (Stetten 2), a partial cranium, and Vögelherd 3 (Stetten 3), a partial right humerus. **Archaeological evidence found at site** Stone tools from most periods from the **Mousterian** to the Neolithic were found in the several layers at the site. Key references: **Geology, dating, and paleoenvironment** Müller-Beck 1983, Conard et al. 2004; **Archeology** Riek 1934, Müller-Beck 1983; **Hominins** Gieseler 1971, Churchill and Smith 2000.

voice (L. *vox* = voice) In modern humans it is the sound made when expired air causes the vocal cords to vibrate as in the production of spoken language.

volar (L. *vola* = the sole of the foot, or the palm of the hand) The volar surface refers to the inferior surface, or sole, of the foot and the anterior surface, or palm, of the hand. A movement in the volar direction is a movement that in modern humans takes a finger or thumb towards the palm of the hand. The direction of one of the two main curvatures on the distal articular surface of the trapezium that articulates with the proximal articular surface at the base of the first metacarpal is described as being “dorsovolar” (Marzke et al. 2009).

volcanic ash correlation *See* **tephrochronology**; **tephrostratigraphy**.

von Ebner’s lines **Short-period incremental lines** in **dentine** first described by Victor von Ebner (1902). They appear in predentine as well as dentine and may be spherical (calcospheretic), crescentic, or laminar in appearance. Close to the root surface, where there are few dentine tubules, they appear to intersect tubules at all angles but they become aligned at approximate right angles to the tubules deeper into dentine. von Ebner’s lines reflect the 24 hour (or **circadian**) cycle of **odontoblast** secretory activity (Bromage 1991) and they are equivalent to **cross-striations** in **enamel**. These are illustrated in Bromage (1991), Dean (1998), and Smith (2006). *See also* **dentine development**; **incremental features**.

von Economo neurons (etym. Named after Constantin von Economo, the neuroanatomist who

described them in 1926) A specialized class of projection neuron found in high densities within the **anterior cingulate cortex** and fronto-insular cerebral cortex of great apes and modern humans, but not in other primates. These neurons have a large, spindle-shaped cell body, with a distinctive thick, single basal dendrite in addition to its apical dendrite. von Economo neurons are found in brain areas involved in monitoring social information and feedback regarding internal body states and therefore might play a role in the evolution of specializations for social cognition, particularly self-awareness. von Economo neurons have also been documented in similar cortical areas in elephants and certain whales, suggesting that there may have been convergent evolution of neural circuits that appear to be implicated in complex social cognition.

von Koenigswald Collection The von Koenigswald Collection comprises the hominin and other fossils from **Sangiran** that **Ralph von Koenigswald** collected after the Dutch Geological Survey in Java stopped supporting his research. The collection includes three fragmentary hominin crania (**Sangiran 2, 3, and 4**), six hominin mandibular fragments (**Sangiran 1a, 4, 5, 6a, 6b, and 6c**), and 52 hominin isolated teeth (**Sangiran 7**). It includes the holotypes of *Pithecanthropus dubius*, *Meganthropus palaeojavanicus*, *Hemanthropus peii*, *Sinanthropus officinalis*, *Gigantopithecus blacki*, and *Chinjipthecus atavus*. See also **Senckenberg Forschungsinstitut und Naturmuseum**.

von Koenigswald, Gustav Heinrich Ralph (1902–82) Ralph von Koenigswald was born in Berlin, Germany, and studied geology and paleontology at the Universities of Berlin, Tübingen, and Cologne before completing his doctorate at the University of Munich in 1928. After his graduation he worked at the Bayerische Staatssammlung für Paläontologie (Bavarian State Collection for Paleontology) in Munich, but in 1930 he accepted a position in the Dutch East Indies as a paleontologist with the Dutch Geological Survey in Java. His tasks in Java were to produce a stratigraphic map and to work on the **Pleistocene** mammals, but what drew von Koenigswald to Java was the prospect of discovering more hominins like *Pithecanthropus erectus* (now called *Homo erectus*) recovered by the Dutch anatomist Eugène **Dubois** in the 1890s. In 1931–2 **Cornelius ter Haar** and a

team of surveyors recovered 11 hominin calvaria from **Ngandong** in central Java, and von Koenigswald published a description of the fossils in 1933. A year later the Geological Survey's budget was cut and von Koenigswald lost his salary but he opted to remain in Java to continue his search for fossil hominins. The French prehistorian **Teilhard de Chardin** (who had participated in the excavations at **Zhoukoudian** in China where *Sinanthropus pekinensis* had been discovered) visited Java in 1935 and recognizing the potential of von Koenigswald's field program he arranged funding for it through the Carnegie Institution in Washington DC. A year later von Koenigswald found a child's calvaria at **Modjokerto** (now called **Mojokerto**) in eastern Java and he assigned the specimen to a novel species *Homo modjokertensis*. In 1937 a hominin upper jaw fragment was discovered near the village of **Sangiran** and this was soon followed by the recovery of part of the calvaria of the same cranium; von Koenigswald assigned these fossils to *Pithecanthropus*. Fragments of another cranium were found at Sangiran in 1938 while the German anatomist **Franz Weidenreich** was visiting. Weidenreich had taken over the primary responsibility for the excavations at Zhoukoudian in China after the death of **Davidson Black**. In 1938 von Koenigswald traveled to Beijing to compare the *Pithecanthropus* specimens from Java with the *Sinanthropus* specimens. Weidenreich and von Koenigswald concluded the *Pithecanthropus* and *Sinanthropus* were so similar that they represented geographical variants of a hominin "at the same stage of evolutionary development." Another mandible belonging to *Pithecanthropus* was discovered at Sangiran in 1939, followed in 1941 by a fragment of a large hominin mandible that von Koenigswald assigned to a new genus and species, *Meganthropus palaeojavanicus*. The Japanese invasion of Java brought von Koenigswald's excavations to an end and he was interned in a prisoner of war camp by the Japanese from 1942 to 1945, but he and his wife managed to hide the fossils from his captors. In 1946 von Koenigswald, together with the fossils and his family, traveled to New York where he joined **Franz Weidenreich** at the **American Museum of Natural History**. The two men continued their work on the Chinese and Javan hominins until 1948 when von Koenigswald left to become Professor of Paleontology at the Rijksuniversiteit in Utrecht, The Netherlands. In the 1950s von Koenigswald published on

Gigantopithecus, a giant Pleistocene ape whose remains were found in China by Davidson Black in 1935, and on *Meganthropus*, both of which figured prominently in Franz Weidenreich's theories about how modern humans had evolved from giant apes. von Koenigswald also traveled to southern Africa to inspect the australopith fossils found by Raymond **Dart** and Robert **Broom** and he collaborated then and later with Phillip **Tobias** to compare the hominin fossils discovered in **Olduvai Gorge** with the fossils from Java. During the last decades of his life von Koenigswald worked to encourage the Indonesian researchers and insti-

tutions (Teuku **Jacob** was one of his students) and in 1979 he returned the hominins found at Modjokerto and Ngandong to Indonesia. von Koenigswald retired from his position at the Rijksuniversiteit in 1968 and returned to Germany (along with that part of the Sangiran Collection that was collected after his support from the Dutch Geological Survey in Java had lapsed) to re-establish a center for paleoanthropological research at the **Senckenberg Forschungsinstitut und Naturmuseum** in Frankfurt.

voxel *See* computed tomography.

W

W. Prefix used by the American contingent of the **International Omo Research Expedition** for localities in the **White Sands** group of exposures in the **Usno Formation** (e.g., W. 7). The prefix is also used for fossils found in one of those localities (e.g., W. 7-23).

Wadi Dagadlé (Location not reported, Djibouti; etym. unknown) History and general description Wadi Dagadlé (Oued Dagadlé) is one of several **Plio-Pleistocene** vertebrate and archeological localities prospected by de Bonis and colleagues in 1983. Temporal span and how dated? **Biostratigraphy** suggests the fauna is **Early** to late **Middle Pleistocene**; the **uranium-series dating** ages are problematic but suggest an age of less than 250 ka. Hominins found at site Left maxilla with a fragment P^4-M^3 and a fragment of P^3 . The tooth crowns are large but display a marked diminution in size from M^1-M^3 . The maxilla shows a slight degree of prognathism. Archeological evidence found at site None. Key references: Geology, dating, paleoenvironment, and hominins de Bonis et al. 1984; Archeology N/A.

Wadi el-Mughara (etym. Ar. for the “valley of caves”) The Arabic name for a river valley in Israel, where Dorothy **Garrod** and her team excavated the sites of **el-Wad**, **Skhul**, and **Tabun**. The area is known in Hebrew as *Nahal Me’arot*. See also **Mount Carmel**.

Wadi Halfa (Location 21°57'N, 31°20'E, Sudan; etym. Ar. “valley of Halfa,” named after the nearby town) History and general description A site excavated in 1963-4 by the University of Colorado’s Nubian Expedition during rescue archeology preceding the construction of the Aswan Dam, Wadi Halfa is a terminal **Pleistocene** cemetery containing 36 burials. Temporal span and how dated? Associated Qadan cultural material suggests an age of *c.* 10-14 ka. Hominins found at site Thirty-seven skeletons comprising 13 adult males, 15 adult females, and three juveniles.

The remains closely resemble those from **Jebel Sahaba (Site 117)**. Archeological evidence found at site Qadan (i.e., **Late Stone Age**) lithics. Key references: Geology, dating, and paleoenvironment Hewes et al. 1964, Saxe 1966, 1971; Hominins Armelagos 1964, Greene 1967, Greene and Armelagos 1972, Carlson 1976, Carlson and Van Gerven 1977, Armelagos et al. 1984, Calcagno 1986, Turner and Markowitz 1990, Irish and Turner 1990, Irish 2005; Archeology Saxe 1971.

Wadi Kubbania (Location 24°13'N, 32°51'E, Egypt; etym. unknown) History and general description Fred Wendorf and colleagues found a human fossil in an area with several rich archeological sites along the left bank of the Nile. Temporal span and how dated? The skeleton probably dates to some time prior to the deposition of the Nile silts which cover the coarse laminated sands in the area (i.e., prior to *c.* 20 ka), but subsequent to the development of **bladelet** technology. Hominins found at site The skeleton of a young male (*c.* 20-25 years) was found embedded in a calcareous matrix. The sum of the traits exhibited by the Wadi Kubbania skeleton place it in the **Jebel Sahaba (Site 117)** group. There is evidence of healed injuries and a lesion in the vertebral column. It is curated at the Aswan Museum, Egypt. Archeological evidence found at site The several archeological sites preserved evidence of a heavy use of Nilotic resources, including a reliance on fish and waterfowl, and on starchy plant foods like sedge **underground storage organs**. Key references: Geology, dating, and paleoenvironment Wendorf et al. 1989; Hominins Wendorf and Schild 1986, Stewart and Tiffany 1986, Angel and Kelley 1986; Archeology Wendorf et al. 1989.

Wadi Tushka (Location 22°30'N, 31°45'E, Egypt; etym. Ar. *wadi* = valley, *Tushka* = after nearby village) History and general description This site was discovered by J. Hester and

P. Hoebler under the direction of Fred Wendorf in 1965; excavations were conducted between 1965 and 1966. It is located 3.5 km/2 miles northwest of the abandoned village of Tushka on the western side of the Nile River; elevation is 140 m above sea level. The site comprises two main rock units: the Ballana Formation and the overlying Sahaba Formation; the Ballana consists of lacustrine and eolian silt and sand and the Sahaba of fluvial silt. Temporal span and how dated? Upper Pleistocene (i.e., 18–10 ka) on the basis of radiocarbon dating of charcoal and shell. Hominins found at site Nineteen *Homo sapiens* burials (one infant and 18 adults); two of the latter were identified as males and three as females. Archeological evidence found at site Stone tools belong to the Qadan Industry (around 11,000 artifacts), more than 100 hearths delineated by fire-cracked rocks with associated fish and ungulate bones, grinding stones, and a few examples of worked bone and egg shell. Key references: Geology, dating, and paleoenvironment Wendorf 1968b; Hominins Wendorf 1968b; Archeology Wendorf 1968b.

Wadjak (Location 8°06'S, 112°02'E, Indonesia; etym. named after a local village) History and general description Two modern human crania and various fragmentary specimens were discovered 30 km/19 miles south of Kediri, East Java, in 1889–90 by Eugène Dubois and B.D. van Rietschoten. Temporal span and how dated? Late Upper Pleistocene or **Holocene** faunal association. Hominin found at site Wajak 1 is an adult female cranium; Wajak 2 is a partial adult male cranium. Both are attributed to modern *Homo sapiens*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment von Koensigwald 1956; Hominins Dubois 1921.

Walker, Alan (1938–) Alan Walker was born in Leicester, England, and although he considered attending art school, he eventually decided to study zoology, geology, and paleontology at Cambridge University. He received his BA with honors in the natural sciences from Cambridge in 1962 and then entered the University of London to study anatomy and paleontology as one of John Napier's graduate students. Walker completed his PhD at the University

of London in 1967 and his dissertation, *Locomotor Adaptations in Living and Extinct Madagascan Lemurs*, reflected his developing interest in primate evolution and primate locomotion. Walker accepted a position at Makerere University College in Kampala, Uganda, where he was a lecturer in anatomy from 1965 to 1969, and from 1967 to 1969 he also served as Honorary Keeper of Palaeontology at the Uganda Museum. In 1969 Walker left Uganda for Nairobi where he was a lecturer in anatomy at the University of Nairobi until 1973. During these years in Africa Walker continued to study living primates and also conducted research on fossil primates. In 1970 he was brought into the research team being assembled by Richard Leakey and Glynn Isaac as part of the **East Rudolf Research Project** (renamed the **Koobi Fora Research Project** in 1975), which led to a long association between Walker and Leakey. Walker worked with Leakey and anatomists Michael Day and Bernard Wood to investigate the hominin remains that were being discovered at **East Rudolf** (now **East Turkana**) during the 1970s. Walker, along with Meave Leakey, reconstructed the **KNM-ER 1470** cranium that was discovered in 1972 by Bernard Ngeneo at **Koobi Fora**. In 1976 Leakey and Walker announced the discovery of a nearly complete cranium of a hominin (designated **KNM-ER 3733**) that they suggested represented evidence of *Homo erectus* at *c.*1.8Ma. Since fossils belonging to *Paranthropus boisei* had been found in deposits of about the same age, Leakey and Walker suggested the discovery of **KNM-ER 3733** falsified the **single-species hypothesis**. In 1974 Walker was appointed as a Professor of Anatomy at the Harvard University Medical School and Professor of Anthropology at Harvard University, positions he held until 1978. In 1978 Walker accepted a position as Professor of Cell Biology and Anatomy at the Johns Hopkins University School of Medicine, where he remained until 1995, when he was appointed Professor of Anthropology and Biology at Pennsylvania State University. Throughout the 1980s Walker remained an active member of the Koobi Fora Research Project, although he also worked on other projects relating to primate and human evolution. He published a number of papers re-examining the *Proconsul africanus* fossils discovered by Mary Leakey on Rusinga Island in Lake Victoria in 1948, as well as describing new *Proconsul* fossils found in Kenya. This research was described in *The Ape in the Tree: An Intellectual & Natural History of Proconsul* (2005), which Walker coauthored with his wife Pat Shipman. When Kamoya Kimeu, a member of the

Koobi Fora research team, found the nearly complete skeleton of a hominin at **Nariokotome, West Turkana**, in 1984, Walker was one of the lead investigators that studied the skeleton. Leakey and Walker concluded that **KNM-WT 15000** was one of the oldest and most complete *H. erectus* fossils known, and the results of an extensive study of the remains entitled *The Nariokotome Homo erectus Skeleton* was published in 1993. Walker was also involved in the discovery and analysis of the **KNM-WT 17000** cranium and between 1994 and 1997 Walker worked with Meave Leakey and others on the *Australopithecus anamensis* fossils found at **Kanapoi** in northern Kenya. Walker was elected a Fellow of the Royal Society in 1999 and retired from teaching in 2010.

Walker circulation In the tropical Pacific, Sir Gilbert Walker first noted the anomalous longitudinal (or zonal) circulation that is associated with the **Southern Oscillation Index**. Normal tropical circulation is a cross-latitudinal (or meridional) equator-ward flow of the trade winds feeding the **intertropical convergence zone**, and is part of the **Hadley circulation**. The Walker circulation (also known as the Walker cell) sets up the sea-surface temperature gradient in the tropical Pacific associated with the La Niña phase of the El Niño Southern Oscillation. *See also* **El Niño Southern Oscillation**.

walking *See* **foot function**; **gait**; **walking cycle**.

walking cycle A walking (or gait) cycle describes the movements, distance covered, and time elapsed during one stride [from the initial substrate contact of one foot through to substrate contact of that same (or ipsilateral) foot]. The beginning of the walking cycle (conventionally 0%) is initiated with heel strike of a single foot, at which time that foot is in contact with the ground for the roughly 60% of the gait cycle, known as the stance phase. Toe-off, or **push-off**, initiates the swing phase, which comprises the remaining 40% of the walking cycle. During the stance phase the center of gravity starts low, rises to its highest point in the middle of stance phase, and falls again at toe-off. At two points during the walking cycle, the opposite (contralateral) foot is in stance phase at the same time as the ipsilateral foot; this is known as the double stance phase. The first occurs from 0% to approximately 10% of the walking cycle, and the second occurs prior to toe-off, in which heel contact has

occurred with the opposite (contralateral) foot (approximately 50–60% of the walking cycle).

Wallace's Line The western boundary of Wallacea. *See* **Wallacea**.

Wallacea The region in Southeast Asia/Australasia where Alfred Russel Wallace showed that the fauna is transitional (i.e., it is neither Southeast Asian nor Australian). Its western boundary is Wallace's Line, which runs between Bali and Lombok in the south then northwards between the eastern edge of the **Sunda** continental land mass (i.e., Borneo) to the west and Kalimantan and Sulawesi to the east. The eastern boundary of Wallacea, also called Lydekker's Line, is the northwestern edge of **Sahul** (i.e., Wallacea excludes the New Guinea and the Aru Islands). Wallacea includes islands such as Sulawesi and the Lesser Sunda Islands (e.g., Flores, Lombok).

Warendorf (Location 51°57'21"N, 7°57'08"E, Germany; etym. named after a nearby town) History and general description Hominin remains uncovered in layers of silt and gravels in the 1990s have been attributed to *Homo neanderthalensis*. Temporal span and how dated? The finds have no secure context, but the excavators believe the hominin remains date a Weichselian interstadial (c.70–40 ka) based on geological correlation, lithic typology, and faunal analysis. Hominins found at site Incomplete right parietal that has been suggested to be identical to **La Chapelle-aux-Saints** and **Neanderthal 1**. Archeological evidence found at site **Middle Paleolithic** assemblage attributed to the Keilmessergruppen technocomplex. Key references: Geology, dating, and paleoenvironment Street et al 2006; Archeology Czarnetzki and Trelliso-Carreno 1999; Hominins Czarnetzki and Trelliso-Carreno 1999.

warp (ME *warpen* = to twist, so to twist or bend out of shape) A warp is a representation of the differences in the coordinates of landmarks or semilandmarks between two objects of interest. *See also* **transformation grids**.

warthog The vernacular name for the taxa within the genus *Phacochoerus*. *See also* **Suidae**.

Washburn, Sherwood Larned (1911–2002) Sherwood Washburn, who was born in Cambridge, Massachusetts, USA, attended Groton

School from 1926 to 1931, where he took a special interest in the natural history collections housed in the Groton Museum, and during school vacations he worked at the Museum of Comparative Anatomy at Harvard University. Washburn entered Harvard University in 1931 intending to study zoology, but, after taking a course in anthropology with Alfred Tozzer, he switched to anthropology. He completed his BA in anthropology in 1935 and continued his graduate studies in anthropology at Harvard with Ernest Hooton. Washburn joined the Asiatic Primate Expedition in 1937, where he assisted Johns Hopkins University primate morphologist Adolph Schultz preparing primate skeletons, and was also influenced by another member of the expedition, Ray Carpenter of Columbia University, who was observing gibbon behavior. While in graduate school Washburn studied comparative anatomy and vertebrate paleontology, including a term spent at Oxford University with anatomist Wilfrid Le Gros Clark. Washburn became increasingly interested in primate evolution, and this was reflected in his Harvard PhD dissertation entitled *A Preliminary Metrical Study of the Skeleton of Langurs and Macaques*, which he completed in 1940. The year before he had been appointed a Professor of Anatomy at Columbia University and had begun to conduct experimental research into primate, including human, evolution. At Columbia Washburn became associated with a group of prominent scientists, including the Russian geneticist Theodosius Dobzhansky, who also taught at Columbia, William King Gregory and George Gaylord Simpson, both of whom were paleontologists at the American Museum of Natural History, and Paul Fejos of the **Viking Fund** (later the **Wenner-Gren Foundation for Anthropological Research**). Washburn left Columbia University in 1947 to accept a position as Professor of Anthropology at the University of Chicago. In 1948 he received a grant from the Viking Fund to travel to Africa where he studied monkeys in Uganda, and in South Africa he inspected the **australopith** fossils discovered by Raymond Dart and Robert Broom. In 1950 Washburn and Theodosius Dobzhansky organized a symposium on the “Origin and Evolution of Man” held at the Cold Spring Harbor Biological Laboratory, which served to bring new ideas from the **modern evolutionary synthesis** into the study of human evolution. Washburn was also involved, with Sol Tax and Alfred Kroeber, in organizing a conference held in New York City in 1952 on the topic of “Anthropology Today,” also sponsored by the

Wenner-Gren Foundation. At both conferences Washburn presented papers intended to bring about the modernization of physical anthropology. Washburn had published his manifesto in a groundbreaking paper entitled “The new physical anthropology” in the *Transactions of the New York Academy of Sciences* in 1951. In it he urged that physical anthropologists abandon the use of anthropometry and craniometry and their focus on racial classification, and instead stress the importance of evolutionary biology, population genetics, and an appreciation of variation among modern human and extant higher primate populations. In 1955 Washburn made his second trip to Africa to attend the **Third Pan-African Congress on Prehistory and Quaternary Studies**, held in Livingstone, Northern Rhodesia (now Zambia). While there he took the opportunity to study baboon behavior at a game reserve near Lake Victoria. This strengthened Washburn’s interest in the study of living primates as a means of understanding early hominin behavior, and he contributed a paper on this subject at a conference on “Evolution and Behavior” held in 1955. In 1959 he organized a conference on “The Social Life of Early Man” sponsored by the Wenner-Gren Foundation. It brought together scientists from various disciplines to discuss the relevance of studies of primate behavior, archeology, and cultural anthropology to the problem of the reconstruction of early hominin behavior. In the midst of all of this activity Washburn left the University of Chicago in 1958 to accept a position as Professor of Anthropology at the University of California at Berkeley when its anthropology department was beginning to develop into an influential center of paleoanthropological research. He continued to promote the study of primate behavior and issues related to human evolution, and he became interested in the role of hunting in the evolution of human culture. In 1961 Washburn organized yet another conference sponsored by the Wenner-Gren Foundation, this time on the subject of “Classification and Human Evolution,” which not only discussed primate studies and human evolution but also introduced the new developments in molecular anthropology. Washburn wrote widely on the subjects of primate behavior, human evolution, and the concept of “race” during the 1960s and 1970s, and his courses at the University of California, Berkeley, influenced a large number of students. He was instrumental in encouraging primate studies, which have contributed significantly to contemporary theories of human evolution, and in

establishing primate research facilities in the USA. Washburn retired from teaching in 1979.

WCFP Acronym for the West Coast Fossil Park. See **Langebaanweg**; **West Coast Fossil Park**.

weaning See **age at weaning**.

wear facets See **tooth wear**.

Weibull hazard model A general “failure” model that has a number of applications in demography. The model was first put forward in the late 1930s by Waloddi Weibull and published in its fullest form in 1951. In the Weibull hazard model the hazard of death at exact age t is $h(t) = \frac{\beta}{\alpha} (\frac{t}{\alpha})^{(\beta-1)}$ and the **survivorship** to exact age t is $s(t) = \exp(-(\frac{t}{\alpha})^\beta)$. The probability density function for age at death is, as in all hazard models, the product of the hazard and the survivorship. The log/log scale (both the hazard and age measured on a logarithmic scale) is particularly useful because the produced plot of log hazard against log age forms a straight line (see Weiss 1990). Although the Weibull is often used to represent immature mortality, in the **Siler hazard model** the Weibull’s potential role is taken by a **negative Gompertz hazard model**. This is necessary because the Weibull survivorship function reaches zero at very advanced ages, whereas the negative Gompertz model’s survivorship does not. The Weibull has also been used to represent other distributions in human biology, such as the post-partum time interval to initiation of breastfeeding (Holman and Grimes 2003) and the length of post-partum amenorrhea (Holman et al. 2006).

Weidenreich, Franz (1873–1948) Franz Weidenreich was born in Edenkoben in the Palatinate, Germany. He entered university in 1893 to study medicine, first in Munich and then at Kiel and Berlin; Weidenreich’s doctoral thesis on the central nucleus of the human cerebellum was completed in 1899 at Strasbourg. For the next 2 years he worked with the German anatomist and anthropologist Gustav **Schwalbe** on human anatomy and physiology, focusing on the spleen and milk secretion. After working briefly with the German immunologist Paul Ehrlich in Frankfurt, Weidenreich returned to Strasbourg as Professor of Anatomy. There, between 1902 and 1914, Weidenreich’s research interests included hematology

and histology, the human chin, and the morphology of the pelvis in primates and its relationship to upright posture and bipedal locomotion. Weidenreich’s scientific work stopped during WWI and after the German defeat in 1918 Weidenreich was dismissed from his Professorship at Strasbourg. In 1919 he left for Heidelberg and in 1921 he was appointed Professor of Anatomy at the University of Heidelberg. The move to Heidelberg marked a shift in Weidenreich’s research. He published a lengthy paper on evolution and development in 1920, and another substantial paper on the anatomy of the human foot in 1921. His interests turned to the human skeleton, and in 1925 he published a report on a human skull excavated in Weimar-Ehringsdorf. In *Rasse und Körperbau (Race and Bodily Structure)* (1927) Weidenreich analyzed human racial variation from the perspective of evolutionary theory and he later criticized the politicization of race by the Nazi party. These studies resulted in Weidenreich being appointed Professor of Physical Anthropology at the Johann Wolfgang Goethe University in Frankfurt in 1928. Thereafter, Weidenreich increasingly focused his research upon human paleontology and prepared an exhibition at the Senckenberg Natural History Museum outlining the stages of human evolution. However, Weidenreich’s book on race and his own Jewish background made it increasingly difficult to remain in Germany and he was dismissed from his position at Frankfurt in 1933. The University of Chicago offered him a position as Professor of Anatomy soon thereafter and Weidenreich taught briefly at the university but in 1935 he accepted an invitation from the Rockefeller Foundation to replace the recently deceased Davidson **Black** as Professor of Anatomy at the **Peking Union Medical College** and Honorary Director of the **Cenozoic Research Laboratory**. This placed Weidenreich at the center of the remarkably productive excavations at **Zhoukoudian** (formerly Choukoutien) that had already produced several *Sinanthropus pekinensis* (now called *Homo erectus*) specimens. The quantity and variety of skeletal material belonging to *Sinanthropus* meant that in addition to describing individual fossils Weidenreich could also conduct comparative studies of the material. He published an extensive account of *Sinanthropus* in an article titled “The *Sinanthropus* population of Choukoutien (Locality 1) with a preliminary report on new discoveries” in the *Bulletin of the Geological Society of China* in 1935. In 1936 Weidenreich published a comparative study of endocranial casts of *Sinanthropus*, comparing them to other hominins and the great apes. This was

followed by a comparative study of *Sinanthropus* mandibles in 1936, and similarly comprehensive monographic studies of the dentition (1937), the extremity bones (1941), and the crania (1943) followed. Between 1935 and 1937 excavations at Zhoukoudian, conducted primarily by Wenzhong Pei and a team of Chinese colleagues, resulted in the recovery of several more calvaria and other skeletal material that expanded the already impressive quantity of material housed at the Cenozoic Research Laboratory. The Japanese invasion of China made excavations at Zhoukoudian impossible by 1937 and the following year Weidenreich accepted invitations to travel in Europe and America. After presenting the evidence for *Sinanthropus* at an anthropological congress held in Copenhagen, Weidenreich traveled to The Netherlands to visit Eugène Dubois, who in the 1890s had discovered *Pithecanthropus erectus* (now *Homo erectus*) on the island of Java, and to inspect the *Pithecanthropus* specimen. From Europe, Weidenreich then traveled to Java where he met with the German paleontologist Ralph von Koenigswald, who had found further *Pithecanthropus* fossils. This meeting led to von Koenigswald traveling to Beijing in 1939 where he and Weidenreich compared the *Pithecanthropus* remains from Java with the *Sinanthropus* material from China. They concluded that the two hominins were so similar in morphology as to belong to the same stage of human evolution, the differences between them indicating no more than geographical variation. Weidenreich remained in China until 1941, but as conditions worsened he made plans to leave the country and return to the USA. Before leaving China Weidenreich and the Chinese staff of the Cenozoic Research Laboratory prepared casts of the major *Sinanthropus* fossils and all the material was photographed. It was believed that the fossils themselves were in danger of being captured by the Japanese so arrangements were made for them to be packed in crates and sent to America with a contingent of American Marines leaving China, but along the way the fossils were lost and have never been recovered. Weidenreich obtained a position at the **American Museum of Natural History** in New York City, where he remained for the rest of his career. It was during this period that Weidenreich proposed his polycentric theory of human evolution. In this theory, based in part upon his comparisons of *Sinanthropus* and *Pithecanthropus* and upon modern geographical variation in modern humans, Weidenreich suggested that *Sinanthropus* and *Pithecanthropus*

had evolved in parallel, one group in China and the other in Java. In 1945 Weidenreich proposed a theory of human origins that suggested hominins and modern humans had evolved from *Gigantopithecus*, a giant ape discovered in 1935 but not described by von Koenigswald until 1952. Weidenreich elaborated on his theory in *Apes, Giants, and Humans*, published in 1946, and embarked on a monograph the *Morphology of Solo Man*; this remained unfinished at his death and it was published posthumously in 1951. See also **multiregional hypothesis**.

Weimar-Ehringsdorf See Ehringsdorf.

Weiner, Joseph See Piltown.

Weiss' model life tables A series of model life tables published in 1973 by Kenneth M. Weiss and based on census data from "anthropological" samples as well as life tables from archeologically recovered skeletal samples. These model life tables are often seen as a useful contrast to the **Coale and Demeny model life tables** which were based on large historical census data sets. Weiss' models are keyed by **life expectancy** at age 15 (a measure of adult mortality) and **survivorship** to age 15 (a measure of juvenile mortality). He combined life expectancies at age 15 of 15.0, 20.0, 22.5, 25.0, 27.5, 30.0, 32.5, and 35.0 years with survivorships to age 15 (based on a radix of 100) of 30, 35, 40, 45, 50, 55, 60, 65, and 70 to obtain 72 model life tables. The highest-mortality model [using Weiss' notation where "MT" stands for model tables; e.g., MT:22.5-30 refers to a model life table with a life expectancy of 22.5 years at age 15 and a survivorship of 30 (out of a radix of 100) at age 15] is MT:15.0-30.0, which has a life expectancy at age 15 of only 15 more years and survivorship to age 15 of only 30%. The lowest-mortality model is MT:35.0-70.0, which has a life expectancy at age 15 of 35 more years and survivorship to age 15 of 70%. The adult mortality for Weiss' models is generally higher than that for the Coale and Demeny models and there is very little overlap in mortality between the two sets of models. Unfortunately, the Coale and Demeny models may not be appropriate for comparison with prehistoric samples, whereas the Weiss models are based, in part, on skeletal data from which the age estimates may not be reliable. Gurven and Kaplan (2007) have presented parameter estimates for **Siler hazard models** based on

demographic studies of extant **hunter-gatherers**, forager-horticulturalists, and acculturated hunter-gatherers. These could be taken as a basis for comparison to paleodemographic analyses.

welded tuff A sedimentary deposit consisting primarily of pyroclastic material erupted from a volcano, in which the heat of the eruptive cloud results in the partial melting of glass phases, effectively welding the particles together. Although not as dense and homogeneous as **obsidian**, welded tuffs are typically massive and glassy, and are occasionally utilized as raw material in stone tool manufacture.

Wenner-Gren Foundation for Anthropological Research In 1951, the name of the **Viking Fund, Inc.**, which had been established by Axel Wenner-Gren 10 years earlier in 1941, was changed to the Wenner-Gren Foundation for Anthropological Research, Inc. Axel Wenner-Gren was a Swedish entrepreneur, the owner of the Electrolux Company, and in the 1930s one of the richest men in the world. He was persuaded by Paul Fejos, a Hungarian medical doctor and ethnographic film maker, that well-directed giving could make a significant contribution to the young and relatively neglected field of anthropology. Wenner-Gren endowed the Foundation with US \$2 million of Electrolux stock, and because the Foundation does not fundraise the residue of that stock is the sole source of the Foundation's endowment. The original intention was to develop the Foundation into a broad-based, worldwide anthropological research institute. In the period between 1945 and 1980, in addition to hosting conferences and seminars and providing funds for research and publication, the Foundation housed nine research laboratories, had a library of over 28,000 volumes, and provided office space for visiting anthropologists in its New York City premises. Paul Fejos ran the Foundation from its inception until his death in 1963 and was succeeded by his young widow, Lita Binns Fejos (later Lita Osmundsen), who headed the Foundation until her retirement in 1986. Since that time there have been three presidents of the Foundation (Sydel Silverman, Richard Fox, and Leslie Aiello). The mission of the Foundation is to "support significant and innovative anthropological research into humanity's biological and cultural origins, development and variation and to foster the creation of an international community of research scholars in

anthropology." From the outset the Foundation has made significant contributions to the field of human origins. In the 1940s and early 1950s human origins-related initiatives included support for Willard Libby to develop **radiocarbon dating** when many other funding sources considered the research too risky, as well as funding for Ralph von **Koenigswald** to spend 2 years at the **American Museum of Natural History** to carry out collaborative research with Franz **Weidenreich** on hominin fossils from Southeast Asia. The Foundation also funded a French Upper Paleolithic Research Program, which over a number of years supported excavations at Roc-aux-Sorciers in Angles-sur-l'Anglin (Vienne) (by Suzanne de Saint-Mathurin and Dorothy Garrod) and at Le Colombière (Ain) (by Hallam Movius). The Foundation also supported a number of other excavations, for example at Ksar 'Akil (Lebanon), Cap Ashkar (Morocco), and Ouad Akarit (Tunisia), as well as publishing projects (e.g., the preparation of Weidenreich's monograph on the hominin remains from **Ngandong**). In 1946 the Foundation introduced the **Viking Summer Seminars in Physical Anthropology** (they ran from 1946 to 1951, and in 1953). Under the leadership of Sherwood **Washburn**, these seminars helped introduce genetics and evolutionary theory to biological anthropology, thereby in large measure determining the course of the modern subdiscipline of human origins research. The Early Man in Africa program (1947–55) was initiated by Fr. Teilhard de Chardin (a Fellow of the Foundation) to call attention to the extraordinary significance of the human origins in southern Africa, to date the southern Africa cave deposits, and to facilitate multidisciplinary team research. By the end of the 1950s 75 grants has been awarded under this program, including funds for field research at **Olduvai Gorge** (Louis **Leakey**), the **Cave of Hearths** (C. van Riet Lowe), and **Hopefield** (Ronald Singer), for the purchase of equipment for research on the southern African australopiths (John Robinson), and for their morphological analysis (Clark **Howell**). In 1946 the Foundation introduced the **Viking Fund Medal**. Medals were awarded annually until 1961 and five awards have been made since that time. The Supper Conferences began in 1944 under the aegis of the Viking Fund and they were continued by the Foundation for three and a half decades. These evening meetings provided a forum for discussion and debate for the growing field. In addition to many of the grantees and the awardees of the Viking Fund Medal, the roster of

paleoanthropological speakers over the years includes Emiliano Aguirre, Karl Butzer, Leslie Freeman, Alexander Marshack, Phillip Tobias, Richard Lee, Glynn Isaac, and Richard Leakey. In 1949 the Foundation was instrumental in the establishment of the **American Institute of Human Paleontology**. The aim of the Institute was to provide a forum to increase knowledge of early humans and the founding members were Loren C. Eiseley (President), Joseph Birdsell, Paul Fejos, Theodore McCown, Hallam Movius, Dale Stewart, and Sherwood Washburn. The main accomplishment of the Institute was to acquire, with Wenner-Gren financial support, the Barlow/Damon collection of molds of hominin fossils. The collection of molds was deposited with the University of Pennsylvania Museum of Archaeology and Anthropology and it provided the basis of their hominin casting program. During the 1950s the Foundation supported the research of the plastics engineer, David Gilbert, to develop a new and highly accurate molding technique. This led to the establishment of the **Anthrocast** program in 1965. Between 1968 and 1976 Anthrocast provided over 16,000 replicas of 180 different fossil specimens to institutions and researchers worldwide. The Anthrocast molds are currently curated at the University of Pennsylvania Museum of Archaeology and Anthropology and casts continue to be available on a limited basis through their casting program. In 1958 the Foundation acquired Burg Wartenstein castle in Austria as a gift from Axel Wenner-Gren. Between 1959 and 1980 Burg Wartenstein was the Foundation's European headquarters and the primary venue for its International Symposium Program. International Symposia were (and still are) meetings of intensive discussion that aim to include international scholars with broad interests. During the 1960s and 1970s the Foundation hosted almost 2000 scholars at 86 symposia held at the castle and elsewhere during the summer months. The titles of landmark meetings that focused on paleoanthropology and the year they were held are given below (the publication date and the organizers/editors are given in parentheses): *Social Life of Early Man*, 1959 (1961, Washburn), *Early Man and Pleistocene Stratigraphy in the Circum-Mediterranean Regions*, 1960 (1962, Blanc and Howell), *African Ecology and Human Evolution*, 1961 (1963, Howell and Bourlière), *Classification and Human Evolution*, 1962 (1963, Washburn), *Background to Evolution in Africa*, 1965 (1967, Bishop and Clark), *Man the Hunter*, 1966 (1968, Lee and DeVore held in Chicago), *Calibration of Hominoid*

Evolution: Recent Advances in Isotopic and Other Dating Methods as Applicable to the Origin of Man, 1971 (1972, Bishop and Miller), *Earliest Man and Environments in the Lake Rudolf Basin*, 1973 (1976, Coppens, Howell, Isaac, and R. Leakey, held in Nairobi and Lake Rudolf, Kenya), *After the Australopithecines*, 1973 (1975, Butzer and Isaac), and *Early Hominids of Africa*, 1974 (1978, Jolly). The results of these meetings were published through the Foundation's **Viking Fund Publications in Anthropology**, as well as through special arrangement with publishing houses (such as Aldine Publishers) and various university presses. Throughout this time the Foundation continued to fund research in human origins. In 1965 it established the Origins of Man program (1965–72) under the guidance of Walter William (Bill) Bishop, C. K. Brain, J Desmond Clark, Francis Clark Howell, Louis Leakey, and Sherwood Washburn. In the 1960s and 1970s over 300 grants were made in paleoanthropology. These grants continued to support excavations in southern African (e.g., Swartkrans, Brain; Elandsfontein, Singer) as well as survey, excavation, geology, dating, Plio-Pleistocene vertebrate paleontology, and hominin analyses throughout East and central Africa [e.g., Ethiopia (Omo; Howell), Chad (Yves Coppens), Olduvai Gorge (Louis Leakey), Baringo (Phillip Tobias), and Olorgesailie (Bishop and Leakey)]. Foundation grants also funded Middle and Late Stone Age research (Desmond Clark), stratigraphy in the Albert Rift (Bishop), suid paleontology (Basil Cook and Shirley Coryndon), and the Miocene primates recovered from sites in Ugandan and Kenya (David Pilbeam, Peter Andrews, and Louis Leakey), as well as pioneering work in primate behavior (Jane Goodall, Diane Fossey, Robin Dunbar, etc.). Outside of Africa grants funded research in Europe and Asia (e.g., Clacton, Singer; Torralba and Ambrona, Aguirre, Howell, and Butzer; *Homo erectus* in Indonesia, Jacob, Sartono, and von Koenigswald; the **Mousterian**, Bindford and Klein; the Perigordian, Movius; the Paleolithic of Turkey and Syria, Solecki; Upper Paleolithic notations and art, Marshack, etc.). Funding was also provided for publication projects including among many others *Catalogue of Fossil Hominids* (Oakley), *Nomenclature of the Hominidae* (Campbell), the **Shanidar** reports (Solecki), and the description of the Pech de l'Aze child (Vallois). The late 1970s were a time of major change for the Foundation. Financial exigencies forced the termination of the Anthrocast program, and the sale of Burg Wartenstein and the Foundation's New York offices.

Since 1980 the majority of the Foundation's support has gone to graduate students. Many leading researchers in the field of human origins have benefited from support under the Foundation's doctoral research program (Dissertation Fieldwork Grant) or the Developing Country Training Fellowship program (now the Wadsworth International Fellowship program), which provides the opportunity for students from developing countries (e.g., Jackson Njau and Yohannes Haile-Selassie) to earn doctorates at world-class universities. The Foundation currently provides up to \$5 million per year to support the field of anthropology, and this money is divided among the subfields, including paleoanthropology, in rough proportion to the numbers of applications received. Details of the programs and how to apply can be found at www.wennergren.org.

Wenner-Gren Foundation Supper Conferences See **Wenner-Gren Foundation for Anthropological Research**.

West Coast Fossil Park (or WCFP) This educational, research, and tourism institution in South Africa, which incorporates the Langebaanweg paleontological site, was established in 1998. At the end of 2005, the WCFP became an independent institution, managed by the WCFP Trust, and separate from Iziko Museums, although the collections from Langebaanweg currently remain housed at the South African Museum, Iziko Museums of Cape Town. The open-air archeological locality known as the **Anyskop Blowout** is also located inside the boundaries of the WCFP, approximately 1 km/0.6 miles south of the Pliocene fossil beds. See **Langebaanweg**.

West Turkana (Location 3°35'–4°30'N, 35°40'–35°55'E, Kenya; etym. refers to a region to the west of Lake Turkana, a lake named after the Turkana, a Nilotic tribe that live around the lake) History and general description West Turkana refers to a substantial area of exposures on the northeastern shore of Lake Turkana whose size and complexity makes it equivalent to the larger study areas in Ethiopia (e.g., the **Hadar study area** and **Middle Awash study area**). In 1980, the Koobi Fora Research Project, led by Richard Leakey and in affiliation with the **National Museums of Kenya**, surveyed the exposures between Kalakol (formerly Ferguson's Gulf) to the south and Kokuro to the north. Subsequent field reconnaissance was carried out in 1981 and 1982 and

aerial photographs were taken in 1983. These confirmed the presence of Plio-Pleistocene sediments in a c.10 km-/6 mile-wide strip between Lake Turkana to the east and the Labor and Murua Rith hills to the west. Collection was begun in 1984 and the search for fossil and archeological evidence has been carried out subsequently by various teams. Between 1980 and 1989, the main paleontological effort was led by Richard Leakey and after 1989 by Meave Leakey; archeological investigations have always been led by Helene Roche. The many cumulative months of field seasons resulted in substantial collections that are held in the National Museums of Kenya in Nairobi. The sediments exposed in West Turkana belong to the Nachukui Formation. This ranges in age from 4.3–0.7 Ma, and it includes many of the tuffs recognized in the **Koobi Fora Formation** to the east and the **Shungura Formation** exposed in the lower reaches of the Omo River. The Nachukui Formation comprises eight members, all named after lagas, or ephemeral streams. From oldest to youngest they are the Lonyumun, Kataboi, Lomekwi, Lokalalei, Kalochoro, Kaitio, Natoo, and Nariokotome. The main fossil locality complexes are given below in alphabetical order (each full name is followed by its two-letter abbreviation): Kaitio (KI), Kalochoro (KL), Kalakodo (KK), Kangaki (KG), Kangatukuseo (KU), Kokiselei (KS), Lomekwi (LO), Lokalalei (LA), Loruth Kaado (LK), Nachukui (NC), Nasechebun (NS), Nanyangakipi (NN), Nariokotome (NK), Natoo (NT), and Naiyena Engol (NY). Localities within each complex are identified using roman numerals (e.g., Nariokotome III). Each hominin from West Turkana has the prefix "KNM" for the Kenya National Museum (the old name for the National Museums of Kenya), where they are curated, "WT" for West Turkana, and then the field number (e.g., **KNM-WT 15000**). Temporal span and dating methods The Nachukui Formation ranges in age from 4.3 to 0.7 Ma, based on various **radiogenic dating** methods, plus **magnetostratigraphy** and **biostratigraphy**. Hominins found at site Fossil hominins recovered from West Turkana have been assigned to *Australopithecus afarensis* (e.g., **KNM-WT 8556**), *Kenyanthropus platyops* (e.g., **KNM-WT 40000**), *Paranthropus aethiopicus* (e.g., **KNM-WT 16002**, **KNM-WT 17000**), *Paranthropus boisei* (e.g., **KNM-WT 17400**), and *Homo erectus* (e.g., **KNM-WT 15000**). Archeological evidence found at site More than 60 **Oldowan** and **Acheulean** sites have been recorded in West Turkana, grouped into eight major complexes and ranging from 2.3 to

0.7 Ma. Organized debitage sequences have been demonstrated at Lokalalei 2C site (2.3 Ma) using technological analysis and reconstruction of the cores. Key references: Geology, dating, and fauna Harris et al. 1988; Hominins Brown et al. 1985, Walker et al. 1986, Leakey and Walker 1988, Walker and Leakey 1993; Leakey et al. 2001; Archeology Roche et al. 1999, 2003, Delagnes and Roche 2005.

Western Margin One of the major fossiliferous subregions within the **Middle Awash study area**; the others include the **Central Awash Complex**, **Bouri Peninsula**, and **Bodo-Maka**. The Western Margin consists of a more than 30 km-/19 mile-wide strip of sediments that lie against the western escarpment of the **Afar Rift System** between approximately 10°00' and 10°10'N. Localities within the Western Margin include Adu Dora, Alayla, **Asa Koma**, Digiba Dora, and **Saitune Dora**.

white matter A term that describes regions of the central nervous system that contain large bundles, or tracts, of **axons**. The myelin sheath that encircles axons in the white matter gives it a whitish appearance in fresh brain tissue, hence its name.

White Sands One of two hominin-bearing localities in the **Usno Formation** in the **Lower Omo Valley** (the other one is called **Brown Sands**). Fossils found in the White Sands locality have been given the prefix “W” for White Sands. *See also* *Australopithecus afarensis*; **Usno Formation**.

White, Timothy Douglas (1950–) Tim White was born in Los Angeles, and he completed BS degrees in biology and anthropology at the University of California at Riverside in 1972. After graduating, White entered the University of Michigan where he studied physical anthropology with Milford Wolpoff, Philip Gingerich, Loring Brace, and William Farrand. He completed his MA in 1974 and during that year he also became a member of the **East Rudolf Research Project** where he was part of the team of researchers led by Richard Leakey and Glynn Isaac at **Koobi Fora**, in Kenya. In 1976 White conducted anatomical studies of the hominin fossils discovered by Mary Leakey at **Laetoli** and he began a collaboration with Donald Johanson on the interpretation of the fossils Johanson had discovered at **Hadar**, in Ethiopia, between 1973 and 1975. White completed his PhD at the University of

Michigan in 1977 with a dissertation titled *The Anterior Mandibular Corpus of Early African Hominidae: Functional Significance of Shape and Size*. In the same year he became a Professor of Anthropology at the University of California at Berkeley and a year later, in 1978, he joined Mary Leakey's research team at Laetoli, where he assisted in the excavation of the **Laetoli hominin footprints**. In 1981 White joined his Berkeley colleague Desmond Clark along with Ethiopian graduate student Berhane Asfaw in the **Middle Awash Research Project**. The project was designed to be a multidisciplinary investigation of the geology, paleontology, and archeology of the hominin-bearing deposits of the Middle Awash region of Ethiopia. Over the following decades the Middle Awash Research Project expanded to include scientists who specialized in a variety of disciplines including archeology, geochemistry, geochronology, invertebrate and vertebrate paleontology, paleobotany, sedimentology, and structural geology, from more than 19 countries. Under joint leadership the Middle Awash Research Project has continued to unearth a wealth of hominin and animal fossils as well as archeological material. During the 1992–3 season White and two colleagues, Gen Suwa and Berhane Asfaw, discovered the fossil hominin remains at **Aramis**, in the Middle Awash study area. White and his colleagues concluded the hominin was an entirely new species, which they named *Australopithecus ramidus* in 1994; a year later the new species was transferred to a new genus as *Ardipithecus ramidus*. The fossils were dated c.4.4 Ma, making them among the oldest known possible hominin fossils at the time. Further evidence of that taxon came in the form of a fragile, poorly preserved but remarkably complete associated skeleton. That specimen, **ARA-VP-6/500**, other fossil evidence of that taxon, and a substantial body of contextual evidence, were published in 2009. The team made another remarkable discovery in 1997 when then-graduate student Yohannes Haile-Selassie found several hominin cranial fragments and a maxilla in the 2.5 Ma **Bouri Formation**. White and Berhane Asfaw, by then a paleoanthropologist with the Rift Valley Research Service in Ethiopia, assigned these fossils, as well as several other fragments discovered between 1996 and 1998 in the Middle Awash, to a new species they named *Australopithecus garhi* in a paper published in *Science* in 1999. These fossils not only filled in an important gap in the temporal record of hominin evolution, but they were also associated with some of the earliest evidence of animal butchery. The

Middle Awash Project team made yet another significant discovery near the village of **Herto** near the Awash River in 1997. This consisted of two partial adult *Homo sapiens* crania and one child's cranium that are between 154 and 160 ka. These fossils were among the earliest known modern humans and White's team assigned them to a new subspecies of *H. sapiens*, *Homo sapiens idaltu*. The discovery of a c.1 Ma *Homo erectus* skull (**BOU-VP-2/66**) from the Bouri Formation in 1997 led White and Berhane **Asfaw** to argue that the African and Asian varieties of *H. erectus* represent a single species and not two different species, as has been suggested by some. In addition, at the sites of **Aramis** in 1994 and at **Asa Issie** between 2000 and 2005 White's team recovered a 4.1 Ma collection of teeth and jaw fragments they assigned to *Australopithecus anamensis*; this was the first evidence of *Au. anamensis* from Ethiopia and it significantly enlarged the hypodigm of this taxon. Tim White is currently Professor of Integrative Biology at the University of California at Berkeley and served with the late F. Clark Howell as co-director of the **Laboratory for Human Evolutionary Studies** at the university from 1995 to 2003 when the laboratory was renamed the Human Evolution Research Center. Along with Clark **Howell**, White was also the co-leader of the Revealing Hominid Origins Initiative. He is also curator of biological anthropology at the Phoebe A. Hearst Museum of Anthropology and a research paleoanthropologist at the university's Museum of Vertebrate Zoology.

Wilcoxon signed rank test A nonparametric statistical test used to determine whether the values of a **sample** of measurements are significantly larger or smaller than a second set of values observed for the same sample. Used in the same situations as one would use a paired *t* test, the Wilcoxon signed rank test considers the relative ranking of the differences between pairs of values in the two groups rather than differences themselves.

Wildscheuer (Location 50°25'N, 8°08'E, Germany. etym. Ge. *wild*=wild and *scheuer*=barn, perhaps from being used as a place to house livestock) History and general description This cave site in the Lahn valley, Hess region of Germany was the site of active limestone quarrying and since 1953 it has been completely destroyed. Skull fragments were recovered that were thought to come from *Homo neanderthalen-*

sis but a recent analysis has shown them to be from a cave bear. Temporal span and how dated? No absolute dating methods have been attempted. Hominins found at site None. Archaeological evidence found at site Several lithic remains attributed to the **Middle Paleolithic**, **Aurignacian**, **Gravettian**, and **Madgalenian**, as well as abundant faunal remains. Key references Geology, dating, and paleoenvironment Terberger 1993, Fiedler 1994; Hominins Street et al. 2006; Archeology Terberger 1993, Fiedler 1994.

Wilks' lambda *See* multivariate analysis of variance.

Willandra Lakes (Location 33°S, 143°E, Australia; etym. named after the lake region of the same name) History and general description The earliest remains to be recovered from what is now referred to as the Willandra Lakes were discovered at **Lake Mungo**. When fossils began to be discovered at other lakes in the same complex of dried-up lakes it was decided that the name should be broadened from "Lake Mungo" to "Willandra Lakes." Thus the former Mungo 1 skeleton is now called WLH 1, etc. The Willandra Lakes Hominid 50 (WLH 50) partial cranium was discovered in 1982 in a deflating lake-shore dune in between the dry lakes of Garnpung and Leaghur in the Willandra Lakes region of New South Wales. Modern human footprints (*n* = 124) were discovered in 2006 about 10 km/6 miles north of the WLH 50 find site. Temporal span and how dated? Radiometric dates for WLH 50 range from 13 to 15 ka (**uranium-series dating**) to 29 ka (**electron spin resonance spectroscopy dating** on bone). Optically stimulated **luminescence dating** estimates derived from the associated sediments provide age estimates for the modern human trackways of 19–23 ka. Hominins found at site WLH 50 is the focus of an ongoing debate regarding its relevance to modern human origins. One group of researchers claim that this specimen's robusticity and morphology suggest descent from archaic southeast Asian hominids such as **Ngandong**, thereby supporting an evolutionary explanation in line with the **multiregional hypothesis**. Others claim these same features can be explained by pathology and/or intentional cranial-deformation practices. The modern human footprints were made by adults, adolescents, and children and may indicate collective activities, such

as the hunting of water birds, at ephemeral water sources. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Caddie et al. 1987, Simpson and Grün 1998, Webb et al. 2006; Hominins Stuart-Macadam 1992, Webb 1992, Stringer 1998, Hawks et al. 2000, Webb et al. 2006.

Wilson, Allan Charles (1934–91) Allan Wilson was born in Ngaruawahia, New Zealand, and was raised on his family's farm at Helvetia, Pukekohe. He studied mathematics and chemistry at King's College in Auckland and then entered Otago University where he completed his BSc degree in 1955. Wilson left for the USA in 1955 and completed his MS in zoology in 1957 at Washington State University and in 1961 he completed his PhD at the University of California at Berkeley in biochemistry, where he worked with biochemist Arthur Pardee. Wilson took a postdoctoral fellowship at Brandeis University in 1961 and remained there until 1964 when he left to become Professor of Biochemistry at the University of California at Berkeley, where he remained until his death. At Berkeley, Wilson established a laboratory where he conducted research in molecular biology, developing novel methods for investigating evolutionary change and using genetic information to reconstruct phylogenies. Wilson, working with Vincent Sarich, then a graduate student, used a new technique called micro-complement fixation to compare the degree of similarity of **albumin**, a blood protein, among different species of primates. The results of their research supported conclusions reached earlier by Morris Goodman who, using an immunological method, had shown that modern humans were more closely related to the African apes, and particularly to chimpanzees, than to the Asian apes. Significantly, however, Wilson and Sarich also concluded from their research that mutations in the albumin molecule occurred at a constant rate, and thus the degree to which these molecules differed among species could be used to calculate how much time had elapsed since those species had shared a common ancestor. Thus, they believed they had found a "**molecular clock**" that could be used to date the origin of extant higher primate lineages. Wilson and Sarich published their findings in an article entitled "Immunological time-scale for human evolution" in *Science* in 1967. In that paper Wilson and Sarich argued that the remarkable degree of similarity of the albumins of modern humans and

chimpanzees (nearly 99%) meant that the two lineages must have shared a common ancestor *c.* 5 Ma. Few paleoanthropologists were familiar with the methods used in the paper and most accepted the conventional wisdom of the time which was that the hominin and other hominoid lineages had diverged at least 15 Ma. During the 1970s, Wilson continued to develop and employ new and existing molecular biology techniques (e.g., **polymerase chain reaction** and the relative rate test) to expand the role of molecular biology in providing information about **phylogeny** and the timing of events in evolution. During the 1970s and early 1980s, Wilson and his team began to focus their attention on collecting evidence for mutations in **mitochondrial DNA** (mtDNA) in extant higher primate taxa. On the basis of this research, Wilson, along with S.D. Ferris and Wesley M. Brown, published an article in the *Proceedings of the National Academy of Sciences USA* in 1981 titled "Evolutionary tree for apes and humans based on cleavage maps of mitochondrial DNA." mtDNA seemed an ideal subject for genomic research of relatively recent events in evolutionary history because there are many copies within a single cell, it is passed directly from mother to offspring, and mutations accumulate at a relatively rapid rate. Wilson's new collaborators, Rebecca Cann and Mark Stoneking, collected samples from individuals representing different populations of modern humans from across the world, and compared the number of mutations present in the mtDNA from these groups. The results of this study were published in 1987 in *Nature* in an article titled "Mitochondrial DNA and human evolution." In it Cann, Stoneking, and Wilson argued that the relatively small number of mutations found across all the modern human populations they sampled indicated that all modern humans were derived from a single *c.* 200 ka founder population. They also argued that their research suggested that this ancestral population lived in Africa, and that this evidence was incompatible with the tenets of the **multiregional hypothesis**, namely that *Homo sapiens* in Asia had evolved from populations of *Homo erectus* living in that region. Wilson and his colleagues suggested instead that the ancestral group of *Homo sapiens* in Africa they identified gave rise to populations that had migrated out of Africa and replaced pre-sapiens hominins in all the major regions of the Old World. The significance and controversial nature of these conclusions was picked up by the media, and because mtDNA is transmitted down the female line, and because this

implied that all modern humans could, theoretically, be traced back to a single female, this hypothetical founding female was dubbed the “African Eve” or the “**mitochondrial Eve.**” Wilson and his team continued to expand upon and refine this research over the next few years and their results have provided important support for the **out-of-Africa hypothesis.** Wilson died of leukemia in 1991. *See also* Sarich, Vincent.

Wilson bands Wilson bands are abnormal accentuated markings in enamel that follow the contour or alignment of the normal, regular, **striae of Retzius.** Wilson and Shroff (1970) drew attention to the fact that some striae of Retzius may be accentuated in their breadth, color, and because they show a pronounced change in prism orientation along their length. They are sometimes, but not always, associated with surface enamel **hypoplasia.** The disruptive physiological or pathological events that cause accentuated striae may not coincide exactly with the formation of a normal stria of Retzius, so clusters, or groups, of irregularly spaced Wilson bands may be superimposed onto the regular underlying pattern of long-period striae of Retzius. Counts and measurements of Wilson bands are an important way of assessing the degree of stress experienced by an individual during development. The equivalent of Wilson bands in dentine are called **Owen’s lines.**

windlass effect First described by J.H. Hicks (1954) the windlass effect or windlass mechanism converts the foot into a solid lever during the **push-off** phase of walking. The plantar aponeurosis attaches to the calcaneus, runs across the plantar aspect of the foot, wraps around the metatarsal heads, and inserts into the base of the proximal phalanges. During the push-off phase of walking the metatarsophalangeal joints dorsiflex, tightening the plantar aponeurosis, raising the **longitudinal arch,** and shortening the foot. The hindfoot inverts relative to the forefoot, locking the calcaneocuboid joint, and converting the midfoot into a stiff lever that facilitates efficient propulsion during bipedal locomotion.

windlass mechanism *See* windlass effect.

winnowing (OE *windwain* = the use of wind to separate the lighter chaff from the denser, heavier, seed) The removal by flowing water of the smallest subset of flaked stone artifacts or bone from an arche-

ological or paleontological site. The effects of winnowing are typically recognized in archeological contexts by comparing the size distribution of artifacts in an assemblage to those from experimentally derived **lithic assemblages.** The degree to which an assemblage has been winnowed is important to consider when making behavioral inferences since winnowing can alter the spatial integrity of an archeological site and remove certain classes of evidence. For example, by preferentially removing the smaller byproducts of flint knapping, particularly small flakes, flake fragments, and angular waste, winnowing can make it difficult to examine patterns of artifact manufacture and curation or make it difficult to determine whether artifacts were produced at, or away from, a site.

Witwatersrand University Department of Anatomy The Department of Anatomy of the Witwatersrand University was established in 1919. The first head of the department, Edward Stibbe, was replaced by Raymond Dart in 1923, and it was during his long tenure that the Department’s involvement in human evolution research began. After Dart’s involvement with **Taung,** the next fossil site that Wits Anatomy Department researchers, particularly Phillip Tobias, were involved in was **Makapansgat.** Then, just a few years after Tobias replaced Raymond Dart as Head of Department in 1959, Witwatersrand University took over the land that included the site at **Sterkfontein** and the **Palaeo-Anthropology Research Unit** within the department restarted excavations at Sterkfontein in 1966. The new project was headed by Tobias, with Alun Hughes, and later Ronald Clarke, in day-to-day charge of the excavation. Other field projects that in one form, or another, have come under the purview of the Witwatersrand University Department of Anatomy include those at **Drimolen, Gladysvale, and Gondolin.**

WK Acronym of Wayland’s Korongo, a locality at **Olduvai Gorge.** Handaxes and cleavers were found on the scree below Bed IV at this site in 1932, but it was not formally excavated until 1970. Handaxes, cleavers, and scrapers were then found *in situ,* as well as **OH 28,** which comprises the shaft of a left femur and much of a left pelvic bone. *See also* **Olduvai Gorge.**

WLH Acronym for Willandra Lakes hominids and the prefix for fossils recovered from the Willandra Lakes region in Australia. *See* **Willandra Lakes.**

WLH 50 [NB: Webb (1989, 1990) does not use a hyphen, but Stringer (1998) and Hawks et al. (2000) do] Site **Willandra Lakes**. Locality Garnpung/Leaghur 20. Surface/in situ Surface. Date of discovery On, or before, 1982. Finders Unknown. Unit N/A. Horizon A deflating lake-shore dune in between the dry lakes of Garnpung and Leaghur. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Electron spin resonance spectroscopy dating** points to an age of 29 ± 5 ka (Caddie et al. 1987) and **uranium-series dating** suggests a younger age of 15–13 ka (Simpson and Grun 1998). Developmental age Adult. Presumed sex Male. Brief anatomical description The frontal region and the posterior part of the calvaria. Announcement Webb 1989. Initial description Webb 1990. Photographs/line drawings and metrical data Webb 1989, 1990, Stringer 1998, Hawks et al. 2000 (these latter authors also cite measurements taken from a website maintained by Peter Brown). Detailed anatomical description Webb 1990. Initial taxonomic allocation The presumption is that the early authors (e.g., Webb 1989) interpreted WLH 50 as an example of “archaic *H. sapiens*.” Taxonomic revisions Stringer (1998) recognizes it as “anatomically modern” (*ibid*, p. 332) and by implication regards it as belonging to *Homo sapiens* and Hawks et al. 2000 refer to it as “modern human” (*ibid*, p. 21). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance The WLH 50 calvaria was a key item of evidence cited by researchers (e.g., Thorne and Wolpoff 1992, Hawks et al. 2000) who interpreted its morphology as evidence of morphological continuity between the pre-modern *Homo* populations in Indonesia (e.g., Ngandong) and the early occupants of Australia. However, others interpret it as being “no closer metrically to the Ngandong than to the African archaic sample” (Stringer 1998, p. 331). Location of original WLH 50 has been reburied.

WLM Acronym for the western lake margin and the term used for the western margin of the paleolake some call **Lake Olduvai**. See **Lake Olduvai**; **Olduvai Gorge**.

WMC Acronym for Waki-Mille confluence, a collection area within the **Woranso-Mille study area**, Central Afar, Ethiopia.

Wolo Milo One of the Early and Middle **Pleistocene** sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Wolokeo One of the Early and Middle **Pleistocene** sites in the exposures of the **Ola Bula Formation** within the **Soa Basin**, central Flores, Indonesia.

Wolpoff, Milford H. (1942-) Milford Wolpoff was born in Chicago, Illinois, USA, and he traces his interest in human origins to his reading Roy Chapman Andrew’s *Meet Your Ancestors* (1945). Nonetheless, when he entered the University of Illinois at Urbana-Champaign it was to study physics, but after taking anthropology and archeology courses with Donald Lathrap he changed his major and received his BA in anthropology in 1964. He remained at his alma mater to pursue his PhD in physical anthropology, where he focused his studies on hominin dental evolution under the mentorship of Eugene Giles. During the course of this research in 1966 Wolpoff had the opportunity to work with John **Robinson**, who by then had left South Africa for the University of Wisconsin. Wolpoff completed his PhD in 1969, taught anthropology at Case Western Reserve University from 1968 to 1971 and then in 1971 he accepted a position in the Department of Anthropology at the University of Michigan where he has remained for the last four decades. In 1971 Wolpoff published his dissertation, entitled *Metric Trends in Hominid Dental Evolution*, and with David Brose, an archeologist at Case Western, he published an influential article in *American Anthropologist* entitled “Early Upper Paleolithic man and Late Middle Paleolithic tools.” In it the authors argued that because the changes in stone tool industries from the **Middle Paleolithic** to the **Upper Paleolithic** did not correspond chronologically with the fossil evidence showing the transition from Neanderthals to anatomically modern humans, this suggested that the new tool types were not necessarily introduced by Cro-Magnon newcomers that replaced the Neanderthals, but rather were the product of behavioral evolution within *Homo neanderthalensis*. Wolpoff participated in a significant re-evaluation of *H. neanderthalensis* during the 1970s and 1980s when he and several colleagues began to examine anew the large collection of Neanderthal remains discovered at **Krapina**, in Croatia,

early in the 20thC by the Croatian paleontologist Dragutin Gorjanović-Kramberger. Fred Smith, a graduate student who worked with Wolpoff, studied the bones and Wolpoff followed this work by investigating almost 300 teeth from the Krapina collection. This research expanded into a substantial new study of the Krapina remains and the publication by Jakov Radović, Fred Smith, Erik Trinkaus, and Wolpoff of *The Krapina Hominids* (1988). This strengthened Wolpoff's conviction that Neanderthals had not been replaced by a population of anatomically modern humans that had evolved elsewhere, but had themselves evolved *in situ* into modern humans. Wolpoff was also a trenchant advocate of the **single-species hypothesis**, which argued that only one hominin species should exist at any one time in the course of human evolution. As a result, Wolpoff argued that the gracile and robust australopiths in southern Africa belonged to the same species; human phylogeny was more like the straight trunk of a tree with a few minor branches, rather than a bush branching off into many different species. By the early 1980s Wolpoff began to promote, along with Australian anthropologist Alan Thorne, a view of recent human evolution that is referred to as the **multiregional hypothesis**. Thorne and Wolpoff published a paper in the *American Journal of Physical Anthropology* entitled "Regional continuity in Australasian Pleistocene hominid evolution" in 1981 where they presented evidence from the fossil record of the region that a distinct geographical population of hominins had persisted in the Far East and Australasia for the last million years. Wolpoff and Thorne later expanded their theory to argue that a similar morphological continuity within geographical regions could be observed in the hominin fossil record over much of the Old World. The multiregional hypothesis as developed by Wolpoff, Thorne, and Wu (1984) argues that the first hominins to leave Africa were *Homo erectus* about a million years ago and they dispersed to populate much of Asia and parts of Europe. Wolpoff and colleagues argued that these regional populations of *H. erectus* evolved semi-independently over time into modern *Homo sapiens*. They claimed that *H. erectus* remains in China resembled morphologically early *H. sapiens* remains in China that already possess some of the distinctive Asian racial features seen in modern populations. Wolpoff published, with his wife Rachel Caspari, a fuller account of the multiregional hypothesis in *Race and Human Evolution* (1997), where they explore the connections between his model of human evolution

and the polycentric theory of human evolution proposed by the German physical anthropologist Franz **Weidenreich** in the 1940s. Wolpoff's multiregional hypothesis not only draws upon paleontological evidence showing racial continuity over long periods for different geographical areas, but it also employed ideas borrowed from population genetics to show how geographical varieties of humans could persist over time while limited gene flow between these populations allowed these geographically distinct populations to remain part of the same species. The multiregional hypothesis was challenged by the **out-of-Africa hypothesis** that argued that modern *H. sapiens* evolved in Africa and then migrated out of Africa and into Asia where it replaced *H. erectus*.

Wonderwerk Cave (Location 27°50'45"S, 29°33'19"E, Northern Cape province, South Africa; etym. Afrikaans, possibly referring to the many paintings formerly preserved on the cave wall). History and general description Formal excavation at this large (approximately 2400 m²) solution cavity in dolomitic **limestone** began in 1943 by Malan and Wells. Karl Butzer worked there from 1974 to 1977 and research was continued in 1978 and thereafter by Peter Beaumont and his colleagues with Anne Thackeray focusing on the later occupation layers. Multiple discontinuous excavations in the cave, some to bedrock at about 6 m in depth, sample an archaeological sequence that features excellent organic preservation, dated from the early **Pleistocene** to the **Holocene**. Temporal span and how dated? **Magnetostratigraphy** suggests the lower-most strata date to the **Olduvai subchron**, a hypothesis supported by a single **cosmogenic nuclide dating** estimate of *c.*2 Ma from these lower-most sediments. **Uranium-series dating** on **speleothems**, a single result from optically stimulated **luminescence dating**, and **radiocarbon dating** on charcoal constrain the ages of overlying strata of more than 350 ka to 1.21±0.05 ka. Hominins found at site None. Archeological evidence found at site The artifact assemblages span the **Early**, **Middle**, and **Later Stone Ages**. The site's preservation of multiple (*n*=6) Early Stone Age strata in a cave setting is unusual, and these levels are characterized by **handaxes**, rare prepared **cores**, and **blades**. They are variably attributed to the **Acheulean** and **Fauresmith** stone industries, and on the basis of uranium-series age estimates on speleothem, are more than 276 ka. Middle Stone Age levels date to between *c.*70 to more than 220 ka and include

Levallois flakes, cores, blades, and a variety of retouched **points**. The Later Stone Age strata are attributed to the “Wilton Complex” of southern Africa, and are notable for a series of engraved stones, many depicting mammals, and extinct **mega-fauna** (*Equus capensis* and *Megalotragus* sp.) in layers radiocarbon dated to between 3.99 ± 0.06 ka and 10.00 ± 0.07 ka. All strata preserve **specularite** or **hematite** introduced into the cave by hominins and the Early Stone Age strata include evidence for hearths, and remarkably, vegetation mats interpreted as bedding material. Macrofauna are highly fragmented, but the large **micromammalian** samples are well preserved. Key references: Geology, dating, and paleoenvironment Butzer 1984, Beaumont and Vogel 2006, Chazan et al. 2008; Archeology Thackeray et al. 1981, Beaumont 1990, Beaumont and Vogel 2006.

woodland The most widespread biome in tropical Africa, woodlands are areas of clumped trees that do not have a continuous canopy, and thus there is a grassy understory (NB: forests do not have a grass understory). In general, woodlands are 8–20 m in height and the tree canopies cover at least 40% of the surface. Like other biomes, woodlands are made up of a number of ecosystems that form a continuum from open to closed, with more closed woodland ecosystems associated with high mean annual rainfall. Average mean annual rainfall in woodland habitats ranges from 600 to 1000 mm (Bourliere and Hadley 1983). Woodlands in Africa are confined to tropical and subtropical regions. Most trees are deciduous or semi-deciduous but many woodlands contain some evergreen species. Woodland trees tend to be smaller than forest trees, and the density of coverage is often related to annual precipitation (Sikes 1999, Jacobs 2004) or seasonal fluctuations in rainfall (Vincens et al. 2007). Woodlands of different types (such as *Acacia* and **miombo woodland**) are a significant component of modern sub-Saharan African landscapes, and were likely to have been so throughout the whole of **hominin** evolutionary history. Early hominin sites, such as **Hadar**, are described as mosaic habitats that included open and closed woodlands, shrublands, **edaphic** grasslands, and gallery forests. While *Australopithecus afarensis* lived in several different types of biome, the most common of these were woodland habitats. Based on faunal evidence from **Olduvai Gorge** Bed I, it is likely

that some African early Pleistocene woodland habitats were more species rich than modern woodland in the same region, suggesting there were differences between past and present **ecosystems** (Fernandez-Jalvo et al. 1998).

Woranso-Mille Paleontological Research Project (or **WORMILPRP**) A multidisciplinary project conducting field and laboratory research on the geology and paleontology of the Mio-Pliocene deposits bound by the towns of Mille, Chifra, and Kasagita, in the central Afar region of Ethiopia that make up the **Woranso-Mille study area**. The **WORMILPRP** started with an intensive paleontological survey of the north and central Afar region in 2002, but annual fieldwork concentrating on its current study area did not begin until 2004. The major objectives of the project are to recover early hominin fossils from the late Miocene and Pliocene deposits of the study area to understand the earlier phases of human evolution, to better understand the phylogenetic relationships among early *Australopithecus* species, and to collect new data to help understand the paleoecological and geological context for the early phases of human evolution. Thus far the **WORMILPRP** has been successful in collecting fossil hominins dated to between 3.6 and 3.8 Ma, a time period poorly sampled in the hominin fossil record. The finds include a 3.6 Ma partial skeleton of *Australopithecus afarensis* (KSD-VP-1/1) from the Korsi Dora locality. The project has also collected more than 4800 fossil specimens representing many vertebrate taxa; project geologists have established refined stratigraphic sections for much of the study area and geochronologists have generated radiometric ages for most of the fossiliferous horizons within the study area. The **WORMILPRP**, which is directed by Ethiopian paleoanthropologist Yohannes **Haile-Selassie**, involves many specialists from various academic institutions around the world. The project is also actively engaged in training graduate and undergraduate students from Ethiopia and the USA.

Woranso-Mille study area (Location $11^{\circ}30'N$, $40^{\circ}30'E$, Central Afar region, Ethiopia; etym. name of nearby rivers) History and general description What is now referred to as the **Woranso-Mille study area** was identified as a potential source of hominin fossils by the **International Afar Research Expedition** (or **I.A.R.E.**)

in the early 1970s, but it was first intensively investigated in 2003 by the **Woranso-Mille Paleontological Research Project**. Four collection areas [Am-Ado (AMA), Aralee Issie (ARI), Mesgid Dora (MSD), and Makah Mera (MKM)] extending *c.* 5 km/3 miles along the north bank of the Mille River in the northwest of the study area have yielded more than 4300 vertebrate fossils including 26 dentognathic hominin specimens; the **KSD-VP-1/1** associated skeleton comes from a locality in another part of the study area. Temporal span and how dated? **Potassium-argon dating** and **magnetostratigraphy**. Most of the hominin fossils are bracketed by the overlying 3.57 ± 0.014 Ma Kilaytoli Tuff (KT) and an underlying 3.82 ± 0.18 Ma **basalt**. Other hominins are just above, within, or just below the 3.72 ± 0.03 Ma Arala Issie Tuff (AT). Hominins found at site The initial collection of 26 dentognathic hominin specimens included fragments of mandibular corpus and maxillae some with teeth, an associated partial mandibular and maxillary dentition, and isolated teeth. The mandibular and dental morphology and the dental metrics are mostly in the zone of overlap between the **Allia Bay** part of the hypodigm of *Australopithecus anamensis* and the **Laetoli** part of the hypodigm of *Australopithecus afarensis*. An associated skeleton assigned to *Au. afarensis* was reported separately. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Haile-Selassie et al. 2007, Deino et al. 2010; Hominins Haile-Selassie et al. 2010a, 2010b; Archeology N/A.

word In any given modern human language a word consists of two components: phonemes, the basic units of sounds, and morphemes, the basic units of meaning, composed of phonemes. In written languages phonemes are represented by letters and morphemes are the combinations of these letters into a meaningful unit called a word (e.g., the sounds or phonemes /k/a/t/ = the morpheme *cat*). There is a long-standing debate as to whether or not words are unique to modern human language and whether or not they exist in the communication systems of other primates (Cheney and Seyfarth 1992, Deacon 1997, Hauser et al. 2002, Pinker and Jakendoff 2005). For example Cheney and Seyfarth (1992) have argued that alarm calls in vervet monkeys function much like words in human language. They note that vervet alarm calls are referential; that is, like words, they point to specific referents (i.e., things out in the

world) in their absence. However, Deacon (1997) and others (e.g., Pinker and Jakendoff 2005) have argued that words do more than point to things in the world such as predators, they also point to symbols or to other words in the lexicon. Furthermore, Pinker and Jakendoff (2005) noted that words are compositional and generative. That is, elements of words (phonemes) can be combined recursively to generate new words and meanings. A word's meaning may change not only depending on the audience, but its linguistic function may change with respect to the same audience (e.g., from a noun as in "wave the *flag*" to a verb as in "*flag* the taxi"). None of these features characterize the calls or songs reported in nonhuman animals. *See also* **language**.

working memory A common way of referring to short-term, or temporary, **memory**. In research, working memory has been studied in relation to a modern human's or nonhuman animal's **memory span**. Working memory is regarded as a fundamental component of the cognitive system for one's ability to recall immediately what just happened is required to adaptively respond to any situation. For this reason, short-term memory is believed play a vital role in everyday decision-making. Coolidge and Wynn (2007) have argued that working memory is unique to modern humans. However, there is ample evidence from cognitive science and neuroscience that this perspective should be rejected (Tomasello and Call 1997). Nonetheless, there is evidence to suggest there are important differences in the working memory systems of modern human and nonhuman primates. For example, a recent study demonstrated that young chimpanzees outperformed modern human subjects in a working memory visual-spatial task (Inoue and Matsuzawa 2007). The authors argued that language, not any uniquely modern human or ape memory system, modulated performance and contributed to the species difference in performance.

woven bone *See* **bone**.

Wu, Xinzhi [吴新智] (1928–) Wu Xinzhi was born in Hefei, Anhui Province, in eastern China. He graduated from the senior high school

affiliated with Wuhan University, in Hubei Province, in 1946. He briefly studied at Tongji University in Shanghai from 1946 to 1947, but in 1947 he entered the Shanghai Medical College to study medicine. While there Wu also studied anatomy at the Ministry of Health from 1952 to 1953. Immediately after completing his medical degree from the Shanghai Medical College in 1953, Wu accepted a position as a research assistant at the Dalian Medical College, in Dalian, Liaoning Province, where he stayed until 1957. Later that year, however, Wu entered the graduate school of the **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP) at the Chinese Academy of Sciences in Beijing. By the time Wu arrived at the IVPP it had become an important institutional center for paleontological, archeological, and paleoanthropological research in China. Wu completed his graduate degree in 1961 and later that year became an assistant researcher at the IVPP. During the 1960s Wu conducted research on the *Homo erectus* fossils of China, and he also became interested in the differences among fossil humans in Asia. This interest in geographical variation in early *Homo sapiens* and *H. erectus* in Asia can be linked to the polycentric theory of human evolution proposed by Franz **Weidenreich**, who had served as the director of the Cenozoic Research Laboratory from 1935 until 1941. Wu was among the scientists who studied the so-called **Dali** cranium, which was discovered in 1978 near Jiefang Village, Shaanxi Province. Wu came to consider this specimen represented an archaic *H. sapiens* with cranial dimensions and morphological features intermediate between *H. erectus* and *H. sapiens*. In 1984 Wu joined Milford **Wolpoff** and Alan Thorne in advocating a theory they called the **multiregional hypothesis**, which built upon Franz Weidenreich's earlier suggestion that there had been a long period of continuous evolutionary development in Asia where *H. erectus* populations had developed geographical morphological characteristics and that these populations had evolved into modern *H. sapiens* populations that displayed similar regional morphological characteristics. Throughout the 1980 and 1990s Wu conducted research into human evolution in China that focused on the relationship of *H. erectus* in Asia to later populations of *H. sapiens*. Wu collaborated with American physical anthropologist Frank Poirier on *Human Evolution in China: a Metric Description of the*

Fossils and a Review of the Sites (1995), which offered a detailed and comprehensive review of the hominin fossils and archeological remains from China. This work argued for the indigenous evolution of modern humans in Chinese from Asian populations of *H. erectus*, and rejected the **out-of-Africa hypothesis**. In 1998 Wu published a paper, in Chinese, in *Acta Anthropologia Sinica* that argued for continuities in cranial and dental traits from archaic *H. sapiens* in China to modern *H. sapiens* in China, as well as from archeological evidence, for a long period of continuous evolutionary change within China, with limited gene flow between this population and other human populations outside of China (NB: he did concede that in other parts of the world there may have been more replacement than continuity). He characterized this theory as "continuity with hybridization," which he presented as a submodel of the multiregional hypothesis. Wu reiterated his support for the multiregional hypothesis in a number of articles, in both English and Chinese, including "On the origins of modern humans in China" published in *Quaternary International* in 2003. He has also published criticisms of the evidence from molecular anthropology that appears to support the out-of-Africa hypothesis as it relates to human populations in China. Besides being a strong advocate of, and an important contributor to, the literature supporting the multiregional hypothesis, Wu continued to conduct basic research on newly discovered hominin fossils in China and has published broadly on paleoanthropology. He published, in collaboration with Weiwen Huang and Guoqin Qi, an important book on Chinese prehistoric sites titled *中国古人类遗址 (Paleolithic Sites in China)* in 1999. Wu has spent his entire career at the Institute of Vertebrate Paleontology and Paleoanthropology where he served as a researcher and later as the IVPP's vice director. In 1986 he was appointed a board member of the Chinese Society for Anatomical Sciences, later becoming its Vice Chairman and the Director of the Society's professional committee on anthropology. He was awarded a prize by the Chinese Academy of Sciences in 1991 for his research into Chinese paleoanthropology and in 1999 he was elected an Academician of the Chinese Academy of Sciences.

Würm See glacial cycles.

Wuyun See Bubing Basin.

X

X chromosome One of the sex chromosomes in modern humans, the great apes, and in most mammals. Normal males possess one X chromosome; normal females possess two X chromosomes. *See also* **Y chromosome**.

X chromosome inactivation X chromosome inactivation (also known as Lyonization) is the process where one (i.e., one copy) of the X chromosomes in females is packaged into heterochromatin such that all, or most, of its gene expression is silenced. This results in dosage compensation so that females do not have twice as much X chromosome gene expression as males. In female mammals, one X chromosome is randomly inactivated early in embryonic development through the initiation of the X inactivation center (Xic). Since inactivation is random, different areas of the body may have different active X chromosomes. If different alleles are present on each X chromosome in a female, this can result in a “patchy phenotype” (e.g., hair color in calico cats).

X-linked X-linked refers to any trait, the alleles for which are located on the X chromosome. These traits can be dominant (in which case, the trait will be present in the phenotype whether one or two alleles for that trait are present in females) or recessive (in which case, the trait will only be present in females if two alleles for the trait are present). Because males normally have only one X chromosome (i.e., they are **hemizygous**) their phenotype will be influenced by whichever allele is present at the locus for a trait.

xeric (Gk *xeros* = dry) An **environment** or **habitat** that is dry.

Xujiayao (许家窑) (Location 40°06'N, 113°59'E, northern China; etym. named after the local village) History and general description This open-air site, discovered in 1974, is located on the west

bank of Liyigou, a small tributary of the Sanggan River about 1 km/0.6 miles southeast of Xujiayao village and 4 km/2.5 miles south of the town of Gucheng, Yanggao County, Shanxi Province. The site is represented by two localities (74093 and 73113), with the majority of the archeological materials recovered from Locality 74093. Excavations in 1976, 1977, and 1979 by the **Institute of Vertebrate Paleontology and Paleoanthropology** under the direction of Professor Jia Lan Po produced large assemblages of hominin fossils, stone artifacts, and vertebrate fossils. These collections make Xujiayao one of the most productive and important (but least-discussed) paleoanthropological sites in mainland East Asia. Temporal span and how dated? According to the original stratigraphic profile, fossils and lithic artifacts are concentrated 8–12 m below the topsoil. **Uranium-series dating** on rhinoceros teeth from a depth of 8 m yields an age range of 125–104 ka. However, a recent geomagnetic study (Løvlie et al. 2001) suggests that the fossil deposits may correspond with the early **Brunhes**, indicating that Xujiayao is coeval with **Zhoukoudian Locality 1**. A program of optically stimulated **luminescence dating** is currently being planned to determine a more reliable age range. Hominins found at site The Xujiayao hominin collection consists of a juvenile maxillary fragment with I¹ (erupting), C (unerupted), M¹ (newly erupted), and M² (erupting), 12 parietal fragments from individuals of different ages, two occipital bones, a temporal bone, a mandibular fragment, and two isolated molars; at least 11 individuals may be represented in the collection. Archeological evidence found at site More than 13,500 stone artifacts have been reported. These include polyhedral cores, **scrapers**, **points**, **anvils**, **gravers**, **choppers**, **spheroids** (potential bolas balls), and other multi-functional implements made from vein **quartz** (65%), **chert**, agate, **quartzite**, metamorphic limestone, and other siliceous and igneous rocks. Most tools are small – it is hypothesized that Xujiayao may constitute one of the principal forerunners of the North Chinese **microlithic** tradition – and

over half show evidence of secondary retouch. A taphonomic study conducted by Norton and Gao (2008) on percussion and tooth-mark frequency and cutmark patterns indicate that the Xujiayao hominins had regular primary access to intact artiodactyls and equid long bones, and thereby procured a regular supply of protein and fat. Repository Institute of

Vertebrate Paleontology and Paleoanthropology (original), Beijing, China. Key references: Geology, dating, and paleoenvironment Chen et al. 1984, Løvlie et al. 2001; Hominins Jia et al. 1979, Wu 1980, 1986, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Brown 2001; Archeology Jia et al. 1979, Wu and Olsen 1985, Norton and Gao 2008.

Y

Y chromosome One of the sex chromosomes in modern humans, the great apes, and in most mammals. Normal males possess one Y chromosome, whereas normal females possess no Y chromosomes. The Y chromosome is much smaller than the X chromosome and only the tips of the Y chromosome (known as the pseudoautosomal regions) undergo **recombination** with the X chromosome during **meiosis**. The non-recombining portion of the Y chromosome contains the *SRY* gene which is the sex-determining gene. The non-recombining portion of the Y chromosome has been examined extensively to investigate modern human population history worldwide (e.g., Hammer et al. 1997, 1998, 2001, Underhill et al. 2000, 2001, Karafet et al. 2008) as well as nonhuman primate population history (e.g., Burrows and Ryder 1997, Stone et al. 2002, Tosi et al. 2002). Hundreds of studies of the modern human Y chromosome have dealt with the geographic origin (Africa) and subsequent global dispersal of modern human males, thereby providing a male-based scenario complementary to the micro-evolutionary historical reconstruction yielded by female-based data (e.g., **mitochondrial DNA**). *See also* X chromosome.

Y-linked The term Y-linked refers to any **trait**, the alleles for which are located on the Y chromosome. The Y chromosome is small and contains few genes, thus Y-linked traits are rare and because only males normally possess Y chromosomes they are passed from fathers to sons.

Ya5 One of the subfamilies of Alu repeat elements that are most active in modern humans. *See* Alu repeat elements.

Ya8 One of the subfamilies of Alu repeat elements that are most active in modern humans. *See* Alu repeat elements.

Yamashita-cho *See* Ryukyu Islands.

YDS Acronym for Younger Dryas stadial. *See* Younger Dryas.

Young's modulus *See* elastic modulus.

Younger Dryas The Younger Dryas was a cold interval in the North Atlantic between 12.8 and 11.5 ka that briefly reversed the warming that took place after the termination of the **Last Glacial Maximum**. It is named for the occurrence of a cold-tolerant plant species in Scandinavia, the alpine/tundra wildflower *Dryas octopetala*. Ice rafting in the North Atlantic suggests that it may be considered as the most recent **Heinrich event**. Cold sea surface temperatures in the North Atlantic and a brief resumption of a glacial-type climate had implications for African precipitation patterns, generally indicating drying. Such is the complexity of the global climate systems that the Younger Dryas in the northern hemisphere coincided with a warm period in the southern hemisphere such that glaciers retreated in what is now New Zealand.

Yuanmou (Location 25°40'N, 101°53'E, China; etym. unknown) History and general description This site is in the Yuanmou Basin, 110 km/66 miles northwest of Kunming. The two original hominin incisors were recovered in 1965 from the Yuanmou Formation. Temporal span and how dated? Early estimates of the antiquity of this site suggested it may be as old as *c.*1.7 Ma, but a careful assessment of the magnetic polarity stratigraphy suggests that the predominant normal polarity of the Yuanmou Formation most likely corresponds to early in the Brunhes chron, *c.*0.7 Ma, and equivalent to **Oxygen Isotope Stage 17**. This is also consistent with the **electron spin resonance spectroscopy dating** estimates of Huang and Grün (1998). Hominins found at site Two incisors that broadly resemble those from *Homo erectus* sites. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Li et al. 1976, Cheng

et al. 1977, Jiang et al. 1989, Huang and Grün 1998, Hyodo et al. 2002; Hominins Hu 1973, Zhou and Hu 1979, Qian and Zhou 1991; Archeology N/A.

Yunxian Quyuanhekou (郧县曲远河口) (Location 32°50'23.97"N, 110°34'42.35"E, central China; etym. named after the local county and the confluence of local rivers) History and general description An open-air site located at Xuetang Liangzi (a known **Paleolithic** locality) just northwest of Mituosi village and the confluence of Quyuan and Han Rivers, or Quyuanhekou (Quyuan River Mouth), Yunxian County, Hubei Province. Collaboration between Chinese and French researchers has thus far resulted in the completion of a **computed tomography** (or CT) prototype of Yunxian II in 2004. Although the reconstruction was principally based on EV 9002, morphometric data from nine Asian *Homo erectus* casts (**Zhoukoudian** III, X, XI, and XII, **Hexian**, **Sangiran** 17, and **Ngandong** 6, 7, and 12) were also referenced. The new cast suggests that (a) the cranial capacity of Yunxian II is within the range of *H. erectus* variability and (b) the mid-facial morphology is likely not anatomically modern-like. Temporal span and how

dated? **Electron spin resonance spectroscopy dating** of nine stratigraphically associated animal teeth produces a mean early-uptake model age of 581 ± 93 ka and a mean late-uptake model age of 1051 ± 150 ka. These dates contradict the evidence from **magnetostratigraphy** that points to an age of 870–830 ka. At present, a mid-Middle Pleistocene age for the Yunxian hominins is the most reasonable estimate. Hominins found at site Two large, presumably male, and badly crushed adult crania (EV 9001 and EV 9002), discovered in 1989 and 1990, respectively. Archeological evidence found at site Some 300 artifacts have been recovered from the site. These include large cores, uni- and bifacial tools worked on pebbles and large cobbles (e.g., **choppers**), **flakes**, and flake fragments. The raw material is predominately (70%) **quartz** and **quartzite**. Repository Hubei Institute of Cultural Relics and Archaeology (original and CT prototype), Wuhan, China. Key references: Geology, dating, and paleoenvironment Chen et al. 1997, Li and Feng 2001; Hominins Li and Etler 1992, Pope 1992, Wu and Poirier 1995, Zhang 1998, Brown 2001, Li and Feng 2001, Violet et al. 2005; Archeology Li et al. 1998, Li and Feng 2001.

Z

Zafarraya (Location 36°57'05"N, 4°07'36"W, Spain; etym. local name for the basin) History and general description A karstic cave located in the northeast of the Málaga province. The cave opening is located about 1100 m above sea level on the southern side of the Sierra de Alhama, and has two distinct areas, the entrance and the cave. The true cave is inclined and is divided into three parts: the entrance hall, the back hall, and the diverticulum at the rear. The excavations of Barroso-Luiz and Medina-Lara from 1980 to 1983 defined five main layers (A–E) near the entrance to the cave. Subsequent work in the early 1990s concentrated on extending the excavations further into the cave. However, the sediments in the interior proved to be highly homogenous, forcing the workers to create artificial levels at 5 cm intervals (I1, I2, I3, etc.). Temporal span and how dated? A uranium-series dating age of 33.4±2 ka was given for an ibex tooth associated with the hominin remains in level D. A tooth from level I8 was found to have a uranium-series date of 31.7±3.6 ka, and a radiocarbon dating age of 31.8±0.5 ka. The mean of three uranium-thorium dates of other samples was c.26.0 ka BP, whereas its radiocarbon equivalent was 29.8±0.6 ka BP. Hominins found at site The first hominin remains from this site were discovered in 1986 by García Sánchez in the lower layers D and E. Most were concentrated near the entrance to the cave, largely in the same level near the bottom of the excavation and centralized around an apparent fireplace. Both adult and juvenile specimens were found, including a well-preserved *Homo neanderthalensis* mandible. Archeological evidence found at site A typical Mousterian lithic assemblage was recovered. However, the scarcity of secondary products and debitage in the assemblage imply that little tool production was done within the cave. The hominin remains were found around a well-defined hearth. *Capra pyraïneica* (i.e., ibex) makes up more than 90% of the identified faunal assemblage. Key references: Geology, dating, and paleoenvironment Hublin et al.

1995; Hominins García Sánchez 1986, Hublin et al. 1995, Sanchez 1999; Archeology Barroso-Ruiz et al. 1984, Hublin et al. 1995.

Zdansky, Otto (1894–1988) A colleague of John Gunnar Andersson who carried out excavations at Locality 1 at Choukoutien (now called Zhoukoudian) in 1921 and 1923. In 1926, while working in Professor Wiman's laboratory in Uppsala, Sweden, examining material excavated from what is now called the Lower Cave at Zhoukoudian, Zdansky recognized a hominin lower premolar and an upper molar tooth, the first of what were to be many fossil hominins recovered from Zhoukoudian. *See also* *Homo erectus*; Zhoukoudian; Zhoukoudian Locality 1.

zeugopod (Gk *zeug* = join and *pod* = foot) The intermediate of the three compartments of a tetrapod limb. The proximal compartment is the **stylopod** (the upper arm or the thigh), the intermediate one is the zeugopod (the forearm or the lower leg), and the distal one is the **autopod** (the hand or the foot).

Zhiren 3 Site Zhirendong. Locality N/A. Surface/in situ *In situ*. Date of discovery May 2008. Finder N/A. Unit B. Horizon Layer 2. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Flowstone level above, dated to 106.2±6.7 ka. Nearest underlying dated horizon N/A. Geological age c.110 ka. Developmental age Late adolescent/young adult. Presumed sex Unknown. Brief anatomical description Edentulous mandibular fragment extending from middle of the right P₄ alveolus to the distal portion of the left P₄ alveolus; there is damage to both P₄ alveoli and enlargement of both P₃ alveoli. While the morphology of the chin appears similar to a modern human, aspects of the mandibular corpus are more similar to Late Pleistocene archaic hominins. Announcement Jin et al.

2009. Initial description Jin et al. 2009. Photographs/line drawings and metrical data Liu et al. 2010, Jin et al. 2009. Detailed anatomical description Liu et al. 2010. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current convention taxonomic allocation *H. sapiens*. Informal taxonomic category Modern human. Significance If dates are secure, hominin remains at this site represent the earliest evidence of modern humans in East Asia. The so-called “mosaic” features of the gnathic remains have cited as evidence of admixture between anatomically modern and archaic *H. sapiens* populations. Location of original **Institute of Vertebrate Paleontology and Paleoanthropology**, Chinese Academy of Sciences, Beijing, China.

Zhiren Cave *See* Zhirendong.

Zhirendong (Location 22°17'13.6''N, 107°30'45.1''E, 2 km/1.2 miles northwest of Chongzuo Eco-Park within the Mulanshan, Chongzuo City, Guangxi Zhuang Autonomous Region, southern China) History and general description In November 2007 researchers from the **Institute of Vertebrate Paleontology and Paleoanthropology** and the Chongzuo Biodiversity Research Center of Peking University recovered a collection of mammalian fossils that included evidence of anatomically modern *Homo sapiens*. If dates at this site are secure, they represent the oldest evidence of modern humans in East Asia. Temporal span and how dated? Biostratigraphy, uranium-series dating, and stratigraphic correlation to Oxygen Isotope Stages suggest an age of *c.*110 ka. Hominins found at site The fragmentary hominin remains consist of gnathic and dental evidence, most notably **Zhiren 3**. Archeological evidence found at site None reported. Key references: Geology, dating, and paleoenvironment Liu et al. 2010, Jin et al. 2009; Hominins Liu et al. 2010; Archeology N/A.

Zhongshan *See* Bubing Basin.

Zhoukoudian History and general description The most productive fossil hominin locality in China, Zhoukoudian (former transliteration: Choukoutien) was recognized as a UNESCO World Heritage Site in 1987. The cave complex that produced both the “Peking Man” (originally attributed to the new hominin genus and species *Sinanthropus pekinensis*, now referred to *Homo erectus*) and the

“Upper Cave” fossils is located approximately 42 km/26 miles south of Beijing. In 1918, the Swedish geologist John Gunnar **Andersson** discovered the site having been led to the nearby “Chicken Bone Hill” by villagers who knew he was looking for fossils. In 1921, Andersson and Otto **Zdansky**, an Austrian paleontologist, commenced excavations on the neighboring “Dragon Bone Hill” after quarrymen showed them exotic quartz found during mining operations. Among the fossils that were excavated from there in 1923 Zdansky recognized two isolated teeth as potentially hominin and in 1926 an isolated lower first molar was sent to Davidson **Black** for analysis. Black, a Canadian chairing the anatomy department at the **Peking Union Medical College**, appreciated the specimen’s importance and uniqueness and within a year Black had formally proposed a new taxon name *Sinanthropus pekinensis* for what he judged to be a new species. Large-scale excavations overseen by Black started in 1927 and continued after his death in 1934. In 1928 the first hominin cranium was recovered from Zhoukoudian, followed in the next 2 years by discoveries of the first stone tools and ash layers containing burned bone that were interpreted as evidence of the controlled use of fire. After Black’s death, excavations were directed by his successor, German anthropologist Franz **Weidenreich**, until they were halted in 1937 by the outbreak of the Second Sino-Japanese War. Nearly 200 *H. erectus* fossils representing up to 45 individuals were recovered from Zhoukoudian from 1921 to 1966. In addition, tens of thousands of stone artifacts and fossils representing at least 98 nonhuman mammalian species have been produced by these excavations. All of the *H. erectus* fossils derive from **Zhoukoudian Locality 1** in the Lower Cave, an approximately 40 m-thick depositional sequence that has been divided into layers. These are numbered 1–17 with Layer 1 being the highest and the youngest stratum and 17 the deepest and the oldest; most of the hominin fossils derive from Layers 8–9 and 3–4. The Upper Cave at Zhoukoudian was discovered in 1930 and excavations from 1933 to 1934 produced three skulls; the remains from at least eight individuals have been attributed to modern *Homo sapiens* and date to the Upper Pleistocene. Temporal span and how dated? *See* **Zhoukoudian Locality 1; Zhoukoudian Upper Cave**. Hominins found at site The history of discovery of the Zhoukoudian *H. erectus* fossils is fascinating, but fraught with tragedy and loss. Fortunately, Weidenreich was an extraordinarily meticulous and conscientious

scientist who photographed, casted, and described in fine detail all of the hominin fossils discovered at Zhoukoudian. He produced four monographs on the *Sinanthropus* fossils and they remain the definitive descriptions of these fossils. Paleoanthropology owes Weidenreich a substantial debt because all of the “Peking Man” fossils became yet another casualty of WWII. Entrusted to a US Marine contingent tasked with escorting the fossils safely out of occupied China, the American servicemen had the bad luck to arrive at the Port of Beijing on December 7, 1941. With the US now at war with Japan following that day’s attack on Pearl Harbor, the Marines were imprisoned as prisoners of war and the “Peking Man” fossils were never to be seen again. Archeological evidence found at site Tens of thousands of quartz, flint, and sandstone tools have been found at Zhoukoudian Locality 1. Most can be assigned to one of four primary tool types (choppers, scrapers, points, and burins) that were manufactured by a variety of hard-hammer percussion techniques. Initial interpretations of *H. erectus*’ behavior at Zhoukoudian suggested that the site was a home base where hunted animals were consumed, tools were made, and fire was controlled. However, a more recent, taphonomically informed study suggests that giant cave hyenas were the primary resident of the Lower Cave and that *H. erectus* could be best characterized as a transient scavenger who used (but did not necessarily control) fire during their more sporadic and ephemeral occupations of the site. Key references: see **Zhoukoudian Locality 1; Zhoukoudian Upper Cave**. See also Davidson Black; John Gunnar Andersson; Otto Zdansky.

Zhoukoudian Locality 1 (周口店第一地点) (Location 39°41′18.77″N, 115°55′32.50″E, northern China; etym. named after the local village) History and general description Although it is referred to as “Locality 1” it is effectively a fossil site in its own right. The site is situated on the northeastern slope of Longgushan (Dragon Bone Hill) near Zhoukoudian village, 50 km/31 miles southwest of Beijing Municipality. The site, which is referred to as “Locality 53” in John Gunnar Andersson’s field notes, is subdivided into three, areas, the “Main Deposit,” the “Lower Fissure,” and the “Kotzetang.” Sporadic excavations began in 1921, but large-scale excavations did not commence at Locality 1 until 1927 and they continued until the Second Sino-Japanese war broke out in 1937. Locality 1 has been made unnecessarily confusing

because of the proliferation of systems used to describe it (e.g., loci, layers, and levels). The loci identified by a capital letter are effectively spatially bound “localities” within Locality 1 where at least one hominin specimen has been found (e.g., two calvariae have been found at Locus L, which in Davidson Black’s terminology are “Skull I” and “Skull II”). Both layers and levels use arabic numerals (e.g., Layer 8 is equivalent to Level 22). The layers are numbered 1–17 with Layer 1 being the highest and the youngest stratum and 17 the deepest and the oldest; most of the hominin fossils derive from Layers 8–9 and 3–4. Temporal span and how dated? Locality 1 is divided into 17 stratigraphic horizons. Layers 1–13 are considered to be culture- and fossil-bearing layers. Until very recently it was thought that Locality 1 in the Lower Cave was entirely **Middle Pleistocene** in age. An age range of *c.* 500–230 ka for hominin occupation at Zhoukoudian’s Lower Cave was supported by a number of studies published from the late 1970s through the late 1990s employing **fission-track dating**, **uranium-series dating**, and **electron spin resonance spectroscopy dating**. A review by Zhou Ming Zhen and Ho Chuan Kun (1990) suggests an age range between 520±61 ka (for Layer 11) and 230+30/–23 ka (for Layer 4). However, because of the large margins of error in the methods used, most dates are likely not very reliable. Renewed efforts in the last decade using higher-precision techniques and refined correlations to deep-sea **Oxygen Isotopic Stages** and **loess** sequences indicate that the layers of interest are older than previously thought. **Thermal ionization mass spectrometry uranium-series dating** of Layer 3, which yielded Skull V, are *c.* 500–400 ka and the dates for Layers 8–11, which yielded Skulls II, III, X, XI, and XII, are more than 600 ka. Likewise, a recent **cosmogenic nuclide dating** study suggests an age of 770±80 ka for Layers 7–10. Together with climatic correlations, the hominin-bearing layers are now bracketed between 780 and 400 ka. This means that **Hexian** (437–387 ka) and **Tangshan Huludong** (*c.* 620 ka) are **coeval** with some of the later Zhoukoudian hominins. Hominins found at site Before full-scale excavation commenced at Locality 1, Otto Zdansky and Davidson Black recovered three teeth. Between 1927 and 1937, five calvariae (Skulls II, III, X, XI, and XII) and other cranial fragments belonging to 13 individuals, 15 mandibular fragments belonging to 14 individuals, two humeral fragments, seven femoral fragments, one left clavicular fragment, a lunata, and

147 teeth belonging to at least six individuals were unearched. Between 1949 and 1966, additional specimens were found either during excavations (teeth and craniognathic fragments) or in older, pre-WWII collections (a humeral fragment, a tibial fragment, and a right lower molar). Altogether, up to 40 individuals may be represented in the Zhoukoudian Locality 1 hominin (aka “Peking Man”) collection. The *H. erectus* fossils recovered from the Lower Cave at Zhoukoudian were each assigned alphanumeric designations reflecting the location (=“Locus”) and sequence of their discovery. In addition, Weidenreich proposed a new numbering scheme for the cranial (Weidenreich 1943) and postcranial (Weidenreich 1941b) remains. For the cranial (i.e., the calvariae and facial fragments) he replaced the informal specimen numbers used by the people who discovered and initially described the fossils (see Weidenreich 1943, Table 1, p. 5). For example, the first calvaria discovered in 1929 was informally known as “D I” (having been the first hominin recovered from Locus D in Layers 8–9), but in Weidenreich’s scheme it is referred to as “Skull II.” The other five most complete calvaria are designated as follows: “E I” (from Locus E, Layer 11, discovered in 1929) is “Skull III”; “H III” (from Locus H, Layer 3, discovered in 1934 and previously referred to by Weidenreich as “Skull III”) is “Skull V”; “L I” (from Locus L, Layers 8–9, discovered in 1936 and previously referred to as “Skull I Locus L”) is “Skull X”; “L II” (from Locus L, Layers 8–9, discovered in 1936 and previously referred to as “Skull II Locus L”) is “Skull XI;” and “L III” (from Locus L, Layers 8–9, discovered in 1936 and previously referred to as “Skull III Locus L”) is “Skull XII” (NB: in the section on “Choukoutien, Locality 1” in Oakley et al. 1975 Susan Limbrey uses arabic instead of roman numerals, as in “D 1,” “E 1,” etc., and uses the prefix “Upp.” for the two teeth sent back to Sweden and “Ckn.” for the fossils that stayed in China). Weidenreich used the same type of scheme for the postcranial remains, with separate sequences of Roman numerals used for the femora, the two humeral remains, and for the clavicle and the lunate (see Weidenreich 1941b, Table 1, p. 6). Archaeological evidence found at site Large numbers of artifacts and debitage have been collected from Layers 1–13. **Quartz** (89%) or vein quartz, is the primary raw material used. Most of the tools are of **Mode 1** type and standardization is poor. Zooarcheological analyses and the presence of hyena coprolites suggest that *H. erectus* and carnivores may have competed

with each other for food and shelter in the cave. As early as the 1930s, evidence of hearth and ash deposits (e.g., from Layer 10) has been noted; however, recent investigation failed to find features of *in situ* burning or direct evidence for use of fire by *H. erectus*. Key references: Geology, dating, and paleoenvironment Wu and Wang 1985, Zhou and Ho 1990, Grün et al. 1997a, Zhou et al. 2000, Goldberg et al. 2001, Shen et al. 2001, 2009; Hominins Black 1927, Weidenreich 1936a, 1936b, 1937, 1939c, 1941b, 1943, Wu and Dong 1985, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Tattersall and Sawyer 1996, Holloway 2000, Brown 2001, Wu et al. 2010; Archeology Teilhard de Chardin and Pei 1932, Pei and Zhang 1985, Wu and Olsen 1985, Zhang 1985, Binford and Stone 1986, Wu and Poirier 1995, Weiner 1998, Wu et al. 1999, Boaz et al. 2004. A concise history of the initial phase of fieldwork (i.e., exploration and subsequent excavations) at Zhoukoudian Locality 1 can be found in Black (1934). *See also Zhoukoudian Locality 1 hominins.*

Zhoukoudian Locality 1 hominins Site Zhoukoudian Locality Locality 1. Surface/in situ *In situ*. Date of discovery 1923–66. Finders The hominins were recovered by unnamed excavators. Unit N/A. Horizon Most hominins come from Layers 8–9 and 3–4. Bed/member N/A. Formation N/A. Group N/A. Geological age A review by Zhou Ming Zhen and Ho Chuan Kun (1990) suggests an age range between 520±61 ka (for Layer 11) and 230+30/-23 ka (for Layer 4). However, because of the large margins of error in the methods used, most dates are likely not very reliable. The combination of higher precision dating techniques and correlations with deep-sea **Oxygen Isotopic Stages** and loess sequences suggests the hominin-bearing layers are now bracketed between 780 and 400 ka. Developmental age Both adults and juveniles are represented in the collection. Presumed sex Sex is largely assigned on the basis of the overall size of the specimens. Brief anatomical description There are several well-preserved calvariae (e.g., Skulls II, III, X, XI, and XII), isolated cranial bones, maxillary and mandibular fragments (some with teeth) (e.g., Maxillae III, V, and VI; Mandibles B I, G I), isolated teeth, and some postcranial fossils (e.g., Femora I and IV and Humerus II). The endocranial volumes of the calvariae range from 915 cm³ (Skull III) to 1225 cm³ (Skull V). Announcements and initial descriptions Most of the fossils recovered in the 1920s were announced by Davidson **Black** (see Black 1934 for references). Photographs/line drawings,

metrical data, and detailed anatomical description The main Locality 1 collection is well illustrated and meticulously described in the monographs published by Franz Weidenreich (1936a, 1936b, 1937, 1939c, 1941b, 1943). Initial taxonomic allocation *Simanthropus pekinensis*. Taxonomic revisions *Homo erectus* (Weidenreich 1940). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance There has never been any serious suggestion that the hominins recovered from Locality 1 sample a taxon other than *H. erectus* and as such they comprise the single largest site collection of that taxon. Location of originals or surviving casts University of Uppsala, Sweden (two teeth recovered by Otto Zdansky); American Museum of Natural History, New York, USA (casts of the 1927–37 materials); Institute of Vertebrate Paleontology and Paleoanthropology, Beijing, China (originals of the hominins recovered post-WWII).

Zhoukoudian Upper Cave (Location 39°41' 18.77"N, 115°55'32.50"E, Beijing, China; etym. named after the local village) History and general description The second, and less well-known, locality at the Zhoukoudian site is called Upper Cave (or UC) because it is literally situated above Locality 1 (the latter is sometimes also referred to as Lower Cave). The UC was discovered in 1930 during fieldwork at Locality 1, with excavations taking place in 1933 and 1934. The UC, which is 4 m wide and 8 m deep, comprises an Entrance, Upper Room, Lower Room, and Lower Recess. Five cultural layers were identified: Layers 1–3 in the Entrance and Upper Room and Layers 4 and 5 in the Lower Room. Taphonomic analysis of the UC faunal assemblage suggests that hunter-gatherers were involved with the formation of the animal bones found in the cultural layers. Pei Wenchung suggested that the Lower Recess most likely served as a natural trap, and this hypothesis is supported by the results of taphonomic analyses, the presence of multiple semi-articulated deer skeletons, and the absence of *Celtis* seeds. The reason why UC receives so much attention is the presence of multiple modern human fossils, thought to have been interred, and the archeological evidence of modern human behavior. The evidence for modern human burials is strong, but examination of the casts of the modern human postcranial remains suggests that at least some of the limb bones appeared to have been chewed (epiphyses are missing and the midshafts display

multiple toothmarks) by carnivores. A likely scenario is that the modern human remains were interred, but not deeply enough, and carnivores subsequently dug up the burials and gnawed on some of the bones. Temporal span and how dated? The UC deposits have been dated using conventional **radiocarbon dating**, **thermoluminescence dating**, **uranium-series dating**, and more recently **AMS radiocarbon dating**. The chronometric dates from Layer 4 where the modern human burials are reportedly derived are between *c.*34 and 10 ka BP. Although some researchers have argued for an Early **Holocene** age for the modern human burials, the faunal composition, particularly the presence of extinct species (e.g., *Hyaena ultima*), suggests a **Late Pleistocene** age. Assuming this is true, then the presence of warm-adapted species (e.g., *Acinonyx jubatus*) would suggest an **Oxygen Isotope Stage 3** age of occupation, rather than a warm period during the Holocene, as proponents of a more recent, Neolithic, age have suggested. Hominins found at site The hominin fossils, which represent at least eight individuals, include three relatively intact crania (UC 101, 102, 103), four mandibles, dozens of loose teeth, and an assortment of postcranial fragments. UC 101 has been interpreted to be an aged male, while UC 102 a middle-aged female, and UC 103 a teenage female; all are considered modern human. The UC modern human fossils, particularly the three crania, have been used as evidence, primarily by Chinese paleoanthropologists, of morphological continuity between *Homo erectus* from Zhoukoudian Locality 1 and modern Chinese. However, the results of multivariate analyses (Cunningham and Jantz 2003) suggest that none of the UC crania have particularly strong phenetic ties to modern-day Chinese and instead, their affinities are with European Caucasoid (UC 101), Melanesian (UC 102), and Eskimo (UC 103) populations. Archeological evidence found at site Excavations at UC have yielded small stone flake tools and evidence of what are assumed to be personal adornments (e.g., perforated shell, bone, teeth, and stone). Some of these perforated artifacts were found near the necks of some of the interred humans and they are most likely necklaces. A perforated bone needle suggests a reliance on sewn clothing, and several bones and artifacts were covered with red hematite. Most of the artifacts are associated with the modern human burials from Layer 4, but some were excavated from the upper layers. The presence of sea shells (*Areca* sp.) attests to either a regional trade network or to long-range mobility. Repository Most of the UC materials are

stored in the Institute of Vertebrate Paleontology and Paleoanthropology, the Zhoukoudian Museum, and the Geological Sciences Museum, Beijing, China. However, as with the Zhoukoudian Locality 1 *H. erectus* fossils, most of the original UC *Homo sapiens* fossils were lost during WWII. Casts of the three modern human crania (UC 101, 102, 103) are housed in many repositories around the world. Zinjanthropus Leakey, 1959 (Swa. *Zinj* = East Africa and Gk *anthropos* = human being) Genus established by Louis Leakey in 1959 to accommodate fossil hominins recovered in 1955 and 1959 in Bed I, Olduvai Gorge, Tanzania. John Robinson (1960) suggested it was a junior synonym of *Paranthropus* and Leakey (1963) subsequently sank *Zinjanthropus* into *Australopithecus*.

Zinjanthropus boisei Leakey, 1959 (etym. Swa. *Zinj* = East Africa, Gk *anthropos* = human being, and *boisei* to recognize the substantial help provided to Louis and Mary Leakey by Charles Boise) Hominin species established by Louis Leakey in 1959 to accommodate fossil hominins recovered in 1955 and 1959 in Bed I, Olduvai Gorge, Tanzania. Arguably the most distinctive early hominin taxon. The skull resembles an exaggerated version of *Paranthropus robustus*, with ectocranial crests, a massive, flat, broad face, large, robust mandibular corpora, small anterior teeth, molarized premolar crowns and roots, and large molar tooth crowns, and there is substantial cranial sexual dimorphism. The genus *Zinjanthropus* is now regarded as a junior synonym of either *Australopithecus* or *Paranthropus*. Until the discovery of *Homo habilis* Louis Leakey assumed that *Z. boisei* was the manufacturer of the "Oldowan pre-Chelles-Acheul culture" (Leakey 1959, p. 491). First discovery OH 3 (1955). Holotype OH 5 (1959). Main sites Chesowanja, Konso, Koobi Fora, Malema, Olduvai Gorge, Peninj (Natron),

Omo-Shungura Formation, West Turkana. *See also Zinjanthropus*.

Zlatý Kůň (Location 49°55'N, 14°05'E, Czech Republic; etym. Czech for golden horse) History and general description Cave site in the Bohemian Karst, Central Bohemia, in the Zlatý Kůň Hill, 500 m from Koneprusy village. Hominin remains were found together with Pleistocene fauna and lithic artifacts between 1950 and 1953. Initially thought to represent the early Upper Paleolithic, this specimen has now been redated to the Late Paleolithic (Magdalenian). Temporal span and how dated? Radiocarbon dating of human bone provided a date of 12,900 years BP. Hominins found at site Zlatý Kůň 1 and 2 are two pieces from the same *Homo sapiens* calvaria. Additional specimens include a zygomatic bone, a mandible, five vertebrae, and three ribs. Archeological evidence found at site Non-diagnostic Upper Paleolithic tools were recovered. Key references: Geology, dating, and paleoenvironment Svoboda et al. 2002; Archeology Svoboda 2000; Hominins Vlček 1971, Smith 1982.

zoarcheology (Gk *zoio* = a living being and *arkhaiologia* = the study of antiquity) Zooarcheology is a subdiscipline of archeology concerned with the study of the animal remains from archeological sites, including bone, teeth, antlers, and shells. Zooarcheological data are used to reconstruct hominin diets and subsistence strategies, past environments, and the interactions between people and animal communities. As a result, zooarcheology provides information critical to understanding both hominin evolution and how environments have changed through time. For example, zooarcheological evidence concerning the foraging behavior of Middle Stone Age hominins plays a central role in attempts to understand the origins of modern human behavior. Some argue that Middle Stone Age hominins exploited animal resources less effectively than their Later Stone Age successors, although a growing body of evidence suggests that Middle Stone Age subsistence was essentially similar to that of Later Stone Age hominins and modern human hunter-gatherers. *See also diet reconstruction*.

Zoologische Staatssammlung München (or ZSM) This museum contains the Zoological Collection of the State of Bavaria, Germany. The collection was begun when the Elector of Bavaria in

the mid-18thC decided to start collecting natural history objects. From the beginning of the 19thC the collection was housed in the Wilhelminum, a building owned by the Academy of Science, and its first curator was Johann von Spix, who added his own important South American material to the collection. During WWII the Wilhelminum was bombed, but most of the collection had been transferred to safety in the countryside. After the war a temporary home was found for the collection in the Nymphenburg Castle until a new purpose-built facility was constructed in its present location on Münchhausenstrasse. Parts of a separate collection, the Anthropologische Staatssammlung, including the Selenka Collection, which consists of the skulls of 59 Sumatran and 328 Bornean orangutans of all ages and sexes, were transferred to the Zoologische Staatssammlung in 2000. Contact information E-mail zsm@zsm.mwn.de. Postal address Münchhausenstr. 21, 81247 München, Germany. Website www.zsm.mwn.de. Tel +49 (0)89 8107 0.

Zourhah See El Harhoura.

Zuttiyeh (Location 32°51'N, 35°30'E, Israel; etym from Ar. *Mugharet el-Zuttiyeh* = Cave of the Robbers) History and general description F. Turville Petre spent the summer of 1925 excavating this cave site, which is located in the Wadi Amud about 3.5 km/2 miles northwest of the Sea of Galilee. Temporal span and how dated? The nature of the lithic assemblage suggests an age of more than 200 ka. Hominins found at site A nearly complete frontal with part of the left zygomatic. Keith (1927) originally referred to the specimen as *Neanderthaloid*, but more recently authors have moved away from this interpretation, suggesting that the hominin from Zuttiyeh belongs to the population that may have given rise to the later population sampled at sites such as *Skhul*. Archaeological evidence found at site The assemblage was originally regarded as being Lower Levantine *Mousterian*, but it is now recognized that the industry at Zuttiyeh is closer to the much older *Acheulo-Yabrudian*. Key references: Geology, dating, and paleoenvironment N/A; Hominins Turville-Petre 1927, Keith 1927, Sohn and Wolpoff 1993, Zeitoun 2001; Archaeology Garrod and Bate 1937, Bar-Yosef 1989.

zygomatic prominence A bulbous protuberance at the anterior end of the zygomatic arch in the region of the zygomaticomaxillary suture. It is one of the features Rak (1983) linked with *Australopithecus africanus* (e.g., Sts 5, Sts 71) and similar morphology is also seen in *Paranthropus robustus* and in *KNM-WT 17000*; zygomatic prominences contribute to the wide mid-faces of these taxa. The zygomatic prominence marks the more-or-less abrupt transition from the forward-facing facial surface of the zygomatics to the laterally facing surface of the their temporal process. When the zygomatic prominences project anteriorly they contribute to the “dishing” of the face seen in some archaic hominins.

zygomaticoalveolar crest The anatomical term for the inferior margin of the maxilla's zygomatic process, which arises from the alveolar process to join the zygomatic process of the temporal bone, thus completing the zygomatic arch. In the great apes and modern humans the zygomaticoalveolar crest usually arches downward as it leaves the maxilla, but in some archaic hominins (e.g., *Australopithecus africanus*, *Paranthropus robustus*, some *Paranthropus boisei*) it is straight so that, when seen in *norma frontalis*, it angles superolaterally to meet the zygomatic process of the temporal.

zygomaticomaxillary fossa A term used by Clarke (1977) for a hollowed area that spans the inferolateral third of the zygomaticomaxillary suture and interrupts the **zygomaticomaxillary step** in the lateral mid-face of *Paranthropus robustus*.

zygomaticomaxillary step A term used by Rak (1983, p. 32) to describe the morphology of the lateral upper mid-face of *Paranthropus robustus* (it is also seen in *KNM-WT 17000*). The anterior surface of the zygomatic bone of *P. robustus* is forward-facing and projects further anteriorly than the medial part of the mid-face. This results in a “step” that coincides with the zygomaticomaxillary suture. In its lower one-third the zygomaticomaxillary step is interrupted by a transverse groove at right angles to its long axis. In his thesis Ron Clarke (1977) refers to this as the **zygomaticomaxillary fossa**. The zygomaticomaxillary step forms the superolateral boundary of the **maxillary trigon** (Rak 1983, Fig. 16, p. 135).
