Foreword

There is at present a consensus that the 21st century will be the century of biology, just as the 20th century was the century of physics. Biology now has larger budgets and a larger workforce than physics, and it faces problems of great significance and relevance to the understanding of human nature and the conduct of human life. The core of all biological research and understanding is the theory of evolution; evolution by natural selection is the central unifying concept of biology. As the great 20th century evolutionist Theodosius Dobzhansky asserted in 1973, “Nothing in biology makes sense except in the light of evolution.”

The theory of evolution has transformed our understanding of life on planet Earth. Evolution provides a scientific explanation for why there are so many different kinds of organisms and why they all share the same chemical components in similar proportions, and why all organisms share DNA as their hereditary material, and why enzymes and other proteins, which are the fundamental constituents and engines of cell processes, are all made up of the same 20 amino acids, despite hundreds of amino acids existing in organisms. Evolution demonstrates why some organisms that look quite different are in fact related, while other organisms that may look similar are only distantly related. It accounts for the origins of humans on Earth and reveals our species’ biological connections with other living things in varying degrees. Evolution explains the similarities and differences among modern human groups and modern human individuals. It enables the development of effective new ways to protect ourselves against constantly evolving bacteria and viruses, and to improve the quality of our agricultural products and domestic animals.

We owe the concept of evolution by natural selection to Charles Darwin. Natural selection was proposed by Darwin primarily to account for the adaptive organization, or design, of living beings; it is a process that preserves and promotes adaptation. Evolutionary change through time and evolutionary diversification (multiplication of species) often ensue as byproducts of natural selection fostering the adaptation of organisms to their milieu. Evolutionary change is not directly promoted by natural selection and, therefore, it is not its necessary consequence. Indeed, some species remain unchanged for long periods of time, as Darwin noted. Nautilus, *Lingula*, and other so-called living fossils were used by Darwin as examples of organisms that have remained unchanged in their appearance for millions of years.

Evolution affects all aspects of an organism’s life: morphology (form and structure), physiology (function), behavior, and ecology (interaction with the environment). Underlying these changes are changes in the hereditary materials. Hence, in genetic terms, evolution consists of changes in an organism’s hereditary makeup and can be seen as a two-step process. First, hereditary variation arises by mutation; second, selection occurs by which useful variations increase in frequency and those that are less useful or injurious are eliminated over the generations. As Darwin (*The Origin of Species*, 1859) saw it, individuals having useful variations “would have the best chance of surviving and procreating their kind” (p. 81). As a consequence, useful variations increase in frequency over the generations, at the expense of those that are less useful or are injurious.

Natural selection is much more than a “purifying” process, for it is able to generate novelty by increasing the probability of otherwise extremely improbable genetic combinations. Natural selection in combination with mutation becomes, in this respect, a creative process. Moreover, it is a process that has been occurring for many millions of years, in many different evolutionary lineages, and in a multitude of species, each consisting of a large number of individuals. Evolution by mutation and natural selection has produced the enormous diversity of the living world with its wondrous adaptations and it accounts for our presence, *Homo sapiens*, on planet Earth.

There is a version of the history of ideas that sees a parallel between two scientific revolutions, the Copernican and the Darwinian. In this view, the Copernican Revolution consisted of displacing the Earth from its previously accepted locus as the center of the universe, moving it to a subordinate place as just one more planet revolving around the sun. Similarly, in a congruous manner, the Darwinian Revolution is

viewed as consisting of the displacement of modern humans from their exalted position as the center of life on Earth, with all other species created for the service of humankind. According to this version of intellectual history, Copernicus had accomplished his revolution with the heliocentric theory of the solar system. Darwin's achievement emerged from his theory of organic evolution. (Sigmund Freud refers to these two revolutions as "outrages" inflicted upon humankind's self-image and adds a third one, his own. He sees psychoanalysis as the "third and most bitter blow upon man's craving for grandiosity," revealing that man's *ego* "is not even master in his own house.")

What the standard versions of the Copernican and Darwinian revolutions say is correct but inadequate. It misses what is most important about these two intellectual revolutions, namely that they ushered in the beginning of science in the modern sense. These two revolutions may jointly be seen as the one Scientific Revolution, with two stages, the Copernican and the Darwinian.

The Copernican Revolution was launched with the publication in 1543, the year of Nicolaus Copernicus' death, of his *De revolutionibus orbium caelestium* (*On the Revolutions of the Celestial Spheres*), and it bloomed in 1687 with the publication of Isaac Newton's *Philosophiae naturalis principia mathematica* (*The Mathematical Principles of Natural Philosophy*). The discoveries by Copernicus, Kepler, Galileo, Newton, and others, in the 16th and 17th centuries, had shown that Earth is not the center of the universe, but is a small planet rotating around an average star; that the universe is immense in space and in time; and that the motions of the planets around the sun can be explained by the same simple laws that account for the motion of physical objects on our planet. These include laws such as $f = m \times a$ (force = mass \times acceleration) or the inverse-square law of attraction, $f = g(m_1 m_2) / r^2$ (the force of attraction between two bodies is directly proportional to their masses, but inversely related to the square of the distance between them).

These and other discoveries greatly expanded modern human knowledge. The conceptual revolution they brought about was more fundamental yet: a commitment to the postulate that the universe obeys immanent laws that account for natural phenomena. The workings of the universe were brought into the realm of science: explanation through natural laws. Potentially, all physical phenomena could be accounted for, as long as the causes were adequately known.

The advances of physical science brought about by the Copernican Revolution had driven humankind's conception of the universe to a split-personality state of affairs, a condition that persisted well into the mid-19th century. Scientific explanations, derived from natural laws, dominated the world of nonliving matter, on the Earth as well as in the heavens. Supernatural explanations, which depended on the unfathomable deeds of the creator, were accepted as explanations of the origin and configuration of living creatures. Authors, such as William Paley in his *Natural Theology* (1802), had developed the "argument from design," the notion that the complex design of organisms could not have come about by chance, or by the mechanical laws of physics, chemistry, and astronomy, but was rather accomplished by an omnipotent deity, just as the complexity of a watch, designed to tell time, was accomplished by an intelligent watchmaker.

Darwin completed the Copernican Revolution by drawing out for biology the notion of nature as a lawful system of matter in motion that modern human reason can explain without recourse to supernatural agencies. Darwin's greatest accomplishment was to show that the complex organization and functionality of living beings can be explained as the result of a natural process: natural selection. The origin and adaptations of organisms in their profusion and wondrous variations were thus brought into the realm of science.

Darwin's theory of evolution by natural selection disposed of Paley's arguments: the adaptations of organisms are not outcomes of chance, but of a process that, over time, causes the gradual accumulation of features beneficial to organisms. There is "design" in the living world: eyes are designed for seeing, wings for flying, and kidneys for regulating the composition of the blood. But the design of organisms is not intelligent, as would be expected from an engineer, but imperfect and worse: defects, dysfunctions, oddities, waste, and cruelty pervade the living world. Darwin's focus in *The Origin of Species* (1859) was the explanation of design, with evolution playing the subsidiary role of supporting evidence.

It follows from Darwin's explanation of adaptation that evolution must necessarily occur as a consequence of organisms becoming adapted to different environments in different localities, and to the ever-changing conditions of the environment over time, and as hereditary variations become available at a particular time that improve, in that place and at that time, the organisms' chances of survival and reproduction.

Origin's evidence for biological evolution is central to Darwin's explanation of design, because this explanation implies that biological evolution occurs, which Darwin therefore seeks to demonstrate in the second half of the book.

Darwin and other 19th century biologists found compelling evidence for biological evolution in the comparative study of living organisms, in their geographic distribution, and in the fossil remains of extinct organisms. Since Darwin's time, the evidence from these sources has become stronger and more comprehensive, while biological disciplines that have emerged recently – genetics, biochemistry, ecology, animal behavior (ethology), neurobiology, and especially molecular biology – have supplied powerful additional evidence and detailed confirmation. Accordingly, evolutionists are no longer concerned with obtaining evidence to support the fact of evolution, but rather are concerned with finding out additional information of the historical process in cases of particular interest. Moreover and most importantly, evolutionists nowadays are interested in understanding further and further how the process of evolution occurs.

Nevertheless, important discoveries continue, even in traditional disciplines, such as paleontology. Skeptical contemporaries of Darwin asked about the “missing links,” particularly between the extant apes and modern humans, but also between major groups of organisms, such as between fish and terrestrial tetrapods or between reptiles and birds. Evolutionists can now affirm that these missing links are no longer missing. The known fossil record has made great strides over the last century and a half. Many fossils intermediate between diverse organisms have been discovered over the years. Two examples are *Archaeopteryx*, an animal intermediate between reptiles and birds, and *Tiktaalik*, intermediate between fishes and tetrapods.

The missing link between apes and humans is not, either, missing any longer. Not one, but hundreds of fossil remains from hundreds of individual hominins have been discovered since Darwin's time and continue to be discovered at an accelerated rate. The history of hominin discoveries is narrated in this encyclopedia, as well as the anatomical and other changes that occur through time.

Darwin wrote two books dedicated to human evolution: *The Descent of Man, and Selection in Relation to Sex* (2 vols, 1871) and *The Expression of the Emotions in Man and Animals* (1872). What we now know about human evolution is immensely more than what Darwin knew. But, even concerning hominin fossil history, much remains to be discovered. Indeed, the sequence that goes from the most primitive hominins to *Homo sapiens*, our species, is not resolved. That is, in many cases we do not know whether a particular hominin fossil belongs to the line of descent that goes to our species, or whether it belongs to a lateral branch.

There are many other important issues concerning the evolutionary origin of modern human traits – anatomical, physiological, behavioral, and cultural – that remain largely unknown. I will briefly point out three great research frontiers that seem to me particularly significant: ontogenic decoding, the brain/mind puzzle, and the ape-to-human transformation. By ontogenetic decoding I refer to the problem of how the unidimensional genetic information encoded in the DNA of a single cell becomes transformed into a four-dimensional being, the individual that develops, grows, matures, and dies. Cancer, disease, and aging are epiphenomena of ontogenetic decoding. By the brain/mind puzzle I refer to the interdependent questions of (a) how the physicochemical signals that reach our sense organs become transformed into perceptions, feelings, ideas, critical arguments, aesthetic emotions, and ethical values; and (b) how, out of this diversity of experiences, there emerges a unitary reality, the mind or self. Free will and language, social and political institutions, technology, and art are all epiphenomena of the modern human mind. By the ape-to-human transformation I refer to the mystery of how a particular ape lineage became a hominin lineage, from which emerged, after only a few million years, modern humans able to think and love, who have developed complex societies and uphold ethical, aesthetic, and religious values. But the modern human genome differs little from the chimp genome.

I will refer to these three issues as the egg-to-adult transformation, the brain-to-mind transformation, and the ape-to-human transformation. The egg-to-adult transformation is essentially similar, and similarly mysterious, in modern humans and other mammals, but it has distinctive human features. The brain-to-mind transformation and the ape-to-human transformation are distinctively human. These three transformations define the *humanum*, that which makes us specifically modern human. Few other issues in human evolution are of greater consequence for understanding ourselves and our place in nature.

The instructions that guide the ontogenetic process, or the egg-to-adult transformation, are carried in the hereditary material. The theory of biological heredity was formulated by the Augustinian monk Gregor Mendel in 1866, but it became generally known by biologists only in 1900: genetic information is contained in discrete factors, or genes, which exist in pairs, one received from each parent. The next step toward understanding the nature of genes was completed during the first quarter of the twentieth century. It was established that genes are parts of the chromosomes, filamentous bodies present in the nucleus of the cell, and that they are linearly arranged along the chromosomes. It took another quarter century to determine the chemical composition of genes: deoxyribonucleic acid (DNA). DNA consists of four kinds of nucleotides organized in long, double-helical structures. The genetic information is contained in the linear sequence of the nucleotides, very much in the same way as the semantic information of an English sentence is conveyed by the particular sequence of the 26 letters of the alphabet.

The first important step toward understanding how the genetic information is decoded came in 1941 when George W. Beadle and Edward L. Tatum demonstrated that genes determine the synthesis of enzymes; enzymes are the catalysts that control all chemical reactions in living beings. Later it became known that amino acids (the components that make up enzymes and other proteins) are encoded, each by a set of three consecutive nucleotides. This relationship accounts for the linear correspondence between a particular sequence of coding nucleotides and the sequence of the amino acids that make up the encoded enzyme.

Chemical reactions in organisms must occur in an orderly manner; organisms must have ways of switching genes on and off since different sets of genes are active in different cells. The first control system was discovered in 1961 by François Jacob and Jacques Monod for a gene that encodes an enzyme that digests sugar in the bacterium *Escherichia coli*. The gene is turned on and off by a system of several switches consisting of short DNA sequences adjacent to the coding part of the gene. (The coding sequence of a gene is the part that determines the sequence of amino acids in the encoded enzyme or protein.) The switches acting on a given gene are activated or deactivated by feedback loops that involve molecules synthesized by other genes. A variety of gene control mechanisms were soon discovered, in bacteria and other micro-organisms. Two elements are typically present: feedback loops and short DNA sequences acting as switches. The feedback loops ensure that the presence of a substance in the cell induces the synthesis of the enzyme required to digest it, and that an excess of the enzyme in the cell represses its own synthesis. (For example, the gene encoding a sugar-digesting enzyme in *E. coli* is turned on or off by the presence or absence of the sugar to be digested.)

The investigation of gene-control mechanisms in mammals (and other complex organisms) became possible in the mid-1970s with the development of recombinant DNA techniques. This technology made it feasible to isolate single genes (and other DNA sequences) and to multiply them, or “clone” them, to obtain the quantities necessary for ascertaining their nucleotide sequence. One unanticipated discovery was that most genes come in pieces: the coding sequence of a gene is divided into several fragments separated one from the next by noncoding DNA segments. In addition to the alternating succession of coding and noncoding segments, mammalian genes contain short control sequences, like those in bacteria but typically more numerous and complex, that act as control switches and signal where the coding sequence begins.

Much remains to be discovered about the control mechanisms of mammalian genes. The daunting speed at which molecular biology is advancing has led to the discovery of some prototypes of mammalian gene control systems, but much remains to be unraveled. Moreover, understanding the control mechanisms of individual genes is but the first major step toward solving the mystery of ontogenetic decoding. The second major step will be the puzzle of differentiation.

A modern human being consists of one trillion cells of some 300 different kinds, all derived by sequential division from the fertilized egg, a single cell 0.1 mm in diameter. The first few cell divisions yield a spherical mass of amorphous cells. Successive divisions are accompanied by the appearance of folds and ridges in the mass of cells and, later on, of the variety of tissues, organs, and limbs characteristic of a human individual. The full complement of genes duplicates with each cell division, so that two complete genomes are present in every cell. Yet different sets of genes are active in different cells. This must be so for cells to differentiate: a nerve cell, a muscle cell, and a skin cell are vastly different in size, configuration, and function. The differential activity of genes must continue after differentiation, because different cells fulfill

different functions, which are controlled by different genes. Nevertheless, experiments with other animals (and some with humans) indicate that all the genes in any cell have the potential of becoming activated. (The sheep Dolly was conceived using the genes extracted from a cell in an adult sheep.)

The information that controls cell and organ differentiation is ultimately contained in the DNA sequence, but mostly in very short segments of it. In mammals, insects, and other complex organisms there are control circuits that operate at higher levels than the control mechanisms that activate and deactivate individual genes. These higher-level circuits (such as the so-called homeobox genes) act on sets of genes rather than individual genes. The details of how these sets are controlled, how many control systems there are, and how they interact, as well as many other related questions, are what needs to be resolved to elucidate the egg-to-adult transformation. The DNA sequence of some controlling elements has been ascertained, but this is a minor effort that is only helped a little by plowing the way through the entire 3000 million nucleotide pairs that constitute the modern human genome. Experiments with stem cells are likely to provide important knowledge as scientists ascertain how stem cells become brain cells in one case, muscle cells in another, and so on.

The benefits that the elucidation of the egg-to-adult transformation will bring to humankind are enormous. This knowledge will make possible understanding the modes of action of complex genetic diseases, including cancer, and therefore their cure. It will also bring an understanding of the process of aging, which kills all those who have won the battle against other infirmities.

Cancer is an anomaly of ontogenetic decoding: cells proliferate despite the welfare of the organism demanding otherwise. Individual genes (oncogenes) have been identified that are involved in the causation of particular forms of cancer. But whether or not a cell will turn out cancerous depends on the interaction of the oncogenes with other genes and with the internal and external environment of the cell. Aging is also a failure of the process of ontogenetic decoding: cells fail to carry out the functions imprinted in their genetic code script or are no longer able to proliferate and replace dead cells.

The brain is the most complex and most distinctive modern human organ. It consists of 30 billion nerve cells, or neurons, each connected to many others through two kinds of cell extension, known as the axon and the dendrites. From the evolutionary point of view, the animal brain is a powerful biological adaptation; it allows the organism to obtain and process information about environmental conditions and then to adapt to them. This ability has been carried to the limit in modern humans, in which the extravagant hypertrophy of the brain makes possible abstract thinking, language, and technology. By these means, humankind has ushered in a new mode of adaptation far more powerful than the biological mode: adaptation by culture.

The most rudimentary ability to gather and process information about the environment is found in certain single-celled micro-organisms. The protozoan *Paramecium* swims apparently at random, ingesting the bacteria it encounters, but when it meets unsuitable acidity or salinity its advance is checked and it starts off in a new direction. The single-celled alga *Euglena* not only avoids unsuitable environments but seeks suitable ones by orienting itself according to the direction of light, which it perceives through a light-sensitive spot in the cell. Plants have not progressed much further. Except for those with tendrils that twist around any solid object and the few carnivorous plants that react to touch, they mostly react only to gradients of light, gravity, and moisture.

In animals the ability to secure and process environmental information is mediated by the nervous system. The simplest nervous systems are found in corals and jellyfishes; they lack coordination between different parts of their bodies, so any one part is able to react only when it is directly stimulated. Sea urchins and starfish possess a nerve ring and radial nerve cords that coordinate stimuli coming from different parts; hence, they respond with direct and unified actions of the whole body. They have no brain, however, and seem unable to learn from experience. Planarian flatworms have the most rudimentary brain known; their central nervous system and brain process and coordinate information gathered by sensory cells. These animals are capable of simple learning and hence of variable responses to repeatedly encountered stimuli. Insects and their relatives have much more advanced brains; they obtain precise chemical, acoustic, visual, and tactile signals from the environment and process them, making possible complex behaviors, particularly in search for food, selection of mates, and social organization.

Vertebrates are able to obtain and process much more complicated signals and to respond to the environment more variably than do insects or any other type of invertebrate. The vertebrate brain contains

an enormous number of associative neurons arranged in complex patterns. In vertebrates the ability to react to environmental information is correlated with an increase in the relative size of the cerebral hemispheres and of the neopallium, an organ involved in associating and coordinating signals from all receptors and brain centers. In mammals, the neopallium has expanded and become the cerebral cortex. Modern humans have a very large brain relative to their body size, and a cerebral cortex that is disproportionately large and complex even for their brain size. Abstract thinking, symbolic language, complex social organization, values, and ethics are manifestations of the wondrous capacity of the modern human brain to gather information about the external world and to integrate that information and react flexibly to what is perceived.

With the advanced development of the modern human brain, biological evolution has transcended itself, opening up a new mode of evolution: adaptation by technological manipulation of the environment. Organisms adapt to the environment by means of natural selection, by changing their genetic constitution over the generations to suit the demands of the environment. Modern humans, and modern humans alone to any substantial degree, have developed the capacity to adapt to hostile environments by modifying the environments according to the needs of their genes. The discovery of fire and the fabrication of clothing and shelter have allowed the ancestors of modern humans to spread from the warm tropical and subtropical regions of the Old World, to which we are biologically adapted, to almost the whole Earth; it was not necessary for wandering hominins that they wait until genes would evolve providing anatomical protection against cold temperatures by changing their physiology or by means of fur or hair. Nor are modern humans biding their time in expectation of wings or gills; we have conquered the air and seas with artfully designed contrivances: airplanes and ships. It is the modern human brain (the human mind) that has made humankind the most successful, by most meaningful standards, living species.

There are not enough bits of information in the complete DNA sequence of a modern human genome to specify the trillions of connections among the 30 billion neurons of the modern human brain. Accordingly, the genetic instructions must be organized in control circuits operating at different hierarchical levels so that an instruction at one level is carried through many channels at a lower level in the hierarchy of control circuits. The development of the modern human brain is indeed one particularly intriguing component of the egg-to-adult transformation.

Within the last two decades, neurobiology has developed into one of the most exciting biological disciplines. An increased commitment of financial and human resources has brought an unprecedented rate of discovery. Much has been learned about how light, sound, temperature, resistance, and chemical impressions received in our sense organs trigger the release of chemical transmitters and electric potential differences that carry the signals through the nerves to the brain and elsewhere in the body. Much has also been learned about how neural channels for information transmission become reinforced by use or may be replaced after damage; about which neurons or groups of neurons are committed to processing information derived from a particular organ or environmental location; and about many other matters. But, for all this progress, neurobiology remains an infant discipline, at a stage of theoretical development comparable perhaps to that of genetics at the beginning of the 20th century. Those things that count most remain shrouded in mystery: how physical phenomena become mental experiences (the feelings and sensations, called “qualia” by philosophers, that contribute the elements of consciousness), and how out of the diversity of these experiences emerges the mind, a reality with unitary properties, such as free will and the awareness of self, that persist through an individual’s life.

I do not believe that the mysteries of the mind are unfathomable; rather, they are puzzles that modern humans can solve with the methods of science and illuminate with philosophical analysis and reflection. And I will place my bets that, over the next half century or so, many of these puzzles will be solved. We shall then be well on our way toward answering the biblical injunction: “Know thyself.”

A contemporary development that would have greatly delighted Darwin is the determination of the DNA sequence of the modern human genome, an investigation that was started under the label, the Human Genome Project, which opens up the possibility of comparing the modern human DNA sequence with that of other organisms, observing their similarities and differences, seeking to ascertain the changes in the DNA that account for distinctively modern human features. The Human Genome Project was initiated in 1989, funded through two US agencies, the National Institutes of Health (NIH) and the Department of Energy (DOE), with eventual participation of scientists outside the USA. The goal set was to obtain the complete

sequence of one human genome in 15 years at an approximate cost of \$3000 million, coincidentally about \$1 per DNA letter. A private enterprise, Celera Genomics, started in the USA somewhat later, but joined the government-sponsored project in achieving, largely independently, similar results at about the same time. A draft of the genome sequence was completed ahead of schedule in 2001. In 2003 the Human Genome Project was finished, but the analysis of the DNA sequences chromosome by chromosome continued over the following years. Results of these detailed analyses were published on June 1, 2006. The draft DNA sequence of the chimpanzee genome was published on September 1, 2005 (an entry in the encyclopedia presents the first fossil evidence of panins ever to be discovered). In the regions of the genome that are shared by modern humans and chimpanzees the two species are about 99% identical. These differences may seem very small or quite large, depending on how one chooses to look at them: 1% is only a small fraction of the total, but it still amounts to a difference of 30 million DNA nucleotides out of the 3 billion in each genome.

Twenty-nine percent of the enzymes and other proteins encoded by the genes are identical in both species. Out of the one hundred to several hundred amino acids that make up each protein, the 71% of nonidentical proteins that differ between modern humans and chimps do so by only two amino acids, on average. If one takes into account DNA stretches found in one species but not the other, the two genomes are about 96% identical, rather than nearly 99% identical as in the case of DNA sequences shared by both species. That is, a large amount of genetic material, about 3% or some 90 million DNA nucleotides, have been inserted or deleted since ancestors went their separate evolutionary ways, about 8–6 million years ago. Most of this DNA does not contain genes coding for proteins, although it may include toolkit genes and switch genes that impact developmental processes, as the rest of the noncoding DNA surely does.

Comparison of the modern human and chimpanzee genomes provides insights into the rate of evolution of particular genes in the two species. One significant finding is that genes active in the brain have changed more in the human lineage than in the chimp lineage (Khaitovich et al. 2005). Also significant is that the fastest-evolving modern human genes are those coding for transcription factors. These are switch proteins which control the expression of other genes; that is, they determine when other genes are turned on and off. On the whole, 585 genes have been identified as evolving faster in humans than in chimps, including genes involved in resistance to malaria and tuberculosis. (It might be mentioned that malaria is a severe disease for humans but much less so for chimps.)

Genes located on the Y chromosome, found only in the male, have been much better protected by natural selection in the human than in the chimpanzee lineage, in which several genes have incorporated disabling mutations that make the genes nonfunctional. Also, there are several regions of the human genome that contain beneficial genes that have rapidly evolved within the past 250,000 years. One region contains the *FOXP2* gene, involved in the evolution of speech.

Other regions that show higher rates of evolution in humans than in chimpanzees and other animals include 49 segments, dubbed human accelerated regions or HARs. The greatest observed difference occurs in *HAR1F*, an RNA gene that is expressed specifically in Cajal-Retzius neurons in the developing human neocortex from 7 to 19 gestational weeks, a crucial period for cortical neuron specification and migration.

Extended comparisons of the human and chimpanzee genomes and experimental exploration of the functions associated with significant genes will surely advance further our understanding, over the next decade or two, of what it is that makes us distinctively human, what is it that differentiates *H. sapiens* from our closest living species, chimpanzees and bonobos, and will surely shine some light on how and when these differences may have come about during hominin evolution of the human species. Surely also, full biological understanding of the ape-to-human transformation will only come if we solve the other two conundrums: the egg-to-adult transformation and the brain-to-mind transformation. The distinctive features that make us modern human appear early in development, well before birth, as the linear information encoded in the genome gradually becomes expressed into a four-dimensional individual, an individual who changes in configuration as time goes by. In an important sense the most distinctive human features are those expressed in the brain, those that account for the human mind or for human identity.

Francisco J. Ayala
University of California, Irvine

Preface

Once upon a time, say 60 years ago, the only background required to appreciate what was known about human evolution was a familiarity with a relatively sparse fossil record, an understanding of the limited information there was about the context of the sites, some knowledge of gross anatomy, a familiarity with a few simple analytical methods, and an appreciation of general evolutionary principles.

Times have changed. The fossil record has grown exponentially, imaging techniques allow researchers to capture previously unavailable gross morphological and microstructural evidence in unimaginable quantities, analytical methods have burgeoned in scope and complexity, phylogeny reconstruction is more sophisticated, molecular biology has revolutionized our understanding of genetics, evolutionary history, modern human variation, and development, and a host of different developments in biology, chemistry, earth sciences, and physics the have enriched evidence about the biotic, climatic, and temporal context of the hominin fossil record. In short, the fossil evidence and the range of methods used to study human evolution have grown by at least one order of magnitude in the past six decades. Yet there is no single reference source where students and researchers involved in human evolution research, be they archeologists, earth scientists, molecular biologists, morphologists, paleontologists, or paleoecologists, can go to find out about topics as diverse as C_4 plants canalization, the candelabra model, canonical variates analysis, Carabelli(s) trait, carcass transport strategy, cardioid foramen magnum, carrying capacity, and Caume de l'Arago.

Antecedents

Quenstedt and Quenstedt (1936) were probably the first to compile a comprehensive list and associated bibliography of the hominin fossil record. Hue (1937) illustrated some of the hominin fossil evidence, but his bibliographic coverage was less comprehensive than Quenstedt and Quenstedt's. Vallois and Movius' *Catalogue des Hommes Fossiles* (1953) made a commendable attempt to survey the human fossil record, as did Day's *Guide to Fossil Man* (1965). The first comprehensive attempt to collate information about both the hominin fossil record and its context came in the late 1960s and thereafter with the publication of the British Museum (Natural History)'s *Catalogue of Fossil Hominids*. The first volume, "Part I: Africa," edited by Oakley and Campbell, was published in 1967. Subsequent volumes covered fossil hominin discoveries from Europe (Oakley, Campbell, and Molleson 1971) and Asia (Oakley, Campbell, and Molleson 1975). Unfortunately (but understandably given the work involved in assembling a resource such as this in a non-electronic format and on a rapidly enlarging hominin fossil record) only Part I ran to a second updated edition (Oakley, Campbell, and Molleson 1977) and the series has been discontinued. The most recent attempt to take up the challenge of providing a comprehensive catalogue of the fossil evidence for hominin evolution has been the initiative by Orban and her colleagues, entitled *Hominid Remains – an up-date*. This is distributed as part of a general series of publications called the Supplements au Bulletin de la Societe Royale Belge d'Anthropologie et de Prehistoire. The first in the series of separate publications was published in the beginning of 1988 and publication has continued thereafter. Each slim volume covers one or more countries and retains the format of the *Catalogue of Fossil Hominids*. The early issues were organized by an Editor (Orban) and Associate Editors (Slachmuylder, Semal, and Alewaeters). The individual entries are put together by experts who are familiar with one or more temporal phases of the hominin fossil record from that country or countries. Spencer's excellent *History of Physical Anthropology*, published in 1997, is an important and authoritative source of information about the history of paleoanthropology, but although it has entries for the major fossil sites there are few entries about the fossil and archeological evidence. There is also a *Catalogue of Fossil Hominids* available on the internet at <http://gbs.ur-plaza.osaka-cu.ac.jp/kaseki>.

Scope

The long-term plan for the *Wiley-Blackwell Encyclopedia of Human Evolution* (W-BEHE) is that it will be an authoritative and accessible source of information about the hominin clade of the tree of life. Entries cover:

- general evolutionary principles,
- information about the molecular and developmental biological approaches used to help understand the pattern and process of evolution,
- methods used to investigate relationships among the living great apes and modern humans,
- methods germane to understanding the origins and evolutionary history of the hominin clade and its climatic and ecological context,
- what makes the behavior of modern humans distinctive and the evolutionary history of that distinctiveness,
- information about the modern methods used to capture and interpret data from the hominin fossil and archeological records, as well as comparative biology,
- nonhominin fossil evidence germane to the evolution of the hominin clade,
- specialist terms used to describe the hominin fossil and archeological records,
- hypotheses germane to interpreting human evolutionary history,
- biographies of individuals who have made significant contributions to the accumulation of the fossil and archeological, and other, evidence and to its interpretation,
- institutions and organizations that have contributed to our understanding of human evolutionary history,
- information about hominin fossil and comparative great ape collections and about some of the repositories that hold hominin fossil collections.

Organization

The entries for the important fossil and/or archeological sites (later editions will aim to cover *all* the relevant sites) relevant to hominin evolution are structured to make it easier for the reader to find out what they want to know. This is also the case for the entries for the more complete hominin fossils, and for some less complete fossils that have a particular significance. There are also formally structured entries for taxa that have been used to accommodate the hominin fossil record. The depth of the entries varies; the entries for fossils and sites do not aim to be exhaustive, but they are comprehensive. The entries for methods and important biological principles try to explain complex concepts in plain and simple language and where possible they include examples. As Editor I constantly needed to remind myself, the editors, and the contributors that the W-BEHE is *not* an encyclopedia of archeology, earth science, genetics, etc.; readers should go to other sources for technical information about the methods.

The entries have been prepared as a collective exercise. The drafts prepared by an editor or contributor were all screened by me as Editor for depth, style, and intelligibility and then sent to other editors, or to outside experts, for their comments. Human evolution is a controversial field, so where appropriate entries describe competing hypotheses, and if the entry comes down in favor of one of them, the entry explains why. The aim, doubtless not always met, was that the entries are self-contained and intelligible; we did not want users of the W-BEHE to look up one term they did not understand only to be faced with an entry that uses five words they are unfamiliar with. Within the text of entries, where appropriate, any term used that has its own entry are shown in bold.

Planning

The draft list of entries was drawn up by the Editor, four Section Editors (Laura Bishop, paleontology; Craig Feibel, earth sciences; Tom Plummer, archeology; and Anne Stone, molecular biology and genetics) and 17 Topic Editors (Shara Bailey, Robin Bernstein, Mark Collard, Sarah Elton, Matthew Goodrum, Adam Gordon, Katerina Harvati, Lyle Konigsberg, Andrew Kramer, Jacopo Moggi-Cecchi, Osbjorn Pearson, Brian Richmond, Chet Sherwood, Tanya Smith, David Strait, Francys Subiaul, and Christian Tryon). Important advice at this stage also came from several of the Advisory Editors.

The original plan was that these individuals would prepare the entries, but like all strategic plans this one had to be modified. It was clear that the sheer volume of the work involved could not be tackled by these editors, and as polymathic as many of them are, there were still regions of the world (e.g., China) and topics (e.g., paleoclimate, stable isotopes, zooarcheology, etc.) for which we lacked coverage. Also, because this project has been 6 years in the making, circumstances change (children are born, grants are written and awarded, relatives get sick, individuals take up additional responsibilities) so I soon learned that it was adapt or die! Thus, the original editor classification has been abandoned and in its place there are now Associate Editors, Section Editors, and Contributors. The criteria for allocating individuals to categories are inevitably subjective and I am also conscious that my memory is fallible, so I offer my abject apologies to those who feel their contributions have not been recognized at the appropriate level. The Associate Editors did all, or some, of the following. They were the lead author on a substantial number of entries, they contributed generously to the editing well beyond their immediate area of expertise, and they responded promptly and generously to my many unreasonable requests. Only I (and they) know just how hard they worked and how important their contribution was. Section Editors did all, or some, of the above, but unlike the Associate Editors their contributions were focused on their immediate area of expertise. Topic Editors were much like Section Editors, but they contributed fewer entries and their contributions were confined to their immediate area of expertise. Contributors contributed at least one entry, but were not involved in the editing. Several Advisory Editors (e.g., Rebecca Ackermann, Leslie Aiello, Chris Dean, Colin Groves, Benedikt Hallgrímsson, and Bill Kimbel) contributed entries and some of the above played a major editorial role. Many other people offered advice about entries and they are listed in the Acknowledgments; once again my apologies if my system for recording such help has failed. Please, if you do not see your name on that list and you think you should be on it, please do not be bashful about letting me know and I can rectify any omissions in the next edition.

Delivery

I urge those of you who have not read Simon Winchester's *The Meaning of Everything* to do so; those of you who have read it will know the *Oxford English Dictionary* took 70 years to complete. Much of the information in the W-BEHE is time-sensitive and the problem is that if you wait too long for that sincerely promised but much delayed entry you run the risk that many other entries will become outdated in the meantime. Yet you cannot go the press with an encyclopedia that is lacking essential entries. So we had to make a fine judgment about when to stop, and we had to close the headword list knowing we would be leaving some fossil, site, museum, and biographical entries for a later edition. You cannot have an encyclopedia without entries, but you *can* have entries without an encyclopedia. My efforts as Editor, and those of the Associate, Section, and Topic Editors and the Contributors, would have all come to naught without the hard work of the Executive Editors (Amanda Henry and Jennifer Baker) and the Editorial Assistants (Alex Claxton and Erin Mikels), who helped prepare the material for copy-editing and then checked it at various stages in the process my sincere thanks to all of them. Of course the buck stops with the Editor, so any mistakes are my responsibility alone.

The future

The plan is to follow up the hardback library edition with a more affordable edition intended for individuals, an abridged version for students, and an electronic edition that can be updated approximately every 6 months.

Errors

In a project of this scale errors will have been made. The only way to eliminate as many mistakes as humanly possible is to contact me (bernardawood@gmail.com) and I will see to it they are rectified in later editions.

Bernard Wood

The George Washington University, Washington, DC
December 2010

Acknowledgments

It goes without saying that none of this would have been possible without the editors and contributors. At many times in the process it must have seemed as if it was “all grit and no gravy” and I am conscious that contributing in various ways to the *Wiley-Blackwell Encyclopedia of Human Evolution* (W-BEHE) has deflected individuals from their core activities of teaching, grant writing, research, and writing up their research. I am more grateful to them than I can express in words. Some contributions deserve special mention. A few people really *did* read and comment on the entries I sent out for general review, and I am especially grateful to Rebecca Ackermann, Chris Dean, and Alan Bilsborough for consistently doing so. I am also grateful to Katerina Harvati for her support despite having other much more important claims on her time. Colin Groves (in Australia) would be getting up as I was going to sleep, but I cannot recall how many times I would send him complex requests and enquiries at the end of my day and when I woke up they would invariably be answered thoroughly and cheerfully. I am also immensely impressed by the graduate students who gave of their time and expertise; if Jennifer Baker, Amy Bauernfeind, Serena Bianchi, Habiba Chirchir, Andrew Du, Tyler Faith, Liz Renner, Kes Schroer, Steve Wang, and Andrew Zipkin are representative of young researchers then our discipline is in good hands. Lastly, for those who cherish such achievements, Tyler Faith and Christian Tryon tied for the shortest interval (*c.* 18 minutes) between a request and a received entry.

This project could not have been completed without the generosity of the community of scholars who work in paleoanthropology and in cognate areas. People who helped prepare and edit entries include undergraduates, junior and senior graduate students, postdoctoral fellows, and junior and senior professors; some probably felt they had no choice, others I “cold-called” and some I have known for 40 years. The willingness of people, young and old, to work for the common good has been humbling. It is inadequate thanks to list them by name, but that is the currency I must, perforce, use. Some of them devoted substantial time and effort to make sure that entries, especially site entries, were correct; I hope they conclude that the product of their collective labors justifies their efforts: Zeray Alemseged, Juan Luis Arsuaga, Lucinda Backwell, Amy Bauernfeind, Hazel Beeler, John Beeler, Kay Behrensmeier, Miriam Belmaker, Mike Benjamin, Vadim Berg, Serena Bianchi, Felicitas Bidlack, Robert Blumenschine, René Bobe, Silvia Bortoluzzi, Frank Brown, Judith Brown, Peter Brown, Marta Camps, Sarah Cassel, Habiba Chirchir, Rich Cifelli, Robert Cifelli, Bryanne Colby, Paul Constantino, Raymond Corbey, Robin Crompton, Daryl de Ruiter, Alexandra de Sousa, Eric Delson, Catherine Denial, Alnawaz Devani, Marietta Dindo, Eusebio Dizon, Michelle Drapeau, Logan Ferree, Reid Ferring, John Fleagle, Jens Franzen, Pascal Gagneux, Emmanuel Gilissen, John Gowlett, Jay Greene, Nicole Griffin, Ana Gracia, Eileen Le Guillou, Frank Guy, Brian Hall, Will Harcourt-Smith, Malcolm Harman, the late Elizabeth Harmon, Geoffrey Harrison, Terry Harrison, William Hart, Claire Heckel, Andy Herries, Simon Hillson, Leslea Hlusko, Louise Humphreys, David Hunt, Kevin Hunt, Joel Irish, Adam Jagich, Kayla Jarvis, William Jungers, Jon Kalb, John Kappelman, Richard Klein, Chris Kocher, Steve Kuhn, Joel Kuipers, Ottmar Kulmer, Kornelius Kupczik, Joanna Lambert, Beth Lawrie, Daniel Lieberman, Julien Louys, Shannon McFarlin, Andrew McGurn, Lindsay McHenry, Jeff McKee, Roberto Machiarelli, Daniel Miller, Ignacio Martínez, Mary Marzke, Jim Moore, Michael Morwood, Jackson Njau, Jim O’Connell, Rick Potts, Bryan Pratt, Yoel Rak, Jean-Paul Raynal, Safia Razzuqi, Kaye Reed, Liz Renner, Vernon Reynolds, Philip Rightmire, Lorenzo Rook, Chris Ruff, Margaret Schoeninger, Friedemann Schrenk, Geralyn Schulz, Sileshi Semaw, Brian Shea, John Shea, Courtney Snell, Katya Stansfield, Christine Steininger, Chikako Suda-King, Fred Szalay, Mark Teaford, Matt Tocheri, Peter Ungar, Sidney Vasquez, Bence Viola, Julian Waller, Steve Ward, Randy White, Tim White, David Wilkinson, Phillip Williams, Pamela Willoughby, Milford Wolpoff, Barth Wright, Roshna Wunderlich, and Bernhard Zipfel. My thanks also to Francisco Ayala for his interest in the project and for finding the time to write his fine Foreword. I have come to enjoy Francisco’s friendship through CARTA, the brainchild of Ajit Varki, and now co-directed by Fred Gage, Margaret Schoeninger, and Ajit Varki; its meetings and its members have done much to widen my intellectual horizons. All of us involved in CARTA are grateful to the G. Harold and Leila Y. Mathers

ACKNOWLEDGMENTS

Foundation and its Executive Director, James Handelman, for their long-term support for CARTA and to Pascal Gagneux, the Associate Director, and Linda Carlson for organizing it and its meetings. Those of you who know me will realize that I am the last person who should have been entrusted with the task of making sure that thousands of entries were curated so that only the latest versions find their way into the final text; my skills as a curator of references are also sorely lacking. It is no exaggeration to say that without the help of a series of student colleagues, especially Jennifer Baker, Kaitlyn Baraldi, Alex Claxton, Gabriel Mallozzi, and Erin Mikels, that this project would still be “a work in progress;” Kayla Jarvis also helped in many ways. Alex Claxton set up the topic entry list and Erin Mikels took on the task of collating the master reference file; my thanks to them both. Sometimes serendipity comes to one’s aid, and in my case it came in the form of Amanda Henry. She just happened to have defended her thesis at the time of greatest need for the W-BEHE and she was willing to pitch in and help bring the project to fruition. Without her hard work, determination, stamina, common sense, and intelligence we would still be assembling entries. Working with her has been my pleasure and privilege; it was also fun. Amanda and Jennifer Baker read and commented on every entry before they were sent for copy-editing.

My notes remind me that I met with Jane Huber (then an Editor at Blackwell Publishing) in Boston at the end of June 2005. Jane’s encouragement and efficiency were the reason I decided to work with Blackwell on this project, and although she left to work for Oxfam it proved a wise decision for as many will realize Blackwell subsequently merged with Wiley, a publisher with deep connections with paleoanthropology via the *American Journal of Physical Anthropology* and *Evolutionary Anthropology*. Andy Slade has been my supervising editor and W-BEHE’s champion and I thank him for his efforts on its behalf. I was fortunate that Kelvin Matthews, Project Editor for Life Sciences, has been the lead person in the editing and production process within Wiley-Blackwell. His quiet but insistent determination to make sure that W-BEHE happened and his behind-the-scenes work to keep the project on track are sincerely appreciated. Among the many reasons I am grateful to Kelvin is that it was he who arranged for Nik Prowse to be the copy-editor. Nik works from Durham, England, and he and I have never met, but it is no exaggeration to say that without his intelligence, attention to detail (he could have been a neurosurgeon), knowledge, common sense, and good humor the project might well have foundered. The world is replete with people who create problems; Nik (and Kelvin) belong to a much smaller number who were put into this world to solve them.

My sincere thanks are also due to my colleagues at George Washington University. They have tolerated my distraction with W-BEHE and several have made important contributions as editors. I also want to give special thanks to Don Lehman, until recently George Washington University’s Vice-President for Academic Affairs. He not only gave me unstinting support as a University Professor, but via the university’s Signature Program his support made possible work study programs, internships, and graduate fellowships that have supported Erin Mikels, Alex Claxton, and Jennifer Baker. Bill Kimbel, Jacopo Moggi-Cecchi, David Pilbeam, and David Strait were always on hand with support and advice and to remind me there are many more important things in life than editing an encyclopedia.

Finally, my heartfelt thanks to Sally who stoically honed her already considerable Sudoku and KenKen skills while I worked on “just a few more entries.”

Topic Entry List

ANATOMY

I. General terms

- 1) abduction
- 2) abductor
- 3) adduction
- 4) adductor
- 5) agenesis
- 6) anatomical position
- 7) anatomical terminology
- 8) appendicular skeleton
- 9) associated skeleton
- 10) atavism
- 11) atavistic
- 12) autopod
- 13) axial digit
- 14) axial skeleton
- 15) axis
- 16) base
- 17) branchial arches
- 18) calcification
- 19) caudal
- 20) coronal
- 21) cortex
- 22) cortical
- 23) coxa
- 24) cranial
- 25) cross-section
- 26) dento-gnathic
- 27) distal
- 28) epi-
- 29) fibrocartilage
- 30) fovea
- 31) gnathic
- 32) gomphoses
- 33) histology
- 34) human anatomical terminology
- 35) hyaline cartilage
- 36) hyoid
- 37) jaw
- 38) joint
- 39) kyphosis
- 40) ligaments
- 41) lordosis
- 42) mineralization
- 43) muscles of mastication
- 44) *Nomina Anatomica*

- 45) *norma basalis*
- 46) *norma basilaris*
- 47) *norma frontalis*
- 48) *norma lateralis*
- 49) *norma occipitalis*
- 50) *norma verticalis*
- 51) os
- 52) paleoanthropological terminology
- 53) primary cartilaginous joint
- 54) promontory
- 55) pronation
- 56) proximal
- 57) reference digit
- 58) rostral
- 59) secondary cartilaginous joints
- 60) skeleton
- 61) stylopod
- 62) supination
- 63) symphyses
- 64) symphysis
- 65) synchondroses
- 66) syndesmoses
- 67) *Terminologia Anatomica*
- 68) valgus
- 69) varus
- 70) volar
- 71) zeugopod

II. Bone(s)

A. Terms

- 1) alveolar process
- 2) alveoli
- 3) alveolus
- 4) bone
- 5) bone density
- 6) cancellous bone
- 7) cartilage
- 8) chondroblasts
- 9) chondroclasts
- 10) chondrocytes
- 11) compact bone
- 12) connective tissue
- 13) dense bone
- 14) diaphysis
- 15) endochondral ossification
- 16) lamellar bone
- 17) osteoblast

TOPIC ENTRY LIST

- 18) osteoclasts
- 19) osteocytes
- 20) osteogenesis
- 21) osteon
- 22) trabecular bone
- 23) woven bone
- B. Development and response
 - 1) appositional growth
 - 2) endochondral ossification
 - 3) epiphyseal plate
 - 4) epiphysis
 - 5) Harris lines
 - 6) interstitial growth
 - 7) intramembranous ossification
 - 8) modeling
 - 9) ossification
 - 10) ossification center
 - 11) osteoblast
 - 12) osteoclasts
 - 13) osteocytes
 - 14) osteogenesis
 - 15) primary centers of ossification
 - 16) secondary centers of ossification

- 159) vicariance
- 160) vicariance biogeography
- 161) vicariance event

FUNCTIONAL MORPHOLOGY

I. Terms

- 1) allometric
- 2) allometry
- 3) anisotropy
- 4) body size
- 5) bone strength
- 6) brachial index
- 7) center of mass
- 8) crural index
- 9) Curve of Spee
- 10) COM
- 11) dexterity
- 12) humerofemoral index
- 13) intermembral index
- 14) economy
- 15) efficiency
- 16) elastic modulus
- 17) failure
- 18) force
- 19) force plate
- 20) ground reaction force
- 21) isotropy
- 22) kinematics
- 23) kinetics

- 24) knuckle-walking
 - 25) locomotion
 - 26) microstrain
 - 27) negative allometry
 - 28) orthograde
 - 29) orthotropy
 - 30) Poisson's ratio
 - 31) ponderal index
 - 32) positive allometry
 - 33) posture
 - 34) pressure pad
 - 35) pronograde
 - 36) proxy
 - 37) scaling
 - 38) shear modulus
 - 39) stature
 - 40) strain
 - 41) strain gage
 - 42) strain gauge
 - 43) strength
 - 44) stress
 - 45) transverse isotropy
 - 46) Young's modulus
- II. Methods
- 1) COT
 - 2) electromyography
 - 3) EMA
 - 4) EMG
 - 5) fracture and deformation biomechanics
 - 6) cross-sectional geometry
 - 7) motion analysis
 - 8) PCSA
- III. Behaviors and related terms
- A. Locomotion
- 1) bent-hip bent-knee walking
 - 2) BHBK
 - 3) bipedalism
 - 4) bipedal locomotion
 - 5) clavicle, evolution in hominins
 - 6) cursorial
 - 7) double stance phase
 - 8) dynamic modeling
 - 9) eversion
 - 10) foot arches
 - 11) foot function
 - 12) foot movements
 - 13) footprints
 - 14) fulcrum
 - 15) fulcrumate
 - 16) gait
 - 17) hominin footprints
- 18) heel strike
 - 19) inversion
 - 20) Koobi Fora hominin footprints
 - 21) Laetoli hominin footprints
 - 22) lateral longitudinal arch
 - 23) lever
 - 24) locomotion
 - 25) longitudinal arch
 - 26) medial longitudinal arch
 - 27) midfoot break
 - 28) midtarsal break
 - 29) plantar aponeurosis
 - 30) pre-eminent bipedalism
 - 31) pronation
 - 32) proximal humerus, evolution in hominins
 - 33) push-off
 - 34) scapula, evolution in hominins
 - 35) stance phase
 - 36) stride
 - 37) supination
 - 38) swing phase
 - 39) toe-off
 - 40) transverse arch
 - 41) walking cycle
 - 42) windlass effect
 - 43) windlass mechanism
- B. Manipulation
- 1) 2D:4D
 - 2) dexterity
 - 3) hand, evolution in hominins
 - 4) hand, relative length of the digits
 - 5) hand, tool-use and tool-making
 - 6) opposable thumb
 - 7) power grip
 - 8) precision grip
 - 9) prehensile
- C. Mastication
- 1) anisognathous
 - 2) balancing side
 - 3) bite force
 - 4) chewing
 - 5) chewing cycle
 - 6) comminution
 - 7) gape
 - 8) mastication
 - 9) mastication, muscles of
 - 10) masticatory apparatus
 - 11) mandibular scaling
 - 12) phase I
 - 13) phase II

TOPIC ENTRY LIST

- 14) power stroke
- 15) swallowing
- 16) working side

GENETICS AND MOLECULAR BIOLOGY

- 1) 3'
- 2) 5'
- 3) aDNA
- 4) adaptive landscapes
- 5) albumin
- 6) allele
- 7) Alu
- 8) Alu elements
- 9) Alu repeat elements
- 10) Alus
- 11) amino acid
- 12) ancient DNA
- 13) antibody
- 14) anticodon
- 15) antigen
- 16) apoptosis
- 17) array
- 18) ascertainment bias
- 19) aspartic acid
- 20) *ASPM*
- 21) bacteriophage
- 22) balanced polymorphism
- 23) balanced translocation
- 24) balancing selection
- 25) Barr body
- 26) base pair
- 27) bottleneck
- 28) bp
- 29) broad-sense heritability
- 30) cDNA
- 31) centimorgan
- 32) centric fusion
- 33) centromere
- 34) chromatin
- 35) chromosome
- 36) chromosome banding
- 37) chromosome number
- 38) chromosome painting
- 39) CNV
- 40) coalescence
- 41) coalescent
- 42) coalescent theory
- 43) coalescent time
- 44) codon
- 45) complementary DNA
- 46) complex trait
- 47) copy number variation
- 48) crossing over
- 49) cytogenetic
- 50) Darwinian fitness
- 51) deleterious mutation
- 52) deletion
- 53) denature
- 54) deoxyribonucleic acid
- 55) diploid
- 56) directional selection
- 57) divergence time
- 58) dizygotic twins
- 59) D-loop
- 60) DNA
- 61) DNA chip
- 62) DNA hybridization
- 63) DNA microarray
- 64) DNA methylation
- 65) DNA sequencing
- 66) domain
- 67) dominance
- 68) dominant allele
- 69) dosage compensation
- 70) downstream
- 71) draft sequence
- 72) drift
- 73) duplication
- 74) dynamic mutation
- 75) effective population size
- 76) electrophoresis
- 77) enhancer
- 78) enzyme
- 79) epigenetics
- 80) epigenesis
- 81) epistasis
- 82) euchromatin
- 83) eukaryote
- 84) exon
- 85) expressivity
- 86) extension
- 87) finished sequence
- 88) fitness
- 89) fitness landscapes
- 90) fixation
- 91) fixation indices
- 92) fluorescence *in situ* hybridization
- 93) FISH
- 94) founder effect
- 95) *FOXP2*
- 96) *FOXP2*
- 97) frameshift mutation

- 98) F statistics
 99) F_{ST}
 100) F_{IS}
 101) F_{IT}
 102) functional genomics
 103) gamete
 104) gametic phase
 105) gel electrophoresis
 106) gene
 107) gene conversion
 108) gene duplication
 109) gene expression
 110) gene family
 111) gene flow
 112) gene genealogy
 113) gene pool
 114) gene tree
 115) genome
 116) genetic bottleneck
 117) genetic code
 118) genetic correlation
 119) genetic distance
 120) genetic drift
 121) genetic hitchhiking
 122) genetic load
 123) genetic map
 124) genetic variation
 125) genome
 126) genomic imprinting
 127) genomics
 128) genotype
 129) germ cells
 130) germline
 131) globins
 132) haemoglobin
 133) HARs
 134) H or H^2
 135) h or h^2
 136) HLA
 137) haplogroup
 138) haploid
 139) haplotype
 140) Hardy–Weinberg equilibrium
 141) hemizygous
 142) hemoglobin
 143) heritable
 144) heritability
 145) heterochromatin
 146) heteroplasmy
 147) heterosis
 148) heterozygote
 149) heterozyous advantage
 150) heterozygous
 151) heterozygous advantage
 152) heterozygosity
 153) *homeobox* genes
 154) homeodomain
 155) homologous
 156) homozygote
 157) homozygous
 158) housekeeping gene
 159) *HOX* genes
 160) human accelerated regions
 161) Human Genome Project
 162) human leucocyte antigens
 163) hybrid
 164) hybridization
 165) hybrid zone
 166) hypervariable region
 167) IBD
 168) IBS
 169) ID
 170) identical by descent
 171) identical by state
 172) immunochemistry
 173) immunoglobulins
 174) immunological distance
 175) imprinting
 176) indel
 177) independent assortment
 178) insertion
 179) introgression
 180) intron
 181) jumping genes
 182) karyotype
 183) knock-in
 184) knock-out
 185) lactase persistence
 186) lactose intolerance
 187) LD
 188) LINE
 189) linkage
 190) linkage analysis
 191) linkage disequilibrium
 192) locus
 193) LOD score
 194) long interspersed nucleotide element
 195) Lyonization
 196) major histocompatibility complex
 197) meiosis
 198) melanin
 199) Mendelian inheritance
 200) Mendelian laws
 201) messenger RNA

TOPIC ENTRY LIST

- 202) metacentric
 203) methylation
 204) MHC
 205) microarray
 206) microsatellite
 207) minisatellite
 208) mismatch distribution
 209) missense mutation
 210) mitochondria
 211) mitochondrial DNA
 212) Mitochondrial Eve
 213) mitochondrial genome
 214) mitogen
 215) mitosis
 216) mobile genetic element
 217) model organism
 218) molecule
 219) molecular biology
 220) molecular clock
 221) molecular evolution
 222) monogenic trait
 223) monosomy
 224) monozygotic twins
 225) morpholino
 226) mosaic
 227) multipoint mapping
 228) mutation
 229) mutation rate
 230) narrow-sense heritability
 231) N_e
 232) nonsense mutation
 233) nonsynonymous mutation
 234) nonsynonymous substitution
 235) normalizing selection
 236) Northern blotting
 237) nuclear DNA
 238) nucleotide
 239) nucleus
 240) Okazaki fragment
 241) oligonucleotide
 242) open reading frame
 243) ORF
 244) orthologous genes
 245) orthologue
 246) overdominance
 247) paralogue
 248) paralogous genes
 249) parental effects
 250) p arm
 251) PCR
 252) pedigree
 253) penetrance
 254) phage
 255) phase
 256) phenotype
 257) phenotypic variance
 258) physical map
 259) pigmentation
 260) plasmid
 261) pleiotropy
 262) ploidy
 263) point mutation
 264) poly-A tail
 265) polygenic trait
 266) polymerase
 267) polymerase chain reaction
 268) polymorphic
 269) polymorphism
 270) polypeptide
 271) population
 272) population bottleneck
 273) population genetics
 274) population structure
 275) positive assortment
 276) positive assortative mating
 277) positive selection
 278) permutation
 279) primer
 280) probe
 281) prokaryote
 282) promoter
 283) protein
 284) protein clock
 285) protein domain
 286) proteome
 287) pseudogene
 288) purifying selection
 289) q arm
 290) QTL
 291) quantitative genetics
 292) quantitative traits
 293) quantitative trait locus
 294) race
 295) random assortment
 296) random drift
 297) random mating
 298) reading frame
 299) recessive trait
 300) recombination
 301) recombination fraction
 302) recombination hotspot
 303) relative rate test
 304) relative risk
 305) replacement substitution

- 306) replication
 307) reproductive success
 308) restriction enzyme
 309) restriction fragment length polymorphism
 310) retrotransposition
 311) RFLP
 312) ribonucleic acid
 313) ribosomes
 314) ribosomal ribonucleic acid
 315) RNA
 316) Robertsonian translocation
 317) Robertsonian fusion
 318) reverse transcription polymerase chain reaction
 319) RT-PCR
 320) satellite DNA
 321) segregation
 322) segregational distortion
 323) selection
 324) selection coefficient
 325) selective sweep
 326) selfish DNA
 327) sex chromosomes
 328) sexual selection
 329) short interspersed nuclear element
 330) short tandem repeat
 331) siglecs
 332) silent substitution
 333) SINE
 334) single nucleotide polymorphism
 335) SNP
 336) somatic cells
 337) Southern blotting
 338) splicing
 339) stabilizing selection
 340) STR
 341) structure
 342) subdivision
 343) substitution
 344) susceptibility
 345) synonymous mutation
 346) synonymous substitution
 347) synteny
 348) tandem repeat array
 349) tandemly repeated sequences
 350) tandem repeats
 351) telocentric
 352) trait
 353) transcript
 354) transcription
 355) transcription factor
 356) transcriptome
 357) transfer RNA
 358) transgenic mice
 359) translation
 360) translocation
 361) transmutation
 362) transposition
 363) transposon
 364) trinucleotide repeat
 365) triplet codon
 366) trisomy
 367) tRNA
 368) unbalanced translocation
 369) untranslated region
 370) upstream
 371) underdominance
 372) uracil
 373) variable number of tandem repeats
 374) vector
 375) VNTR
 376) virulence
 377) X chromosome
 378) X chromosome inactivation
 379) X-linked
 380) Ya5
 381) Ya8
 382) Y chromosome
 383) Y-linked
- GROWTH AND DEVELOPMENT**
- 1) acceleration
 - 2) adrenarcho
 - 3) allometric
 - 4) allometry
 - 5) androgens
 - 6) bimaturism
 - 7) biogenetic law
 - 8) branchial arches
 - 9) canalization
 - 10) childhood
 - 11) clock model
 - 12) cross-sectional data
 - 13) development
 - 14) developmental stability
 - 15) differentiation
 - 16) dissociation
 - 17) epigenetic
 - 18) epigenetics
 - 19) epigenetic landscape
 - 20) estrogens
 - 21) evo-devo
 - 22) evolutionary developmental biology
 - 23) evolvability

TOPIC ENTRY LIST

- 24) genetic assimilation
- 25) gestation
- 26) gestation length
- 27) growth spurt
- 28) growth factors
- 29) growth hormone
- 30) growth plate
- 31) heterochrony
- 32) hypermorphosis
- 33) hypomorphosis
- 34) infant
- 35) integration
- 36) isometry
- 37) longitudinal data
- 38) Meckel's cartilage
- 39) menarche
- 40) menopause
- 41) meristic
- 42) meristic variation
- 43) modularity
- 44) module
- 45) morphogenesis
- 46) morphogenetic fields
- 47) morphological integration
- 48) negative allometry
- 49) neonate
- 50) neoteny
- 51) norm of reaction
- 52) ontogenetic scaling
- 53) ontogeny
- 54) ossification
- 55) paedomorphosis
- 56) peak growth velocity
- 57) pedomorphic
- 58) pedomorphosis
- 59) peramorphosis
- 60) positive allometry
- 61) progenesis
- 62) programmed cell death
- 63) puberty
- 64) reaction norm
- 65) scaling
- 66) secondary sexual characteristics
- 67) secular trend
- 68) senescence
- 69) sexual dimorphism
- 70) spatial packing hypothesis
- 71) timing
- 72) transformation grid
- 73) velocity curve
- 74) weaning

HISTORY

I. Biographies

- 1) Alemseged, Zeresenay (1969–)
- 2) Andersson, Johan Gunnar (1874–1960)
- 3) Arambourg, Camille Louis Joseph (1885–1969)
- 4) Arsuaga Ferreras, Juan Luis (1959–)
- 5) Asfaw, Berhane (1954–)
- 6) Barlow, George
- 7) Bar-Yosef, Ofer (1937–)
- 8) Binford, Lewis (1930–)
- 9) Bishop, Walter William (Bill) (1931–77)
- 10) Black, Davidson (1884–1934)
- 11) Blanc, Alberto Carlo (1906–60)
- 12) Boise, Charles Watson (1884–1964)
- 13) Boule, Marcellin (1861–1942)
- 14) Brain, Charles Kimberlin (Bob) (1931–)
- 15) Bräuer, Günter (1949–)
- 16) Broom, Robert (1866–1951)
- 17) Brown, Francis H. (1943–)
- 18) Brunet, Michel (1940–)
- 19) Cann, Rebecca L. (1951–)
- 20) Clark, John Desmond (1916–2002)
- 21) Clarke, Ronald J. (1944–)
- 22) Coon, Carleton Stevens (1904–81)
- 23) Coppens, Yves (1934–)
- 24) Dart, Raymond Arthur (1893–1988)
- 25) Darwin, Charles Robert (1809–82)
- 26) Day, Michael Herbert (1927–)
- 27) Deacon, Hilary John (1936–2010)
- 28) Dubois, Marie Eugène François Thomas (1858–1940)
- 29) Garrod, Dorothy Annie Elizabeth (1892–1968)
- 30) Goodman, Morris (1925–2010)
- 31) Haile-Selassie, Yohannes (1961–)
- 32) Hay, Richard L. (1929–2006)
- 33) Heinzelin, Jean de (1920–98)
- 34) Holloway, Ralph (1935–)
- 35) Howell, Francis Clark (1925–2007)
- 36) Howells, William White (1908–2005)
- 37) Hrdlička, Aleš (1869–1943)
- 38) Hublin, Jean-Jacques (1953–)
- 39) Huxley, Thomas Henry (1825–95)
- 40) Isaac, Glynn Llywelyn (1937–85)
- 41) Jacob, Teuku (1929–2007)
- 42) Johanson, Donald Carl (1943–)
- 43) Jones, Trevor
- 44) Kamoya
- 45) Keith, Arthur (1866–1955)
- 46) Keyser, André (1938–2010)

- 47) Kimeu, Kamoya (1940–)
 - 48) Koenigswald, Gustav Heinrich Ralph von (1902–82)
 - 49) Leakey, Louis Seymour Bazett (1903–72)
 - 50) Leakey, Mary Douglas Nicol (1913–96)
 - 51) Leakey, Meave (1942–)
 - 52) Leakey, Richard Erskine Frere (1944–)
 - 53) Le Gros Clark, Wilfrid Edward (1895–1971)
 - 54) Le Riche, William Harding
 - 55) Lordkipanidze, David (1963–)
 - 56) Napier, John Russell (1917–87)
 - 57) Neander, Joachim
 - 58) Oakley, Kenneth Page (1911–81)
 - 59) Osmunden, Lita
 - 60) Pei, Wenzhong [裴文中] (1904–82)
 - 61) Retzius, Anders Olaf (1796–1860)
 - 62) Robinson, John Talbot (1923–2001)
 - 63) Sarich, Vincent M. (1934–)
 - 64) Schepers, G. (Gert) W. H.
 - 65) Schmerling, Philippe-Charles (1790 or 1791–1836)
 - 66) Schwalbe, Gustav (1844–1916)
 - 67) Sergi, Giuseppe (1841–1936)
 - 68) Sergi, Sergio (1878–1972)
 - 69) Smith Woodward, Sir Arthur
 - 70) Stringer, Christopher Brian (1947–)
 - 71) Tobias, Phillip Vallentine (1925–)
 - 72) Tomes, Sir Charles Sissmore (1846–1928)
 - 73) Tomes, Sir John (1815–95)
 - 74) Trotter, Mildred
 - 75) Vallois, Henri Victor (1889–1981)
 - 76) Vandermeersh, Bernard (1937–)
 - 77) Van Wesele, Andreas
 - 78) Vesalius, Andreas
 - 79) von Koenigswald, Gustav Heinrich Ralph (1902–82)
 - 80) Walker, Alan (1938–)
 - 81) Washburn, Sherwood Larned (1911–2002)
 - 82) Weidenreich, Franz (1873–1948)
 - 83) Weiner, Joseph
 - 84) White, Timothy Douglas (1950–)
 - 85) Wilson, Allan Charles (1934–91)
 - 86) Wolpoff, Milford H. (1942–)
 - 87) Wu, Xinzhi [吴新智] (1928–)
 - 88) Zdansky, Otto (1894–1988)
- II. Collections
- 1) CISC
 - 2) Cobb Collection
 - 3) Dart Collection
 - 4) Dubois Collection
 - 5) George S. Huntington Collection
 - 6) Hamann–Todd Collection
 - 7) Huntington (George S.) Collection
 - 8) Powell Cotton Collection
 - 9) Raymond A. Dart Collection
 - 10) Terry (Robert J.) Collection
- III. Institutions
- 1) American Institute of Human Paleontology
 - 2) American Museum of Natural History
 - 3) Anthrocast
 - 4) Aristotle University of Thessaloniki, Department of Geology
 - 5) Bernard Price Institute for Palaeontological Research
 - 6) Boise Fund
 - 7) BPI
 - 8) Brussels Natural History Museum
 - 9) Burg Wartenstein International Symposium Program
 - 10) CAS
 - 11) Carnegie Institution for Science
 - 12) Carnegie Institution of Washington
 - 13) Cenozoic Research Laboratory

LIFE HISTORY

- 1) altricial
- 2) adolescence
- 3) adolescent growth spurt
- 4) adrenarche
- 5) age at maturity
- 6) age at weaning
- 7) androgens
- 8) antagonistic pleiotropy hypothesis
- 9) catch-up growth
- 10) Charnov's "dimensionless numbers"
- 11) childhood
- 12) development
- 13) DLNs
- 14) disposable soma hypothesis
- 15) Euler-Lotka equation
- 16) estrogens
- 17) fecundity
- 18) fixation
- 19) genetic correlation
- 20) genotype-environment interaction
- 21) gestation
- 22) gestation length
- 23) generation time
- 24) grandmother hypothesis
- 25) growth
- 26) growth factors
- 27) growth hormone

- 28) growth plate
- 29) growth spurt
- 30) heritability
- 31) interbirth interval
- 32) K -selection
- 33) life history
- 34) maternal effect
- 35) maternal energy hypothesis
- 36) maximum life span
- 37) menarche
- 38) menopause
- 39) mortality
- 40) mutation accumulation hypothesis
- 41) parent/offspring conflict
- 42) precocial
- 43) post-weaning dependency
- 44) puberty
- 45) r -selection
- 46) reproductive effort
- 47) reproductive investment
- 48) reaction norm
- 49) secondarily altricial
- 50) secondary sexual characteristics
- 51) secular trend
- 52) senescence
- 53) weaning
- 54) trade-off

MORPHOMETRY

- I. Capturing morphology
 - 1) body size
 - 2) body-mass estimation
 - 3) cross-sectional geometry
 - 4) discrete morphological variants
 - 5) discrete traits
 - 6) epigenetic traits
 - 7) hyperostotic
 - 8) hypostotic
 - 9) macrostructure
 - 10) microstructure
 - 11) moments of area
 - 12) non-metrical traits
 - 13) proxy
 - 14) qualitative variants
 - 15) variability
 - 16) variable
 - 17) variance
 - 18) variation
- II. Data capture
 - A. Terms
 - 1) Cartesian coordinates
 - 2) condylar position index

TOPIC ENTRY LIST

- 3) coordinate
 - 4) coordinate data
 - 5) cross-sectional data
 - 6) head-balancing index
 - 7) hyperostotic
 - 8) hypostotic
 - 9) nuchal area height index
 - 10) occipital index
 - 11) occipital length index I
 - 12) occipital length index II
 - 13) pixel
 - 14) PM plane
 - 15) posterior maxillary plane
 - 16) supraorbital height index
 - 17) voxel
- B. Methods
- 1) beam-hardening
 - 2) CAT
 - 3) CBA
 - 4) computed axial tomography
 - 5) computed tomography
 - 6) computer-assisted tomography
 - 7) confocal microscopy
 - 8) confocal scanning light microscope
 - 9) conventional radiography
 - 10) crown area
 - 11) crown base area
 - 12) crown module
 - 13) CSLM
 - 14) CT
 - 15) CT-number scale overflow
 - 16) gray-scale image
 - 17) gray-scale values
 - 18) image stack
 - 19) lack-of-signal artifacts
 - 20) lack of spatial resolution
 - 21) landmark
 - 22) μ CT
 - 23) micro-computed tomography
 - 24) micro-CT
 - 25) microtomography
 - 26) normal views
 - 27) partial volume averaging
 - 28) PCSOM
 - 29) petro-median angle
 - 30) petrous angle
 - 31) photon starvation
 - 32) plain film radiography
 - 33) plane of interest
 - 34) portable confocal scanning microscope
 - 35) semilandmarks
 - 36) sliding landmarks
 - 37) SR- μ CT
 - 38) synchrotron
 - 39) synchrotron radiation micro-computed tomography
- III. Data analysis
- A. Terms
- 1) bending energy
 - 2) dimension
 - 3) form
 - 4) parameter
 - 5) orthogonal
 - 6) regression
 - 7) shape
 - 8) size
- B. Methods
- 1) Procrustes analysis
 - 2) Procrustes distance
 - 3) Procrustes metric
 - 4) Procrustes shape coordinates
 - 5) thin-plate spline interpolation
 - 6) TPS
 - 7) transformation grid
 - 8) relative warps
 - 9) shape space
 - 10) shape variables
 - 11) warp
- NERVOUS SYSTEM**
- I. Terms
- 1) brain size evolution, molecular basis
 - 2) central nervous system
 - 3) chemoarchitecture
 - 4) cytoarchitecture
 - 5) encephalization
 - 6) encephalization quotient
 - 7) endocranial volume
 - 8) fMRI
 - 9) functional magnetic resonance imaging
 - 10) hemispheric dominance
 - 11) lateralization
 - 12) magnetic resonance imaging
 - 13) MRI
 - 14) neocortex ratio
 - 15) PET
 - 16) petalia
 - 17) positron emission tomography
 - 18) transduction
 - 19) torque
- II. Macrostructure
- 1) accessory olfactory system
 - 2) allocortex

- 3) amygdala
 - 4) angular gyrus
 - 5) anterior cingulate cortex
 - 6) arcuate fasciculus
 - 7) association cortex
 - 8) auditory cortex
 - 9) basal ganglia
 - 10) basal nuclei
 - 11) brain
 - 12) brain mass
 - 13) brain size
 - 14) brain specific mass
 - 15) brain tissue volume
 - 16) brain volume
 - 17) brain weight
 - 18) Brodmann's areas
 - 19) Broca's area
 - 20) calcarine sulcus
 - 21) central sulcus
 - 22) cerebellum
 - 23) cerebral cortex
 - 24) cerebral hemispheres
 - 25) cerebral petalia
 - 26) cerebrospinal fluid
 - 27) corpus callosum
 - 28) corpus striatum
 - 29) CSF
 - 30) diencephalon
 - 31) dura mater
 - 32) ECV
 - 33) endocasts
 - 34) endocranial cast
 - 35) endocranial capacity
 - 36) endocranial cavity
 - 37) endocranial volume
 - 38) endolymph
 - 39) extrastriate cortex
 - 40) fissures
 - 41) forebrain
 - 42) frontal lobe
 - 43) GI
 - 44) gyri
 - 45) gyrification index
 - 46) gyrus
 - 47) hindbrain
 - 48) hippocampus
 - 49) hypothalamus
 - 50) isocortex
 - 51) lateral fissure
 - 52) lateral geniculate nucleus
 - 53) lateral sulcus
 - 54) leptomeninges
 - 55) limbic cortex
 - 56) limbic system
 - 57) lunate sulcus
 - 58) microcephaly
 - 59) midbrain
 - 60) motor speech areas
 - 61) neocortex
 - 62) occipital lobe
 - 63) olfactory bulb
 - 64) parietal lobe
 - 65) pars opercularis
 - 66) pars orbitalis
 - 67) pars triangularis
 - 68) piriform cortex
 - 69) planum temporale
 - 70) postcentral gyrus
 - 71) posterior parietal cortex
 - 72) precentral gyrus
 - 73) prefrontal cortex
 - 74) primary visual cortex
 - 75) prosencephalon
 - 76) pyriform cortex
 - 77) striate cortex
 - 78) striatum
 - 79) subarachnoid space
 - 80) subdural space
 - 81) sulcus
 - 82) supramarginal gyrus
 - 83) Sylvian fissure
 - 84) telencephalon
 - 85) temporal lobe
 - 86) topographic
 - 87) thalamus
 - 88) visual cortex
- III. Microstructure
- 1) axon
 - 2) Brodmann's areas
 - 3) Broca's area
 - 4) dendrite
 - 5) dendritic arbor
 - 6) glia
 - 7) gray matter
 - 8) minicolumn
 - 9) mirror neurons
 - 10) myelin
 - 11) neuron
 - 12) neuropil
 - 13) neurotransmitter
 - 14) Nissl stain
 - 15) pachymeninx
 - 16) parcellation
 - 17) pyramidal cells

TOPIC ENTRY LIST

- 18) radial unit hypothesis
- 19) synapse
- 20) Tpt
- 21) V1
- 22) von Economo neurons
- 23) white matter

IV. Special senses

- 1) auditory ossicles
- 2) bony labyrinth
- 3) cochlea
- 4) cochlear duct
- 5) incus
- 6) internal ear
- 7) labyrinth
- 8) malleus
- 9) membranous labyrinth
- 10) organ of Corti
- 11) perilymph
- 12) semicircular canals
- 13) stapes

PALEOANTHROPOLOGY

I. Terms

- 1) *Helicobacter pylori*
- 2) hpAfrica
- 3) hpAsia
- 4) hpSahul
- 5) hpMaori
- 6) human
- 7) Mitochondrial Eve
- 8) paleoanthropology
- 9) reassembly
- 10) reconstruction
- 11) reconstruction algorithm

II. Taxa

A. Higher taxa

- 1) Archanthropinae
- 2) Australopithecinae
- 3) australopithecine
- 4) Hominidae
- 5) Hominina
- 6) Homininae
- 7) Hominini
- 8) Hominoidea
- 9) Neanthropinae
- 10) Paleoanthropinae
- 11) Panina
- 12) Paranthropinae
- 13) Pithecanthropidae

B. Genera

- 1) *Africanthropus* Dreyer, 1935
- 2) *Anthropopithecus* de Blainville, 1839

- 3) *Ardipithecus* White et al., 1995
- 4) *Atlanthropus* Arambourg, 1955
- 5) *Australopithecus* Dart, 1925
- 6) *Heoanthropus*
- 7) *Hesperanthropus*
- 8) *Homo*
- 9) *Homo* Linnaeus, 1758
- 10) *Javanthropus* Oppenoorth, 1932
- 11) *Meganthropus*
- 12) *Notanthropus*
- 13) *Orrorin*
- 14) *Palaeoanthropus*
- 15) *Paranthropus*
- 16) *Paraaustralopithecus* Arambourg and Coppens, 1968
- 17) *Pithecanthropus* Haeckel, 1866
- 18) *Plesianthropus* Broom, 1938
- 19) *Praeanthropus*
- 20) *Sahelanthropus* Brunet et al., 2002
- 21) *Sinanthropus* Black, 1927
- 22) *Telanthropus*
- 23) *Zinjanthropus* Leakey, 1959
- 24) *pre-Zinjanthropus*

C. Species

- 1) *Africanthropus njarasensis* Weinert, 1939 (Reck and Kohl-Larsen, 1936)
- 2) *Anthropopithecus erectus* Dubois, 1893
- 3) *Ardipithecus kadabba* Haile-Selassie et al., 2001
- 4) *Ardipithecus ramidus* (White et al., 1994) White et al., 1995
- 5) *Atlanthropus mauritanicus* Arambourg, 1955
- 6) *Australopithecus aethiopicus* Arambourg and Coppens, 1968
- 7) *Australopithecus afarensis* Johanson, 1978
- 8) *Australopithecus africanus* Dart, 1925
- 9) *Australopithecus anamensis* Leakey et al., 1995
- 10) *Australopithecus bahrelghazali* Brunet et al., 1996
- 11) *Australopithecus boisei* (Leakey, 1959)
- 12) *Australopithecus garhi* Asfaw et al., 1999
- 13) *Australopithecus prometheus* Dart, 1948
- 14) *Australopithecus ramidus* White et al., 1994
- 15) *Australopithecus sediba* Berger et al., 2010

- 16) *Australopithecus transvaalensis* Broom, 1936
- 17) *Australopithecus walkeri* Ferguson, 1989
- 18) *Eoanthropus dawsoni* Dawson and Woodward, 1913
- 19) *Homo africanus* (Dart, 1925)
- 20) *Homo antecessor* Bermúdez de Castro et al., 1997
- 21) *Homo antiquus* Ferguson, 1984
- 22) *Homo calpicus* Falconer, 1864
- 23) *Homo capensis* Broom, 1918
- 24) *Homo cepranensis* Mallegni et al. 2003
- 25) *Homo erectus* (Dubois, 1893)
- 26) *Homo ergaster* Groves and Mazák, 1975
- 27) *Homo floresiensis* Brown et al., 2004
- 28) *Homo florissbadensis* Drennan, 1935
- 29) *Homo gaugengensis* Curnoe, 2010
- 30) *Homo georgicus* Gabounia et al., 2002
- 31) *Homo habilis* Leakey, Tobias and Napier, 1964
- 32) *Homo habilis sensu lato*
- 33) *Homo habilis sensu stricto*
- 34) *Homo heidelbergensis* Schoetensack, 1908
- 35) *Homo helmei* Dreyer, 1935
- 36) *Homo (Javanthropus) soloensis* Oppenoorth, 1932
- 37) *Homo kanamensis* Leakey, 1935
- 38) *Homo leakeyi* Clarke, 1990
- 39) *Homo louisleakeyi* Kretzoi, 1984
- 40) *Homo microcranous* Ferguson, 1995
- 41) *Homo modjokertensis* von Koenigswald, 1936
- 42) *Homo mousteriensis*, Forrer, 1908
[*Homo mousteriensis hauseri* Klatsch and Hauser, 1909]
- 43) *Homo neanderthalensis* King 1864
- 44) *Homo nocturnus*
- 45) *Homo (Proanthropus) louisleakeyi* Kretzoi, 1984
- 46) *Homo ramidus* (White et al., 1994)
- 47) *Homo rhodesiensis* Woodward, 1921
- 48) *Homo rudolfensis* (Alexeev, 1986)
Groves 1989 sensu Wood, 1992
- 49) *Homo saldanensis* Drennan, 1955
- 50) *Homo sapiens* Linnaeus, 1758
- 51) *Homo soloensis* Oppenoorth 1932
- 52) *Homo spelaeus* Lapouge, 1899
- 53) *Homo spyensis* Krause, 1909
- 54) *Homo steinheimensis* Berkheme, 1936
- 55) *Homo sylvestris*
- 56) *Homo troglodytes* Linnaeus, 1758
- 57) *Homo transcaalensis* (Broom, 1936)
- 58) *Kenyanthropus platyops* Leakey et al., 2001
- 59) *Meganthropus africanus* Weinert, 1950
- 60) *Meganthropus palaeojavanicus* von Koenigswald in Weidenreich, 1945
- 61) *Orrorin tugenensis* Senut et al., 2001
- 62) *Palaeoanthropus njarasensis* Reck and Kohl-Larsen, 1936
- 63) *Palaeoanthropus palestinensis*
- 64) *Palaeoanthropus palestinus* McCown and Keith, 1939
- 65) *Paranthropus aethiopicus* (Arambourg and Coppens, 1968) Wood and Chamberlain, 1987
- 66) *Paranthropus boisei* (Leakey, 1959) Robinson, 1960
- 67) *Paranthropus crassidens* Broom, 1949
- 68) *Paranthropus palaeojavanicus* (von Koenigswald in Weidenreich, 1945)
- 69) *Paranthropus robustus* Broom, 1938
- 70) *Paraustralopithecus aethiopicus* Arambourg and Coppens, 1968
- 71) *Pithecanthropus dubius* Von Koenigswald, 1950
- 72) *Pithecanthropus erectus* (Dubois, 1892)
- 73) *Pithecanthropus modjokertensis* (von Koenigswald, 1936)
- 74) *Pithecanthropus robustus* Weidenreich, 1945
- 75) *Pithecanthropus rudolfensis* Alexeev, 1986
- 76) *Plesianthropus transvaalensis* (Broom, 1936) Broom, 1938
- 77) *Praeanthropus afarensis* (Johanson, 1978)
- 78) *Praeanthropus africanus* Weinert, 1950
- 79) *Sahelanthropus tchadensis* Brunet et al., 2002
- 80) *Sinanthropus lantianensis* Woo, 1964
- 81) *Sinanthropus pekinensis* Black, 1927
- 82) *Telanthropus capensis* Broom and Robinson, 1949

- 83) *Tchadanthropus uxoris* Coppens, 1965. Unavailable (proposed conditionally)
- 84) *Zinjanthropus boisei* Leakey, 1959
- D. Subspecies
- 1) *Ardipithecus ramidus kadabba* Haile-Selassie, 2001
 - 2) *Australopithecus africanus aethiopicus* Tobias, 1980
 - 3) *Australopithecus africanus afarensis* Johansen 1978
 - 4) *Australopithecus africanus africanus* Dart, 1925
 - 5) *Australopithecus africanus habilis* (Leakey, Tobias and Napier, 1964)
 - 6) *Australopithecus africanus modjokertensis* (von Koenigswald, 1936)
 - 7) *Australopithecus africanus robustus* Broom, 1938 (Broom, 1938)
 - 8) *Australopithecus africanus tanzaniensis* Tobias, 1980
 - 9) *Australopithecus africanus transvaalensis* (Broom, 1936)
 - 10) *Homo antiquus praegens* Ferguson, 1989
 - 11) *Homo erectus capensis* (Broom and Robinson, 1949)
 - 12) *Homo erectus erectus* (Dubois, 1983)
 - 13) *Homo erectus heidelbergensis* Schoetensack, 1908
 - 14) *Homo erectus javanensis* (Eickstedt, 1932)
 - 15) *Homo erectus leakeyi* (or *Homo leakeyi*) Heberer, 1963
 - 16) *Homo erectus mauritanicus* (Arambourg, 1954)
 - 17) *Homo erectus olduvaiensis* Tobias, 1968
 - 18) *Homo (erectus or sapiens) palaeohungaricus* Thoma, 1966
 - 19) *Homo erectus pekinensis* (Black, 1927)
 - 20) *Homo erectus reilingensis* Czatnetzki, 1989
 - 21) *Homo erectus sinensis* (Weinert, 1931)
 - 22) *Homo neanderthalensis aniensis* Sergi, 1935
 - 23) *Homo neanderthalensis soloensis* Oppenoorth, 1932
 - 24) *Homo sapiens idaltu* White et al., 2003
 - 25) *Homo sapiens neanderthalensis* King, 1864
 - 26) *Homo sapiens palestinus* McCown and Keith, 1934
 - 27) *Homo sapiens protosapiens* Montandon, 1943
 - 28) *Homo sapiens rhodesiensis* Woodward, 1921
 - 29) *Homo sapiens shanidarensis* Senyürek, 1957
 - 30) *Homo sapiens soloensis* Oppenoorth, 1932
 - 31) *Homo sapiens steinheimensis* Linnaeus, 1758
 - 32) *Paranthropus robustus crassidens* Broom, 1949
 - 33) *Paranthropus robustus robustus* Broom, 1938
- E. Informal terms
- 1) AMH
 - 2) anté-Néandertalien
 - 3) “archaeomorphous” *Homo sapiens*
 - 4) australopith
 - 5) Chellean man
 - 6) “classic” Neanderthals
 - 7) “Dawn Man”
 - 8) early African *Homo erectus*
 - 9) hominid
 - 10) hominin
 - 11) homininan
 - 12) hominine
 - 13) Lantian Man
 - 14) Levantine Neanderthals
 - 15) modern human
 - 16) Nanjing Man
 - 17) Neanderthaloid
 - 18) neoanthropic man
 - 19) Ngandong hominins
 - 20) Palaeanthropi
 - 21) paleoanthropic man
 - 22) paninan
 - 23) panini
 - 24) paranthropoid
 - 25) Peking Man
 - 26) Phaneranthropi
 - 27) pithecanthropine
 - 28) -pithecus
 - 29) prehominine

Informal taxonomic categories

Individual fossils are placed in one of six informal taxonomic categories, namely ‘Possible hominins’, ‘Archaic hominins’, ‘Megadont archaic hominins’, ‘Transitional hominins’, ‘Pre-modern *Homo*’ and ‘Anatomically modern *Homo*’. These are inclusive grade categories. Whereas clades reflect the *process* of evolutionary history, the grade concept is based on the *outcome* of evolutionary history. Taxa in the same grade have similar relative brain sizes, they are judged to eat foods with the same mechanical properties and they share the same posture and mode(s) of locomotion; no store is set by how they came by those behaviors. The judgment about how different two masticatory systems or two locomotor strategies have to be before the taxa concerned are considered to belong to different grades is a subjective one, but until we can be sure we are generating reliable hypotheses about the relationships among hominin taxa the grade concept enables taxa to be sorted into broad functional categories, albeit sometimes frustratingly ‘fuzzy’ (e.g., where to place *Homo floresiensis*) ones.

A

2D:4D *See* hand, relative length of the digits.

3' One of the two ends of a single strand of DNA. It is called the 3' (or "three prime") end because the third carbon of the nucleotide at that end has a hydroxyl group attached. The other end, the 5' (or "five prime") end, is so-called because the fifth carbon of the deoxyribose sugar of the nucleotide at that end has a terminal phosphate group attached to it. The direction towards the 3' end of a single strand of DNA is called the **downstream** direction because as you move in that direction the number of carbon molecules in the sugars in the DNA backbone decreases. The significance of the directionality of a DNA sequence is that the processes of **replication** and **transcription** only occur in the 5' to 3' direction. *See also* DNA.

5' One of the two ends of a single strand of DNA. It is called the 5' (or "five prime") end because the fifth carbon of the deoxyribose sugar of the nucleotide at that end has a terminal phosphate group attached to it. The other end, the 3' (or "three prime") end, is so-called because the third carbon of the nucleotide at that end has a hydroxyl group attached. The direction towards the 5' end is called the **upstream** direction because as you move in that direction the number of carbon molecules in the sugars in the DNA backbone increases. The significance of the directionality of a DNA sequence is that the processes of **replication** and **transcription** only occur in the 5' to 3' direction. *See also* DNA.

a The abbreviated form of annum. The joint IUPAC-IUGS Task Group (2006-016-1-200) in 2006 urged that the SI unit a be used for both ages and time spans (i.e., 36 ka for 36 thousand years and 2.3 Ma for 2.3 million years). The IUPAC-IUGS Task Group discourage the use of y, yr and yrs in combination with k, K, m, M, etc.

abduction (L. *ab* = away and *ducere* = to lead) Limbs Refers to moving a limb away from the midline (i.e., the true **sagittal** plane) when the body is in the **anatomical position**. Digits In the case of the hands and feet abduction means moving fingers or toes away from the **reference digit**. The reference digit of the hand is the middle finger; the reference digit of the foot is the second toe. Thus, the muscles that move the limbs away from the midline (e.g., the deltoid and the gluteus medius) and those that move a digit away from the reference digit (e.g., the dorsal interosseus muscles of the hand) are referred to as **abductors**. *See also* **abductor**; **reference digit**.

abductor Any muscle that contributes to moving a limb away from the midline reference plane (e.g., deltoid, gluteus medius), or a digit away from the **reference digit** (e.g., dorsal interossei of the hand).

Abdur (Location 15°09'N, 39°52'E Eritrea; etym. the name of a nearby village) History and general description Faure and Roubet (1968) had reported finding Acheulean artifacts on the surface of marine

deposits on the African shore of the Red Sea. Abdur is a Pleistocene reef terrace on the western shore of the Buri Peninsula, and is northeast of the Danakil Depression. The terrace, comprised of a 6.5 km/4 mile by 1 km/0.6 mile exposure of the Abdur Reef Limestone (or ARL), is divided into three sections: Abdur North (AN), Abdur Central (AC) and Abdur South (AS). Obsidian and quartz artifacts have been found in AN and AS, with most of the evidence coming from AN and the artifacts coming from the "basal cobble zone," the "lower part of the lower shell zone" and the "beach facies" (Walter et al. 2000, p. 67). Temporal span and how dated? Five of six dates based on **uranium-series dating** (uranium-thorium) performed on coral aragonite suggest the ARL was deposited between 136 and 118 ka, with a mean age of $c.125 \pm 7$ ka. Hominins found at site None. Archeological evidence found at site Bifaces made from chert and quartz and flake and blade tools mainly from obsidian. The artifacts are consistent with the early **Middle Stone Age**. Key references: Geology, dating, and fauna Walter et al. 2000; Hominins N/A; Archeology Walter et al. 2000.

"Abel" The informal name given by Michel Brunet to a hominin mandibular fragment recovered in 1994 by the **Mission Paléoanthropologique Franco-Tchadienne** (French-Chadian Paleanthropological Mission, or MPFT) at a site in Chad called **Koro Toro**. Brunet and his colleagues assigned the specimen to a new species, *Australopithecus bahrelghazali*. He gave the specimen the name Abel to honor the memory of Abel Brillanceau, a colleague and close friend who died while doing field research.

abiotic (Gk *a* = not and *bios* = life) In relation to hominins this term subsumes all the "non-living" factors (e.g., climate and physical catastrophes such as massive volcanic eruptions, tsunamis, etc.) that might have influenced the outcome of human evolution.

Abri Bourgeois-Delaunay *See* La Chaise.

Abri d'Aurignac *See* Aurignac.

Abri Moula-Guercy (Location 44°52'59"N, 4°50'51"E, France; etym. Fr. *abri* = rock-shelter, Moula = the name of the discoverer, Guercy = the limestone outcrop in which the cave lies) History

and general description This site, sometimes referred to as Baume Moula-Guercy (*baume* is Provençal for cave) or just Moula-Guercy, lies 80 m above the right bank of the Rhône river, in the east side of the Serre de Guercy, a small limestone outcrop in the town of Soyons, in the Ardeche region of southeast France. Discovered in 1970, the site was not excavated until 1991, when a team led by Alban Defleur began to explore the rock-shelter and deep cave beneath. They uncovered 20 layers, all of which are exclusively **Middle Paleolithic**. This site is best known for the abundant evidence of defleshing and disarticulation on bones assigned to *Homo neanderthalensis*, which the authors have suggested is due to cannibalism. It is also one of the few well-preserved sites with hominin fossils of Eemian age. Temporal span and how dated? The site represents the period between **Oxygen Isotope Stages** 6 and 4. Most of the site is dated using **biostratigraphy**, but an ash layer near the top of the site has been dated using **thermoluminescence dating** to 72 ± 12 ka. The hominin layer is estimated to be between 100 and 120 ka. Hominins found at site Neanderthals are the second most abundant taxon recovered from layer XV; 78 bone fragments were recovered, representing at least six individuals. The majority of these bones show cut-marks and intentional fractures that have been interpreted as attempts at marrow extraction; the patterns are similar to those found on deer bones found at the same site. Archeological evidence found at site The artifacts from the layer containing the fossil hominins are attributed to the Ferrassie **Mousterian**. Key references: Geology, dating, and paleoenvironment Sanzelle et al. 2000, Defleur et al. 1998, 2001; Hominins Defleur 1995, Defleur et al. 1998; Archeology Defleur 1995, Defleur et al. 1998.

Abri Pataud (Location 44°56'N, 1°00'E, France; etym. Fr. *abri* = rock-shelter, and Pataud after the name of the family who owned the land) History and general description One of several rock-shelter sites along the Vézère River in southwest France. The site was obscured by farm buildings until 1953 when Hallam Movius began exploring the site, and it was systematically excavated between 1958 and 1964 by a joint French and American team led by Movius. Temporal span $c.34-19$ ka. How dated? Conventional **radiocarbon dating**. Hominins found at site Partial skeletons of three adult and two adolescent modern human skeletons were found in the Proto-Magdalenian layer. Archeological

evidence found at site Thirteen numbered archeological layers represent an almost complete **Upper Paleolithic** sequence, from basal **Aurignacian** to a possibly lower **Solutrean** level, separated by unnamed sterile layers. Abundant fauna and some pollen suggest a cold environment consistent with the **Last Glacial Maximum**, but with local river valleys providing **refugia** for warm-climate species. Key references: Geology, dating and paleoenvironment Donner 1975, Movius Jr. 1975, Wilson 1975, Bricker and Mellars 1987; Hominins Billy 1975; Archeology Movius Jr. 1975.

Abri Peyrony See Combe-Capelle.

Abri Suard See La Chaise.

abridged life table A complete life table gives mortality per individual year of age, while an abridged life table lumps various ages together. It is common in **paleodemography** to use age classes starting at 0, 1, 5, 10, 15, 20, 25, 30, 40, and 50, where the end of an age class is implied by the next age class. For example, the first few age classes in the above list would be 0–0.9973 (where 0.9973 is 364/365 days, 1–4.9973, and 5–9.9973. The last age class is considered to be open, so that the last age class in the above list is 50+. Any life table function which involves person-years will require that the last age interval be closed, which is usually done by continuing the age progression so that 50+ becomes 50–60. Using the notation ${}_nD_x$ to represent the number of deaths between age x and age $x+n$, the symbols for the abridged life table example here would be: ${}_1D_0$, ${}_4D_1$, ${}_5D_5$, ${}_5D_{10}$, ${}_5D_{15}$, ${}_5D_{20}$, ${}_5D_{25}$, ${}_{10}D_{30}$, ${}_{10}D_{40}$, and ${}_{10}D_{50}$.

absolute dating (L. *absolutus* = free or unrestrained) In physics, "absolute" means being free, or independent, of arbitrary standards. Thus, absolute dating methods were so labeled because they were regarded as not being arbitrary in that they are based on physical or chemical systems whose dynamics are predictable. This predictability means they can be used to calibrate events or measure the passage of geological time. Very few of the current techniques can be used to determine the age of the fossils or artifacts themselves; in most cases they are used to date surrounding sediments or associated igneous rocks, which have a known stratigraphic relationship to the fossils in question. **Radiocarbon dating** is perhaps the best-known absolute dating method, but

several others (e.g., **potassium-argon dating**, **thermoluminescence dating**, **uranium-series dating**) are used to provide age estimations for fossil hominins beyond the age range of radiocarbon dating (i.e., older than approximately 50 ka). All absolute dates have various associated errors. Occasionally these are errors in the measurement of the physical parameter used [i.e. the amount of carbon-14 (^{14}C) isotope present in the sample]. Errors can also arise from imperfect calibration of the physical parameter to the geological time scale or from various alterations of the dated material after it was deposited. Thus, whenever the age of a tuff, cave deposit, directly dated fossil, etc. is cited it should include its error term expressed either in standard deviation units or as years, depending on the dating technique being utilized. Geochronologists are moving away from the old divisions of absolute and relative methods, and tend to refer to absolute dating methods as methods that provide a "numerical age estimate". See also **geochronology**.

AC Acronym for Abdur Central. See **Abdur**.

acceleration (L. *accelerationem* = a hastening) A heterochronic process that produces peramorphic results by dissociating ancestral patterns of ontogeny. Specifically, shape change is accelerated and progresses further for a given size in descendants relative to ancestors; adult size and duration of growth found in the ancestor remain unchanged in the descendant.

accelerator mass spectrometer (AMS) A specialised mass spectrometer that can extend the range of carbon dating back to 50–60 ka. This technique uses an accelerator to produce ions with very high kinetic energies; this is done to increase the ionization state of the ions from the sample in order to facilitate the removal of potential contaminants (particularly ^{14}N and ^{13}CH) that would interfere with the counting of ^{14}C ions in the detector. The technique is referred to as **AMS radiocarbon dating**, to distinguish it from **conventional radiocarbon dating**. See also **radiocarbon dating**.

accentuated line A pronounced line within a tooth corresponding to the temporary slowing of movement of the developing **enamel** or **dentine** front, or to a change in chemical composition, that does not result from an intrinsic rhythm (see **incremental features**), but rather relates to a

(non-specific) stressor event. The **neonatal line** found in teeth developing just prior to, during, and immediately after birth is the best-known example. Accentuated lines are sometimes found in association with enamel **hypoplasias**, but they can occur without there being any surface manifestation of developmental stress (syn. pathological lines, **Wilson bands**, or accentuated striae of Retzius).

accentuated striae of Retzius *See* Wilson bands.

accessory cusp A cusp on a maxillary (upper) or mandibular (lower) molar tooth that is not one of the main cusps (i.e., not the **proto-**, **para-**, **meta-**, or **hypocone** on a maxillary molar, and not the **proto-**, **ento-**, **meta-**, or **hypoconid**, or **hypoconulid**, on a mandibular molar). For example, the **metaconule** is an accessory cusp between the metacone and protocone on a maxillary molar, and the **tuberculum sextum** is an accessory cusp between the **entoconid** and the **hypoconulid** on the **talonid** component of the crown of a mandibular molar. *See also* **cusp**.

accessory olfactory system *See* olfactory bulb.

accretion model (L. *accrescere* = to grow) Refers to the mode of origin of the Neanderthals. The model suggests that the distinctive morphology of *Homo neanderthalensis* did not arise suddenly, but emerged gradually, or grew (i.e., accreted), over a period of several hundred thousand years (Hublin 1998). Although Jean-Jacques **Hublin** (1982, 1986, 1998, 2009) is its contemporary proponent, this type of evolutionary scenario was first proposed by Piveteau (1970), and then developed by Vandermeersch (1978b). The model proposes that initially there were relatively few distinctive features (e.g., facial recession and a wide occipital torus) and what features there were occurred at a relatively low frequency, but through time the number and frequency of distinctive features increased. Dean et al. (1998) provided the most comprehensive explanation of the model. They suggested that Neanderthal evolution occurred in four stages (*ibid*, Table 1, p. 487): Stage 1 or the early pre-Neanderthal stage, Stage 2 or the pre-Neanderthal stage, Stage 3 or the early Neanderthal stage, and Stage 4 or the classic Neanderthal stage. Examples of Stage 1 Neanderthal specimens

include those from **Arago**, **Mauer**, and **Petralona**. Specimens from **Sima de los Huesos**, **Reilingen**, **Steinheim**, and **Swanscombe** have been assigned to Stage 2, with **Bilzingsleben** and **Vértesszöllös** considered as Stages 1 or 2. Examples of specimens assigned to Stage 3 include **Ehringsdorf**, **Biache**, **Saccopastore**, and **Shanidar**, with **Amud**, **Monte Circeo**, **La Chapelle-aux-Saints**, **La Ferrassie**, **La Quina**, **Neanderthal**, and **Spy** examples of specimens included in Stage 4. As for the morphological features that emerge at each stage, the Stage 2 morphology includes an incipient **suprainiac fossa**, a small **jxtamastoid eminence**, and an incipient occipital bun. The changes that occur at Stage 3 include a smaller mastoid process, a larger **jxtamastoid process**, an anterior **mastoid tubercle**, and a more exaggerated occipital bun. At Stage 4 the additions include greater midfacial **prognathism**, a more exaggerated suprainiac fossa, and a larger piriform, or nasal, aperture. However, Hublin (1998, 2009) emphasized that there is a shift in the frequencies of these features and that stages primarily result from discontinuity in the fossil record. He proposed that the taxon name *Homo neanderthalensis* should be used for *all four stages*. Other researchers support the accretion model, but they would confine the hypodigm of *H. neanderthalensis* to the later stages, and would use *Homo heidelbergensis* for the early stages (e.g., the hominins from **Sima de los Huesos**). *See also* *Homo heidelbergensis*; *Homo neanderthalensis*.

acculturation The adoption by one group of a large number of cultural behaviors from another group. Thus, in the terminology of dual inheritance theory, acculturation is a form of group-level horizontal cultural transmission.

accuracy (L. *accurare* = to do with care) Accurate refers to something that is true, or close to the truth. Thus, accurate estimates of measurements or dates are ones that are very close to the real dimensions or ages. A series of accurate measurements are not necessarily close to each other, however. Imagine a dartboard with three darts placed equidistant on a circle around the bull's eye. Each dart is close to the bull's eye, but not particularly close to the other darts. *See also* **precision**.

acetabulo cristal buttress *See* acetabulo cristal pillar.

acetabulo cristal pillar (L. *acetum* = vinegar, *abulum* = small receptacle, and *crista* = crest) Thickening of mostly the outer table of the iliac blade part of the pelvic bone between the acetabular fossa and the iliac crest about one-third of the way between the anterior and posterior superior spines. The thickening is seen in pre-modern *Homo*, but not in anatomically modern humans (Stringer 1986b). Its presence is interpreted as evidence that the gluteal muscles were playing a significant abducting role (i.e., working isometrically to prevent the pelvis from dipping down on the side where the leg is no longer in contact with the ground because it is in the swing phase of the **walking cycle**). For example, Day (1971) refers to the acetabulo cristal pillar as the “vertical iliac pillar” or “vertical iliac bar” and suggests that its presence in **OH 28** is evidence that “the alternating pelvic tilt mechanism of striding bipeds was well developed” (*ibid*, p. 384). See also **pelvic bone**.

Aché A group of foragers (also known as the Guayaki) living in eastern Paraguay, an environment of mixed broadleaf evergreen forest and grassland. There are four main groups of Aché who distinguish themselves based on language, customs, and geographic range, and all contrast themselves from the neighboring sedentary farmers with whom they usually have only hostile interactions. All four Aché groups have been studied by ethnographers, and the northern group has been the particular subject of subsistence studies by behavioral ecologists. Most of the northern Aché were full-time foragers until the 1970s; now roughly 130 of this group live in an agricultural settlement. Some of these 130 people still spend a considerable amount of time in the forest on extended foraging trips, where they hunt a wide range of animals with bows, and gather plant foods. Studies of their diet have enabled several researchers to test hypotheses about evolutionary ecology in the absence of agriculture, and to use them as analogues for pre-agricultural human ancestors. Studies of the Aché have suggested that both plant and animal foods are important in an optimal diet, that men and women have different foraging goals which must be accounted for in behavioral ecology studies (Hill et al. 1987), and that hunting may be a social signal as well as a method of provisioning (Wood and Hill 2000).

Acheulean Originally proposed in the 19thC by Gabriel de Mortillet; takes its name from the French village of Saint-Acheul in the Somme River Valley

where numerous **handaxes** had been recovered. In 1872 Gabriel de Mortillet named the **industry** “l’Epoque de St Acheul”, but in 1925 the name was changed to Acheulean. Earlier mention of handaxes was made by John Frere who in 1797 sent two examples from Hoxne, Suffolk, UK, to the Royal Academy in London claiming that “they belonged to a very ancient period indeed” and had been produced by “people who had not the use of metals.” Given the general lack of knowledge of evolution in those times his claims were mostly ignored. The oldest and youngest reported Acheulean sites were in Africa from 1.6–0.16 Ma. Acheulean sites are found in a substantial portion of Eurasia (but they are generally absent from Asia east of **Movius’ Line**). Most Eurasian Acheulean sites date from the Middle Pleistocene (i.e., they are *c.*500 ka). Handaxes and similar implements (such as **cleavers** and **picks**) define the Acheulean; these tool types are not *confined* to the Acheulean, but when they occur at other sites they are rare and are typically outnumbered by **flakes**, **cores**, and other smaller modified tools such as **scrapers**. The Acheulean is preceded by the **Oldowan**, and many of the non-handaxe Acheulean tools are Oldowan-like, emphasizing the retention of an older but effective stone tool technology. Similarly, some later Acheulean sites, including for example those in the Somme River Valley and in the **Kapthurin Formation** of Kenya, show evidence for the use of **Levallois** technology for large flake production. This technique is seen more commonly in later **Middle Paleolithic** or **Middle Stone Age** sites, and this also suggests local technological continuity. The Acheulean site of **Gesher Benot Ya’akov** in Israel documents the earliest controlled use of fire, as well as nut fragments and processing equipment (Goren-Inbar et al. 2002a, 2002b). Meat was very likely an important component of the hominin diet, but Acheulean hunters may have been relatively ineffective compared with later populations at bringing down large game (Klein et al. 2007). Although traditionally associated with *Homo erectus*, Acheulean tools were likely made and used by more than one hominin taxon. Interpretations of the Acheulean vary widely. Its seemingly static nature is usually attributed to **social learning** and **cultural transmission**, in combination with functional constraints (cutting, scraping), repeated resharpening, and raw-material constraints (e.g., large tabular chunks versus small elongated pebbles). Some workers have speculated that the quite unchanging basic features of Acheulean implements

were genetically determined, and that the variability of the final products may have signaled the genetic qualities of the maker. The Acheulean is unique in the evolution of hominins in that neither before nor since has such a singular technology dominated the activities of hominins for so long over so much of the planet.

Acheulian Alternative spelling for **Acheulean** (*which see*).

Acheulian industrial complex *See* **Acheulean**.

actualistic studies (L. *actus* = an act) Such studies, which reconstruct activities to understand the role or function of that activity, are used in archeology and paleontology. For example, in archeology, researchers use tools in controlled circumstances to help determine what paleolithic artifacts were used for. For example, if an artifact made by a skilled knapper is used to whittle wood, the wear on the modern tool can be compared with the wear on ancient artifacts to see if the wear facets show the same macro- and microwear. In paleontology, actualistic research involves studying the factors that determine the formation and nature of present-day bone assemblages and then applying that knowledge to the paleontological record. Actualistic studies are uniformitarian in the sense that they assume that processes observed in the present are same as those that took place in the past (*see* **uniformitarianism**). In turn, inferences about the past are interpreted in terms of processes operating in the present. Actualistic research methodologies range from naturalistic to experimental. In a naturalistic context, the analyst observes and records natural processes and their resulting effect on bone assemblages. In an experimental context, the analyst controls some or all of the taphonomic processes affecting bone assemblages. Actualistic research provides the basis for most taphonomic and zooarcheological analysis and interpretation and is thus central to reconstructing the behavioral and paleoenvironmental signals encoded in the fossil record.

acute margin Another term for a sharp edge on a stone tool.

adaptation (L. *adaptare* = to fit) A useful feature or trait that (a) promotes survival and reproduction and (b) is shaped by natural selection, and

formulating and testing hypotheses of adaptation is a major focus of paleoanthropological research. Adaptations are therefore heritable and perform functions. The term is also used to describe the process by which features that promote or enhance fitness evolve under **natural selection**, which can be **directional selection** or **balancing selection** (also known as stabilizing selection). Evolutionary biologists differ as to whether understanding the genesis of a trait is important in determining its adaptive status, some noting the importance of distinguishing between current function and original function(s). In some cases the function of a current trait can be assessed experimentally, but in most cases in evolutionary biology describing a phenotypic trait as a current or previous adaptation should be seen as an hypothesis. The frequency of a heritable variant, the **trait**, predominates or becomes fixed in a population because the individuals possessing it enjoy greater reproductive success (**fitness**) than those that lack it. It is common for workers to think of adaptive traits as being **derived** (i.e., **apomorphic**), but this need not be the case if a **primitive** trait has been retained in a population as a result of stabilizing selection. Adaptation can also be used as an adjective in connection with a taxon, as in “the dentition of *Paranthropus boisei* is better adapted for chewing than for slicing food.” In such usage, adaptation is being used in an informal sense (i.e., “better adapted” can be read to mean “functions better”). So, what needs to be done to strengthen an hypothesis that a trait in a **hominin** taxon is an adaptation in the non-historical sense? If a trait seems to have an obvious function (e.g., the **acetabulocrystal buttress** of the pelvic bone functions in bipedal hominins as a bony strut that links the proximal attachment of the hip abductors with the acetabulum of the hip joint) then all well and good. But just because our present knowledge does not allow us to assign a function to a trait, it does not follow the trait has no function; we may not yet understand what its function is. For example, if we did not know about the way the specialized receptors in the **semicircular canals** of the **membranous labyrinth** of the **inner ear** respond to motion, we would perhaps be inclined to assume that the shape of that part of the bony labyrinth of a fossil **hominid** was not adaptive. Therefore, adaptation will tend to be under-recognized (i.e., it is prone to **type I error**). It can be difficult, if not impossible, to firmly establish

whether or not a given trait has been subjected to natural selection in fossil hominins, so the identification of adaptations in paleoanthropology is inevitably conjectural. *See also* **phylogenetic lag**; **structure–function relationships**.

adaptive landscapes *See* fitness landscapes.

adaptive radiation (L. *adaptare* = to fit and *radius* = ray) The relatively rapid diversification of a lineage into **species** that evolve a range of new **adaptive strategies** that facilitate their occupation of a range of new **adaptive zones**. An example is the simultaneous appearance (at least in geological time) of multiple pig species at the same site(s) at several times during the **Pliocene** and **Pleistocene**. During the last 4 Ma approximately six pig species have coexisted at the same locality (i.e., **sympatrically**) at the same time (i.e., **synchronically**). A number of these species exhibit M₃ hypsodonty and craniofacial elaboration (bosses, crests, tusks). This is usually interpreted as an adaptive response to more open, grassland environments.

adaptive strategy (L. *adaptare* = to fit and *strategos* = general) Sewall-Wright's term for the set of traits that enables organisms of a species to survive and reproduce. The origin of these trait sets can vary; they may have been inherited from a recent common ancestor or they may be the result of independent adaptation to similar environmental conditions (i.e., **parallel evolution** or **convergent evolution**). An adaptive strategy can be shared by more than one species (syn. organizational plan). *See also* **adaptive type**; **adaptive zone**; **grade**.

adaptive type (L. *adaptare* = to fit, *typus* = image) According to Huxley (1958) an adaptive type is a fossil taxon with a more derived **phenotype**, or organizational plan, that replaces an older fossil taxon with a less derived organizational plan. In some cases the replacement is straightforward, involving just two taxa. In others, the old organizational plan is replaced by several new organizational plans, which are then reduced in number by extinction, until only one is left. Regardless of the mode of replacement, the new taxon is called an adaptive type because, according to neo-Darwinian principles, it must have been more successful than the taxa it superseded. The rise and success of a new organizational plan is evidence that it was better adapted than

the older one, and that it was also better adapted than any potential competitor. The terms adaptive type and **grade** are interchangeable. Huxley's (1958) term "organizational plan" is equivalent to Sewall-Wright's **adaptive strategy** (syn. grade). *See also* **adaptive strategy**; **adaptive zone**; **grade**.

adaptive zone (L. *adaptare* = to fit and *zona* = girdle) Taxa that occupy the same adaptive zone survive and reproduce in a similar manner. That is, they have the same **adaptive strategy**. The relationship between adaptive strategies and **adaptive types**, or **grades**, is such that some adaptive zones are occupied by taxa that have the same adaptive strategy and so represent an adaptive type or grade. Occasionally, a lineage will rapidly diversify into several species that occupy a range of new adaptive zones. This is referred to as an **adaptive radiation**. *See also* **adaptive radiation**; **adaptive strategy**; **adaptive type**; **grade**.

adduction (L. *adducere* = to bring towards) **Limbs** Adduction refers to moving a limb towards the midline (i.e., the true **sagittal plane**) when the body is in the **anatomical position**. **Digits** In the case of the hands and feet, adduction means moving fingers or toes towards the **reference digit**. The reference digit of the hand is the middle finger; the reference digit of the foot is the second toe. Thus, the muscles that move the limbs towards the midline (e.g., teres major and obturator internus) and those that move a digit towards the reference digit (e.g., the palmar interosseus muscles of the hand) are referred to as **adductors**. *See also* **adductor**; **reference digit**.

adductor Any muscle that contributes to moving a limb towards the midline reference plane (e.g., teres major, obturator internus), or a digit towards the **reference digit** (e.g., palmar interossei of the hand). *See also* **reference digit**.

adDNA *See* ancient DNA.

adolescence (L. *adolescencia* = youth) Adolescence is the stage of modern human life history that follows the juvenile stage and the event of puberty. The length of adolescence varies across modern human populations; it ends when adult skeletal lengths, dental development, and sexual maturation are attained (e.g., the age range of its ending is from 17 to 25 years). The defining characteristic of adolescence is a spurt in height (unique to modern humans among extant higher primates; several

nonhuman primate species undergo growth spurts in craniofacial dimensions) and mass (shared with many nonhuman primates). The intensity and duration of this spurt shows much variation among and within modern human populations. The onset of menstruation (**menarche**) in modern human girls usually follows within 1 year of the peak velocity of the growth spurt, and for 1–3 years they experience a period of “adolescent subfecundity” (where menstrual cycles are often irregular or anovulatory). Sexual maturation in modern human boys precedes the time of peak growth velocity, but the full development of modern human male secondary sexual characteristics takes much longer to manifest. This results in subfecund, adult-looking girls, and fecund, non-adult-looking boys. It has been proposed that this is an adaptation that enables each sex to learn as much as possible about their adult social, economic, and sexual roles in society, with as little risk as possible. It has been suggested that the adolescent stage evolved either in archaic or anatomically modern *Homo sapiens*, but it is difficult to determine, at the current time, whether extinct hominin taxa underwent a growth spurt and, if so, whether it was more similar to that of modern humans or that of nonhuman primates.

adolescent growth spurt (L. *adolescere* = to grow up, from *ad* = forward and *alescere* = to grow) Adolescence in modern humans is the period of **life history** between puberty and maturity. During the adolescent stage of modern human development rapid gains in height and weight usually occur beginning on average between ages of 10 (females) and 12 (males). This period of the highest growth velocity, second only to that experienced in infancy, usually lasts between 8 and 10 years. There is significant variation in the onset and intensity of the adolescent growth spurt within and among modern human populations, with some showing a clear and marked spurt in stature while others demonstrate no clear evidence of such a spurt. While many species of nonhuman primates have been shown to have growth spurts in mass, modern humans are the only primates that show evidence for a spurt in linear skeletal dimensions. This intense growth is seen in almost all skeletal elements, with the exception of the female pelvis (instead of experiencing a major spurt in growth, the female pelvis grows slowly until adulthood). The later onset and longer duration combined with the generally higher growth velocity experienced during the adolescent growth spurt in modern

human males when compared with females is largely responsible for their greater average adult height.

adrenarche (L. *ad* = near, *renal* = kidney, and Gk *arkhe* = beginning) The onset of prepubertal adrenal androgen production (specifically of dehydroepiandrosterone, or DHEA, and dehydroepiandrosterone sulfate, or DHEAS) after a post-infancy period of very little adrenal activity. While circulating levels of adrenal androgens in nonhuman primates are generally higher than those in nonprimate mammals, none show the same pattern that is seen in modern humans and chimpanzees: a sharp postnatal decline in levels from birth with subsequent elevations before sexual maturation usually around 6–10 years of age. It has been suggested that differences in patterns of adrenal androgen secretion may be due to differences in the timing of the regression of the fetal zone and development of the *zona reticularis* (or ZR), the region of the adult adrenal gland where these hormones are produced. Specifically, these two events occur in closer temporal proximity in primates other than chimpanzees, such as baboons, whose DHEAS levels peak shortly after birth and decline steadily thereafter. It has been proposed that the decline in serum DHEA/DHEAS prior to adrenarche acts as a mechanism to delay skeletal maturation in concert with prolonged prepubertal growth (Bogin 1997). The outward effects of adrenarche (e.g., changes in body fat distribution, growth of body hair) noticeably alter an individual’s physical appearance. It has been suggested that adrenarche and the slowed growth prior to it is critical to the development of an individual’s cognitive function. It also aids the perception by others that an individual is transitioning from a child to a juvenile.

ADU Abbreviation of Aduma, a site in the Middle Awash study area, Ethiopia. *See* Aduma.

ADU-VP Acronym for Aduma – Vertebrate Paleontology. Prefix for fossils from the site of Aduma.

ADU-VP-1/3 Site Aduma. Locality Aduma. Surface/in situ Surface collection from **lag deposits**. Date of discovery 1996. Finder Timothy Douglas White. Unit N/A. Horizon Bed B. Bed/member Ardu Beds. Formation **Bouri Formation**. Group Middle Awash. Nearest overlying dated horizon Bed A, Ardu Beds. Nearest underlying dated horizon Bed C, Ardu Beds, followed by the **Herto Formation**.

Geological age **Late Pleistocene**, associated with **Middle Stone Age** artifacts and sediments dated between 79 and 105 ka (Yellen et al. 2005). **Developmental age** Adult. **Presumed sex** Unknown. **Brief anatomical description** The most complete of five fragmentary crania from Aduma, ADU-VP-1/3 preserves part of the frontal squame and much of the parietals and occipital. The occipital is rounded and the parietals have a strong sagittal curvature, indicating a globular **neurocranium**. **Announcement** Haile-Selassie et al. 2004b. **Initial description** Haile-Selassie et al. 2004b. **Photographs/line drawings and metrical data** Haile-Selassie et al. 2004b. **Detailed anatomical description** Haile-Selassie et al. 2004. **Initial taxonomic allocation** *Homo sapiens*. **Taxonomic revisions** N/A. **Current conventional taxonomic allocation** *Homo sapiens*. **Informal taxonomic category** Anatomically modern human. **Significance** The Aduma crania are clearly anatomically modern and even though their dating is not precise they add support to the hypothesis that modern humans evolved in Africa. **Location of original National Museum of Ethiopia**, Addis Ababa, Ethiopia.

Aduma (Location 10°25'N, 40°31'E, Ethiopia; etym. named after a nearby Afar village) **History and general description** A region in the **Middle Awash study area** with **Early, Middle, and Later Stone Age** archeological sites. The locality was briefly surveyed by John Kalb in 1976, but excavations were not undertaken until John Yellen and Alison Brooks excavated there between 1993 and 1998 under the aegis of the **Middle Awash Research Project**. A variety of **lacustrine, fluvial, and tuffaceous** sediments crop out in the area; the majority of the *in situ* (Middle Stone Age) archeological sites occur within the Ardu Beds (informally subdivided into Ardu A–C from bottom to top). The archeological sites in the Ardu Beds are important for documenting temporal trends within the Middle Stone Age, and are associated with fossil fauna (including hominins) that suggest use of a range of habitats, but with a strong reliance on riverine resources. **Temporal span** Multiple radiometric methods provide a general estimate of the age of the Ardu Beds. An **argon-argon dating** age estimate on pumice of *c.*180 ka from the base of the sequence and a **radiocarbon dating** result of 10.50±0.07 ka on *Unio* sp. shell from sterile sediments capping the sequence provide bracketing ages. Although there are inconsistencies and stratigraphic reversals, **thermoluminescence dating** and optically stimulated **luminescence dating** (single and

multiple-grain) ages on silt and sand and **uranium-series** estimates on fossilized mammal and *Clarias* sp. bone and crocodile teeth suggest an age range of *c.*80–100 ka for most of the archeological sites. **How dated?** ⁴⁰Ar/³⁹Ar, ¹⁴C, optically stimulated luminescence dating, thermoluminescence dating, and U-series. **Hominins found at site** Four adult hominins, a cranium (ADU-VP-1/3), parietal fragments (ADU-VP-1/1 and 1/2), and unidentified cranial fragments (ADU-VP-1/6), all attributed to *Homo sapiens*, were recovered from the surface of Aduma (likely from Ardu B sediments). **Archeological evidence found at site** The approximately 16,200 lithic artifacts are made of **lava** (including **obsidian**), **quartz**, and **chert**, and include cores for the production of **blades, bladelets, Levallois** and other flakes, diverse **retouched** pieces dominated by **points** and **scrapers**, and rare **grindstones**. The assemblages are notable for showing temporal variation among Middle Stone Age assemblages, particularly a decrease in core and flake/blade size with increased stratigraphic height. More than 30 taxa are recognized among the recovered fauna. Rare cutmarks implicate the role of hominins in the accumulation of at least some of this fauna. The combination of taxa that are water-dependent (e.g., *Crocodylus niloticus*, *Clarias* sp., and *Unio* sp.) and water-independent (e.g., *Oryx*) suggest the presence of steep ecological gradients away from a forested river margin to a **savanna grassland**; soil isotopic and pollen data also support the latter suggestion. **Key references:** **Geology and dating** Yellen et al. 2005; **Hominins** Haile-Selassie et al. 2004b; **Archeology** Yellen et al. 2005.

Aduma cranium See ADU-VP-1/3.

aeolian (Gk *Aeolus* = god of the winds) Deposited primarily by wind action. Clay-sized aeolian material is often difficult to recognize, being readily integrated into soils or sedimentary deposits. The large volumes of glacially derived silts subject to aeolian transport are responsible for **loess** deposits. Sand-size aeolian material commonly forms dunes in dry environments and coastal areas. Volcanic ash can be subjected to aeolian transport and reworking prior to deposition. At **Laetoli**, most of the sediments comprising the **Laetoli Beds** are either primary air-fall tuffs, or they are formed from airfall tuffs that have been reworked by aeolian processes.

Afalou See Afalou-Bou-Rhumel; Ibero-maurusian.

Afalou-Bou-Rhummel (Location 36°45'N, 5°35'E, Algeria) History and general description Site discovered by Camille Arambourg in April 1928. It is a rock-shelter located on the southern shore of the Gulf of Bejaïa. The hominin fossils found at this site were described as a distinctive type or race similar to those found only at other North African sites, now called the Afalou or Mechta-Afalou type. Temporal span and how dated? Late Pleistocene/Holocene c.15–11 ka. Hominins found at site At least 50 *Homo sapiens* individuals (26 male, 14 female, six juvenile) buried in cemeteries. Archeological evidence found at site Iberomaurusian, backed microlithic blades of La Mouillah type and anthropomorphic and zoomorphic clay figurines. Key references: Geology, dating, and paleoenvironment Hachi 1996; Hominins Hachi 1996; Archeology Hachi 1996, Hachi et al. 2002. *See also* Iberomaurusian.

Afar Rift System This is part of the East African Rift System, which comprises a series of river valleys and basins that extends from the Afar Rift System in the northeast, via the Main Ethiopian Rift System, to the Omo Rift Zone in the southwest. The Afar Rift System includes the Gona, Middle Awash, and the Dikika study areas.

Afar Triangle *See* Awash River.

aff. Abbreviation of affinity. It is a term used in taxonomy to suggest that a specimen belongs to a hypodigm that is closely related to, but not necessarily synonymous with, a known taxon. Thus, a small piece of thick cranial vault might be assigned to “*Homo aff. H. erectus*.”

Africanthropus Dreyer, 1935 (Gk *anthropos* = human being; this name refers to a “human-like” creature from Africa) A new genus established by Weinert (1939) to accommodate the species *Palaeoanthropus njarasensis* that Kohl-Larsen and Reck (1936) had proposed for the Eyasi 1 calvaria. Type species *Africanthropus njarasensis* Weinert, 1939.

***Africanthropus njarasensis* Weinert, 1939 (Reck and Kohl-Larsen, 1936)** Weinert (1939) transferred the species previously known as *Palaeoanthropus njarasensis* to a new genus, *Africanthropus*, as *Africanthropus njarasensis*. First discovery Eyasi 1. Holotype Eyasi 1. Paratypes N/A. Main sites Eyasi.

Afro-European hypothesis *See* *Homo heidelbergensis* Schoetensack, 1908.

Afro-European sapiens hypothesis *See* replacement with hybridization; out-of-Africa hypothesis.

age at maturity This is generally taken to mean age at reproductive maturity. It has been proposed that there is a relationship between life span and age at maturity and specifically that the ratio of adult life span to age at maturity differs among lineages but is fixed within them (Charnov and Berrigan 1990). The relationship between these two variables has been proposed to relate to the cost of reproduction (i.e., older mothers produce offspring that are more likely to survive than younger mothers).

age at weaning Weaning is most often defined as a process that begins with the introduction of supplemental foods to the nursing infant and ends with the complete termination of breast feeding. The length of this process is extremely variable, both within and among species. The end of the weaning process represents a time when offspring are, to varying degrees, responsible for their own foraging, ingestion, and food supply. However, in modern humans and many nonhuman primates, weaned juveniles forage either in different circumstances from adults, or continue to receive provisioning in some way from adults in the group. This is called the period of “postweaning dependency” and it is also seen in other nonprimate mammals, specifically the social carnivores. Among many large-bodied mammalian taxa, the timing of the end of the weaning period coincides with the attainment of a critical body weight by offspring. This weight is measured variably as a multiple of birth weight or as some proportion of adult (specifically maternal) weight.

age estimate In paleoanthropology, an age estimate indicates the number of years that are thought to have elapsed between an event (e.g., the deposition of a bone or artifact) and the present day. Paleoanthropological age estimates are expressed in thousands (ka) and millions (Ma) of years. *See also* geochronology.

age-heaping A common problem in reported ages, where the ages are rounded up or down to particular values, for example ages that end in zeroes or fives. This results in the histogram for ages having

"heaps" (higher bars) on the particular ages. Age-heaping is viewed as problematic when using "known-age" samples to work out aging methods, as the age-heaping is a clear sign that the ages are not actually known. As a consequence, some researchers will only use reference skeletal collections that have documented birth and death dates.

agenesis (Gk *a* = absence, without and *genesis* = birth or origin) Absence or lack of development of an anatomical structure. Agenesis is one of the most common dental anomalies seen in modern humans, especially in the third molars. Agenesis of other teeth has been estimated at a frequency of 2–10% depending on the population, with most of these cases involving only one or two teeth. Agenesis also occurs in fossil hominins. For example, at least one individual of *Homo floresiensis* (LB1) appears to show agensis of the lower right second premolar (RP₄) and upper right third molar (RM³). It has been suggested that this may be a consequence of the small size of the individual (Brown et al. 2004), but KNM-WT 15000 also has agensis of the M₃s.

agglomerate A coarse-grained clastic rock formed during volcanic activity. The **clasts** range in size from small pebbles to large boulders and tend to be angular in shape; they are usually enclosed in a fine-grained matrix. Examples include the fronts of lava flows where cooling lava on the surface of the flow is broken up and deposited by the underlying still molten portion of the flow; agglomerates also occur within actual volcanic vents where episodes of explosive release of volcanic gases fracture the pre-existing rocks.

aggressive scavenging *See* scavenging.

Ahmado The name used by **International Afar Research Expedition** for the collecting area now known as Am-Ado within the **Woranso-Mille study area**, Central Afar, Ethiopia.

AHOB *See* **Ancient Human Occupation of Britain Project**.

AHS Acronym for Awoke's hominid site at **Omo-Kibish** in the **Omo-Turkana Basin**. It was named after Awoke Amzahe, an Ethiopian scientist who found the fossil. *See also* **Omo-Kibish**.

***Ailuropoda-Stegodon* fauna** A cave fauna named after two consistent components, *Ailuropoda*,

which is the only genus in the subfamily Ailuropodinae of ursids (i.e., bears) and *Stegodon*, a genus of proboscideans within the extinct subfamily Stegodontinae. The *Ailuropoda-Stegodon* fauna is found in caves in southern China, Vietnam, and Laos, but the existence of distinct lithologies in the caves suggest different environmental settings, the faunal elements also indicate a mixed environmental signal (e.g., *Pongo* indicates a rainforest environment, whereas the presence of horses indicates a more open landscape), and many layers contain a temporal mix of genera (e.g., *Mastodon*, *Stegodon*, and *Elephas*). Most observers now consider the *Ailuropoda-Stegodon* fauna to be a faunal palimpsest (i.e., a mixed assemblage containing elements from several different faunas).

Ain Hanech (also written as Ain Hanech) (Location 36° 16' 39" N, 8° 19' 0" E, Algeria; etym. local settlement name) History and general description Archeological site located within the Ain Hanech Formation in the Ain Boucherit and Ain Hanech areas of northeastern Algeria. The site was discovered and initially excavated by Camille Arambourg in 1947 during the course of a paleontological survey conducted between 1931 and 1948; further excavations took place in 1992–3 and 1998–9. This Algerian site has yielded some of the oldest stone tools in North Africa. Temporal span A *terminus post quem* for the site is provided by the Ain Boucherit fossil-bearing stratum, which is estimated to be 2.4–2.0 Ma. The site itself has been estimated to 1.8 Ma. How dated? **Biostratigraphy** and **magnetostratigraphy**. Hominins found at site None. Archeological evidence found at site **Lithic** artifacts have been recovered from layers A (youngest), B, and C within Unit T. These artifacts are considered a North African variant of the **Oldowan** industrial complex. Artifacts recovered from overlying calcretes, paleosols, and colluvia have been attributed to the **Acheulean**. At one time the **Oldowan** and **Acheulean** artifacts were thought to be associated, but this is now known not to be the case. **Key references:** Geology and dating Sahnouni et al. 2002; Hominins N/A. Archeology Sahnouni and de Heinzelin 1998, Sahnouni et al. 2002.

A.L. (also written as AL) Acronym for Afar Locality. Prefix for fossils recovered from the **Hadar** study area, Ethiopia.

A.L. 129-1 Site **Hadar**. Locality Afar Locality 129. Surface/in situ Surface. Date of discovery

October 30, 1973. Finder Donald Johanson. Unit N/A. Horizon N/A. Bed/member Sidi Hakoma. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Basalt. Nearest underlying dated horizon Sidi Hakoma Tuff. Geological age *c.*3.3 Ma. Developmental age Adult. Presumed sex Female, based on small size. Brief anatomical description Well-preserved right distal femur (A.L. 129-1a) and proximal tibia (A.L. 129-1b), with an associated proximal femoral fragment (A.L. 129-1c) broken inferior to the lesser trochanter (NB: A.L. 128-1, a left proximal femur fragment, may belong to the same individual). Announcement Johanson and Taieb 1976. Initial description Johanson and Coppens 1976. Photographs/line drawings and metrical data Johanson and Coppens 1976. Detailed anatomical description Johanson and Coppens 1976. Initial taxonomic allocation Specimen bears morphological similarities to proximal femora assigned to *Australopithecus* sp. Taxonomic revisions *Australopithecus afarensis*. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance One of the first hominin specimens to be recovered from Hadar, its functional morphology was interpreted as evidence of adaptations to bipedalism. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 162-28 Site Hadar. Locality Afar Locality 162. Surface/in situ Surface. Date of discovery 1974. Finder N/A. Unit N/A. Horizon Kada Hadar Tuff. Bed/member Denen Dora. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon BKT-2. Nearest underlying dated horizon Kada Hadar Tuff. Geological age *c.*3.15 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Partial calvaria composed of left and right parietals and occipital. Announcement Kimbel et al. 1982. Initial description Kimbel et al. 1982. Photographs/line drawings and metrical data Kimbel et al. 1982. Detailed anatomical description Kimbel et al. 1982. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance Compared to other larger calvariae (e.g. A.L. 333-45, A.L. 444-2), the small size of A.L. 162-28 suggests a high level of cranial sexual dimorphism in *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 199-1 Site Hadar. Locality Afar Locality 199. Surface/in situ Surface. Date of discovery October 17, 1974. Finder Ato Alemayehu Asfaw. Unit N/A. Horizon N/A. Bed/member Sidi Hakoma. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Basalt. Nearest underlying dated horizon Sidi Hakoma Tuff. Geological age *c.*3.3 Ma. Developmental age Adult. Presumed sex Female, based on small size. Brief anatomical description Right half of the maxilla bearing C–M³. Announcement Johanson and Taieb 1976. Initial description Johanson and Taieb 1976. Photographs/line drawings and metrical data Kimbel et al. 1976. Detailed anatomical description Johanson and Coppens 1976. Initial taxonomic allocation Specimen bears morphological similarities to *Australopithecus* sp. and *Homo*. Taxonomic revisions *Australopithecus afarensis*. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance Found within 15 m of, and in the same horizon as, A.L. 200-1. Although both bear adult dentitions, A.L. 199-1 is smaller than A.L. 200-1. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 200-1a Site Hadar. Locality Afar Locality 200. Surface/in situ Surface. Date of discovery October 17, 1974. Finder Ato Alemayehu Asfaw. Unit N/A. Horizon N/A. Bed/member Sidi Hakoma. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Basalt. Nearest underlying dated horizon Sidi Hakoma Tuff. Geological age *c.*3.4 Ma. Developmental age Adult. Presumed sex Uncertain. Brief anatomical description Complete maxilla containing both left and right I¹–M³. The maxilla has I²/C diastemata, extensive ribbon-like wear on the incisors and premortem enamel chipping of the C and P³. Announcement Johanson and Taieb 1976. Initial description Johanson and Taieb 1976. Photographs/line drawings and metrical data Kimbel et al. 1976. Detailed anatomical description Johanson and Coppens 1976. Initial taxonomic allocation It was assessed as bearing morphological similarities to *Australopithecus* sp. and *Homo*. Taxonomic revisions *Australopithecus afarensis*. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance First complete australopithecine maxilla from Hadar. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 288-1 Site Hadar. Locality Afar Locality 288. Surface/in situ Surface. Date of discovery 1974. Finders Donald Johanson and team. Unit N/A. Horizon Kada Hadar 1. Bed/member Kada Hadar. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon BKT-2. Nearest underlying dated horizon Kada Hadar Tuff. Geological age *c.*3.2 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description A.L. 288-1 (or “Lucy”) is a remarkably complete associated skeleton of a fossil hominin. The cranial vault remains include portions of the parietals, occipital, left zygomatic, and frontal bones. The mandible includes the right P₃–M₃, LP₃, M₃, and two M₁ fragments. The postcranial skeleton is represented by the right scapula, humerus, ulna, radius, a portion of the clavicle, the left ulna, radius, and capitate, and the axial skeleton is represented by lumbar and thoracic vertebrae and ribs. The left pelvic bone, sacrum, and left femur are well preserved. Remains of the right leg include fragments of the tibia, fibula, talus, and some foot and hand phalanges. Announcement Johanson and Taieb 1976. Initial description Johanson and Taieb 1976. Photographs/line drawings and metrical data Johanson et al. 1982. Detailed anatomical description Johanson et al. 1982. Initial taxonomic allocation Specimen bears morphological similarities to *Australopithecus* sp. Taxonomic revisions *Australopithecus afarensis*. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance A.L. 288-1 was the first relatively complete hominin associated skeleton of this antiquity, and it remains the best preserved associated skeleton of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 333-1 Site Hadar. Locality Afar Locality 333. Surface/in situ Surface. Date of discovery 1975. Finder N/A. Unit N/A. Horizon Denen Dora 2. Bed/member Denen Dora. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Kada Hadar Tuff. Nearest underlying dated horizon Triple Tuff-4. Geological age *c.*3.2 Ma. Developmental age Adult. Presumed sex Male, based on canine size. Brief anatomical description Partial facial skeleton, and maxilla containing the right P³–P⁴, left C–P³. Announcement N/A. Initial description Kimbel et al. 1982. Photographs/line drawings and metrical data Kimbel et al. 1982. Detailed anatomical

description Kimbel et al. 1982, 2004. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance This specimen shares the maxillary morphology demonstrated in other *Au. afarensis* specimens (e.g., A.L. 444-2) and it was used in the reconstruction of a composite skull of *Au. afarensis*. Along with smaller specimens (e.g., A.L. 200-1 and A.L. 417-1) it demonstrates the extent of the sexual dimorphism of the maxillary region and the palate. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 333-45 Site Hadar. Locality Afar Locality 333. Surface/in situ Surface. Date of discovery 1975. Finder N/A. Unit N/A. Horizon Denen Dora 2. Bed/member NA. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Kada Hadar Tuff. Nearest underlying dated horizon Thin Tuff 4. Geological age *c.*3.2 Ma. Developmental age Adult. Presumed sex Male, based on size and robusticity. Brief anatomical description A cranium that preserves the posterior portion of the cranial vault together with a well-preserved cranial base. Announcement Johanson et al. 1982. Initial description Kimbel et al. 1982. Photographs/line drawings and metrical data Kimbel et al. 1982, 1984. Detailed anatomical description Kimbel et al. 1982. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance First complete adult cranium of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 333-105 Site Hadar. Locality Afar Locality 333. Surface/in situ Surface. Date of discovery 1975. Finder N/A. Unit N/A. Horizon Denen Dora 2. Bed/member Denen Dora. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Kada Hadar Tuff. Nearest underlying dated horizon Triple Tuff-4. Geological age *c.*3.2 Ma. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Distorted, partial juvenile cranium. The cranial vault is represented by the frontal, the right temporal, the posterior portion of the left temporal, parts of the parietals, and fragments of the sphenoid and occipital. The

face is represented by the right side of the maxilla (including the right dm^{1-2} , an unerupted M^1 , and a di), plus fragments of the nasal, lacrimal, zygomatic, vomer, and palatine bones. Announcement N/A. Initial description Kimbel et al. 1982. Photographs/line drawings and metrical data Kimbel et al. 1982. Detailed anatomical description Kimbel et al. 1982. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance Despite being a juvenile it shows the taxonomically distinctive craniofacial morphology of *Au. afarensis*, and it is the first partially complete juvenile cranium of that taxon. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 333-115 Site Hadar. Locality Afar Locality 333. Surface/in situ Surface. Date of discovery 1975. Finder N/A. Unit N/A. Horizon Denen Dora. Bed/member Denen Dora 2. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Kada Hadar Tuff. Nearest underlying dated horizon Triple Tuff 4. Geological age *c.*3.2 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A partial left foot including portions of all five metatarsals, all five proximal phalanges, and the fourth and fifth intermediate phalanges. Announcement Johanson et al. 1982. Initial description Latimer et al. 1982. Photographs/line drawings and metrical data Latimer et al. 1982. Detailed anatomical description Latimer et al. 1982. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance The first articulated foot skeleton of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 400-1a&b Site Hadar. Locality Afar Locality 400. Surface/in situ Surface. Date of discovery 1976/77. Finder Dato Adan. Unit NA. Horizon Sidi Hakoma 2. Bed/member Sidi Hakoma. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Basalt. Nearest underlying dated horizon Sidi Hakoma Tuff. Geological age *c.*3.3 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A mandible that includes the left

I_1-M_3 and the right I_2-M_3 (A.L. 400-1a) and a maxilla with the right canine (A.L. 400-1b). Announcement Johanson et al. 1982. Initial description White and Johanson 1982, Johanson et al. 1982. Photographs/line drawings and metrical data White and Johanson 1982, Johanson et al. 1982. Detailed anatomical description White and Johanson 1982, Johanson et al. 1982. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance One of the most complete and best preserved mandibles of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 417-1a-d Site Hadar. Locality Afar Locality 417. Surface/in situ Surface. Date of discovery 1990-3, 1999. Finders Dato Adan and team. Unit N/A. Horizon Sidi Hakoma. Bed/member 33 m above the Sidi Hakoma Tuff. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon Basalt. Nearest underlying dated horizon Sidi Hakoma Tuff. Geological age *c.*3.3 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description Skull comprising the well-preserved left side of the mandible including $C-M_3$ (A.L. 417-1a), part of the right side of the mandible with M_2-M_3 (A.L. 417-1b), the basioccipital, basisphenoid, and right alisphenoid (A.L. 417-1c), and a maxilla including the right I^2-M^3 and the left $C-M^3$ (A.L. 417-1d). Announcement Kimbel et al. 1994. Initial description Kimbel et al. 1994. Photographs/line drawings and metrical data Kimbel et al. 1994, 2004. Detailed anatomical description Kimbel et al. 1994, 2004. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance This presumed female skull of *Au. afarensis* enabled researchers to assess the extent of cranial sexual dimorphism in *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 438-1a-v Site Hadar. Locality Afar Locality 438. Surface/in situ Surface and *in situ*. Date of discovery February 24, 1992. Finders Donald Johanson and team. Unit N/A. Horizon Kada Hadar-2. Bed/member 10-12 m below the BKT-2. Formation Hadar Formation. Group N/A. Near-

est overlying dated horizon BKT-2. Nearest underlying dated horizon KHT. Geological age *c.*3.0 Ma. Developmental age Adult. Presumed sex Male, based on skeletal size and robusticity. Brief anatomical description An associated skeleton consisting of a frontal fragment (A.L. 438-1b), the right side of the mandible (A.L. 438-1g) and a fragment of maxilla (A.L. 438-1s). Preserved dental elements consist of the right I₁, P₄ fragment, M₁, M₃ (A.L. 438-1h-k), upper molar root fragment (A.L. 438-1q), and a lower molar root (A.L. 438-1u). The forelimb fossils include a fragment of a clavicle (A.L. 438-1v), a right proximal humeral shaft and two shaft fragments (A.L. 438-1c, n, o), a left ulna (A.L. 438-1a), a right ulna shaft fragment (A.L. 438-1m), a right proximal radial fragment (A.L. 438-1l), and several metacarpals including the right MC2 (A.L. 438-1f) and the left MC2-3 (A.L. 438-1d, e). Announcement Kimbel et al. 1994. Initial description Kimbel et al. 1994. Photographs/line drawings and metrical data Kimbel et al. 1994, 2004, Drapeau et al. 2005. Detailed anatomical description Kimbel et al. 2004, Drapeau et al. 2005. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance The A.L. 438-1 associated skeleton has the most complete ulna of *Au. afarensis*, and it is the first specimen to possess metacarpals in association with forelimb remains. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 444-2a-h Site Hadar. Locality Afar Locality 444. Surface/in situ Surface. Date of discovery February 26, 1992. Finder Yoel Rak. Unit N/A. Horizon N/A. Bed/member Kada Hadar-2. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon BKT-2. Nearest underlying dated horizon Kada Hadar Tuff. Geological age *c.*3.0 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description Well-preserved (75–80% complete) hominin skull, including the frontal bone (A.L. 444-2d), portions of the right and left parietals (A.L. 444-2d, e, g), a fragment of the left squamous temporal (A.L. 444-2f), the posterior parts of both temporal bones (A.L. 444-2f), the occipital squama (A.L. 444-2f), the right zygomatic (A.L. 444-2c), the maxilla with the right I¹, C, and P⁴-M³ and left I¹, C, and P³-M³ (A.L. 444-2a), fragments of the nasal bones (A.L. 444-2h), and the right side of the

mandibular corpus and the symphyseal region with left and right incisors, the right canine, and damaged right P₄-M₁ (A.L. 444-2b). Announcement Kimbel et al. 1994. Initial description Kimbel et al. 1994. Photographs/line drawings and metrical data Kimbel et al. 1994, 2004. Detailed anatomical description Kimbel et al. 2004. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current convention taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance First complete adult skull of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 666-1 Site Hadar. Locality Afar Locality 666. Surface/in situ Surface. Date of discovery November 2, 1994. Finders Ali Yesuf and Maumin Allahendu. Unit N/A. Horizon N/A. Bed/member N/A. Formation Busidima Formation. Group N/A. Nearest overlying dated horizon BKT-3. Nearest underlying dated horizon BKT-2. Geological age *c.*2.35 Ma. Developmental age Adult. Presumed sex Male. Brief anatomical description The maxilla, broken along the intermaxillary suture, with the left P³-M³, the right P³-M¹ with M² and M³ roots, and other isolated dental fragments. Announcement Kimbel et al. 1996. Initial description Kimbel et al. 1996. Photographs/line drawings and metrical data Kimbel et al. 1996, 1997. Detailed anatomical description Kimbel et al. 1996, 1997. Initial taxonomic allocation *Homo* sp. Taxonomic revisions *Homo* aff. *Homo habilis*. Current convention taxonomic allocation *H.* aff. *H. habilis*. Informal taxonomic category Transitional hominin. Significance A.L. 666-1 was found in the same layer as Oldowan flakes and choppers, and it is the first evidence of a *Homo habilis* facial morphotype in the middle Pliocene. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

A.L. 822-1 Site Hadar. Locality Afar Locality 822. Surface/in situ Surface. Date of discovery October 26, 2000. Finders Dato Adan and team. Unit N/A. Horizon Kada Hadar 1. Bed/member N/A. Formation Hadar Formation. Group N/A. Nearest overlying dated horizon BKT-2. Nearest underlying dated horizon KHT. Geological age *c.*3.1 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description A well-preserved skull that includes a well-

preserved mandible with portions of the dentition preserved; most of the calvaria is preserved along with the zygomatics, and the maxilla including the right C-M³. Announcement Kimbel et al. 2003. Initial description Kimbel et al. 2003. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance First relatively complete female skull of *Au. afarensis*. Its postcanine dentition is large compared to other inferred female australopith specimens (e.g., A.L. 417-1), and the specimen allows for a systematic evaluation of **sexual dimorphism** in *Au. afarensis*. Location of original **National Museum of Ethiopia**, Addis Ababa, Ethiopia.

²⁶Al/¹⁰Be ratio See cosmogenic nuclide dating.

ALA Abbreviation of Alayla, and the prefix for fossils recovered from Alayla in the **Western Margin, Middle Awash study area**, Ethiopia.

ALA-VP-2/10 Site Alayla. Locality Alayla VP Locality 2. Surface/*in situ* Surface. Date of discovery July, 1999. Finder Yohannes Haile-Selassie. Unit N/A. Horizon N/A. Bed/member Asa Koma Member. Formation Adu-Asa Formation. Group N/A. Nearest overlying dated horizon Wittli Mixed Magmatic Tuff. Nearest underlying dated horizon Ladina Basaltic Tuff. Geological age c.5.2–5.8 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right side of the mandibular corpus with M₃, together with associated teeth (left I₂, C, P₄, M₂, and part of the M₃ root). Announcement Haile-Selassie 2001. Initial description Haile-Selassie 2001. Photographs/line drawings and metrical data N/A. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus kadabba*. Taxonomic revisions *Ardipithecus kadabba* (Haile-Selassie 2004). Current conventional taxonomic allocation *Ar. kadabba*. Informal taxonomic category Possible primitive hominin. Significance **Holotype** of *Ar. kadabba*. Location of original **National Museum of Ethiopia**, Addis Ababa, Ethiopia.

albumin (*L. alba*=white) A **protein** given its name because it turns white when it is heated, or

coagulated (it is coagulated albumin that gives the non-yolk part of a cooked egg its white color). Albumin is produced by the liver, and is the most abundant protein in the clear, plasma, component of fresh blood. Its molecular weight is relatively small (67 kDa) and it only contains 585 amino acids in its active form. Its main function is to attract and maintain water in the bloodstream, but it also transports hormones (e.g., thyroid hormone), fatty acids, and bilirubin. The importance of albumin for human evolution is that it was one of the first molecules to be used to measure the closeness of the relationships between the extant **great apes**. Morris Goodman (1962) obtained albumin from modern humans, chimpanzees, gorillas, orangutans, and other primates, and injected it into woolly monkeys. It did not harm the monkeys, but because it was not their own albumin they reacted by generating **antibodies** to the injected **antigen** (i.e., the foreign albumin). Goodman then used the antiserum made when modern human albumin was injected into the woolly monkey to investigate the similarity of albumin antigens between pairs of taxa (e.g., modern human and chimpanzee albumins vs modern human antiserum; modern human and gorilla albumins vs modern human antiserum; chimpanzee and orangutan albumins vs modern human antiserum, etc.). When the modern human antiserum and the fresh albumins from the extant great apes other than *Pan* meet and react with the antiserum, they coagulate and form a white spur. Goodman showed that the reactions between the modern human antiserum and modern human and chimpanzee albumin were so similar there was no spur, yet when modern human antiserum was used to compare the albumins from modern humans and gorillas, there was a definite spur. In 1962 this was a novel use of **immunochemistry**, and along with Emil Zuckerkandl's (1960) use of chromatography to compare the structure of the hemoglobins of the extant great apes it represented the first use of biomolecules (e.g., albumin and hemoglobin) to compare the molecular affinities of the extant great apes. Jerold Lowenstein (1981) spearheaded attempts to see if it was possible to detect albumin in fossils, and then use this preserved albumin in a form of radioimmunoassay in much the same way that Goodman had used the albumins from living taxa. However, it was never possible to be sure that any albumin extracted from the fossils was undamaged, and this once promising technique has since fallen into disuse. See also **immunochemistry**; Morris Goodman.

Alcel+A+C *See* **alcelaphine plus antilopine criterion**.

Alcelaphinae (L. *alces* = elk and Gk *elaphus* = deer) In this alternative interpretation of bovid taxonomy, the tribe Alcelaphini is elevated to a subfamilial level. It is a subfamily of antelopes, family Bovidae, which comprises hartebeest (the eponymous *Alcelaphus* sp.), wildebeest (*Connochaetes* sp.), and their allies. This subfamily likely arose during the late middle Miocene but it is extremely common in fossil assemblages by the later Pliocene. Modern alcelaphines prefer open grassland habitats and are restricted to Africa, although at least some examples (e.g., *Damalops*) have been recovered from the Asia. The relative proportion of alcelaphine fossils at hominin sites has been used as an important indicator of the presence of open habitats in the past as part of the **alcelaphine plus antilopine criterion** developed by Elisabeth Vrba. *See also* Alcelaphini.

alcelaphine Informal name for any antelope belonging to the subfamily Alcelaphinae.

alcelaphine plus antilopine criterion (AAC or Alcel+A+C) Developed by Elisabeth Vrba, this is a method of **paleoenvironmental reconstruction** that relies on the relative abundance of **alcelaphine** bovids and **antilopine** bovids. Vrba found that in modern African game reserves characterized by closed habitats, the bovid tribes Alcelaphini and Antilopini make up a low percentage (<40%) of the bovid sample, whereas in more open habitats they make up a high percentage (>60%) of the bovid sample. The AAC has been widely used in paleoenvironmental studies at Olduvai Gorge in Tanzania and at sites in the Blaauwbank valley in South Africa.

Alcelaphini A tribe of the family Bovidae that includes wildebeest, hartebeest, bonteboks, and their allies. Alcelaphine bovids are grazers with a preference for open grassland habitats and are characterized by hypsodont teeth and cursorial limb adaptations. Most alcelaphine bovids are of medium to large size (about 60–230 kg) and are highly gregarious, often forming large migratory herds. In attempts at the **paleoenvironmental reconstruction** of fossil assemblages, frequencies of alcelaphine bovids are often used to track the presence of open grasslands. For example, in the

Turkana Basin, changes in the frequencies of fossil alcelaphines, together with other open habitat taxa, has been interpreted as evidence for an expansion of grassland environments associated with the origin of the genus *Homo*. *See also* Alcelaphine plus Antilopine Criterion.

Alemseged, Zeresenay (1969–) Born in Axum, Ethiopia, Zeresenay Alemseged attended Addis Ababa University, graduating in 1990 with a BSc in geology. Thereafter he worked from 1991 to 1993 as a junior geologist in the Paleoanthropology Laboratory of the National Museum of Ethiopia in Addis Ababa. In 1993 he moved to France to enroll as a graduate student in the Institute of Evolutionary Sciences, University of Montpellier II, where in 1994 he obtained an MSc in paleontology. Alemseged stayed in France, but moved to the University of Paris VI for his PhD, which was awarded in 1998 for a thesis entitled “*A. aethiopicus*-*A. boisei* transition and paleoenvironmental changes in the Omo Ethiopia.” Alemseged worked from 1998 to 2000 as research associate in the French Center for Ethiopian Studies in Addis Ababa, Ethiopia, then from 2000 to 2003 as postdoctoral research associate in the Institute of Human Origins at Arizona State University, and then from 2004 to 2008 as senior researcher in the Department of Human Evolution at the Max-Planck Institute for Evolutionary Anthropology, in Leipzig, Germany. Since 2008 he has held the Irvine Chair of Anthropology at the California Academy of Sciences. Zeresenay Alemseged began his investigation of the Dikika study area in 1999, and he and Denis Geraads reported Acheulean and Middle Stone Age tools from the Asbole area. During initial surveys the team identified extensive fossil deposits in the central Dikika area and in 2000 they recovered the first evidence of DIK-1-1, the most complete early hominin infant skeleton known and DIK-2-1, the earliest hominin from the Hadar Formation. In 2010 the same team also claimed to have discovered the earliest known evidence for tool use and meat consumption. *See also* DIK-1-1; Dikika study area.

alkenones Complex molecules produced by a limited number of types of algae, used as biomarkers in paleoclimate research. Alkenones are well-preserved in marine sediments and first appeared in the Cretaceous. They are useful for paleoclimate reconstruction because their molecular structure varies with environmental conditions, with warmer sea

surface temperatures favoring the diunsaturated over the triunsaturated form. Sea surface temperature reconstructions are computed from a paleoclimate index (U^{37}) which is based upon the abundance ratio of the diunsaturated to the triunsaturated form of the alkenones. Calibrations are based on *Emiliani huxleyii* which first appeared 250 ka (Pagani et al. 1999). In some lakes, including several in Africa, alkenones have been used to reconstruct lake surface temperature. The carbon isotopic composition of alkenones is also used to reconstruct past carbon dioxide concentrations in the atmosphere, beyond the range of the ice cores (*c.*800 ka). While there are large uncertainties, carbon dioxide levels appear to have been below 500 parts per million since the Oligocene.

allele (Gk *allos* = another) Refers to alternate forms of a **gene** at a specified site, or **locus**, in the **genome**, or alternate forms of a particular **DNA sequence**. For example, if you think of a locus in the genome as the “street address,” the allele at that locus is analogous to the type of house present at that address. All houses serve the same purpose of providing shelter but the types of house can differ quite radically (i.e., one may be a luxury mansion while another is a modest bungalow). The genome is arranged into units called **chromosomes**, and with certain exceptions every chromosome is present as a pair in the cell; therefore, for each gene there is a pair of alleles (the exception is the X chromosome in males). The particular combinations of alleles at a locus can have significant effects on function. For example, in modern humans the S allele at the beta globin locus is protective against **malaria** if present with a wild-type allele (s) in the **heterozygous** form (i.e., Ss). However, if both copies of the beta globin allele are the S type, as in the **homozygous** dominant form (i.e., SS), a person will suffer from sickle-cell anemia.

Allen’s Rule This concept (probably better described as a trend) is attributed to Joel Allen (1877). It states that animals living at lower average temperatures tend to have smaller appendages (i.e., shorter limbs or tails). **Neanderthals** and some other high-latitude archaic *Homo* specimens have the type of body proportions (i.e., relatively shorter distal limb lengths and larger bi-iliac breadths) that would be predicted from Allen’s Rule (Trinkaus 1981, Ruff 1994, 2002). These body proportions

appear, at least in part, to have resulted from climatic influences (Holliday 1999, Ruff 1994, 2002). This hypothesis is given support by research indicating that limb bone **robusticity** in modern humans might be more influenced by temperature than by habitual activity (Pearson 2000), although others have argued strongly that behavior affects the skeleton more strongly than climate (Finlayson 2004). Relatively early in hominin evolutionary history there is evidence of a relationship between temperature and postcranial morphology, for example the **KNM-WT 15000** associated skeleton has been interpreted as having tropical body proportions (Ruff and Walker 1993). However, it has been argued that KNM-WT 15000 shows signs of skeletal pathology (Ohman et al. 2002) and caution should be exercised before extrapolating from it to other members of the species.

Allia Bay (Location 3°35’4’’N, 36°16’4’’E, Kenya; etym. takes its name from the bay in Lake Turkana, just south of Koobi Fora) History and general description The site comprises an isolated set of exposures that forms the most southerly subregion of the **Koobi Fora** complex of sites. It includes a *c.*4.2 Ma “bone bed” that was most likely in a meander of a channel of the ancestral Omo River. The first fossil hominins were found in 1982. The collecting areas at Allia Bay are numbered in the same way as they are in other parts of the Koobi Fora site complex, with the numbering starting at 200. Fossil specimens from the site are given the KNM-ER prefix. All the fossil hominins from Allia Bay have been assigned to *Australopithecus anamensis*, although in some respects the fossils from this site resemble younger specimens attributed to *Australopithecus afarensis* more than they do conspecifics from the older site of **Kanapoi**. Temporal span All the hominin specimens come from *c.*3.9–4.1 Ma sediments beneath or within the Moiti Tuff which has been dated to 3.97±0.034 Ma (McDougall and Brown 2008). A hominin radius, KNM-ER 20419, was initially described as having been found at a younger locality “east of Allia Bay” (Heinrich et al. 1993, p. 139). However, this specimen’s location has since been reported as being “Sibilot” (Ward et al. 1999b, p. 198). How dated? **Argon-argon dating, potassium-argon dating, and magnetostratigraphy.** Hominins found at site Thirteen hominin specimens found between 1982 and 1995 were described by Leakey et al. (1995); a further 11 found between 1995 and 1997 were

announced by Leakey et al. (1998). Archeological evidence found at site None. Key references: Geology and dating Heinrich et al. 1993, Leakey et al. 1995, 1998; Hominins Heinrich et al. 1993, Leakey et al. 1995, 1998, Ward et al. 1999b.

allocortex (Gk *allos* = other and L. *cortex* = bark, thus the “outer covering” of the cerebral cortex) Refers to the parts of the **cerebral cortex** that have fewer than six layers of cells. Allocortical areas are concerned with the processing of olfaction (i.e., the piriform cortex, which is also called the paleocortex), as well as memory and spatial navigation (i.e., the hippocampus, which is also called the archicortex). *See also cerebral cortex*.

allometric *See allometry*.

allometry (Gk *allos* = other and *metron* = measure) Towards the end of the 19thC several researchers (e.g., Dubois 1898, 1914, Lapique 1898, Snell 1891) recognized that there is a predictable relationship between brain size and body size. In the early part of the 20thC, Pezard (1918) and Huxley (1924) introduced the terms “heterogonic” and “constant differential growth,” respectively, for this relationship. Huxley (1927, 1931) went on to show that the phenomenon was widespread, and that such a relationship could apply to dimensions of the same individual at different stages in its development, or to the same dimensions of different individuals of the same species at the same or different stages of development. Subsequently, Huxley and Tessier (1936) proposed the term allometry for the study of the growth or size of one part of an organism with respect to the growth or size of the whole (or another part which is taken as a **proxy** for the whole) of the same organism. Today, the term allometry is used in two senses, which can be a source of confusion. Allometry is often used to refer generally to the study of the “consequences of differences in size.” In this sense, allometry is equivalent to the term **scaling**. However, allometry can also be used in a more specific sense to refer to changes in shape of part, or the whole of an organism, that are associated with changes in the overall size of the organism. When a variable increases in size more slowly than body size, this is called **negative allometry** (i.e., the variable becomes proportionally smaller as overall body size increases). The term used when a variable increases in size more quickly than body size is **positive allometry** (i.e., the variable becomes proportionally larger as overall body size increases).

In both negative and positive allometry any change in size will result in a change in **shape**. When used in this sense, the opposite of allometry is **isometry**, which refers to examples when shape is maintained as size increases. In other words, an isometric variable increases in size at the same rate as body size. *See also scaling*.

allopatric *See allopatry; speciation; vicariance biogeography*.

allopatric speciation A mode of speciation in which new species evolve as a consequence of the original species population being divided by a geographic barrier. The resulting physical isolation leads to a loss of gene flow, and the accumulation of genetic differences in the new populations is due to **genetic drift**, **natural selection**, and **mutation**. Eventually, these genetic differences lead to reproductive isolation, such that even if the physical barrier between the populations disappears they remain genetically isolated. Note that **peripatric speciation** can be thought of as a special case of allopatric speciation.

allopatry (Gk *allos* = other and *patris* = fatherland) When two organisms have geographic ranges that are entirely separate and distinct, and do not overlap anywhere. Given the nature of the fossil record it is difficult to be certain which hominin species were truly allopatric, but, for example, *Australopithecus africanus* (southern Africa) and *Australopithecus afarensis* (East Africa) were probably allopatric. Allopatric speciation, in which a single species splits into two separate species after a subsection of the ancestral population is geographically and reproductively isolated, is thought to be the most common cause of **speciation**. Geographic barriers that might promote allopatric speciation include mountain ranges, rifts formed by plate tectonics, substantial rivers, and rising sea levels that form islands out of areas that were previously connected. Forest fragmentation may also cause geographic isolation and hence allopatric speciation. It is likely that allopatric speciation was the mechanism by which many hominin species arose. *See also speciation; vicariance biogeography*.

alluvial (L. *alluere* = to wash against) Non-marine sediments deposited by water that is flowing. If there is evidence to attribute the sediments to a more specific depositional mechanism (e.g., fluvial,

lacustrine, etc.) then the term alluvial should be avoided. *See also* **riverine**.

alpha taxonomy (Gk *alpha* = first, and *taxis* = to arrange or “put in order”) Mayr et al. (1953) is one of the few sources that defines the terms “alpha” (and “beta” and “gamma”) taxonomy; for example, these terms do not appear in the index of Simpson’s (1961) *Principles of Animal Taxonomy*. Mayr et al. (1953) suggest that “the taxonomy of a given group, therefore, passes through several stages. . . informally referred to as alpha, beta, and gamma taxonomy” (*ibid*, p. 19). The distinction made by Mayr et al. is that alpha taxonomy is about species being “characterized and named,” beta taxonomy involves arranging species in “a natural system of lesser and higher categories,” and gamma taxonomy involves the “analysis of intraspecific variation” (*ibid*, p. 19). If you subscribe to the philosophy that the reconstruction of phylogeny in the form of a **cladogram** should inform how higher-order taxa are arranged in a classification, then what alpha taxonomy refers to is taxonomy minus **phylogeny reconstruction**, and what Mayr et al. (1953) called beta taxonomy is the process of phylogeny reconstruction. But Mayr et al. (1953) also caution that it is “quite impossible to delimit alpha, beta and gamma taxonomy sharply from one another, since they overlap and intergrade” (*ibid*, p. 19). While it is common for reference to be made to alpha taxonomy, you very seldom read, or hear, any reference to beta or to gamma taxonomy. *See also* **systematics; taxonomy**.

Altamura (Location 40°52'21"N, 16°35'17"E, Italy; etym. named after Altamura, a nearby town) History and general description The hominin partial skeleton including a cranium known as Altamura 1 was found in 1993 in a cavity in the Grotta di Lamalunga, a karstic limestone cave near Altamura, Bari, Apulia, in southern Italy. The bones are covered in a variably thick coating of calcareous material. Temporal span and how dated? Biostratigraphic evidence points to a Late Pleistocene date. Hominins found at site Altamura 1, most likely belonging to *Homo neanderthalensis*. Archeological evidence found at site None. Key references: Geology and dating N/A; Hominins Pesce Delfino and Vacca 1993, Vacca and Pesce Delfino 2004; Archeology N/A.

Altamura 1 Site Altamura. Locality Grotta di Lamalunga. Surface/in situ *In situ*. Date of discovery

October 1993. Finders Members of Centro Altamurano Ricerche Speleologiche (C.A.R.S.), the local speleological society and Eligio Vacca of the University of Bari. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Estimated to be **Middle Pleistocene**. Developmental age Adult. Presumed sex? Male. Brief anatomical description Fairly complete skeleton covered with flowstone. Announcement Pesce Delfino and Vacca 1993. Initial description Pesce Delfino and Vacca 1993. Photographs/line drawings and metrical data Pesce Delfino and Vacca 1993, 1996, Vacca and Pesce Delfino 2004. Detailed anatomical description N/A. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The skeleton purportedly exhibits a mix of Neanderthal and anatomically modern human characteristics, but it is difficult to be sure because its detailed morphology is obscured by a thick layer of **flowstone**. Location of original The skeleton is still *in situ* in Grotta di Lamalunga except for a portion of the scapula that has been removed for DNA analysis.

altricial (*L. alere* = to nourish) The whereabouts of taxa along the altricial–**precocial** spectrum depends upon the state of the newborn. Taxa with newborn that are at a relatively early stage of development at the time of birth are called altricial. Altricial offspring usually have their eyes and ears closed, and they lack fur or feathers and they possess little to no ability to move independently. They are thus reliant on parental units for varying lengths of time after birth for temperature regulation, food, and transport. For instance, domestic cats are altricial because newborn kittens are unable to move on their own, and they rely on the mother to clean them, transport them, and direct them to the nipple. Compared to nonhuman primates, most of which are considered relatively precocial at birth, modern humans are described as secondarily altricial (Portmann 1941) for modern human babies require intensive parental care. The various manifestations of modern human newborn altriciality (e.g., poor temperature regulation, reliance on parents for feeding, poor motor control and coordination) are thought to have evolved as a consequence of a combination of a relatively large **neonate** and a relatively large neonatal

brain size that caused the length of gestation to be reduced to increase the likelihood of a successful birth through the modern human birth canal. The high “catch-up” rates of **brain growth** during the first year of postnatal life are also likely to be consequence of this strategy.

Alu The name given to a **restriction enzyme** cut site with the sequence AGCT. This particular cut site was named “Alu” because it has a sequence recognized by an endonuclease (an enzyme that acts like scissors on specific DNA sequences) isolated from the bacterium *Arthrobacter luteus*. *See also Alu repeat elements*.

Alu elements *See Alu repeat elements*.

Alu repeat elements A family of short interspersed nucleotide elements (or **SINEs**) of DNA, and they are common in all primates, including the **great apes** and modern humans. Each Alu repeat element is approximately 300 **base pairs** (bp) in length, and the origin of **Alu** elements has been traced back to the 7SL RNA gene. Alu repeat elements are a class of retrotransposons (i.e., sequences that are transcribed from DNA to mRNA and then the mRNA is copied back into DNA, which is inserted elsewhere in the genome) and were originally named for the Alu restriction enzyme cut site (with the sequence AGCT) that is typically found within the element. Alu elements account for as much as 10% of the modern human genome (Smit 1996) but less than 0.5% vary (i.e., they are **polymorphic**). Alu repeat elements can help regulate the **transcription** of the DNA sequence by binding regulatory proteins, and they influence evolution via unequal **crossing over** of chromosomes and **gene duplication**. They are useful for phylogenetic analyses and for studies of population history because (a) the insertion of an Alu element has a known ancestral state (i.e., no Alu insertion), (b) each Alu insertion is almost certainly homologous since the probability of two insertions at the same location within the genome is very small, (c) Alu insertions are stable, and (d) they are easy to analyze (Batzer et al. 1996, Sherry et al. 1997, Stoneking et al. 1997, Watkins et al. 2001). The most recently active Alu subfamilies in modern humans are the Ya5 and Ya8 subfamilies. Alu elements that are polymorphic within modern humans are especially useful for studies of population history while fixed Alu insertions are useful for phylogenetic studies within primates (Salem et al. 2003).

Alus *See Alu repeat elements*.

alveolar process (L. *alveolus* = small hollow, dim. of *alveus* = hollow, and *processus* = to go forward or advance) The inferior part of the upper jaw (i.e., the **maxilla**) and the superior part of the body or corpus of the lower jaw (i.e., the **mandible**). The maxillary and the mandibular alveolar processes are where the roots of the upper and lower teeth, respectively, are embedded.

alveoli Plural of *alveolus* (*which see*).

alveolus (L. *alveolus* = small hollow, dim. of *alveus* = hollow) The name for the socket in the alveolar process of the **maxilla** or **mandible** into which the root of a tooth is embedded. The plural of *alveolus* is *alveoli*.

AMA Prefix for fossils recovered from the **Am-Ado** collecting area, **Woranso-Mille study area**, **Afar Rift System**, Ethiopia. *See Am-Ado*.

Am-Ado Collecting area initially identified by the **International Afar Research Expedition**, but now within the **Woranso-Mille study area**, **Afar Rift System**, Ethiopia.

Amba East Collecting area within the **Central Awash Complex**, Western Margin, **Middle Awash study area**, Ethiopia.

Amboseli live/dead study This is an elegant use of contemporary data to validate the assumption that bone assemblages at fossil sites are an accurate reflection of the types of animals that lived in and around that site. Two researchers, David Western and Kay **Behrensmeyer**, collected live/dead census data (i.e., census data for live animals and for animal carcasses in the same location) in the Amboseli National Park across four periods ranging from 5 to 6 years. During each of the four periods, and across the four decades that separated the beginning of the first period and the end of the last, a period that showed “rapid ecological change” (Western and Behrensmeyer 2009, p. 1063), they found highly significant correlations for variables such as **relative taxonomic abundance** between the live and dead data sets. They also found similar values for “standard ecological measures of community structure” (*ibid*, p. 1063). Thus, the study suggests that as long as post-depositional taphonomic biases are taken

into account, then at least in tropical settings fossil animal **assemblages** can be used to make inferences about paleohabitats. *See also* **paleoenvironmental reconstruction**; **taphonomy**.

Ambrona (Location 41°09'34"N, 2°29'55"W, Spain; etym. named after a nearby town) **History and general description** This site lies along the Masegar River, and it, along with the nearby site of **Torralba**, was originally excavated by Clark **Howell** and Les Freeman in the early 1960s. They believed the sites to be contemporaneous, and presented their finding of many faunal remains, particularly from elephants, and a quantity of stone tools, as the earliest evidence of hunting. Later researchers, including Lewis **Binford** and Richard Klein, argued that the faunal profiles from these sites suggested scavenging, not hunting. The most recent analysis by Santonja and Pérez-González has shown that, first, Ambrona is significantly older than Torralba, and second, there is a mix of natural and human components to the site, and thus too little evidence of actual interaction between the hominins and fauna that it is impossible to say anything more than some butchery occurred at the site. **Temporal span and how dated?** Based on the **uranium-series date** of a nearby river terrace, and on fauna and stratigraphic correlation, the site is thought to be from **Oxygen Isotope Stage 12** (c.470–430 ka). **Hominins found at site** None. **Archeological evidence found at site** Large quantities of faunal remains, a very few of which have cutmarks, and a few stone tools. Key references: **Geology, dating, and paleoenvironment** Villa et al. 2005, Freeman 1994, Villa et al. 2005; **Hominins** N/A; **Archeology** Freeman 1994, Villa et al. 2005.

AME Prefix for fossils recovered from **Amba East, Central Awash Complex**, Western Margin, **Middle Awash study area**, Ethiopia. *See* **Amba East**.

ameloblast [obsolete *amel* = enamel (ME, ultimately from OF *esmail*) and Gk *blastos* = germ] The name given to secretory and maturational (i.e., functional) enamel-forming cells. Ameloblasts are derived from the **inner enamel epithelium**. As they mature, they become elongated, with their long axis at approximately right angles to the future **enamel-dentine junction** (or EDJ). During enamel formation, secretory ameloblasts move away from the EDJ and secrete enamel

matrix from the Tomes' process located on the end of the cell facing the EDJ. The secreted matrix forms elongated **enamel prisms** approximately 5 µm in diameter. Think of the way a long bead of toothpaste is extruded from a toothpaste tube when the latter is squeezed. The free end of the bead is at the EDJ and the longer the tube is squeezed the further away from the EDJ the tube moves. Secretory ameloblasts cease to lay down enamel matrix when the final thickness of enamel is completed. They then switch function and become maturational ameloblasts. These alternately remove water and degraded proteins or pump in calcium to facilitate the final mineralization of enamel. Finally, ameloblasts become the reduced enamel epithelium that covers the crown and then lies dormant until the tooth erupts, after which it is shed. **Short-period** and **long-period incremental lines** produced by ameloblasts are believed to represent interruptions in the secretion or mineralization of the matrix. *See also* **enamel formation**; **incremental features**.

amelogenesis (Gk *amel* = pertaining to enamel and *genesis* = birth or origin) The process of enamel formation by **ameloblasts**. *See also* **enamel development**.

American Institute of Human Paleontology

In 1949 the **Viking Fund** was instrumental in the establishment of this institute. Its aim was to provide a forum to increase knowledge of early humans, and the founding members were Loren C. Eiseley (President), Joseph Birdsell, Paul Fejos, Theodore McCown, Hallam Movius, Dale Stewart, and Sherwood **Washburn**. An important accomplishment of the Institute was to acquire, with financial support from the **Wenner-Gren Foundation for Anthropological Research**, the Barlow/Damon collection of molds of hominin fossils. The collection was deposited with the University of Pennsylvania Museum of Archaeology and Anthropology and it provided the basis of that museum's hominin casting program. The Barlow/Damon molds were at the Penn Museum from 1952 to 1964 when they were returned to the the Wenner-Gren Foundation for Anthropological Research and put into storage. They were sent back to the University of Pennsylvania Museum of Archaeology and Anthropology in 1980 and they remain there. During the 1950s the Wenner-Gren Foundation supported the research of the plastics

engineer, David Gilbert, to develop a new and highly accurate molding technique. This led to the establishment of the **Anthrocast** program in 1965. The first molds were made in the field in 1962 and molding continued until 1974. Between 1968 and 1976 Anthrocast provided over 16,000 replicas of 180 different fossil specimens to institutions and researchers worldwide. The Anthrocast molds are currently curated in the University of Pennsylvania Museum of Archaeology and Anthropology and casts continue to be available on a limited basis through their casting program. *See also Viking Fund; Wenner-Gren Foundation for Anthropological Research.*

American Museum of Natural History (or AMNH) In 1869 Albert Smith Bickmore was successful in his proposal to create a natural history museum in New York City. He gained the support of William E. Dodge, Jr, Theodore Roosevelt, Sr, Joseph Choate, and J. Pierpont Morgan. On April 6, 1869 the museum became a reality when the Governor of New York, John Thompson, signed a bill creating the AMNH American Museum of Natural History. The collections relevant to paleoanthropology are the extensive collections of northwest coast Native Americans as well as great ape remains. There are 11 *Gorilla gorilla beringei* skeletal specimens all of which are from Zaire (present-day Democratic Republic of the Congo). Most of the 68 *Gorilla gorilla gorilla* skeletal specimens come from the Central African Republic or Cameroon; one comes from the Congo and the rest are unlabelled. None of the 21 skeletal specimens labeled *Gorilla gorilla* have any information about location; there is one *Gorilla* sp. The AMNH also holds the remains of 86 specimens of *Pongo pygmaeus*: 44 of these comprise skeletal remains with the remaining samples comprising soft tissues. The records simply list "Borneo" as the collection location. The great apes are part of the mammals collection. Contact Department of Mammalogy. Tel +1 202 769 5474. E-mail mammvisits@amnh.org.

AMH *See* anatomically modern humans.

amino acid (Gk *ammoniacos* = the pungent resin that is the source of ammonia, NH₃, was first collected from near the temple of Amen in Libya) Relatively small **molecules** that are the components of **proteins**. There are 20 different standard amino acids. Chemically, amino acids

are distinctive in having amine (NH₂) and carboxyl (COOH) groups. If they are attached to the alpha carbon they are called alpha amino acids, and these are the ones that make up the larger protein molecules. Differences in the side chains among amino acids determine their properties (i.e., whether they are acids or bases, hydrophilic or hydrophobic). Amino acids are transported by specific **transfer RNAs** (or tRNAs) and they are joined together in a sequence encoded by messenger RNA (mRNA) to form a **polypeptide** chain. The latter process occurs in a reaction catalyzed by **ribosomes** and is referred to as **translation**. Proteins consist of one or more of these polypeptide chains. *See also protein; translation.*

amino acid racemization Amino acids exist in two **antimeric** forms, a "right-handed" or D-form, and a "left-handed" or L-form. When proteins are assembled in cells the component amino acids are all in the L-form, but they convert at a predictable rate by a process called **racemization** to the D-form. Racemization is also known as **epimerization**. This apparently regular and predictable process has been used as a **molecular clock** for dating. *See also amino acid racemization dating.*

amino acid racemization dating (AARD) The apparently regular and predictable process of **amino acid racemization** has been used as a **molecular clock** for dating, but because the process proved to be temperature-dependent, the dates were found to be unreliable, and the method fell into disuse. Recently, the principle has been revived and applied to the epimerization of isoleucine, an amino acid preserved within the calcite crystals of ostrich eggshell to develop **ostrich egg shell dating** but the problem of temperature-dependency persists.

AMOC *See* Atlantic Meridional Overturning Circulation.

AMS *See* accelerator mass spectrometer.

AMS radiocarbon dating First used in 1977, this is a direct ion-counting method of **radiocarbon dating**. It uses a particle accelerator to produce ions with a +3 charge state and in this state many of the ions that interfere with the counting of ¹⁴C can be easily removed, thus allowing the accurate

measurement of very low concentrations of ^{14}C . Because this method, called **accelerator mass spectrometry** (or AMS), enables the direct measurement of individual ^{14}C atoms much smaller samples can be processed than with other techniques; AMS can routinely date samples of 1 mg of carbon. This means that previously undateable samples, such as single hominin teeth and individual grains of domesticated cereals, can now be dated. Typical starting weights required for AMS (e.g., 10–20 mg of seed/charcoal/wood, 500mg of bone, 10–20 mg of shell carbonate) are about 1000 times less than the weights required by conventional counting systems. The AMS method also allows for more thorough chemical pretreatment of samples, this is particularly important for older samples (> 25 ka BP) where small amounts of modern carbon contamination may have a large effect on the measured ^{14}C fraction and hence the date. *See also radiocarbon dating.*

Amud (Location 32°52'N, 35°30'E, Israel; etym. named after the Wadi Amud) History and general description Amud cave is approximately 5 km northwest of the Sea of Galilee, and is situated in a steep cliff face above the Wadi Amud. Excavations sponsored by the University of Tokyo began in the early 1960s under H. Suzuki. The researchers quickly found **Amud 1**, a fairly complete but poorly preserved adult, presumed male, *Homo neanderthalensis*, and further excavations by the team recovered fragments of at least three other individuals. The lithic evidence and the morphological affinities of the hominin remains suggested the site represents the transition between the **Middle and Upper Paleolithic**. Work was resumed in 1991 by a joint Israeli-American team led by Erella Hovers, Yoel Rak, and William Kimbel. The results of these excavations include a greatly expanded understanding of the lithic industry, the identification and study of fire places and fire-related behavior, the secure dating of the site, and more hominin remains, including an associated skeleton of a neonate, **Amud 7**, that may have been intentionally buried. Temporal span Early comparative analysis of the **Mousterian** lithic industry gave a date of *c.*30 ka, but recent **thermoluminescence dating** on a number of burned lithic artifacts for the various stratigraphic horizons indicates two occupation events, dated to 70 and 55 thousand years ago. A smaller sample of age estimates by electron spin resonance yielded comparable dates. The hominin remains are asso-

ciated with the younger ages. How dated? Electron spin resonance spectroscopy dating, and thermoluminescence dating. Hominins found at site The remains of 18 hominins have been found, of which seven appear to be under the age of 2 years. They include a fairly complete skeleton of an adult male (Amud 1) and the skeleton of an infant (Amud 7). Archeological evidence found at site The Middle Paleolithic layer, Level B, has been divided into four stratigraphic units, all of which contain lithic assemblages roughly equivalent, but not identical, to those found at Tabun B. Hovers (1998) argues that the dates and appearance of the assemblages from these layers at Amud show that there was not a single sequence of technological change within the Levantine later Middle Paleolithic, as suggested from the archeological sequence at **Tabun**. Phytolith studies from sediment samples collected at the site provide evidence of the use of several kinds of plants and suggest that dates, figs, and grass seeds may have been part of the diet of the Amud hominins. Faunal evidence suggests hunting and transport into the site of mostly gazelle and fallow deer. Lithic production activities were differentially organized in the cave's space. Fire places were common features and ashes constitute the majority of the sediment bulk. Key references: Geology and dating Suzuki and Takai 1970, Grün and Stringer 1991, Schwarcz and Rink 1998, Valladas et al. 1999, Rink et al. 2001. Amud 1 Site Amud. Locality N/A. Surface/in situ In situ. Date of discovery July 1961. Finders H. Suzuki and others. Unit B1/6. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 55 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description A nearly complete but poorly preserved adult skeleton. Announcement Vallois 1962. Initial description Suzuki and Takai 1970. Photographs/line drawings and metrical data Suzuki and Takai 1970. Detailed anatomical description Suzuki and Takai 1970. Initial taxonomic allocation Due to what was

seen as its combination of Neanderthal and modern human features, Suzuki (1970) interpreted the skeleton as being intermediate between the **Tabun** and **Shanidar** specimens on the one hand, and the more clearly modern human-like **Skhul** and **Qafzeh** specimens on the other. Taxonomic revisions Hovers et al. (1995) cite a number of cranial and mandibular synapomorphies as evidence that the remains should be assigned to *Homo neanderthalensis*, but Arensburg and Belfer-Cohen (1998) rejected that proposal. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance At 1740 cm³, Amud 1 appears to have the largest cranial capacity of any known hominin. Location of original Department of Anatomy, Tel Aviv University, Israel

Amud 7 Site Amud. Locality Middle Paleolithic layers. Surface/in situ *In situ*. Date of discovery 1992. Finders Excavation team led by Yoel Rak, William Kimbel, and Erella Hovers. Unit Layer B2/8, square K3a. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 50–60 ka. Developmental age Neonate (*c.*10 months). Presumed sex Unknown. Brief anatomical description From the cranium, only the occipital, fragmentary parietals, nearly complete mandible, and a few maxillary teeth remain. Several postcranial elements are preserved, including thoracic and limb elements. Announcement Rak et al. 1994. Initial description Rak et al. 1994. Photographs/line drawings and metrical data Rak et al. 1994, 1996. Detailed anatomical description N/A. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance The remains of this young individual preserve several morphological features that have been put forward as *H. neanderthalensis* autapomorphies (e.g., an oval foramen magnum and a medial pterygoid tubercle). Location of original Department of Anatomy, Tel Aviv University, Israel.

Amudian (etym. After the site of Amud, Israel) A stone tool industry found in the Near East that appears in the late **Middle Paleolithic** or early **Upper Paleolithic**. It is characterized by backed blades and Levallois-style flake production.

amygdala (L. *corpus amygdaloideum* from the Gk *amygdalē* = almond) A small almond-shaped complex of neurons in the medial temporal lobe of the **cerebral hemispheres**, located at the tip of the inferior horn of the lateral ventricle, near the tail of the caudate nucleus. It is part of the **limbic system**, and its major function is to attach **emotional valence to learning** and to consolidate **memory**. The amygdala is reciprocally connected to the **hypothalamus**, **hippocampal formation**, **neocortex**, and **thalamus**. It also coordinates the actions of the **autonomic nervous system** and the **endocrine system**. Barger et al. (2007) showed that the lateral nucleus of the amygdala in modern humans is larger than would be expected based on **allometric scaling** to overall **brain size** in living apes. This relative increase in the volume of the lateral nucleus of the amygdala suggests there has been some reorganization of the amygdala's connections with the orbitofrontal and temporal parts of the **cerebral cortex** in the course of human evolution.

AN Acronym for Abdur North. *See* **Abdur**.

anagenesis (Gk *ana* = up and *genesis* = birth or origin) An evolutionary pattern (or **mode**) in which an ancestral **species** evolves into a descendant species without lineage splitting. Anagenesis is the alternative to **cladogenesis**. For example, it has been claimed that *Australopithecus anamensis* and *Australopithecus afarensis* are time-successive species in the same lineage (Kimbel et al. 2006) in which case the relationship between them is anagenetic.

anagenetic *See* anagenesis.

anagenetic unit *See* grade.

analogous (Gk *analogos* = resembling, from *ana* = according to and *logos* = ratio) A trait (i.e., structure, gene, or developmental pathway) in two or more taxa that was *not* inherited from the most recent common ancestor. Analogous traits have similar functions, but not necessarily a similar structure. The eyes of vertebrates and cephalopods (e.g., octopuses) are an example of an analogy. They perform the same basic function, but in the former the retina is inverted (i.e., the receptors are towards the back of the retina, and the nervous connections are deep to them so that the light has

to traverse the nervous connections before it reaches the receptors) whereas in cephalopods it is not (i.e., the receptors are towards the front of the retina, and the nervous connections are superficial, so that the light does not have to traverse the nervous connections before it reaches the receptors). *See also* analogue; **homologue**; **homoplasy**.

analogue (Gk *analogos* = resembling) An example that serves as an illustration of an organism without being closely related to it. For example, the differences between the masticatory systems of bears and pandas, animals that are distantly related to hominins, has been compared to the differences between the masticatory system of *Australopithecus africanus* or *Australopithecus afarensis*, on the one hand, and that of *Paranthropus robustus* or *Paranthropus boisei*, on the other. In this case pandas serve as an analogue for *P. robustus* and *P. boisei*. *See also* homologue; homology.

analysis of covariance (or ANCOVA) A variant of **multiple regression** in which a continuous variable is dependent on continuous and categorical variables (where the categorical variables are converted to binary dummy variables). It is typically used to determine whether the slopes and/or intercepts of scaling relationships between continuous variables differ between groups. For example, if cranial capacity and body mass is known for samples of individuals belonging to three different species, ANCOVA can be used to identify whether a significant difference exists between the three species in the scaling relationship between cranial capacity and body mass. The first step determines whether there is a significant interaction between the continuous and categorical independent variables (i.e., do the scaling slopes differ between groups). A significant result indicates the slopes differ significantly from each other, and no further analysis is conducted. A non-significant result indicates that the scaling slope cannot be distinguished statistically between the groups. In that case the next step determines whether the common scaling slope differs significantly from zero, and whether the intercepts differ between groups (e.g., whether cranial size is larger in one species than another at any given body size).

analysis of variance (or ANOVA) A statistical test most commonly used to determine whether there is a significant difference in the mean of a

continuous variable between two or more groups. For example, if cranial capacity is known for samples of crania belonging to three different species, ANOVA can be used to identify whether a significant difference exists between the three species in mean cranial capacity. A non-significant result indicates that the means of all groups cannot be said to differ from each other significantly. A significant result indicates that the null hypothesis that all means are equal is incorrect; however, when more than two groups are included in the analysis, a significant result does not indicate which group or groups differ from the others. Typically this question is addressed using a series of pairwise tests in which an ANOVA is performed on each possible pair of groups from the total number of groups to identify which groups differ significantly in their means. Results from an ANOVA performed for two groups (as opposed to three or more) are equivalent to the results of a *t* test. ANOVA is a **parametric statistical test**; an equivalent **nonparametric statistical test** is the **Kruskal–Wallis test**. ANOVA is appropriate for a single continuous variable, but an extension to the multivariate case is also available. *See also* **Kruskal–Wallis test**; **multivariate analysis of variance**.

anatomical position The position of the body that is used as a reference when describing the surfaces of the body, the spatial relationships of the body parts, and the movements of the axial and postcranial skeleton. The anatomical position assumes the individual is standing, looking forward, with their legs and feet together, with their arms by their side, and with their palms facing forward. The plane that divides the body into right and left halves is the sagittal plane; it is also called the midline. All the surfaces that face towards the front when an individual is in the anatomical position are called anterior or ventral, and all the surfaces that face towards the back are called posterior or dorsal. Superior is nearer to the crown of the head; inferior is nearer to the soles of the feet. Medial is nearer to the midline of the body; lateral is further from the midline of the body. With respect to the limbs, proximal is in the direction of the root of the limb and distal is in the direction of the tips of the fingers or toes. Moving a whole limb forwards is to flex it; moving a whole limb backwards is to extend it. Moving a limb away from the body is to abduct it and moving it back towards the midline is to adduct it.

These latter terms also apply to movements of the fingers and toes, except that the reference digit of the hand is the middle finger and the reference digit of the foot is the second toe.

anatomical terminology The first serious systematic study of modern human anatomy in the Western tradition was undertaken by the Greek physicians Herophilus (335–280 BCE) and Erasistratus (304–250 BCE) and the first recorded human dissections were carried out at the Museum and Library of Alexander the Great, in what is now Alexandria, Egypt. However, by the time of Galen, physician to the Roman imperial court in the 2ndC AD, the practice of human dissection had effectively ceased. Its revival was largely due to the efforts of a young anatomy teacher called Andreas Van Wesele (who is better known by the latinized version of his family name, Andreas Vesalius). His seven-volume treatise *De Humani Corporis Fabrica Libri Septem* (“On the Fabric of the Human Body”, or just the *Fabrica*) must rank among the foremost contributions to biology. In the Preface to the *Fabrica* Vesalius chronicles his dissatisfaction with his own anatomy teaching and writes that it was during a visit to Bologna in 1540, when he was given the opportunity to compare the skeletons of a monkey and a modern human, that he realized that much of the “human” anatomy described in the Galenic texts was based on monkey and not human anatomy. It was this appreciation that stimulated Vesalius to embark on the dissections on which the *Fabrica* is based. The latter comprises seven “books” totaling approximately 660 pages, or 400,000 words, plus excellent illustrations made by apprentices working in the studio of the painter Tiziano Vecellio, better known as Titian. The *Fabrica* was published in 1543, when Vesalius was still only 29; the scale and pace of Vesalius’ achievement is without parallel in biology. This historical preamble explains why the original anatomical terms were Greek, and then why they were subsequently supplemented with Latin terminology. It is important that anatomical terminology transcends the barriers of language so at an early stage it was decided informally that any new anatomical terms should be based on Latin. This policy was formalized in 1895 when the first Basle edition of the *Nomina Anatomica* was produced. In 1950 responsibility for monitoring and maintaining human anatomical nomenclature passed to the International Anatomical

Nomenclature Committee (IANC), and in 1989 it was transferred to the Federative Committee on Anatomical Terminology (FCAT). This body, under the aegis of the International Federation of Associations of Anatomists (IFAA), is now responsible for modern human anatomical terminology. The latest version of official modern human anatomical terminology is in a book called *Terminologia Anatomica* (1998). Two versions of each anatomical term are given in the *Terminologia Anatomica*: the Latin version and the approved English language version. English is the official language of anatomical terminology (just as it is the official language for air traffic control). Thus, the English-language version of *corpus mandibulae* is the “body of the mandible” and the English-language version of *facies articularis capitis fibulae* is the “articular facet on the head of the fibula.” Some terms are the same in both Latin and English (e.g., sternum, os centrale, tibia, sustentaculum tali). Many anatomical terms were based on the everyday Latin (and sometimes Greek) vocabulary. Thus, the “cup-like” articular surface of the hip joint on the pelvis is called the acetabulum because Pliny thought it resembled a Roman vinegar (*acetum*) receptacle (*abrum*), and the condylar process of the mandible takes its name from the Greek word for a “knuckle”. Researchers sometimes use the Latin versions of terms, but if you choose to use *os coxae* instead of the English language terms hip bone or pelvic bone, then logically you should use *os scaphoideum* instead of the scaphoid and *caput ulnae* instead of the head of the ulna. It is best to be consistent and use the English-language term(s) listed in the *Terminologia Anatomica* rather than continuing to use arcane terminology.

ancient DNA (aDNA) (OF *ancien* from the L. *ante*=before and DNA=deoxyribonucleic acid) **Deoxyribonucleic acid**, or DNA, that is extracted from old or poorly preserved bone, teeth, hair, tissue, or coprolites. The analysis of DNA extracted from archeological and paleontological materials is a relatively new area of research that was made possible by the technological revolution in genetics that began in the 1980s. The first experiments to determine whether DNA survived in ancient material used dried tissue, such as skin from a quagga (an extinct form of the plains zebra; Higuchi et al. 1984) and a 2400-year-old Egyptian mummy (Pääbo 1985a), and brain tissue preserved in anoxic

conditions under water, such as at Windover Pond and Little Salt Spring, Florida (Doran et al. 1986, Pääbo 1986, Pääbo et al. 1988). A few years later, DNA was extracted from 300–5500-year-old modern human bone (Hagelberg et al. 1989). Although early work relevant to hominins primarily demonstrated the presence of DNA in ancient materials, subsequent analyses have addressed questions regarding the relationship between *Homo neanderthalensis* and modern humans, the initial colonization of the Americas, regional population history, social organization at a particular site, diet, the sex of individuals, and relationships among individuals within a cemetery (e.g., Krings et al. 1997, Stone and Stoneking 1998, Poinar et al. 2001, Krause et al. 2007a). Most ancient DNA research has targeted **mitochondrial DNA (mtDNA)** because of its high **copy number** in cells. Several studies have examined nuclear DNA **loci**, including **Y chromosome** sequences for sex identification and **short tandem repeat (STR)** loci for determining relatedness among individuals. Most recently, high-throughput emulsion **polymerase chain reaction (PCR)** and **pyrosequencing** have been used for complete mitochondrial DNA or genome sequencing. One of the major concerns in ancient DNA research is contamination. Precautions must be taken to ensure the authenticity of the results. The so-called **criteria of authenticity** for ancient DNA results include a physically isolated work area, the extensive use of controls to test reagents, small size of PCR products, cloning of PCR products, assessment of preservation, and reproducibility of results (Handt et al. 1994a, 1996, Richards et al. 1995, Stoneking 1995, Cooper and Poinar 2000). In particular, because ancient DNA analyses are destructive, time-consuming, and expensive, assessments of DNA preservation such as testing the DNA from associated faunal remains or the extent of **amino acid racemization** is recommended. For the latter, high levels of **racemization** are thought to be associated with poor DNA preservation and, specifically, the lower the ratio of the D to L enantiomers of **aspartic acid**, the better DNA preservation is expected to be (Poinar et al. 1996). However, Collins et al. (2009) found no correlation between aspartic acid racemization and DNA preservation in a large sample of ancient specimens from different sites and time periods.

Ancient Human Occupation of Britain Project (AHOB) A project designed to investigate ancient human occupations of Britain and

continental Europe from the **Paleolithic** to the **Mesolithic**. The AHOB project, which has been funded by the **Leverhulme Trust**, is a multi-disciplinary collaborative project directed by Christopher **Stringer** that involves members and associate members from various fields including paleoanthropology, paleontology, archeology, and the earth sciences. The first phase of the AHOB project, which was confined to Great Britain, ran from 2001 to 2006 and its successes included the excavations at **Pakefield**. The second phase extended the scope of investigation from Britain to continental Europe and ran from 2006 to 2009 and included the excavations at **Happisburgh**. The third phase, "Dispersals of Early Humans: Adaptations, frontiers and new territories," began in October 2009, and will run for 3 years, and its members come from Britain, Europe, and North America. The third phase of the AHOB project focuses on four complementary research questions: (a) what is the chronology of human dispersals over the last million years and where were the frontiers of human occupation at different times?, (b) how did the nature of occupation change through time, and what were the factors controlling dispersal into marginal environments: climate, resource availability, and changing geography?, (c) was occupation continuous or episodic, and how viable were human populations at the limits of their range?, and (d) what survival strategies were deployed in these marginal situations: seasonal migration, technological innovation, or physical adaptation? For information about the personnel involved in the AHOB 3 project see www.ahobproject.org/People.php and for the resources and publications produced by the three AHOB projects see www.ahobproject.org/Publications.php.

ANCOVA Acronym for **analysis of covariance** (*which see*).

Andersson, Johan Gunnar (1874–1960) Johan Gunnar Andersson was born in Knista, Sweden, and studied geology at the University of Uppsala. In 1914 Andersson became a geological and mining advisor to the government in China. In this capacity he worked with China's National Geological Survey, led by V.K. Ting (Wenjiang Ding). He became interested in the paleontology and archeology of China and he began searching for fossils in traditional Chinese pharmacies where they were sold for use in traditional

medicines. He published a description of some Neolithic implements in 1920 and conducted research at a prehistoric site in Hunan in the early 1920s. It was around that time that Andersson learned of a fossiliferous cave site near Peking (now Beijing) called Choukoutien (now Zhokoudian) and in 1919 he published a “Preliminary description of a bone-deposit at Chow-kou-tien in Fangshan-hsien, Chili Province” in *Geografisker Annaler*. Andersson conducted sporadic excavations at Choukoutien (and at other sites) over the next few years. In 1921 he was joined by the Austrian paleontologist Otto Zdansky, and their excavations at Choukoutien began to yield Cenozoic fossils, including what was then thought to be the tooth of an anthropoid ape. In 1923 Zdansky left China for Sweden and the fossils he and Andersson had unearthed from Choukoutien were sent to the University of Uppsala for analysis by Zdansky and the paleontologist Carl Wiman. In 1924–5 Wiman and Zdansky found what they interpreted to be a hominin tooth in the collection and this prompted them to suggest that a tooth found in 1921 might have belonged to a hominin and not to an ape. Andersson learned of Wiman and Zdansky’s conclusions by letter and with support from the Swedish industrialist Axel Lagrelius the China Fund (which in 1921 became the Swedish China Research Committee) was established to fund and organize paleontological exploration in China, including at Choukoutien. By this time Andersson had enlisted the help of Canadian anatomist Davidson Black (they had first met in 1919). Black was initially the Professor of Embryology and Neurology at the newly created Peking Union Medical College, and only later did he hold the Chair of Anatomy. He joined forces with Weng Wenhao, who was the director of China’s Geological Survey, to conduct large-scale excavations at Choukoutien. In 1926 Andersson founded the Museum of Far Eastern Antiquities in Stockholm, Sweden, to house part of the paleontological and archeological remains he collected in China; the remaining portion stayed in China. Andersson left China in 1925 to become director of the museum, a position he held until 1938, and the excavations in China were left to Black and Weng. The hominin teeth identified by Zdansky (possibly also Wiman), along with subsequent material discovered by Black and his Chinese colleagues at Choukoutien, resulted in the recognition of a new hominin species that Black named *Sinanthropus pekinensis* Black, 1927 (now *Homo erectus*). See also *Sinanthropus pekinensis*; *Homo erectus*.

Andresen lines The eponymous name recognizes Viggo Andresen’s (1898) description of the microstructure of dentine. Andresen’s name is used for the long-period (greater than circadian) incremental features in dentine, which correspond to striae of Retzius in enamel (Dean et al. 1993a). They are the 2D manifestation of a 3D structure, namely the surface of the developing dentine. Counts and measurement of Andresen lines have been used to infer the rate of dentine secretion and extension, as well as the age at death in developing teeth (e.g., Dean et al. 1993a, Smith et al. 2006). See also dentine development; incremental features.

androgens (Gk *andro* = male and *gennan* = to produce) A class of steroids with 19 carbon atoms (“C19 steroids”) that are produced by conversion of pregnenolone (itself produced from cholesterol) in various tissues in the body but mainly in the gonads and adrenal glands. Androgen steroids include testosterone, dihydrotestosterone (or DHT), and the adrenal androgens dehydroepiandrosterone (or DHEA), and dehydroepiandrosterone sulfate (or DHEAS). Contrary to popular understanding, androgens, while responsible for many aspects of masculine phenotype and behavior, are not strictly “male” hormones. In addition to their importance in normal male fetal and postnatal development, androgens are implicated as playing key potentiating roles in various behaviors in both modern humans and nonhuman primates and their levels are themselves affected by behavior and emotion. For example, seasonal shifts in reproductive behavior and associated agonistic interactions and territorial aggression are associated with changes in gonadal androgen levels. Similarly, gonadal androgens are elevated in modern humans preceding physical or mental contests and they remain elevated in winners of these contests but decline in the losers. Levels of circulating gonadal androgens vary substantially among modern human populations, potentially related to differences in diet and body composition. Prolonged, chronically elevated levels of androgens may be associated with a number of health consequences, including prostate cancer.

Anglian See glacial cycles.

angular gyrus (L. *angulus* = angle and Gk *gyros* = ring, circle) The angular gyrus of the cerebral cortex corresponds to Brodmann’s area 39,

which is part of the inferior **parietal cortex**. It lies immediately posterior to the **supramarginal gyrus**. The cortex of the angular gyrus is involved in processing the spatial relationships among objects, the semantics of words, and mathematical problems. The cortex of the angular gyrus is also involved in the memory of meaningful gestures and the sequence of actions of the upper limb; hence the angular gyrus, like the supramarginal gyrus, has been implicated in the neural basis of the production and use of tools.

angular unconformity *See* unconformity.

anisognathous *See* chewing.

anisotropy (Gk *an* = not, *iso* = equal, and *tropus* = direction) Meaning directionally dependent. In paleoanthropology, anisotropy is used most commonly either in reference to the material properties of a substance (e.g., **bone** or **enamel**) or to **dental microwear** textures. Materials are anisotropic when their material properties, particularly their various measures of material behavior (stiffness as reflected by the **elastic modulus** or **Young's modulus**, shear stiffness as reflected by the **shear modulus**, and the relationship between axial and lateral strains as reflected by **Poisson's ratio**) are different in different directions and/or planes. Bone, like many other biological materials, is anisotropic, although its material properties can approach **orthotropy** or **transverse isotropy**, which can be thought of as special cases of anisotropy. With respect to dental microwear, anisotropy is a term used to describe the orientation of microwear features. Microwear is anisotropic when the features are consistently aligned in a given direction (i.e., as when microwear scratches are parallel). Anisotropic microwear textures are typically found in folivorous primates. *See also* **dental microwear**.

anorthoclase feldspar A mineral of the **feldspar** group in which sodium (Na) and potassium (K) are the dominant cations (i.e., positively charged ions). The chemical formula is (Na or K)AlSi₃O₈. Anorthoclase feldspar is common in alkaline (i.e., Na- and K-rich) lavas and in the **sediments** derived from them. Older anorthoclase feldspars, especially those with high potassium content, may be suitable for **potassium-argon dating**.

ANOVA Acronym for **analysis of variance** (*which see*).

antagonistic pleiotropy theory (Gk *pleion* = more) One of several theories put forward to explain the evolution of **senescence**. The antagonistic pleiotropy theory (Williams 1957) builds upon the premise that a **gene** can have both beneficial and detrimental effects on **fitness**. More specifically, it suggests that genes that confer fitness benefits early in the life cycle and/or at reproductive age may also have deleterious effects later in life. For example, in young males testosterone can benefit fitness through its effects on **body size**, coloration, secondary sexual ornamentation, and competitive behavior. However, later in the life cycle testosterone can have negative effects (e.g., depression of the immune system, or predisposing individuals to prostate cancer, etc.). *See also* **senescence**.

Antarctic Circumpolar Current The ocean current that flows from west to east around Antarctica. It is the strongest ocean current in the world at 125 Sverdrups (or 125×10⁶ m³/s), and it is the dominant feature of the Southern Ocean circulation. It is the cause of the thermal isolation of Antarctica, which has supported a large ice sheet throughout much of the **Cenozoic**.

ante-Néandertalien *See* pre-Neanderthal hypothesis.

antelope (Gk *antholpos* = a fabulous beast from the orient) An informal name for a member of any of the taxa within **Antilopini**, a tribe of the family **Bovidae** that includes the gazelles and their allies.

anterior buttress A bony column that begins lateral to the nasal, or piriform, aperture and then runs inferiorly to the **canine eminence**.

anterior cingulate cortex (L. *cingulum* = collar and *cortex* = shell, husk) The cingulate cortex is part of the **limbic lobe**, the portion of the **cerebral cortex** that wraps around the **corpus callosum**. The cingulate cortex is involved in regulating emotional and cognitive behavior. Its anterior portion is home to a class of large spindle-shaped neurons called **von Economo neurons**, which occur in high densities exclusively among large-brained and social mammals (e.g., whales, dolphins, great apes, modern humans, and elephants). The anterior cingulate cortex has been implicated in emotional self-control, focused problem solving,

error recognition, and adaptive responses to changing conditions.

anterior condylar canal *See* hypoglossal canal.

anterior fovea *See* fovea; fovea anterior (mandibular); fovea anterior (maxillary).

anterior fovea (mandibular) *See* fovea anterior (mandibular).

anterior fovea (maxillary) *See* fovea anterior (maxillary).

anterior pillars Columns of bone described by Yoel Rak that run from the side of the nasal, or piriform, aperture down to the **alveolar process** of the upper jaw. Rak (1983) makes the point that the anterior pillars are found in many (e.g., *Sts 5*, *Sts 71*, *Sts 17*, *Stw 13*), but not all (e.g., *Sts 52a*), of the faces of *Australopithecus africanus* (anterior pillars are also present on *Stw 252*, a specimen found subsequent to Rak's 1983 study). They are also present in a reduced form in *Paranthropus robustus*, but they are not seen as distinct structures in *Australopithecus afarensis*, in most *Paranthropus boisei* specimens (but note that the presumed *P. boisei* female, KNM-ER 732, has an anterior pillar), or in KNM-WT 17000. Some *Homo* specimens are also said to have an anterior pillar (e.g., *Stw 53*, *OH 24*). The anterior pillar is often confused with, but is distinct from, the **canine jugum** that covers the root of the upper canine, and some specimens (e.g., *Sts 5*) display both structures.

anterior teeth Refers to the two incisors and the canine in each quadrant of the jaws; the balance of the teeth in the tooth row are referred to as the posterior, or **postcanine teeth**.

anterior transverse crest Term used by Korenhof (1960) for a structure on the crowns of the maxillary postcanine teeth that others call the **mesial marginal ridge** (*which see*).

anterior trigon crest Term used by Robinson (1956) and Tobias (1967a) for a structure on the crowns of the maxillary postcanine teeth that others call the **mesial marginal ridge** (*which see*).

anthracothere *See* Anthracotheriidae.

Anthracotheriid Unit (AU) The fossiliferous unit at **Toros-Menalla**, one of several “fossiliferous areas” discovered in the **Chad Basin** by the **Mission Paléoanthropologique Franco-Tchadienne**. The Anthracotheriid Unit was initially dated to 6–7 Ma using biochronology, but more recently **cosmogenic nuclide dating** suggests an age range of 6.8–7.2 Ma. *See also* **anthracothere**; **Toros-Menalla**.

Anthracotheriidae (Gk *anthrax* = coal or carbuncle, *therion* = beast) A family of artiodactyls that lived in the Old World and North America. They arose at the end of the middle Eocene in Asia and were extinct in Africa by the late Miocene. Anthracotheres are quite variable in their dental morphology, ranging from bunodont to selenodont in tooth form. Physically, they appear to have been ectomorphic, having relatively big bodies and small heads and limbs. Some forms (e.g., *Bothriogenys*) likely inhabited semi-aquatic habitats. Their dental and body forms, supposed habitats, and the fact that they disappeared as true hippopotamus arose lead many to consider them as stem hippos, but they are not universally accepted as ancestors of the Hippopotamidae.

Anthrocast *See* American Institute of Human Paleontology.

anthropogenic bone modification Any alteration of the completeness, structure, or surface of bone resulting from hominin activities. It subsumes bone surface modifications (e.g., cutmarks and hammerstone percussion marks) and fracture/breakage patterns associated with carcass butchery and dismemberment, marrow processing, and grease extraction. Other forms of anthropogenic bone modification include tooth marks and digestion, heating, and burning, and use-wear on bone tools. However, anthropogenic tooth marks and evidence of digestion can be difficult to distinguish from similar modifications produced by other taphonomic agents, such as carnivores. Recognition of anthropogenic bone modifications is central to demonstrating that a fossil bone assemblage has been accumulated by hominins and/or altered by hominin activities, as opposed to other taphonomic agents including carnivores, porcupines, or fluvial processes. *See also* **bone breakage patterns**.

anthropoid (Gk *anthropos* = human being) Primates that are relatively modern-human-like.

It is usually used in one of two senses, either to refer to the nonhuman higher primates (i.e., chimpanzee, gorilla, and orangutan and their immediate ancestors) as in “anthropoid apes”, or to all the members of the Anthroidea (i.e., living anthropoids include all the extant New World monkeys, Old World monkeys, and apes, plus modern humans). Strictly speaking, the latter use is the only correct one.

anthropoid apes See anthropoid.

Anthropopithecus de Blainville, 1839 (Gk *anthropos* = human being and *pithekos* = ape-like) A genus created by Henri Marie Ducrotay de Blainville (1839) to accommodate chimpanzee material, but because it postdates Oken’s 1816 designation of *Pan*, it is a junior synonym of *Pan*. *Anthropopithecus* was sometimes used as the generic name for any great ape, but for much of the 19thC it was the genus name of choice for chimpanzees (e.g., Sutton 1883). It was the genus used by Pilgrim for *Anthropopithecus sivalensis*, a fossil ape from the Siwaliks, and Eugène Dubois (1893) used the same genus to accommodate *Anthropopithecus erectus*, the species he introduced to accommodate the Trinil 2 skullcap. However, Dubois subsequently abandoned *Anthropopithecus*, replacing it with *Pithecanthropus* (Dubois 1894), and later still Weidenreich (1940) subsumed *Pithecanthropus* into *Homo*. See also *Pithecanthropus*.

Anthropopithecus erectus Dubois, 1893 (Gk *anthropos* = human being, *pithekos* = ape-like, and L. *erectus* = to set upright) (*NB: this citation is often given the year 1892, but it should be 1893. Dubois was obliged to submit official reports of his field activities to the government of Batavia, and although he first refers to *Anthropopithecus erectus* in the report of his field activities for the third quarter of 1892, the report was not published as a government document until 1893) A hominin species established by Eugène Dubois (1893) to accommodate the Trinil 2 skullcap. The sequence of events was as follows: in 1891 Dubois reported that at Trinil “The most important find is a molar (upper third molar) of a chimpanzee (*Anthropopithecus*). This genus of humanlike apes, now present in West- and Central Equatorial Africa, lived in Pliocene times in British India and, as is clear from the discovery, also during

Pleistocene periods in Java” (Dubois 1891, pp. 13–14) (this, and all the subsequent translations from Dutch are by kind favor of John de Vos). Later in the same year (but published in 1892) he reported that “Close to the site at the left bank of the river where the molar was found, a very nice skullcap was found, which, like the the molar, must undoubtedly attributed to the genus *Anthropopithecus (Troglydites)*” (Dubois 1892, pp. 13–14). Later in the same report Dubois wrote that “With the Pliocene *Anthropopithecus sivalensis*, of which only an incomplete upper jaw is known, only the molar is comparable, however in a limited amount. Probably one cannot exclude a close relation between both,” and he continued “The above mentioned *Anthropopithecus sivalensis* [originally described under the name of *Palaeopithecus* and then as *Troglydites*] represented by an incomplete upper jaw in the Pliocene of the Punjab in 1878 discovered by Theobald” (*ibid*, pp. 13–14). However, it was not until 1892, and the discovery of the straight-shafted Trinil 3 femur, that Dubois decided to name the new taxon *Anthropopithecus erectus*, and in the same year (but published in 1893) he wrote that “The three discovered skeletal elements show that *Anthropopithecus erectus* Eug. Dubois is closer to Man than any other of the anthropoid apes, the most by the femur...” (Dubois 1893, p. 11). In Dubois’ report for the last quarter of 1893 (Dubois 1894, p.14) the new taxon was subsequently transferred to the genus *Pithecanthropus Haeckel, 1868*, as *Pithecanthropus erectus*, and much later it was transferred to *Homo* by Weidenreich (1940). See also *Homo erectus*; *Homo erectus javanensis*; *Pithecanthropus erectus*.

antibody (Gk *anti*=opposite and ME *body*=container) Antibodies (also known as immunoglobulins or Igs) are proteins that are part of the immune system. They are produced by lymphocytes (a type of white blood cell) when the former react with foreign particles (e.g., bacteria and viruses) collectively called antigens. Each antibody reacts to a specific antigen, binding with it and then tagging it for destruction by other parts of the immune system, or blocking it directly from growing or causing damage. Antibodies may be free and soluble, and found in blood and tissue fluids, or they may be bound to the surface of a type of white cell (a type of lymphocyte called B cells, so-called because they mature in the bursa of

Fabricius in birds). Antibodies consist of four chains of **amino acids**, two heavy ones and two light ones. There are five types of antibody: IgA, IgD, IgE, IgG, and IgM. These are defined by differences in the structures, functions, and properties of their heavy amino acid chains. Antibodies raised against foreign **albumins** are the basis of the experiments undertaken by Morris **Goodman** to investigate the relationships among the **great apes**. *See also* **albumin**.

anticline (Gk *anti* = against and *klinein* = to slope) In structural geology this is a type of fold where the oldest rocks occupy the center of the structure and the rocks become progressively younger towards the margins. The simplest form of anticline is a symmetrical arch-shaped fold, which is open downwards. Such folds are important in geological and paleontological fieldwork, as they will determine the direction in which successively older or younger strata are encountered and will cause a repetition of the **outcrop** pattern on either side of the fold's axis. They are common features in tectonically active areas.

anticodon A sequence of three nucleotides in a **transfer RNA** (or tRNA) molecule that is complementary to a **codon** (i.e., a sequence of three nucleotides) in a messenger **RNA** (or mRNA) molecule.

antigen (from *antibody generation*) Any foreign molecule capable of stimulating the production of an **antibody**, or of provoking other responses by the immune system. *See also* **antibody**.

antilopine *See* **Antilopini**.

Antilopini (Gk *antholpos* = a fabulous beast from the orient) A tribe of the family **Bovidae** that includes the gazelles and their allies. Extant members of the tribe include springbok (*Antidorcas marsupialis*), Grant's gazelle (*Gazella granti*), and Thomson's gazelle (*Gazella thomsoni*). **Antilopine** bovids are of small to medium size (approximately 15–65 kg) and they exhibit adaptations for **cursorial** behavior (i.e., running) suited for the open and arid grasslands they typically inhabit. In **paleoenvironmental reconstructions** of fossil assemblages, high frequencies of antilopine and **alcelaphine** bovids are generally interpreted as indicating open habitats. *See also* **antilopine and alcelaphine criterion**.

antimere (Gk *anti* = opposite and *meros* = a part) Refers to the version of a bilateral structure that belongs to the opposite side of the body [e.g., “the crown area of the right P₃ of **KNM-ER 992** is larger than its antimere” (i.e., the left P₃)]. Amino acids come in forms that are antimeres (e.g., D- and L-forms) and the rate of conversion from one antimere to the other has been used as a dating method. *See also* **amino acid racemization dating**; **ostrich egg shell dating**.

antimeric *See* **antimere**.

anvil A stationary object against which another object, such as a bone or **core**, can be struck to fracture it. Anvils are generally made of stone, although materials such as wood may be used when stone is not available (e.g., Tai forest nut-cracking chimpanzees). Anvils can also be used in combination with a hammer, made of stone (a **hammerstone**) or wood. The object to be fractured (e.g., bone, core, nut) is rested on the anvil surface and struck from above with the **hammer**. Bones fractured with the “hammer-and-anvil” technique frequently have opposing load points and surface damage attributable to both the hammerstone and the anvil. Stone cores flaked using a hammer-and-anvil or **bipolar** technique usually have flakes removed from both ends. *See also* **bipolar**; **chimpanzee tool-use**.

Anyskop Blowout (Location 32°58'11.6"S, 18°06'50.66"E, South Africa; etym. in Afrikaans *anyskop* translates to “anise hill”) **History and general description** This open-air archeological locality is located within the boundaries of the West Coast Fossil Park, approximately 1 km/0.6 miles south of the site of **Langebaanweg**. Discovered in the late 1970s, this site was extensively collected and excavated in 2001 and 2002 by researchers from the University of Tübingen, Germany. The archeological remains provide clear evidence that archaic and modern humans occupied this elevated setting during all of the southern African archeological periods, including the **Early Stone Age**, the **Middle Stone Age**, and the **Later Stone Age**. **Temporal span and how dated?** Allocation to the Early, Middle and Late Stone Ages is based on the types of artifact. **Hominins found at site** None. **Archeological evidence found at site** Stone tools (see above), **Late Pleistocene** and **Holocene** fauna, ceramics, and hearths. Key references: **Hominins** N/A; **Archeology** Conrad

2001, 2002, Dietl 2004, Dietl et al. 2005, Kandel 2006. *See also Later Stone Age.*

apatite (Gk *apate* = decept, because of apatite's reputation for being confused with other minerals) Apatite is one of the common names (hydroxyapatite and bioapatite are others) used for the dominant mineral phase of **bone**, **cementum**, and **dentine**, as well as **enamel**. The proper name for bioapatite or hydroxyapatite is apatitic calcium phosphate, chemical formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. Bioapatite or hydroxyapatite makes up approximately 96% of the mineral phase of mature enamel, and this high proportion is responsible for the latter's extreme hardness and resilience to **diagenesis**.

ape (OE *apa* = ill-bred and clumsy. Groves (2008) suggests that *apa* became *apan* (pl.), *apan* became *apen*, and then approximately 1350 years BP *apen* became apes. Before the apes had been investigated scientifically and appreciated on their own terms, they were regarded as being "clumsy" because they lacked **dexterity**) Refers to an informal taxonomic category that includes extant and fossil taxa and it is coincident with the superfamily **Hominoidea**. The extant taxa in this superfamily are chimpanzees/bonobos, gorillas, orangutans and gibbons/siamangs; the fossil taxa are all the extinct forms that are more closely related to chimpanzees/bonobos, gorillas, orangutans and the gibbons/siamangs than to any other living taxon. In the traditional, pre-molecular, taxonomy the informal term ape was equivalent to the families Pongidae and Hylobatidae. syn. hominoid.

ape hand All extant apes are capable of specialized suspensory and climbing behaviors and thus the ape hand, more so than the modern human hand, is well adapted for grasping by hook-like flexed fingers. Extant ape fingers are relatively long and the phalanges are curved to facilitate hanging and grasping. The thumb is relatively short and is not usually used during these locomotor behaviors. These adaptations, and others such as a highly mobile midcarpal joint, are particularly accentuated in orangutans, gibbons, and siamangs to facilitate suspension and, in the hylobatids, ricochet brachiating (Lewis 1989). The gorilla, in contrast, has relatively shorter and straighter phalanges compared to other apes because of its frequent use of terrestrial locomotion. African apes differ from Asian apes in having

scaphoid-os centrale fusion, extra bony ridges, and the bevelling of articular surfaces that make the wrist and finger joints more stable. This increased stability has been interpreted as being advantageous for knuckle-walking locomotion (Tuttle 1969, Richmond et al. 2001).

apical closure The developmental condition that signifies the closing of the root canal at its distal, or apical, end. At this point the growth in length of the root (also called extension) ceases, although secondary dentine secretion continues within the pulp cavity. Apical closure, which is traditionally taken as the final stage of **tooth formation**, can be evident macroscopically, microscopically, or radiographically.

apical tuft (L. *apex* = point and OF *tof(f)e* = projection) The most distal part of the **distal phalanx** of a **manual digit**. The fingers of the primate **hand** each comprise three bones, called the **proximal**, intermediate, and distal phalanges. The small distal phalanx has a base, a shaft, and an apex. In higher primates the apex is rounded and takes the form of a bony excrescence called an apical tuft. The edges of this apical tuft extend more proximally than does its mid-part, and they are referred to as unguis spines. The apical tuft provides bony support for the nail and for the soft tissue, or pulp, that lies beneath the nail. The apical tuft is markedly enlarged in modern humans and in *Homo neanderthalensis*, and it is relatively enlarged in chimpanzees and gorillas compared to other primates. In modern humans, the expanded apical tuft supports the elaboration of a pulpy pad (the "unguis pulp") on the palmar side of the distal phalanx. This palmar pad is functionally compartmentalized such that only the distal end is tethered by ligaments to the bone while the proximal end is more flexible, allowing for deformation in various ways during grasping of objects (Marzke and Marzke 2000) (syn. unguis process, tuberosity, or tuft) (Susman 1979).

Apidima (Location Mani peninsula, Southern Greece; etym. local dialect of Greek for "jump", probably referring to the steep sea-side cliff face where the caves are located) History and general description Discovered in 1978 and partially excavated between 1978 and 1985, the site comprises four limestone caves accessible only by sea.

Temporal span Dating investigations have proved to be inconclusive. Cave A is probably **Middle Pleistocene**, and Cave Γ possibly **Late Pleistocene**. How dated? **Biostratigraphy**, lithic typology, and morphology of the hominin remains. Hominins found at site Cave A: Apidima 1 and 2; Cave Γ : Apidima 3. Archeological evidence found at site Stone artifacts reported from Cave Γ , possibly **Upper Paleolithic**. Key references: Geology and dating Lax 1995, Liritzis and Maniatis 1995; Hominins Pitsios 1985, Harvati and Delson 1999; Archeology Darlas 1995. *See also* **Apidima 1 and 2; Apidima 3**.

Apidima 1 and 2 Site Apidima. Locality Cave A. Surface/in situ *In situ*. Date of discovery 1978. Finders Team from National Kapodistrian University. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Probably **Middle Pleistocene** on morphological grounds. Developmental age Adult. Presumed sex Apidima 2 proposed Female. Brief anatomical description Two crania; Apidima 2 is largely complete, whereas Apidima 1 lacks a face and the superior part of the cranial vault. Announcement Pitsios 1985. Initial description Koutselinis et al. 1995. Photographs/line drawings and metrical data Koutselinis et al. 1995. Initial taxonomic allocation No proper classification or description exists. Taxonomic revisions N/A. Current conventional taxonomic allocation **Pre-Neanderthal** (Harvati and Delson 1999). Significance These specimens represent two out of the total of three fossil hominin crania from the Middle Pleistocene of southeastern Europe. Location of original **Anthropological Museum, National Kapodistrian University, Athens, Greece**. *See also* **Apidima**.

Apidima 3 Site Apidima. Locality Cave Γ . Surface/in situ *In situ*. Date of discovery 1984. Finders Excavating team from the National Kapodistrian University. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Possibly **Late-Terminal Pleistocene**. Developmental age Young adult. Presumed sex Female. Brief anatomical description Largely complete skeleton of a modern human, presumably female and possibly a burial. Announcement Pitsios 1985. Initial description Mompheratou and Pitsios 1995. Line drawings

Mompheratou and Pitsios 1995. Initial taxonomic allocation ***Homo sapiens***. Significance Possible **Upper Paleolithic** burial. The brief description of the stone artifacts suggests they may be **Aurignacian**, and the **Upper Paleolithic**, and the Aurignacian in particular, is almost completely absent from the fossil and archeological records of Greece. Location of original **Anthropological Museum, National Kapodistrian University, Athens, Greece**. *See also* **Apidima**.

Apollo 11 Cave (Location 27°45'S, 17°06'E, Namibia; etym. named after the 1969 return flight and landing of Apollo 11 spacecraft, which occurred the day excavations commenced) History and general description A large (28 m × 11 m) limestone cave on the western slopes of the Huns Mountains. W.E. Wendt excavated 12 m² to a maximum depth of approximately 2 m, recovering more than 50,000 lithic and faunal remains. The site contains a number of **Middle Stone Age** strata including Howieson's Poort and **Still Bay** levels. Stone slabs with painted representations of a rhinoceros and an animal, or perhaps modern human, form are among the earliest known examples of *art mobilier*, with age estimates using all the available data ranging from *c.*20 to 59 ka. Temporal span Wendt recognized eight strata (A–H from top to bottom) separated by unconformities; Jacobs et al. (2008) further subdivided the strata, although correlations with Wendt's scheme are not provided. The sediments have been dated by single-grain optically stimulated **luminescence dating** on sand, conventional **radiocarbon dating** of charcoal, and **accelerator mass spectrometry** age estimates and **amino acid racemization dating** on ostrich egg shell. The pooled samples of age estimates suggests discontinuous hominin occupation of the cave from *c.*0.3 ka to more than 83 ka. Excluding conventional radiocarbon age estimates from the 1970s, the stratum containing the painted slabs (Layer E of Wendt 1976) has an estimated age of 41–59 ka. How dated? ¹⁴C, amino acid racemization dating, accelerator mass spectrometry, and optically stimulated luminescence dating. Hominins found at site None. Archeological evidence found at site More than 27,000 stone artifacts and more than 23,000 faunal elements have been recovered from the Apollo 11 Cave excavations. The former have been divided by Wendt and later researchers into (from bottom to top) early Middle Stone Age, **Still Bay**, Howieson's Poort, late Middle Stone Age, early **Later Stone Age**,

Later Stone Age, and pottery-bearing strata. Apollo 11 Cave reflects the northernmost and westernmost limit of known Still Bay sites, and in addition to the distinctive **bifacial points**, the Still Bay stratum there (Layer G of Wendt 1976, Komplex 2 of Vogelsang 1998) also contains worked **hematite** and **bone tools**. Incised and perhaps painted ostrich egg shell fragments also occur in overlying levels (i.e., Layers F and E of Wendt 1976, and Komplex 3 and 4 of Vogelsang 1998). The associated fauna is interpreted as primarily the result of hominin accumulation, with the notable selective transport of high-utility elements of large **antelopes** that were subsequently discarded in the cave. Key references: Geology and dating Wendt 1976, Vogelsang 1998, Miller et al. 1999, Jacobs et al. 2008; Archeology Wendt 1976, Thackeray 1979, Vogelsang 1998, Jacobs et al. 2008.

apomorphic (Gk *apo* = different from and *morph* = form) A term used in **cladistic analysis** to refer to the state of a **character** that is different from the ancestral or **primitive** condition of that character. Hence it is a “catch-all” word that refers to any derived **character state**. For example, within the hominin clade there are two morphoclines for anterior lower premolar (P₃) root morphology. One leads from the primitive condition [i.e., two roots, one mesiobuccal and one distal (2R: MB+D)] to a derived morphology of root reduction [i.e., a single conical root (1R)], whereas the other leads to a derived morphology of further root complexity [i.e., two plate-like roots, one mesial and one distal (2R: M+D)]. Both of these character states are apomorphic. Apomorphy is one of several terms used in cladistics that is relative. The same morphology can be derived or apomorphic in one context and primitive or symplesiomorphic in another. *See also* **autapomorphy**; **synapomorphy**.

apomorphy (Gk *apo* = different from and *morph* = form) *See* **apomorphic**.

apoptosis (Gk *apo* = from, and *ptosis* = falling) A process (also called programmed cell death) whereby cells in a multicellular organism die according to a program determined by the cell. Apoptosis plays important roles in development, homeostasis, the removal of damaged cells, and the prevention of cancer. There is much apoptosis during the development of the brain, and most of the tubes of the body

(e.g., the tear duct) start as a solid core of cells that becomes tubular when the cells in the middle of the core undergo apoptosis.

appendicular skeleton (L. *appendere* = to hang upon) The hard-tissue components of fore or upper, and the hind or lower, limbs. In the upper limb it comprises the pectoral or shoulder girdle (i.e., the scapula and clavicle), the bone of the arm (humerus), and the bones of the forearm (radius and ulna) and those of the hand (carpals, metacarpals, and phalanges). In the lower limb it comprises the pelvic girdle (i.e., pelvic bone made up of the ilium, ischium, and pubic bones, but not the sacrum), the bone of the leg (femur), the patella, the bones of the lower leg (tibia and fibula), and the bones of the foot (tarsals, metatarsals, and phalanges).

appositional enamel (L. *appositus* = to put near) Strictly speaking, all enamel is appositional, but this term usually refers to the enamel formed during the initial phase of enamel formation, or **cuspal enamel**. *See also* **cuspal enamel**; **enamel development**.

appositional growth *See* **ossification**.

approximal wear *See* **interproximal wear**.

aptation (L. *adaptare* = to fit) There are two main categories of aptations. If a functional **trait** was fixed in a population by **natural selection**, and it still performs that function, then it is referred to as an **adaptation**. But if there is evidence the trait now performs a *different* function, or if what is now a functional trait was non-functional prior to its being co-opted for its current function, then the trait is referred to as an **exaptation** (*sensu* Gould and Vrba 1982). *See also* **adaptation**; **exaptation**.

⁴⁰Ar/³⁹Ar *See* **argon-argon dating**.

ARA *See* **Aramis**.

ARA-VP Acronym for Aramis – Vertebrate Paleontology. Prefix for fossils recovered from Aramis, Middle Awash study area, Ethiopia.

ARA-VP-1/1 Site Aramis. Locality Aramis VP Locality 1. Surface/in situ Surface. Date of

discovery December 17, 1992. Finder Gen Suwa. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Right M³. Announcement White et al. 1994. Initial description White et al. (1994). Photographs/line drawings and metrical data White et al. 1994, Suwa et al. 2009a. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus ramidus*. Taxonomic revisions *Ardipithecus ramidus*. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance First specimen of *Ar. ramidus* to be discovered. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-1/300 Site Aramis. Locality Aramis VP Locality 1. Surface/in situ Surface. Date of discovery December 26, 1993. Finder Unknown. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Associated permanent dentition that includes the crowns and roots of at least one side of all the upper teeth (ARA-VP-1/300A–M) and of all the lower teeth (ARA-VP-1/300N–ZA). Announcement White et al. 2009a. Initial description Suwa et al. 2009a. Photographs/line drawings and metrical data Suwa et al. 2009a. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance Excellently preserved dentition of a single *Ar. ramidus* individual. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-1/401 Site Aramis. Locality Aramis VP Locality 1. Surface/in situ Surface. Date of discovery December 27, 1993. Finder Unknown. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated

horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The symphysis and both sides of the corpus of a subadult mandible containing the crowns and roots of the left and right I₁–M₁, plus the left M₂. Announcement White et al. 2009a. Initial description N/A. Photographs/line drawings and metrical data Suwa et al. 2009b. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance The best preserved mandible of *Ar. ramidus*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-1/500 Site Aramis. Locality Aramis VP Locality 1. Surface/in situ Surface. Date of discovery December 28, 1993. Finder Unknown. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Three pieces (right and left temporal and occipital) of a partial adult cranium. Announcement White et al. 2009a. Initial description Suwa et al. 2009b. Photographs/line drawings and metrical data Suwa et al. 2009b. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance The three pieces (right and left temporal and occipital) of this partial adult cranium were used in the reconstruction of the cranium of the ARA-VP-6/500 associated skeleton. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-1/701 Site Aramis. Locality Aramis VP Locality 1. Surface/in situ Surface. Date of discovery December 20, 1994. Finder Unknown. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age

*c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Proximal end of a left femur. Announcement White et al. 2009a. Initial description Lovejoy et al. 2009b. Photographs/line drawings and metrical data Lovejoy et al. 2009b. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance A fragment of the proximal end of the left femur, one of only two proximal femoral fragments (the other is ARA-VP-6/500-5) in the *Ar. ramidus* hypodigm. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-6/1 Site Aramis. Locality Aramis VP Locality 6. Surface/in situ Surface. Date of discovery December 29, 1993. Finder Gada Hamed. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Several associated teeth, including the left I¹, C, P³, and P⁴, and right, I¹, C, P⁴, M², P₃ and P₄. Announcement White et al. 1994. Initial description White et al. 1994. Photographs/line drawings and metrical data White et al. 1994, Suwa et al. 2009a. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus ramidus*. Taxonomic revisions *Ardipithecus ramidus*. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance Holotype of *Ar. ramidus*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-6/500 Site Aramis. Locality Aramis VP Locality 6. Surface/in situ Surface. Date of discovery November 5, 1994 and thereafter. The first evidence of ARA-VP-6/500 were two fragments of a second right metacarpal found on the surface by Yohannes Haile-Selassie. Thereafter further evidence of the ARA-VP-6/500 partial skeleton was recovered by sieving and surface prospecting and from excavations. Finders Yohannes Haile-Selassie and members of the Middle Awash Research Project. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation Sagantole Formation. Group N/A. Nearest overlying dated horizon

Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description One hundred and thirty recognizable fragments belonging to a single individual were recovered. Most were in perilous condition and much of the cranial morphology has been recovered from micro-CT scans of unconsolidated cranial fragments still in matrix. Much of the cranial vault and the face have been reconstructed. The crowns and roots of all of the upper teeth on the right side, and the left lower canine through to the M₃, are preserved. The right forearm is intact apart from the distal end of the ulna; the partial right hand includes carpal bones and a complete ray. The only evidence of the left forearm is part of the radial shaft, but much of the skeleton of the left hand is preserved. All that remains of the thorax that can be identified precisely are two vertebrae (a cervical and a thoracic) and the left first rib. Much of the left innominate is preserved, but it is crushed and distorted, as is a piece of the lower part of the body of the sacrum, and part of the right ilium. Of the long bones of the lower limb, all that remains is a substantial length of the shaft of the right femur, most of the right tibia, and all but the proximal end of the right fibula. Between them the two preserved foot skeletons provide most of the bones of the tarsus and the toes. Endocranial volume: “300 ± 10 cm³, with a larger range of 280 to 350 cm³” (Suwa et al. 2009b, p. 68e6). Announcement White et al. 2009a. Initial description Lovejoy et al. 2009a–c, Suwa et al. 2009a, 2009b. Photographs/line drawings and metrical data Lovejoy et al. 2009a–c, Suwa et al. 2009a, 2009b. Detailed anatomical description N/A. Initial taxonomic allocation *Ardipithecus ramidus*. Taxonomic revisions None. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance An associated skeleton whose exceptional completeness and eventual preservation is a testament to the many hours of painstaking work, in both the field and laboratory, that went into its recovery, restoration, and reconstruction. This associated skeleton is the centerpiece of the hypodigm of *Ar. ramidus*, and functional interpretations based on it form the main evidential platform for the assumption that *Ar. ramidus* is a basal hominin. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

ARA-VP-7/2 Site Aramis. Locality Aramis VP Locality 7. Surface/in situ Surface. Date of

discovery December 30, 1993. Finder A. Asfaw. Unit N/A. Horizon N/A. Bed/member Lower Aramis Member. Formation **Sagantole Formation**. Group N/A. Nearest overlying dated horizon Daam-Aatu Basaltic Tuff. Nearest underlying dated horizon Gaala Vitric Tuff Complex. Geological age *c.*4.4 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragments of the long bones of an arm of a single individual; the humeral fragment includes the proximal end. Announcement White et al. 1994. Initial description White et al. 1994. Photographs/line drawings and metrical data White et al. 1994. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus ramidus*. Taxonomic revisions *Ardipithecus ramidus*. Current conventional taxonomic allocation *Ar. ramidus*. Informal taxonomic category Possible primitive hominin. Significance The first associated postcranial remains of *Ar. ramidus*, and the size of the humeral head was the source of the initial body mass estimate of approximately 40 kg. Its discoverer claimed that “the arm displays a mosaic of characters usually attributed to hominids and/or great apes” and “a host of characters usually associated with modern apes” (White et al. 1994, p. 311). Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Aragai (Location 00°34'N, 35°50'E, Kenya; etym. local, Tugen, name for the area) History and general description Site within the **Lukeino Formation** in the foothills of the Tugen Hills, Baringo District, Kenya. Along with **Cheboit**, **Kapcheberek**, and **Kapsomin**, **Aragai** is one of four localities from which remains attributed to *Orrorin tugenensis* have been recovered. Temporal span *c.*6–5.7 Ma. How dated? **Argon-argon dating**, **potassium-argon dating**, and **magnetostratigraphy**. Hominins found at site The only specimen recovered to date is BAR 1215'00, a proximal right femur found by M. Pickford in 2000 which has been assigned to *O. tugenensis*. Archeological evidence found at site None. Key references: Geology and dating Hill et al. 1985, Pickford and Senut 2001, Deino et al. 2002, Sawada et al. 2002; Hominins Senut et al. 2001; Archeology N/A.

Arago See Caune de l'Arago.

Arago II Site Caune de l'Arago. Locality N/A. Surface/in situ *In situ*. Date of discovery July 21, 1969.

Finders Henry and Marie-Antionette de Lumley. Unit N/A. Horizon Layer G. Bed/member Middle Stratigraphic Complex. Formation N/A. Group N/A. Nearest overlying dated horizon Speleothem floor just above dates to *c.*350 ka. Nearest underlying dated horizon N/A. Geological age **Arago XXI** from the same layer was directly dated to *c.*400 ka. Developmental age 40–55 years. Presumed sex Female. Brief anatomical description A nearly complete mandible with six teeth and lacking the left ramus. Announcement de Lumley and de Lumley 1971. Initial description de Lumley and de Lumley 1971. Photographs/line drawings and metrical data de Lumley et al. 1982. Detailed anatomical description de Lumley et al. 1982. Initial taxonomic allocation Pre-Neanderthal/*Homo erectus tautavelensis*. Taxonomic revisions Rightmire 1998. Current conventional taxonomic allocation *Homo heidelbergensis*, pre-Neanderthal, or transitional form. Informal taxonomic category Pre-modern *Homo*. Significance The most complete mandible from Arago. Location of original Institut de Paléontologie Humaine, Paris.

Arago XXI Site Caune de l'Arago. Locality N/A. Surface/in situ *In situ*. Date of discovery July 1971. Finders Henry and Marie-Antionette de Lumley. Unit N/A. Horizon Layer G. Bed/member Middle Stratigraphic Complex. Formation N/A. Group N/A. Nearest overlying dated horizon Speleothem floor just above dates to *c.*350 ka. Nearest underlying dated horizon N/A. Geological age Directly dated using **uranium-series dating** to *c.*400 ka (but this is near the maximum limit of this dating method, so the fossil may be older). Developmental age Young adult. Presumed sex Male. Brief anatomical description A deformed cranial fragment with a complete frontal, sphenoid and all of the face. **Arago XLVII**, a right parietal, fits with the frontal and was recovered from the same layer in 1979. Announcement de Lumley and de Lumley 1971. Initial description de Lumley and de Lumley 1971. Photographs/line drawings and metrical data de Lumley and de Lumley 1971, 1973, Spitz 1982a, 1982b, Bouzat 1982. Detailed anatomical description Spitz 1982a, 1982b, Bouzat 1982. Initial taxonomic allocation Pre-Neanderthal/*Homo erectus tautavelensis*. Taxonomic revisions Rightmire 1998. Current conventional taxonomic allocation *Homo heidelbergensis*, pre-Neanderthal or transitional form. Informal taxonomic category Pre-modern *Homo*. Significance One of the most complete pre-Neanderthal or *H. heidelbergensis* fossil faces.

Location of original Institut de Paléontologie Humaine, Paris.

Arago XLVII Site Caune de l'Arago. Locality. Surface/in situ *In situ*. Date of discovery July 1979. Finders de Henry and Marie-Antonette de Lumley. Unit N/A. Horizon Layer G. Bed/member Middle Stratigraphic Complex. Formation N/A. Group N/A. Nearest overlying dated horizon Speleothem floor just above dates to *c.*350 ka. Nearest underlying dated horizon N/A. Geological age This piece likely joins with **Arago XXI**, which has been directly dated to *c.*400 ka. Developmental age 20 years. Presumed sex Male. Brief anatomical description Right parietal. Announcement Grimaud 1982. Initial description Grimaud 1982. Photographs/line drawings and metrical data Grimaud 1982. Detailed anatomical description Grimaud 1982. Initial taxonomic allocation Pre-Neanderthal/*Homo erectus tautavelensis*. Taxonomic revisions Rightmire 1998. Current conventional taxonomic allocation *Homo heidelbergensis*, pre-Neanderthal, or transitional form. Informal taxonomic category Pre-Neanderthal. Significance This parietal fits with **Arago XXI**. Location of original Institut de Paléontologie Humaine, Paris.

aragonite *See* calcium carbonate.

Aralee Issie A collection area initially identified by the **International Afar Research Expedition** but now within the **Woranso-Mille study area**, Central Afar, Ethiopia.

Arambourg, Camille Louis Joseph (1885–1969) Camille Arambourg was born in Paris, France. He graduated from the private school of Sainte-Croix de Neuilly in 1903, and later that year he entered the Institut National Agronomique (National Agronomic Institute) where he completed a degree in agricultural engineering in 1908. Arambourg left France after graduation to join his family in Oran, Algeria, where his father had moved to establish a vineyard. While improving irrigation around the family vineyard Arambourg found specimens of fossil Miocene fish and so began to excavate and collect fossils in the area. As Arambourg's paleontological interests grew he made contacts at the geological laboratory of the Algiers Faculty of Sciences, which allowed him to expand his knowledge of geology and paleontology. When WWI broke out Arambourg left Algeria to join the French army and fought

in the Dardanelles Campaign in 1915 and was stationed in Macedonia from 1916 to 1918. While in Macedonia, Arambourg collected Miocene mammalian fossils from the region around Salonika. At the end of the war Arambourg sent this collection to the **Muséum National d'Histoire Naturelle** (National Museum of Natural History) in Paris and he returned to Algeria. In 1920 Arambourg accepted a position as Professor of Geology at the Institut Agricole d'Alger (Agricultural Institute of Algiers) and over the next decade he collected fossil Miocene fish and Pleistocene vertebrates in Algeria and North Africa. These researches offered Arambourg opportunities to visit the renowned French paleontologist Marcellin Boule at the Muséum National d'Histoire Naturelle in Paris, and in 1930 Arambourg moved to Paris to become Professor of Geology at the Institut National Agronomique. Arambourg continued to conduct paleontological research in Africa, and while excavating the **Upper Paleolithic** site of Bejaia, in northern Algeria, between 1928 and 1930, he found six skeletons of early *Homo sapiens*. Soon thereafter he organized an expedition, the **Mission Scientifique de l'Omo**, to the Omo river valley in Ethiopia from 1932 to 1933 where he collected Pleistocene fossils and explored along portions of Lake Rudolf (now called Lake Turkana). The research conducted during this expedition on the geology, paleontology, and anthropology of the region was later published as *Mission scientifique de l'Omo, 1932–1933* (3 vols., 1935–48). Arambourg was appointed Professor of Paleontology at the **Muséum National d'Histoire Naturelle** in Paris in 1936 and during the 1938–9 field season he explored Cretaceous deposits in Lebanon and Oligocene deposits in Iran. In 1943 Arambourg published a short work on prehistory titled *La genèse de l'humanité (The Genesis of Humanity)*, which went through eight editions by 1969. After WWII, Arambourg excavated the **Villafranchian** site of **Ain Hanech**, near the village of Sétif in northeastern Algeria. In 1947–8 where he discovered Lower Pleistocene mammal fossils and **Lower Paleolithic** artifacts including **spheroid** stones. Even greater success came during excavations at **Ternifine** (now called **Tighenif**) during 1954–5 where he found crude **Acheulean** tools and several mandibles that he attributed to a "pithecanthropoid" form of early human that he called *Atlantropus mauritanicus* (now subsumed into *Homo erectus*). Arambourg's last major work, *Vertébrés villafranchiens d'Afrique du nord (Villafranchian Vertebrates of*

North Africa) was published posthumously in 1979. Arambourg retired from the Muséum National d'Histoire Naturelle in 1955, but he continued to write and conduct research. He served as President of the Société Géologique de France (Geological Society of France) in 1950, President of the Société Préhistorique Française (French Prehistoric Society) in 1956, and he was President of the Fourth Pan-African Congress on Prehistory held in Leopoldville, the Belgian Congo, in 1959. When the **International Omo Research Expedition** was established in 1966 Arambourg became the leader of the French contingent and participated in a limited fashion in its first three field seasons from 1967 until his death in 1969. Regarding human evolution, Arambourg argued that there were long periods of relative biological stability as well as stability in the stone tool industries as seen in the archeological record, punctuated by periods of rapid change. Moreover, he believed that human biological and cultural evolution was progressive and proceeded along successive stages. As a result, Arambourg considered what he referred to as **australopithecines**, **pithecanthropines**, **Neanderthals**, and *Homo sapiens* to represent successive stages of human evolution.

Aramis (Location 10°28'N, 40°26'E, Ethiopia; etym. the site is named after a tributary of the Awash River) History and general description Aramis, the type site of *Ardipithecus ramidus*, is situated between the headwaters of the Aramis and Adgantoli drainages on the west side of the Awash River in the Middle Awash study area in the Afar Depression in the Afar Rift System. All of the localities (ARA-VP) are on exposures of the approximately 300 m-thick Sagantole Formation. Temporal span c.4.2–4.1 Ma. Hominin-bearing localities in the Aramis Member are dated by **argon-argon dating** to 4.419 ± 0.058 Ma and 4.416 ± 0.031 Ma. The hominin-bearing locality in the Adgantole Member is constrained by argon-argon dates of 4.041 ± 0.060 Ma for an overlying volcanic stratum (MA 94–55C), and 4.317 ± 0.055 for the underlying Kullunta basaltic tuff (KUBT). An age of approximately 4.12 Ma has been assigned based on additional dating through **biostratigraphy** of the Aramis Member and from **magnetostratigraphy**. How dated? Argon-argon dating, biostratigraphy, magnetostratigraphy. Hominins found at site Specimens recovered from the Aramis Member attributed to *Ar. ramidus* include the **holotype** ARA-VP-1/1 and the

associated skeleton, **ARA-VP-6/500**. A left maxilla, ARA-VP-14/1, has been attributed to *Australopithecus anamensis*. Archeological evidence found at site None. Key references: Geology and dating WoldeGabriel et al. 1994, 2009, Renne et al. 1999, White et al. 2006b; Hominins White et al. 1994, 2006, 2009; Archeology N/A.

arboreal (L. *arbor* = tree) The term used to describe animals that live in trees. Some of the defining features of **primates** (binocular vision, generalized limb structure retaining a clavicle) are important for life in the trees (e.g., binocular vision helps animals to judge distances). Although Elliott Smith and Wood Jones' arboreal theory, in which they argued that tree living was key to primate origins, has now fallen out of favor, arboreality remains an important trait within the order. Today and in the past many primates use trees for moving, foraging, and resting. Indeed, the vast majority of primates are dependent on trees, and the **platyrrhines** are exclusively arboreal. Nonetheless, many living and extinct primates have successfully radiated into **terrestrial** niches, or have combined life in the trees with life on the ground. The early hominins are a good example of this combination of arboreality and terrestriality, and some researchers have suggested that at least one form of hominin bipedalism may have emerged as a way of moving or foraging in trees (Thorpe et al. 2007). *See also locomotion.*

arboreality (L. *arbor* = tree) The tendency to live partially, or wholly, in the trees. *See arboreal.*

“archaeomorphous” *Homo sapiens* *See* Reilingen calvaria.

Archanthropinae (Gk *arch* = first or primary and *anthropos* = man) A subfamily apparently introduced by Franz Weidenreich in 1946. In the second of his five 1945 Hitchcock Lectures entitled the “The Development of the Specifically Human Form” Weidenreich refers to the introduction by Sir Arthur Keith (1925) of the terms “**neoanthropic man**” and “**paleoanthropic man**”, for modern humans “with all its variants” and Neanderthal man, respectively (Weidenreich 1946, p. 28). Weidenreich proposes that “...only a small step is required to alter the terms in use and to designate all the groups or subfamilies represented by these types as Neoanthropinae and

Paleoanthropinae, respectively” (*ibid*, pp. 28–9). He then goes on to suggest that “...when *Sinanthropus* and *Pithecanthropus* are measured according to the characteristics of the Paleoanthropinae, they reveal new features which are not found in this group and, therefore, have to be classified as a more primitive subfamily, for which the name Archanthropinae (“primary man”) seems to be adequate.” (*ibid*, p. 29). In a subsequent publication Weidenreich (1951) referred *Homo soloensis* to the Archanthropinae. Robert Broom was presumably interpreting Archanthropinae in a different way when he used it as a higher taxon for *Australopithecus prometheus* (Broom 1950), but thereafter the subfamily Archanthropinae fell into disuse.

Archi (Location 38°08′20″N, 15°39′38″E in Calabria, Italy; etym. from the nearby village) History and general description Roadwork on the hill of San Francesco d’Archi yielded an immature hominin mandible in 1970. The stratigraphic and geological context were subsequently investigated and published along with an initial description of the specimen. Temporal span and how dated? Uranium-series dating on marine molluscs in overlying level suggests an age of more than 40 ka. Hominins found at site Archi 1, a mandible, was found in layer C-3, a gravelly layer containing numerous vertebrate faunal remains. The specimen was mostly likely about 3 years old at the time of death and can be confidently assigned to *Homo neanderthalensis*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Ascenzi and Segre 1971; Hominins Mallegni and Trinkaus 1997; Archeology N/A.

arcuate fasciculus (*L. arcuatus* = bent like a bow and *L. fascis* = bundle) A bundle of axons in each cerebral hemisphere that connects **Wernicke’s area** and **Broca’s area** on the dominant side, as well as other areas of the temporal cortex and **frontal cortex** in both hemispheres. In modern humans, damage to this pathway can cause a language deficit known as conduction aphasia, which is a difficulty in repeating words that have been heard; otherwise language comprehension and production are intact. Comparative neuroimaging studies have shown that the arcuate fasciculus in modern humans is larger and makes more extensive interconnections, and thus links a greater number of areas in the temporal cortex and frontal cortex, as compared

with chimpanzees and macaque monkeys. These specializations of the modern human arcuate fasciculus may be important in conveying the stored meaning of words in the temporal cortex to the frontal cortical areas that are involved in sentence comprehension and construction.

Arcy-sur-Cure (Location 47°35′N, 3°45′E, France; etym. after a nearby town) The many caves that constitute the site of Arcy-sur-Cure lie in the limestone cliffs above the Cure river in central France. They were originally excavated for saltpeter, and then since the 1850s they have been excavated with different levels of competence by amateur and professional archeologists. The site comprises a complex of more than 10 named caves, including the **Grande Grotte**, the **Grotte du Renne**, the **Grotte du Hyène**, the **Grotte des Fées**, and the **Grotte du Loup** among others (Leroi-Gourhan 1958). The Grande Grotte is best-known for its c.28–33 ka cave paintings, which are the second-oldest such paintings in France. The Grotte du Renne is best known for several beads and objects of personal ornamentation found in the **Châtelperronian** level, alongside a juvenile *Homo neanderthalensis* and several isolated Neanderthal teeth. Researchers debate whether these finds reflect independent Neanderthal invention of so-called modern behaviors, or evidence of **acculturation** from interaction with modern humans, or if the finds were the product of Neanderthals at all. In the Grotte du Hyène, several hominin remains, including a nearly complete mandible with dentition, were recovered from the lower **Mousterian** levels. A mandible attributed to *Homo neanderthalensis* was found in the Grotte des Fées by de Vibraye in 1859, but researchers at the site have argued on morphological and stratigraphic grounds that this mandible likely represents a **Neolithic** burial. The Grotte du Loup is a minor site, preserving only a few Châtelperronian and Mousterian tools, but contains evidence of a possible Neanderthal burial. For more information, see the individual entries about each cave.

Ardipithecus **White et al., 1995** (etym. *ardi* = ground or floor in the Afar language and *Gk pithekos* = a postfix that means ape or “ape-like”) A genus established in 1995 by White et al. (1995) to accommodate the species *Ardipithecus ramidus*. The authors claimed the new genus was

justified because the type species, *Ar. ramidus* (c.4.4 Ma), was significantly more primitive than species previously assigned to *Australopithecus*. Subsequently a second more primitive and temporally older (c.5.8–5.2 Ma) species, *Ardipithecus kadabba*, was recognized and included in the same genus (Haile-Selassie 2001). Type species *Ardipithecus ramidus* (White et al., 1994) White et al., 1995. *See also* *Ardipithecus ramidus*; *Ardipithecus kadabba*.

***Ardipithecus kadabba* Haile-Selassie, 2001** (etym. *see* *Ardipithecus*, and *kadabba* = a “family ancestor” in the Afar language) A hominin subspecies with the same name was established by Haile-Selassie (2001), but it was subsequently elevated to species rank by Haile-Selassie et al. (2004b). The new species was established to accommodate the original cranial and postcranial remains announced in 2001 and six new dental specimens announced in 2004. All of the hypodigm was recovered from five c.5.8–5.2 Ma localities in the **Middle Awash study area**, Ethiopia. Four of the localities, **Saitune Dora**, **Alayla**, **Asa Koma**, and **Digiba Dora**, are in a region called the **Western Margin**, and one, **Amba East**, is in the **Central Awash Complex** of the Middle Awash study area. The main differences between *Ar. kadabba* and *Ardipithecus ramidus* are that the apical crests of the upper canine crown of the former taxon are longer and the P₃ crown outline of *Ar. kadabba* is more asymmetrical than that of *Ar. ramidus*. The morphology of the postcranial evidence is generally ape-like. Haile-Selassie et al. (2004) suggest that there is a morphocline in upper canine morphology, with *Ar. kadabba* exhibiting the most ape-like morphology, and *Ar. ramidus*, *Australopithecus anamensis*, and *Australopithecus afarensis* interpreted as becoming progressively more like the lower and more asymmetric crowns of later hominins (see Fig. 1D in Haile-Selassie et al. 2004). The proximal foot phalanx (AME-VP-1/71) combines an ape-like curvature with a proximal joint surface that is like that of *Au. afarensis* (Haile-Selassie 2001). Some researchers have suggested that because of its ape-like dental morphology the case for *Ar. kadabba* being a hominin is a relatively weak one. The fossil evidence for *Ar. kadabba* and its context are reviewed in Haile-Selassie and Wolde-Gabriel (2009). First discovery ALA-VP-2/10 (1997). Holotype ALA-VP-2/10 (1997). Paratypes ALA-VP-2/11, -2/101; ASK-VP-3/78, -3/160; DID-VP-1/80; STD-VP-

2/62, -2/63, -2/893; AME-VP-1/71. Main sites Middle Awash study area, Ethiopia.

***Ardipithecus ramidus* (White et al., 1994) White et al., 1995** (etym. *see* *Ardipithecus* and *ramid* = “root” in the Afar language) Hominin species established in 1994 by White et al. to accommodate cranial and postcranial fossils recovered from c.4.5–4.4 Ma localities at **Aramis** on the northeastern flank of the **Central Awash Complex** in the **Middle Awash study area**, Ethiopia. The authors claimed *Ar. ramidus* shares some features with living species of *Pan*, has other features that are shared with the African apes in general and, crucially, has several dental and cranial features that are shared only with later hominins such as *Australopithecus afarensis*. The taxon was initially included within the genus *Australopithecus*, but it was subsequently transferred to a new genus, *Ardipithecus* (White et al. 1995). Fossils recovered from four localities (**Saitune Dora**, **Alayla**, **Asa Koma**, and **Digiba Dora**) in the **Western Margin** region of the Middle Awash study area were initially assigned to *Ar. ramidus* as a separate subspecies, *Ardipithecus ramidus kadabba* (Haile-Selassie 2001), but these and additional specimens were subsequently transferred to separate species, *Ardipithecus kadabba* (Haile-Selassie et al. 2004). The first reported additions to the *Ar. ramidus* **hypodigm** came from the **Gona** study area (Semaw et al. 2005), but subsequently more fossils, including the **ARA-VP-6/500** associated skeleton, recovered from the **Aramis** locality (White et al. 2009a), as well as from two other localities, **Kuseralee Dora** and **Sagantole**, in the **Central Awash Complex** have also been reported (White et al. 2009a). Initial estimates based on the size of the shoulder joint suggested that *Ar. ramidus* weighed about 40 kg, but researchers claim the enlarged hypodigm indicates an estimated body mass of approximately 50 kg (Lovejoy et al. 2009d). The chewing teeth of *Ar. ramidus* are relatively small and the position of the **foramen magnum**, the form of the reconstructed pelvis, and the morphology of the lateral side of the foot have all been cited as evidence that the posture and gait of *Ar. ramidus* were respectively more upright and bipedal than is the case in the living apes. The enamel covering on the teeth is not as thin as that of chimpanzees/bonobos, but it is not as thick as that seen in archaic hominins such as *Au. afarensis* (Suwa et al.

2009a). White et al. (2009a) claim that *Ar. ramidus* is a basal hominin, but this assessment implies that “dental and locomotor specializations evolved independently in each extant great ape genus” (Suwa et al. 2009a, p. 99), and the researchers who judged *Ar. ramidus* to be a basal hominin suggest that its discovery “highlights the alacrity with which similar anatomical structures can emerge,”...“resulting in convergent adaptations” (White et al. 2009a, p. 81). However, by including *Ar. ramidus* in the hominin clade the researchers who found and described it are implicitly assuming there is little, or no, evidence of such “convergent adaptations” (i.e., convergent evolution) in the hominin clade. Yet the inclusion of *Ar. ramidus* in the hominin clade necessitates substantial amounts of convergent evolution in the closely related clades that include the extant great apes. Indeed, the hypothesis that *Ar. ramidus* is not a hominin, but instead is a member of an extinct ape clade, would, in many respects, be more parsimonious than assuming it is a basal hominin. First discovery ARA-VP-1/1 (1993) (N.B.: but if either a mandible, KNM-LT 329, from Lothagam, Kenya or the mandible KNM-TH 13150 from Tabarin, Kenya, prove to belong to the *Ar. ramidus* hypodigm, then they would be the initial discovery). Holotype ARA-VP-6/1 (1993). Paratypes ARA-VP-1/1-4, -1/125, -1/127-9, -1/182, -1/183, -1/200, -1/300, -1/400, -1/401, -1/500, -7/2. Main sites Localities in the Gona and Middle Awash study areas, Ethiopia.

***Ardipithecus ramidus kadabba* Haile-Selassie, 2001** A new subspecies of *Ardipithecus ramidus* proposed by Haile-Selassie (2001) to accommodate 11 fossils recovered from localities in the Western Margin of the Middle Awash study area. When additions were made to the hypodigm Haile-Selassie et al. (2004b), the subspecies was elevated to the level of a separate species as *Ardipithecus kadabba* Haile-Selassie et al., 2004. *See Ardipithecus kadabba* Haile-Selassie et al., 2004.

Arene Candide (Location 44°10'N, 8°20'E, Italy) History and general description A large cave site located on the Ligurian coast of Italy, about 90 m above sea level. Excavations by Bernabo Brea and Cardini began in the early 1940s and culminated in 1942 when the burial of Arene Candide I was discovered; WWII halted work shortly there-

after and it did not resume until 1970, under the direction of Cardini. Temporal span and how dated? Using radiocarbon dating, Arene Candide I assigned an age of 23,440 ± 190 years BP. The upper layers (3–4) were radiocarbon dated to 11,750 ± 95 years BP. Hominins found at site The ceremonial burial of an adolescent *Homo sapiens* male, Arene Candide I, was found in layer 10. The ornate nature of the burial prompted workers to nickname the skeleton “Il Principe” or the prince. At least seventeen other burials dating from the latest Pleistocene have been recovered, many of which are also ornately decorated. Archeological evidence found at site Arene Candide I was found in a bed of red ocher, with a probable cap made of perforated shells and deer bones on its head. Mammoth ivory pendants, a long flint blade, and four perforated elk antler batons also adorned the skeleton. The later burials of the site similarly include ochre and perforated shells, but also have painted pebbles and bone ornaments. A Gravettian industry characterizes the lower layers, whereas the upper layers have a late Epigravettian microlithic industry. Key references: Geology, dating, and paleoenvironment Pettitt et al. 2003; Hominins Cardini 1980, Sergi et al. 1974; Archeology Bietti 1994.

argon-argon dating An isotopic dating method based upon the K/Ar system, in which radioactive ⁴⁰K is driven to ⁴⁰Ar in a reactor, and used as a proxy of K content. Subsequent analyses can be done in a single experiment, by measuring isotopes of Ar in a mass spectrometer. This approach avoids the necessity of separate measurements of K and Ar (in different aliquots of a sample), thus reducing potential error. As a result, single-crystal age determinations have become a possibility. The method has been used to date materials as young as the 79 AD eruption of Vesuvius (Renne et al. 1997) but most applications are to much older rocks. The analytical methods are so sensitive they can be applied to single crystals of feldspar or volcanic glass, and this more precise version is referred to as single-crystal laser fusion ⁴⁰Ar/³⁹Ar dating (e.g., McDougall and Brown 2008).

ARI The acronym for the Aralee Issie collection area. ARI is used as the prefix for fossils recovered from the Aralee Issie collection area, **Woranso-Mille study area**, Afar, Ethiopia. *See also Aralee Issie.*

Aristotle University of Thessaloniki, Department of Geology [Description](#) The School of Geology belongs to the Faculty of Sciences of the Aristotle University of Thessaloniki founded in 1925. arithmetic mean A method for calculating the average of a set of numbers, it is the method commonly referred to simply as the mean. A sample of n values are summed and divided by n . For example, the arithmetic mean of X_1 , X_2 , X_3 , and X_4 is $(X_1+X_2+X_3+X_4)/4$. There are alternative methods to calculate the mean of a set of numbers, such as the **geometric mean**.

ARL Acronym for Abdur Reef Limestone. *See* **Abdur**.

armature (L. *armatura* = armor or equipment) A term used to refer to any item used for offense or defense. In archeology the term armature refers to most **points** and any other obvious hunting equipment (e.g., the wooden spears from **Schöningen**).

array (L. *arredare* = to arrange) An array has two meanings in molecular biology. First, it can be an “orderly arrangement” of repetitive DNA in the genome that has a similar sequence. Such arrays include **microsatellites** and **satellite DNA**. Second, an array is also used in the sense of a microarray, which is a piece of glass that has molecules of DNA, RNA, or protein affixed to it in an orderly arrangement. These microarrays are used to capture molecules of interest. For example, they can be used to identify copy-number variants (or CNVs), DNA expression, or proteins.

Arsuaga Ferreras, Juan Luis (1959–) Born in Madrid, Spain, Juan Luis Arsuaga displayed an early interest in human evolution and prehistory and he earned both his masters and doctoral degree in biological sciences at the Complutense University of Madrid. In 1982 Arsuaga became a member of the excavation team, headed by Emiliano Aguirre, that was investigating potential hominin cave sites in the Sierra de Atapuerca, which is 14 km/8.7

miles east of Burgos in northern Spain. The Sierra de Atapuerca contains many caves and its two most famous sites, the **Sima de los Huesos** and **Gran Dolina**, have yielded some of the earliest hominin fossils and stone tools in Western Europe. Access to the Sima de los Huesos was particularly hazardous, but by 1991 the infrastructure needed to access the cave was in place and the team began excavations with Arsuaga codirecting the effort, together with José María Bermúdez de Castro and Eudald Carbonell i Roura. The Sima de los Huesos has proved to be a rich source of well-preserved pre-modern *Homo* fossils, all of which are assigned to either *Homo neanderthalensis* or *Homo heidelbergensis*. Arsuaga also helped explore and excavate the TD6 level at the Gran Dolina site where six individuals and 268 lithic artifacts were recovered; the hominins from Gran Dolina cave have been assigned to *Homo antecessor*. In 1997, the Atapuerca team won the Prince of Asturias Award for Technical and Scientific Research and the Castilla y León Prize in social sciences and humanities, and in 2000 UNESCO added the Pleistocene sites of the Sierra de Atapuerca to their list of World Heritage Sites. Currently, Arsuaga is a professor at the Complutense University of Madrid in the Faculty of Geological Sciences in the Paleontology Department where he serves as the Director of the Center of Evolution and Human Behavior (UCM-ISCIH). Arsuaga is vice-president of the Commission of Human Paleontology and Paleocology of the International Union Quaternary Research (INQUA). He is a Foreign Member of the US National Academy of Sciences and a member of the Real Academia de Doctores de España.

art (L. *art* = art) The term art refers to the use of non-utilitarian images for symbolism or self-expression. Prehistoric art is divided into mobile (L. *mobilis* = to move) or portable art (e.g., small figurines), and parietal (L. *paries* = wall) or fixed art (e.g., wall paintings or engravings).

artifact Any portable object made, modified, or used by hominins. The earliest artifacts presently known are stone tools and their manufacturing debris from the site of Gona, Ethiopia, dating to 2.55 Ma, although indirect traces of stone tool use may be preserved as cutmarks on bones from the surface at Dikika, Ethiopia dating to 3.39 Ma, but the latter will require additional finds of comparable age for wide acceptance. Because they preserve well, stone tools

form the largest part of the early archeological record, although comparison with extant primates suggests that artifacts of perishable materials (e.g., wood or fiber) remain difficult to detect and their origins may well remain in the realm of speculation. Artifacts are one of the fundamental units of analysis for archeologists.

artiodactyl The informal name for the *Artiodactyla*, the mammalian order that includes all the taxa with an even number of hoofed toes. *See also* *Artiodactyla*.

Artiodactyla (Gk *artios*=even and *daktulos*=toe; literally, the “even-toed”) The name of the mammalian order that includes all the taxa with an even number of hoofed toes. Artiodactyl fossils are common within some hominin faunal communities. The order *Artiodactyla* is now often subsumed within the clade *Cetartiodactyla*, named to reflect the recent DNA studies showing that whales and artiodactyls are closely related (e.g., Ursing and Arnason 1998). There are both ruminating, called **ruminants**, and non-ruminating groups of artiodactyls. Artiodactyls are **terrestrial** and largely **herbivorous**, although some artiodactyl taxa (e.g., the *Suidae*) are more omnivorous. The most diverse family of artiodactyls is the *Bovidae* (antelopes and their allies), although in Africa other common families within this order are the *Suidae* (pigs), the *Hippopotamidae* (hippopotamus), and the *Giraffidae* (giraffes). Other, less common artiodactyls in African hominin sites are the *Camelidae* (camels) and the *Tragulidae* (chevrotains). In Eurasia, the *Cervidae* (deer) are common at hominin sites, as are the *Moschidae* (musk deer). There are other artiodactyl families, both extant and extinct, but these are not known from hominin sites. The earliest known artiodactyl, *Diacodexis*, is from the early Eocene of Portugal.

AS Acronym for Abdur South. *See* *Abdur*.

As Duma (Location 11°10'N, 40°20'E, Ethiopia; etym. named after a local drainage) History and general description Site on the west side of the Awash River in the **Gona Western Margin** sector of the **Gona Paleoanthropological Research Project** study area in the Afar Depression. Located in the headwaters of the Busidima and Gawis drainages. Temporal span Sediments are *c.*4.4 Ma. Hominins found at site Remains of *Ardipithecus ramidus* have

been recovered from several localities. Archeological evidence found at site None. Key references: Geology, dating, and hominins Semaw et al. 2005.

Asa Issie (Location 11°10'N, 40°20'E, Ethiopia; etym. named after a local drainage) History and general description An area of fossiliferous sediments 10 km/6 miles west of **Aramis**. The hominin-bearing localities called Asa Issie and Hana Hari are in exposures of the Adgantole Member of the **Sagantole Formation**. Temporal span The sediments have been dated using biochronology to *c.*4.2–4.1 Ma. Hominins found at site The hominin fossils recovered there, that include a partial maxilla (ARA-VP-14/1), two sets of associated teeth (ASI-VP-2/2 and -2/334), and three postcranial specimens (ASI-VP-2 and -5, and ASI-VP-5/154), have all been assigned to *Australopithecus anamensis*, but are claimed to be transitional between *Ardipithecus ramidus* and *Au. anamensis*. Archeological evidence found at site None. Key references: Geology, dating, and hominins White et al. 2006b.

Asa Koma An area of fossiliferous exposures that lies against the **Western Margin** of the Afar Depression section of the **East African Rift System** in the **Middle Awash study area**, Ethiopia.

ascertainment bias (L. *ad*=near and *certus*=to determine, so certain came to mean “indisputable”; ascertainment is the process of discovering something indisputable by experimentation, so ascertainment bias is a synonym for experimental bias) Refers to the circumstances when **nonrandom sampling** produces false results. Such biases can lead to incorrect inferences about an entire **population** either because of distorted or non-typical sampling of the population, or because the data (i.e., a specific marker) used for the analysis were identified in a biased way. For example, in modern humans many of the first **polymorphic** markers were identified through surveys of Europeans. When these markers were examined, Europeans were found to be the most diverse of the limited numbers of modern humans included in the sample. However, when the modern human samples were expanded to better reflect modern humans across the world (i.e., the geographic representation of “modern humans” was unbiased) the results then showed that modern humans from Africa and not

Europeans are the most diverse (Rogers and Jorde 1996, Wakeley et al. 2001).

Asfaw, Berhane (1954–) Born in Gondar Province, Ethiopia, Berhane Asfaw taught chemistry and physical science in high school in Gondar before moving in 1978 to Addis Ababa to work in the Centre of Research and Conservation of Cultural Heritage in the Ministry of Culture and to attend Addis Ababa University, graduating with a BSc in geology in 1980. He then moved to the University of California, Berkeley, USA where he studied for an MA and PhD, gaining the latter in 1988 for a thesis entitled “New perspectives on the evolution of the hominid frontal bone.” He returned to Addis Ababa where he became paleoanthropology coordinator at the Centre for Research and Conservation of Cultural Heritage and then in 1990 he was appointed the Director of the National Museum of Ethiopia, a post he held until 1992. Since 1997 he has managed the Rift Valley Research Service. Berhane Asfaw’s paleoanthropological fieldwork began in 1980 when he worked at **Melka Kunturé**, but his important involvement with the **Middle Awash research project** began in 1981. In 1983 he reported the discovery of a parietal fragment from **Bodo** and since then he has been either the first author, or a co-author, of papers that have reported the discovery of hominin fossil evidence from **Olduvai Gorge** (Johanson et al. 1987), **Belohdelie** (Asfaw 1987), **Maka** (White et al. 1993), **Konso** (Suwa et al. 1997), **Bouri** (Asfaw et al. 2002), **Herto** (White et al. 2003), and **Aramis** (White et al. 2009a), and announced new taxa, including *Australopithecus ramidus* (White et al. 1994) and *Australopithecus garhi* (Asfaw et al. 1999). He was also the lead organizer of the Paleoanthropological Inventory of Ethiopia. In recognition of his contributions to paleoanthropology, in 2008 Berhane Asfaw was elected as a foreign associate of the US National Academy of Sciences and in 2010 a fellow of the Ethiopian Academy of Sciences. *See also* **Paleoanthropological Inventory of Ethiopia**.

ASI Acronym for the Asa Issie collection area. It is used as the prefix for fossils recovered from **Asa Issie, Middle Awash study area, Ethiopia**.

ASK Acronym for the Asa Koma collection area. It is used as the prefix for fossils recovered from

Asa Koma, Western Margin, Middle Awash study area, Ethiopia.

aspartic acid (etym. a non-essential amino acid found in asparagus, hence its name) It is an empirical observation that fossil bones in which (a) the amino acid content is more than 30,000 parts per million, (b) the ratio of glycine to aspartic acid is between 2 and 10, or (c) the amount of racemized aspartic acid is low (D/L ratios <0.10) are likely to contain sufficient DNA to warrant further analysis (Poinar et al. 1996). *See also* **amino acid racemization dating**.

ASPM *See* **brain size evolution, molecular basis of**.

assemblage Generally, any collection of objects. For archeologists, an assemblage is a stratigraphically bounded spatially associated set of **artifacts**. For example, a single archeological site may contain several artifact assemblages (e.g., as is the case at many of the excavations at **Olduvai Gorge**). These may derive from different **strata** at the site, or from different **facies** within the same stratum (e.g., from channel and floodplain deposits of the same river system). Assemblages form one of the basic comparative units above the level of single artifacts or artifact types, and variations within an assemblage in the range of tool types found have been used to infer past site function(s) (e.g., Binford and Binford 1969 for French **Mousterian** sites). Also used as an inclusive term to describe all the paleontological evidence from a site.

assimilation model A model for the origin of modern humans that accepts an African origin for the biological complex characteristic of modern humans but rejects a total replacement of local archaic populations, including *Homo neanderthalensis*, by modern humans as they spread into Eurasia. This perspective grew out of morphological observations suggesting the archaic contribution to modern human populations throughout Eurasia (and possibly parts of Africa) was always relatively small, though not insignificant, and was limited to morphological details rather than fundamental morphological gestalt. First fully articulated in 1989 (Smith et al. 1989), aspects of the assimilation model were emerging by the mid-1980s. Beginning at this time, the application of **thermoluminescence dating** and **electron spin**

resonance spectroscopy dating to fossil samples in Africa, the Near East, and Europe began to show that modern human anatomy clearly was established earlier outside of Europe than within that continent and also that Neanderthals survived until relatively late in some portions of Europe. This, along with early observations on the origin of extant human mitochondrial DNA, appeared to weaken the possibility of a classical **multiregional hypothesis** for modern human origins. Some “intermediate models,” such as the **replacement with hybridization** model accept the theoretical possibility of admixture but reject any morphological evidence for it. In contrast, the assimilation model has consistently held that evidence for continuity in morphological details is demonstrable in late archaic and early modern human samples in various portions of Eurasia. The assimilation model is consistent with the mostly out-of-Africa genetic model of modern human origins and with the recent evidence from the Neanderthal genome project indicating low levels of Neanderthal contribution to modern Eurasian populations. Recent statements of the assimilation model are found in Smith et al. (2005), Trinkaus (2005, 2007), Smith (2010).

associated skeleton (L. *associare* = to join with) Refers to a fossil specimen that includes more than one skeletal element from the same individual. The term is sometimes used in a more restricted sense to refer to specimens that include evidence of *both* the **skull** and the postcranial skeleton, or *more than one* part of the postcranial skeleton. Associated skeletons are particularly valuable specimens for several reasons. First, most fossil **hominin** taxa are diagnosed and identified on the basis of skull morphology, so associated skeletons that include skull and postcranial elements help sort out which limb bones go with which skulls. For example, the lack of a securely associated skeleton of *Paranthropus boisei* that preserves both taxonomically distinctive skull evidence *and* evidence of the postcranial skeleton is hampering attempts to sort postcranial fossils from East Africa into taxa. Second, because the evidence is from a single individual well-preserved associated skeletons allow researchers to compare the size of the teeth with the rest of the body, or the relative lengths of the limbs and/or limb segments, or the relative sizes of joint surfaces. Examples of associated skeletons include A.L. 288-1 (*Australopithecus afarensis*), KNM-WT 15000 (*Homo ergaster*), and Dederiyeh 1 (*Homo neanderthalensis*).

association cortex (L. *cortex* = husk, shell) This term refers to areas of the **neocortex** that are *not* concerned with the primary processing of sensory or motor information. Association cortex comprises part of the **prefrontal cortex**, the **limbic cortex**, and large regions of the **parietal cortex**, temporal cortex, and occipital cortex. The association cortices are concerned with the higher-order processing and integration of sensory modalities, abstract thinking, and the planning of movements.

asterionic notch (Gk *aster* = star) The asterion is a bilateral bony landmark on the **cranial vault** where the lambdoidal, parietomastoid, and occipitomastoid sutures meet. In modern human crania the mastoid angle of the parietal, the lateral margin of the occipital squame, and the posterior angle of the mastoid portion of the temporal bone articulate in an “edge-to-edge” fashion. But in the African apes, in which **compound temporal-nuchal crests** frequently dominate this part of the vault, the mastoid angle of the parietal is a laterally flaring, nearly horizontal, shelf of bone that fits into a narrow, reciprocal slot in the temporal bone between the base of the squamous and the mastoid portion; the mastoid fits between the flared mastoid angle superiorly and the lateral margin of the nuchal plane (occipitomastoid suture) medially (Kimbel and Rak 1985). Kimbel referred to this morphology as the “asterionic notch” (White et al. 1981, p. 456), whereas Delattre and Fenart (1960) called the tip of the mastoid angle the “angle incisural du parietal,” and the deepest (i.e., most lateral) part of the female part of the bevel in the temporal the “point incisural externe”. This type of asterionic notch articulation is also seen in most crested *Australopithecus afarensis* crania (e.g., A.L. 333-45, A.L. 444-2), including some small, presumably female, individuals (e.g., A.L. 162-28). Large, presumed male, *Paranthropus boisei* crania exhibit different anatomy in this region: the posterior part of the temporal squame overlaps the non-flared mastoid angle of the parietal, which, in turn, overlaps the occipital squame in a beveled imbrication of these bones. In this species the overlap of the temporal squame on the parietal is superiorly extensive further anteriorly, as evidenced in specimens with missing or damaged temporal bones by rugose ridges running

superomedially high up on the exposed parietal surface toward the midline of the vault. *See also* striae parietalis.

astrochronology *See* astronomical time scale.

astronomical theory (Gk *astron* = star and *kronos* = time) Joseph Adhemar, James Croll, and John Murphy each suggested the intensity of the sun's rays could drive glacial cycles, but it was Milutin Milanković, a Serbian astronomer, who provided the mathematical foundation for what became known as astronomical theory. The theory suggests that cyclic changes in three important aspects of the Earth's orbital geometry (precession, obliquity, and eccentricity) largely determine long-term changes in climate. Evidence supporting the theory of astronomical pacing of Earth's climate came from cyclical events in ocean sediments (Hays et al. 1976). *See* astronomical time scale.

astronomical time scale (Gk *astron* = star and *kronos* = time) A geological time scale based on regular changes involving three aspects of the Earth's orbital geometry (i.e., the way it rotates about its axis and the shape of its orbit around the sun), namely precession, obliquity, and eccentricity. Precession, or the "wobble" of the Earth's axis of rotation, has a cycle that completes every 19–23 ka. Precession controls the seasonality of the intensity of the sun's rays on the Earth's surface (called insolation). For example, stronger summer insolation means stronger monsoon intensity. Obliquity, or the tilt of the Earth's axis, has a dominant periodicity of *c.*41 ka and it controls the length of the winter polar darkness. Eccentricity, or the elliptical nature of the Earth's orbit, has *c.*100 and *c.*400 ka cycles. It is thought that obliquity determines the timing (the pacing) of the northern hemisphere glacial cycles with less summer insolation at 65°N resulting in less summer melting and more glacier growth. Note that only eccentricity changes insolation, and even then by a very small amount; the other orbital cycles change only the seasonality or latitudinal distribution of insolation. The climate has not always been uniformly sensitive to these ongoing orbital cycles. Precession has had a long-term influence on the strength of the monsoons (the "23 ka world"). Only at times of global cooling and northern

hemisphere glaciation, as has been the case for the last 3 Ma, do strong signals of obliquity (the "41 ka world") emerge; obliquity paces the timing of glacial/interglacial cycles. For the last 1 Ma, *c.*100 ka-long cycles appear to dominate (called the "100 ka world"). Eccentricity might be driving these cycles, or ice-sheet dynamics might instead be responding to multiples of two or three obliquity cycles. The regularity of these various cycles is such that astrochronology can be used to calibrate, or "tune," other forms of age estimation. (syn. astrochronology). *See also* orbital tuning.

AT Abbreviation of Arala Issie Tuff.

Atapuerca (Location 42°21'N, 3°31'W, Spain) The Sierra de Atapuerca is a series of eroded limestone hills 14 km/9 miles east of Burgos in Northern Spain. It is permeated by several sediment-filled cave systems, one of which is the Cueva Mayor-Cueva del Silo, and within this system are several cave/fissure complexes including the Sima de los Huesos. The first hominin fossils were recovered from the Sima de los Huesos (or SH) in 1976 and since then more than 6500 hominin fossils have been recovered from this location. Just 1 km/0.6 miles away is another system called Trinchera del Ferrocarril, which includes several sites (e.g., Galería, Gran Dolina, and Sima del Elefante), that have yielded hominin fossils and archeological evidence. Excavations at Gran Dolina (or TD) began in 1978 and six levels (TD3–4, 5–7, 10–11) have produced stone artifacts. In 1994 more stone tools and the first hominin fossils were recovered from the Aurora stratum, a lithostratigraphic level within TD6. The Sima del Elefante site, which may be 1.2 Ma, has provided the oldest hominin remains from the Atapuerca hills. *See also* Gran Dolina; *Homo antecessor*; *Homo heidelbergensis*; *Homo neanderthalensis*; Sima del Elefante; Sima de los Huesos.

atavism (L. *atavus* = ancestor, from *atta* = father plus *avus* = grandfather) The term used for a morphological variant or anomaly that usually appears in what is assumed to be an ancestor (recent or distant). Thus, the occasional appearance as a normal variant of contrahentes muscles in the palm of the hand of modern humans (Cihak 1972) would be an example of an atavism, as would be the presence of a rhomboideus occipitalis (Aziz 1981), or an

independent **os centrale** (Cihak 1972) in the carpal bones of the hand of a modern human (in modern humans the **os centrale** normally fuses with the main part of the scaphoid to form the scaphoid tubercle).

atavistic See **atavism**.

ATD Acronym for the Atapuerca – Gran Dolina. It is the prefix for fossils recovered from the **Gran Dolina** site within the Sierra de **Atapuerca**, northern Spain. The prefix ATD is followed by an Arabic number that indicates the **lithostratigraphic** level, then another Arabic number that indicates where in the sequence of **hominins** discovered in the cave that particular specimen was found (e.g., **ATD6-96** is the 96th hominin recovered from the ATD6 lithostratigraphic level).

ATD6-1 through ATD6-12 Site **Gran Dolina**. Locality “6 m² planar section” of TD6 (i.e., in the Aurora stratum). Surface/in situ In situ. Date of discovery July, 1994. Finders Team led by Eudald **Carbonell** and José María **Bermúdez de Castro**. Unit N/A. Horizon TD6. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Pre-780 ka (TD6 is assumed to be in the **Matuyama chron**) and **uranium-series dating** and **electron spin resonance spectroscopy dating** age is 731 ± 63 ka. Developmental age Young adult. Presumed sex Unknown. Brief anatomical description All of the remains, the mandible ATD6-5, plus the isolated teeth listed as ATD6-1-6-4 and ATD6-6-6-12, belong to a single individual, and they comprise the **holotype** of *Homo antecessor*. Announcement Carbonell et al. 1995. Initial description Carbonell et al. 1995. Photographs/line drawings and metrical data Carbonell et al. 1995. Detailed anatomical description Bermúdez de Castro et al. 1997, 1999, Rosas and Bermúdez de Castro 1999. Initial taxonomic allocation The holotype of *H. antecessor*. Taxonomic revisions None. Current conventional taxonomic allocation *H. antecessor*. Informal taxonomic category Pre-modern *Homo*. Significance The holotype of *H. antecessor*. Location of original **Centro Nacional de Investigación sobre la Evolución Humana**, Burgos, Spain.

ATD6-15 Site **Gran Dolina**. Locality “6 m² planar section” of TD6 (i.e., in the Aurora stratum).

Surface/in situ In situ. Date of discovery July, 1994. Finders Team led by Eudald **Carbonell** and José María **Bermúdez de Castro**. Unit N/A. Horizon TD6. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Pre-780 ka (TD6 is assumed to be in the **Matuyama chron**) and **uranium-series dating** and **electron spin resonance spectroscopy dating** age is 731 ± 63 ka. Developmental age Adolescent. Presumed sex Unknown. Brief anatomical description Frontal bone fragment with part of the right supraorbital torus. Announcement Carbonell et al. 1995. Initial description Carbonell et al. 1995. Photographs/line drawings and metrical data Carbonell et al. 1995. Detailed anatomical description Arsuaga et al. 1999. Initial taxonomic allocation *Homo antecessor*. Taxonomic revisions None. Current conventional taxonomic allocation *H. antecessor*. Informal taxonomic category Pre-modern *Homo*. Significance Most complete cranial vault fragment of *H. antecessor*. Location of original **Centro Nacional de Investigación sobre la Evolución Humana**, Burgos, Spain.

ATD6-69 Site **Gran Dolina**. Locality “6 m² planar section” of TD6 (i.e., in the Aurora stratum). Surface/in situ In situ. Date of discovery 1995. Finders Team led by Eudald **Carbonell** and José María **Bermúdez de Castro**. Unit N/A. Horizon TD6. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Pre-780 ka (TD6 is assumed to be in the **Matuyama chron**) and **uranium-series dating** and **electron spin resonance spectroscopy dating** age is 731 ± 63 ka. Developmental age Juvenile. Presumed sex Unknown. Brief anatomical description Much of the lower part of the face of a juvenile hominin. It includes the nasal floor and the floor of the right orbit, plus the roots and crowns of the right I², P³⁻⁴, and M¹, and the left P³ and M¹. Announcement Bermúdez de Castro et al. 1997. Initial description Bermúdez de Castro et al. 1997. Photographs/line drawings and metrical data Bermúdez de Castro et al. 1997. Detailed anatomical description Arsuaga et al. 1999. Initial taxonomic allocation *Homo antecessor*. Taxonomic revisions None. Current conventional taxonomic allocation *H. antecessor*. Informal taxonomic category Pre-modern *Homo*.

Significance The most complete specimen in the hypodigm of *H. antecessor*. **Location of original** Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain.

ATD6-113 **Site** Gran Dolina. **Locality** Between squares G-13 and F-13. **Surface/*in situ*** *In situ*. **Date of discovery** 2006. **Finders** Team led by Eudald Carbonell and José María Bermúdez de Castro. **Unit** Silt layer identified as “Pep.” **Horizon** TD6. **Bed/member** N/A. **Formation** N/A. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** Pre-780 ka (TD6 is assumed to be in the Matuyama chron) and uranium-series dating and electron spin resonance spectroscopy dating age is 731 ± 63 ka. **Developmental age** Young adult. **Presumed sex** Male. **Brief anatomical description** The fragment consists of the left side of the mandibular corpus from the alveolus of the left M₁, the crowns and roots of the left M₂₋₃, and part of the base of the ramus including the lateral prominence. **Announcement** Bermúdez de Castro et al. 2008. **Initial description** Bermúdez de Castro et al. 2008. **Photographs/line drawings and metrical data** Bermúdez de Castro et al. 2008. **Detailed anatomical description** Bermúdez de Castro et al. 2008. **Initial taxonomic allocation** By inference it is assigned to *Homo antecessor*. **Taxonomic revisions** None. **Current conventional taxonomic allocation** *H. antecessor*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** Resembles the morphology of the more complete ATD6-96 mandible. The combination of a reduced M₃ and a relatively primitive corpus morphology is reminiscent of the hominins from Dmanisi. **Location of original** Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain.

ATE Acronym for Atapuerca – Sima del Elefante. It is the prefix for fossils recovered from the Sima del Elefante site within the Sierra de Atapuerca, northern Spain. The prefix ATE is followed by an Arabic number that indicates the lithostratigraphic level, then another Arabic number that indicates where in the sequence of hominins discovered in the cave that particular specimen was found (e.g., ATE9-1 is the first hominin recovered from the ATE9 lithostratigraphic level).

ATE9-1 **Site** Sima del Elefante. **Locality** Square I-31. **Surface/*in situ*** *In situ*. **Date of dis-**

covery 2007. **Finders** Team led by Eudald Carbonell and José María Bermúdez de Castro. **Unit** “c”. **Horizon** TE9. **Bed/member** N/A. **Formation** N/A. **Group** N/A. **Nearest overlying dated horizon** TE9c (see below). **Nearest underlying dated horizon** N/A. **Geological age** A combination of biostratigraphy using rodents and insectivores, an observed reversed magnetic polarity (consistent with the TE16 and older lithostratigraphic layers being in the Matuyama chron), and the cosmic radionuclides ²⁶Al and ¹⁰Be giving an age of 1.22 ± 0.16 Ma for TE9c suggests the ATE9-1 mandible is 1.2–1.1 Ma. **Developmental age** Adult. **Presumed sex** Unknown. **Brief anatomical description** The mandibular corpus fragment extends from the alveolus of the left P₄ to the alveolus of the right M₁. The broken crowns of the right I₂ and C and the left C and P₃ are preserved, as are the roots of the left P₃ and I₂, and the right P₃ and P₄. The crown and root of the left P₄ is also preserved. **Announcement** Carbonell et al. 2008. **Initial description** Carbonell et al. 2008. **Photographs/line drawings and metrical data** Carbonell et al. 2008. **Detailed anatomical description** N/A. **Initial taxonomic allocation** Provisionally assigned to *Homo antecessor*. **Taxonomic revisions** None. **Current conventional taxonomic allocation** *H. antecessor*. **Informal taxonomic category** Pre-modern *Homo*. **Significance** At the time of its discovery it was the earliest reliably dated hominin from Europe. **Location of original** Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain.

Aterian (etym. the name is based on Bir el Ater, a community near the type site of this industrial complex) An industrial complex of the African Middle Stone Age. The type site for the Aterian is Oued Djebbana, Algeria (Morel 1974). Aterian sites occur in northern Africa, from the Maghreb (i.e., the northern parts of Morocco, Algeria, and Tunisia), south to Niger, throughout the Sahara and east to Egypt. Tanged pieces (especially points and scrapers) as well as bifacial points characterize Aterian sites, and these co-occur with a range of otherwise typical Mousterian elements such as side scrapers and diverse Levallois flakes and cores, as well as blades (Wendorf and Schild 1992). The tangs are considered an adaptation for hafting, and the tanged (or pedunculate) pieces are sufficiently distinct that Clark (1988) and McBrearty and Brooks (2000) use

the Aterian as one of the strongest cases for early regional diversity in the archeological record of the Middle Stone Age. Aterian sites may be locally contemporary with other assemblages that lack tanged pieces, and the extent to which the tanged pieces reflect temporal or group variation rather than activity-specific elements of a more generalized toolkit remains unclear (Wendorf and Schild 1992). Aterian sites were formerly considered to date to less than 40 ka, but subsequent age estimates by optically stimulated luminescence dating, thermoluminescence dating, and electron spin resonance spectroscopy dating methods suggests that this age simply represents the upper limit of the conventional radiocarbon dating method previously used. New results from Mugharet el 'Aliya and other sites suggest an antiquity of approximately 35–90 ka for the Aterian (Garcea 2004). Although limited evidence from some sites suggests occupation during conditions more humid than the present, Aterian populations occupied a range of habitats, including desert areas in the present Sahara (Garcea 2004, Vanhaeren et al. 2006). A perforated *Nassarius gibbosulus* shell from Oued Djebbana was transported more than 200 km/144 miles from the Mediterranean Sea (Morel 1974, Vanhaeren et al. 2006), and green silicified tuff used to make artifacts at Adrar Bous, Algeria, were apparently transported 280 km/170 miles (Clark 1993). Such long-distance transport strongly suggests that Aterian populations were either highly mobile and/or had highly developed exchange networks, and it is consistent with expectations for desert-adapted populations. At Dar es Soltane II, Témara (Grotte de Contrabandiers), and Zouhrah (El Harhoura), Aterian artifacts are associated with hominin fossils generally considered to be robust examples of *Homo sapiens*.

Atlanthropus Arambourg, 1955 (Gk *Atlas* = refers to the proximity of the site to the Atlas Mountains, a system of ranges and plateaus in northwest Africa extending from Morocco to Tunisia, and *anthropos* = human being). The taxonomic name given by Camille Arambourg to the genus he established to accommodate a new species he provisionally proposed for three hominin mandibles and a cranial fragment recovered by Arambourg and Hoffstetter in June, 1954 at Ternifine (now called Tighenif), near Mascara, Algeria, in the foothills of the Atlas mountains. Although Arambourg noted the new mandibles

were “very closely related to the Asiatic *Pithecanthropus* and *Sinanthropus*” and that “some features (are) reminiscent of the australopithecines, *Telanthropus* particularly,” (Arambourg 1955, p. 195), he concluded that the fossils “cannot be identified exactly with either *Pithecanthropus* or *Sinanthropus* or *Telanthropus*” so he “assigned to them the provisional name, *Atlanthropus mauritanicus*” (*ibid*, p. 195). Arambourg’s paper was published in the same year as the first edition of Wilfrid Le Gros Clark’s *The Fossil Evidence for Human Evolution*, but in the second, 1964, edition, when discussing the fossil record for *Homo erectus*, Le Gros Clark concludes his discussion of the remains from what is now called Tighenif by writing that “there can be little doubt. . .that these remains do belong to the same species (i.e., to *H. erectus*)” (Le Gros Clark 1964, p. 112). Type species *Atlanthropus mauritanicus* Arambourg, 1955. *See Homo erectus*.

Atlanthropus mauritanicus Arambourg, 1955 (Gk *Atlas* = refers to the proximity of the site to the Atlas Mountains, a system of ranges and plateaus in northwest Africa extending from Morocco to Tunisia, and *anthropos* = human being; L. *Mauritania* = the name of a province of the Roman Empire that is coincident with Morocco and Algeria). The taxonomic name given by Camille Arambourg to three hominin mandibles and a cranial fragment recovered by Arambourg and Hoffstetter in June, 1954 at Ternifine (now called Tighenif), near Mascara, Algeria, in the foothills of the Atlas mountains. Although Arambourg noted the new mandibles were “very closely related to the Asiatic *Pithecanthropus* and *Sinanthropus*” and that “some features (are) reminiscent of the australopithecines, *Telanthropus* particularly,” (Arambourg 1955, p. 195), he concluded that the fossils “cannot be identified exactly with either *Pithecanthropus* or *Sinanthropus* or *Telanthropus*” so he “assigned to them the provisional name, *Atlanthropus mauritanicus*” (*ibid*, p. 195). In 1964 Wilfrid Le Gros Clark formally suggested *Atlanthropus mauritanicus* be sunk into *Homo erectus*. First discovery Ternifine 1, now Tighenif 1 (1954). Holotype None formally proposed, but *de facto* it is Tighenif 1. Paratypes None proposed. Main site Ternifine (but if the Tighenif material proves to be conspecific with the hominin remains from Gran Dolina then *Atlanthropus mauritanicus* Arambourg, 1955 would

have priority over *Homo antecessor*, but because it was just a “provisional” name according to the **International Commission on Zoological Nomenclature** (or ICZN) rules it is therefore not an available name.). *See also* *Homo antecessor*; *Homo erectus*.

Atlantic Meridional Overturning Circulation (AMOC or MOC) Describes the net northward flow of surface water in the Atlantic associated with the Gulf Stream, then it sinking in the North Atlantic to form a current known as North Atlantic deep water which flows southward until it meets with the Antarctic bottom water current, at which point it rises to the surface and either returns northward or connects via the **Antarctic Circumpolar Current** to currents in other ocean basins. The overturning circulation in the Atlantic can be conceptualized as a conveyor belt carrying warm surface water northwards and cold deep oxygenated water southwards. It is thought that changes in the AMOC could cause large changes in continental climate around the Atlantic and also globally. This is because any reduction or interruption of this “conveyor belt” would drastically reduce the heat transported by the oceans from low to high latitudes.

attrition *See* tooth wear.

AU *See* **Anthracotheriid Unit**; **Toros-Menalla**.

auditory cortex *See* temporal lobe.

auditory ossicles (L. *audire* = to hear and *ossiculum* = small bone) Three small bones in the **middle ear**, or tympanic cavity, of mammals. They connect the tympanic membrane (which is at the medial end of the external ear) with the oval window (within which is the outer of the two fluid-filled cavities of the **inner ear**). The **malleus** (L. *malleus* = hammer) has a head (which occupies the epitympanic recess), a handle or manubrium, and a lateral process. The handle attaches to just below the center of the tympanic membrane and the head articulates with the body of the **incus**. The incus (L. *incudere* = to beat upon, hence an anvil) has a body, and two processes, short and long. The long process articulates with the head of the **stapes**. The stapes (L. *stare* = to stand and *pes* = foot, hence a stirrup) has a head, neck, two limbs (or crurae), and a footplate that

fits into the oval window beyond which is the perilymph-filled cochlear part of the inner ear. The footplate is hinged anteroinferiorly and moves like a constrained piston to compress the perilymph. The ossicles articulate via synovial joints; the malleus and incus move as a unit around a horizontal axis that coincides with the anterior ligament of the malleus and the posterior ligament of the incus. Excessive movement of the ossicles is prevented by muscles in the middle ear (the tensor tympani and stapedius attach to the malleus and stapes, respectively) that contract in response to noise above approximately 90 db. Some debate exists about the precise embryological origin of the ossicles, but it is generally believed that most of the malleus and incus develop endochondrally from the Meckel’s cartilage of the first **branchial arch** cartilage, while the head, neck, and crurae of the stapes develop from the second arch (hyoid) cartilage and the stapes footplate derives from the mesoderm of the otic capsule. Auditory ossicles attain their adult size prior to birth. They occasionally survive to be recognized as fossils [e.g., a *Paranthropus robustus* incus (SK 848), an *Australopithecus africanus* stapes (Stw 151)] and at the latest count approximately 25 ear ossicles had been recovered from the **Sima de los Huesos** at **Atapuerca**. *See also* **bony labyrinth**.

auditory tube (L. *audire* = to hear and *tubus* = hollow cylinder) The auditory tube connects the **middle ear** to the nasopharynx. The lateral one-third is bone (so this is the only part that fossilizes) and the medial two-thirds consists of fibrocartilage. The auditory tube is approximately 35 mm long in adult modern humans, and it is oriented 45° to the **sagittal** plane and 30° to the horizontal plane. In infants the auditory tube is shorter and more horizontally inclined; this is one of the reasons children are so prone to middle-ear infections. The auditory tube is inclined more closely to the sagittal plane in extant apes and in archaic hominins, and some specimens of *Paranthropus robustus* and *Australopithecus africanus* have club-like processes, called Eustachian processes, on the medial ends of the bony auditory tube (syn. Eustachian tube, pharyngotympanic tube, tympanic tube).

Aurignac (Location 43°13'22"N, 0°51'57"E, France; etym. Fr. after the nearby town) History and general description Aurignac cave (or Abri d'

Aurignac) is located the foothills north of the Pyrenees mountains. A road-worker found human bones in a shallow cave. Eight years later Édouard Lartet described its stratigraphic sequence and major artifacts, which later became the basis for establishing the “Aurignacian” culture. In 1938–9 Fernand Lacorre investigated Lartet’s backfill and excavated the unexplored terrace outside the cave. Temporal span and how dated? The site has not been dated, but the Aurignacian in Western Europe generally dates between 36 and 26 ka. Hominins found at site Apparently 17 individuals were removed from the site by the discoverer and buried in an unmarked grave. Because these fossils were found on the surface of the deposit, it is likely they post-date the Aurignacian. Archeological evidence found at site Lartet recovered stone and bone tools, bone beads, and abundant faunal remains. Key references: Geology, dating, paleoenvironment, hominins, and archeology Lartet 1861.

Aurignacian A material culture named after the site of **Aurignac** in France. Gabriel de Mortillet was the first to propose an Aurignacian industry for the unique combination of stone tool types, beads, and bone tools, but he abandoned it in his later classification schemes. The Aurignacian was reintroduced and redefined by Henri Breuil in the early 20thC. It is generally thought to be the oldest modern human (or Cro-Magnon) culture in Europe, although there are very few fossils that are securely dated to this time period. The hallmarks of this culture are the use of **blades**, **bone tools**, beads, and other objects of personal decoration, as well as figurines and other figurative art. Its appearance in Eastern Europe around 43 ka and in Western Europe between 40 and 36 ka is consistent with a migration of anatomically modern humans from the Near East. It is replaced by the **Gravettian** culture between 28 and 26 ka. *See also* **Aurignac**.

Aurora archaeostratigraphic set (AAS) Researchers now recognize six layers within the **Aurora stratum**, which is part of **TD6**, a lithostratigraphic level in **Gran Dolina**. The latter is one of the sites within the sediment-filled cave system called the **Trinchera del Ferrocarril**, which is in the Sierra de **Atapuerca**, a series of eroded limestone hills 14 km/9 miles east of Burgos in Northern Spain. *See also* **Aurora stratum**; **Gran Dolina**.

Aurora stratum A layer within **TD6**, which is a lithostratigraphic level in **Gran Dolina**, one of the sites within the sediment-filled cave system called the **Trinchera del Ferrocarril**, one of the cave complexes in the Sierra de **Atapuerca**, a series of eroded limestone hills 14 km/9 miles east of Burgos in Northern Spain. Researchers now recognize six lithostratigraphic layers within the **Aurora stratum**, and they refer to these as the **Aurora archaeostratigraphic set** (AAS).

Australasian strewn-field tektites From time to time the Earth collides with showers of small meteorites, called **tektites**. If the area of impact (the strewn-field) is widespread, and if the tektites are physically or chemically distinctive, and if they can be securely dated at least one location, strewn-field tektites can be used as a dating tool. The Australasian is the largest and the youngest of the major tektite strewn-fields. The *c.*800 ka strewn-field extends across most of Southeast Asia (Vietnam, Thailand, Southern China, Laos, and Cambodia), as well as the Philippines, Indonesia (including **Java**), and Malaysia. It also stretches into the Indian Ocean and south to the western side of Australia. The identification of Australasian strewn-field tektites in sediments is one of the many ways researchers have tried to date hominins from China and Southeast Asia.

australopith Informal name for some, or all, of the fossil **hominins** not included in the genus *Homo*. This term is not used consistently in paleoanthropology. Some workers use this term to categorize *all* non-*Homo* hominins, while others include only non-*Homo* hominins that exhibit **megadontia** (i.e., species typically attributed to *Australopithecus* and/or *Paranthropus*). The term is increasingly used in place of **australopithecine**, because the latter term should *only* be used if the writer believes that all *Australopithecus* and *Paranthropus* taxa belong in their own hominin subfamily, the **Australopithecinae**. Examples of australopith taxa include the **type species** of *Australopithecus*, *Australopithecus africanus*, and *Paranthropus boisei*. *See also* **australopithecine**.

Australopithecinae (L. *australis* = southern and Gk *pithekos* = ape) This formal name should only be used by those who conclude that all *Australopithecus* and *Paranthropus* taxa belong in a

hominin subfamily separate from the genus *Homo*. Some researchers have explicitly abandoned its use. For example, Robinson (1972a) sank *Australopithecus* into *Homo* and abandoned Australopithecinae in favor of a more encompassing Homininae. Anyone who supports all hominins being included within a single tribe cannot logically continue to refer to early hominin taxa as “australopithecines.” See also australopithecine.

australopithecine Informal name for the subfamily Australopithecinae. Strictly speaking this term should only be employed if the user supports elevating the archaic hominin taxa included in genera such as *Australopithecus* and *Paranthropus* to the level of a subfamily. More generally, the term has been used in the past to refer to all, or to most, of the early hominins that do not belong to the genus *Homo*, but researchers are increasingly adopting the term **australopithecine** for this purpose.

***Australopithecus* Dart, 1925** (*L. australis* = southern and Gk *pithekos* = ape) Hominin genus established by Raymond Dart in 1925 to accommodate the type species *Australopithecus africanus*. Because it has priority as the genus name for archaic Pliocene hominins, taxa such as *Paranthropus* and *Plesianthropus*, which were not recognized until 1938, have been sunk into *Australopithecus* by those who recognize only a single genus for these hominins. In the way the taxon is used by lumpers, the genus *Australopithecus* includes species that are bipeds with small brains, large cheek teeth, and small, nonhoning canines. However, it almost certainly subsumes taxa representing parts of more than one clade. Thus, it is very likely that *Australopithecus* is a paraphyletic group (i.e., the taxa it contains represent some, but not all, of the descendants of their most recent common ancestor). The list of species assigned to the genus *Australopithecus* has varied over time. From its discovery up until the seminal publications of John Robinson, the genus subsumed three species, *Au. africanus* from the site of Taung, *Australopithecus transvaalensis* (later, *Plesianthropus transvaalensis*) from Sterkfontein, and *Australopithecus prometheus* from Makapansgat. Robinson sank *Au. prometheus* and *Pl. transvaalensis* into *Au. africanus*, but he did not include the fossil hominins from Swartkrans and Kromdraai, which he interpreted as belonging to the genus *Paranthropus*. In subsequent decades it became conventional to assign all of

the above hominins as well as other species such as *Zinjanthropus boisei* and *Meganthropus africanus* to the genus *Australopithecus*. However, in the 1980s, the researchers who recognized the “robust” species as a monophyletic group revived the genus *Paranthropus* for *P. robustus*, *P. boisei*, and, eventually, *P. aethiopicus*, although many researchers still retain these species in *Australopithecus*. In 1994, a newly identified species, *Australopithecus ramidus*, was transferred to the genus *Ardipithecus* shortly after its initial description, and since that time several early hominin species have been discovered, described, and assigned to genera other than *Australopithecus* (e.g., *Orrorin*, *Sahelanthropus*, *Kenyanthropus*). Since 1996, four new species of *Australopithecus* have been described (*Australopithecus anamensis*, *Australopithecus bahrelghazali*, *Australopithecus garhi*, and *Australopithecus sediba*). In recent years, the evident paraphyly of *Australopithecus* has led a minority of researchers to advocate removing species from the genus until there is sound evidence that it is clearly monophyletic. This position has not gained widespread support, although some workers have transferred the hypodigm of *Au. afarensis* to the genus *Praeanthropus*. See also *Praeanthropus*.

***Australopithecus aethiopicus* (Arambourg and Coppens, 1968)** (*L. australis* = southern, Gk *pithekos* = ape and *aethiopicus* = Ethiopia) A taxon used by researchers who recognize neither *Paraaustralopithecus* nor *Paranthropus* as separate genera, but who do recognize pre-2.3 Ma megadont hominins from the Omo region as a species separate from *Paranthropus boisei*. No one has formally suggested that this binomial be adopted, but Groves (1999) warns that if they did, it would result in homonymy because the taxon name *Australopithecus aethiopicus* is preoccupied by Tobias’s (1980b) usage of *Australopithecus africanus aethiopicus* for the Hadar component of the hypodigm of *Australopithecus afarensis*. See also *Paraaustralopithecus aethiopicus*; *Australopithecus africanus aethiopicus*.

***Australopithecus afarensis* Johanson, 1978** (*L. australis* = southern, Gk *pithekos* = ape and *afarensis* recognizes the contributions of the local Afar people) Hominin species established in 1978 by Donald Johanson and colleagues to accommodate the c.3.7–3.0 Ma cranial and postcranial remains recovered from Laetoli, Tanzania, and Hadar, Ethiopia. White

et al. (1981) compared the **hypodigms** of *Australopithecus afarensis* and *Australopithecus africanus* and made a compelling case for recognizing *Au. afarensis* as a distinct species with generally more primitive craniodental anatomy than *Au. africanus*; Kimbel et al. (1984, 2004), Wood (1991), and Strait et al. (1997) provide supplementary information about the morphological differences between the two hypodigms. Several researchers have drawn attention to dental, facial, and mandibular differences between the early Laetoli component of the hypodigm and the geologically younger Hadar fossils assigned to *Au. afarensis*, and to similarities between the Laetoli remains and those of *Australopithecus anamensis* (e.g., Ward et al. 1999, Kimbel et al. 2006). It remains to be seen whether these similarities are sufficient evidence to sustain the hypothesis that *Au. anamensis* evolved via **anagenesis** into *Au. afarensis*. Rak et al. (2007), on the basis of mandibular ramus form, revived the suggestion (originally advocated for part of the Hadar sample by Olson 1981) that *Au. afarensis* may be a primitive taxon of the clade that includes *Paranthropus boisei*, *Paranthropus robustus*, and *Paranthropus aethiopicus*. The main differences between *Au. anamensis* and *Au. afarensis* relate to details of the jaws and dentition, which are generally more primitive in the former taxon. The curved, receding anterior mandibular corpus and more rectangular dental arch of *Au. anamensis* contrasts with the *Au. afarensis* anatomy. In some respects the teeth of *Au. anamensis* are more primitive than those of *Au. afarensis* (for example, the asymmetry of the premolar crowns and the relatively simple crowns of the deciduous first mandibular molars), but in others (for example, the low cross-sectional profiles and bulging sides of the molar crowns) *Au. anamensis* shows some similarities to *Paranthropus* (see below). The upper limb remains are similar to those of *Au. afarensis*, but a tibia attributed to *Au. anamensis* has features associated with **bipedalism**. Most body mass estimates for *Au. afarensis* range from approximately 30 to 45 kg and known endocranial volumes range between 385 and 550 cm³. This is larger than the average endocranial volume of a chimpanzee, but if the estimates of the body size of *Au. afarensis* are approximately correct then relative to estimated body mass the brain of *Au. afarensis* is not substantially larger than that of *Pan*. It has smaller incisors than those of extant chimps/bonobos, but

its premolars and molars are larger. The hind limbs of A.L. 288-1 are substantially shorter than those of a modern human of similar stature. The appearance of the pelvis and the relatively short lower limb suggests that although *Au. afarensis* was capable of bipedal walking, it was not adapted for long-range bipedalism. This indirect evidence for the locomotion of *Au. afarensis* is complemented by the discovery at Laetoli of several trails of fossil footprints. These provide very graphic direct evidence that a contemporary hominin, presumably *Au. afarensis*, was capable of bipedal locomotion. The upper limb, especially the hand and the shoulder girdle, retains morphology that some workers suggest reflects a significant element of arboreal locomotion. The size of the Laetoli footprints, the length of the stride and stature estimates based on the length of the limb bones suggest that the standing height of adult individuals in this early hominin species was between 1.0 and 1.5 m. Most researchers interpret the fossil evidence for *Au. afarensis* as consistent with a substantial level of **sexual dimorphism**. A few researchers have suggested that sexual dimorphism in *Au. afarensis* is relatively poorly developed (Reno et al. 2003), but most researchers accept that this taxon shows a substantial level of sexual dimorphism. First discovery A.L. 128-1, 129-1 (1973). Holotype LH 4 (1974). Paratypes (e.g., see Johanson et al. 1978 for a complete list) LH 1, 3 (a-t), 3/6 a, 5, 6 (a-e), 7, 8, 10, 11, 12, 13, 14 (a-h); A.L. 128-1, 128-23, 129-1a-c, 129-52, 137-48a-b, 145-35, 161-40, 166-9, 198-1, 198-17a-b, 198-18, 199-1, 200-1a, 200-1b, 207-13, 211-1, 228-1, 241-14, 266-1, 277-1, 288-1, 311-1, 322-1, 333-1, 333-2, 333w-1a-e, 333x-1, 366-1, 388-1, 400-1a-b, 411-1. Main sites Belohdelie (tentative), Dikika, Hadar, Maka, and White Sands, Ethiopia, Koobi Fora, Kenya, and Laetoli, Tanzania. *See also Praeanthropus afarensis*.

***Australopithecus africanus* Dart, 1925**

(*L. australis* = southern, Gk *pithekos* = ape and *L. africanus* = pertaining to Africa) **Hominin species** established in 1925 by Raymond Dart for an immature **skull** recovered from the lime-works at Taungs (now called **Taung**) in 1924. As presently interpreted the taxon *Australopithecus africanus* includes, in addition to the type specimen from Taung, fossils from Member 4 at **Sterkfontein**, fossils initially assigned to *Australopithecus prometheus* from Members 3 and 4 at

Makapansgat, and fossils recovered from lime-workers dumps and extracted *in situ* from the breccia exposed at **Gladysvale**; the hypodigm spans the period between *c.*3.0 and 2.5 Ma. It remains to be seen whether the associated skeleton **StW 573** from Sterkfontein Member 2 and 12 hominin fossils recovered from the **Jakovec Cavern** since 1995 (Partridge et al. 2003) belong to the *Au. africanus* hypodigm; Clarke (2008) suggests they belong to a second, so far unnamed, *Australopithecus* taxon (see below). The hypodigm of *Au. africanus* is one of the better fossil records of an early hominin taxon. The cranium, mandible, and dentition are well sampled. The postcranium and particularly the axial skeleton are less well represented, but there is at least one specimen of each of the long bones. However, many of the fossils have been crushed and deformed by rocks falling on the bones before they were fully fossilized. The picture emerging from morphological and functional analyses suggests that although *Au. africanus* was capable of walking bipedally it was probably more arboreal than most other archaic hominin taxa. It had relatively large chewing teeth and apart from the reduced canines the skull is relatively ape-like. Its mean endocranial volume is approximately 460 cm³. The Sterkfontein evidence suggests that males and females of *Au. africanus* differed substantially in body size, but probably not to the degree they did in *Au. afarensis*. For a long time *Au. africanus* was regarded as the common ancestor of all later hominins, but the discovery of the even more primitive *Australopithecus afarensis* challenged that interpretation. In most cladistic analyses *Au. africanus* is either the sister taxon of *Homo* or *Paranthropus*, or the sister taxon of the common ancestor of the *Homo* and *Paranthropus* clades. Clarke (e.g., 1988, 1999, 2008) has consistently argued, and others have also suggested (Kimbel and White 1988), that the Sterkfontein Member 4 and Makapansgat hypodigm of *Au. africanus* samples a second, *Paranthropus*-like, *Australopithecus* taxon. Clarke (2008) would include Sts 1 and 71, StW 183, 252, 384, 498 and 505, and MLD 2 in the second *Australopithecus* species; the differences between the second taxon and *Au. africanus* relate to dental size and craniofacial structure; details are set out by Clarke (2008, p. 448). First discovery **Taung 1** (1924). Holotype As above. Paratypes None. Main sites Gladysvale, Makapansgat (Members 3 and 4), Sterkfontein (Member 4), and Taung.

***Australopithecus africanus aethiopicus* Tobias, 1980** Phillip Tobias (1980b) made two suggestions about *Australopithecus afarensis*. First, he claimed that *Au. afarensis* was not sufficiently different from *Australopithecus africanus* to merit recognition as a distinct species. Second, he considered the **Hadar** and **Laetoli** parts of the hypodigm were subspecifically distinct, proposing that the Hadar component of the hypodigm be referred to as *Australopithecus africanus aethiopicus*. See also *Australopithecus afarensis*.

***Australopithecus africanus afarensis* Johanson et al., 1978** Phillip Tobias (1980b) proposed that the **Laetoli** part of the *Australopithecus afarensis* hypodigm be referred to as *Australopithecus africanus afarensis*. Even though Tobias proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies) retains the name of the author who proposed the species (i.e., *Australopithecus africanus afarensis* Johanson et al., 1978). The describer of *Australopithecus afarensis* is Johanson et al., 1978, and nothing can alter that, not even the transfer of the type specimen to a subspecies. See also *Australopithecus afarensis*; *Australopithecus africanus aethiopicus*.

***Australopithecus africanus africanus* Dart, 1925** John Robinson (1954a) proposed that the **Taung 1** skull be referred to a subspecies of *Australopithecus africanus* as *Australopithecus africanus africanus*. He did this to distinguish the latter from the “Sterkfontein, Makapan and East Africa” (*ibid*, p. 196) subset of *Au. africanus* which he referred to a separate subspecies, *Australopithecus africanus transvaalensis*. Bernard Campbell (Campbell 1973) subsequently used the same **nomen** to apply to the whole of the hypodigm while most other researchers recognize the taxon at the specific level as *Australopithecus africanus*. Even though Campbell proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies) retains the name of the author who proposed the species (i.e., *Australopithecus africanus* Dart, 1925). The describer of *Au. africanus* is Dart, 1925, and

nothing can alter that, not even the transfer of the type specimen to a subspecies. *See also Australopithecus africanus*; *Australopithecus africanus transvaalensis*.

***Australopithecus africanus habilis* (Leakey, Tobias and Napier, 1964)** A subspecies of *Australopithecus africanus* introduced by Bernard Campbell (Campbell 1973) for the hypodigm most other researchers recognize at the specific level as *Homo habilis*. Even though Campbell proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies) retains the name of the author who proposed the species (i.e., *Homo habilis* Leakey, Tobias and Napier, 1964). The describers of *H. habilis* are Leakey, Tobias and Napier, 1964 and nothing can alter that, not even downgrading to a subspecies.

***Australopithecus africanus modjokertensis* (von Koenigswald, 1936)** A subspecies of *Australopithecus africanus* introduced by Bernard Campbell (Campbell 1973) for specimens from Indonesian sites Ralph von Koenigswald assigned to *Homo modjokertensis*. Most researchers now regard these specimens as being part of the hypodigm of *Homo erectus*. Even though Bernard Campbell proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies) retains the name of the author who proposed the species (i.e., *Homo modjokertensis* von Koenigswald, 1936). The describer of *H. modjokertensis* is von Koenigswald, 1936, and nothing can alter that, not even the downgrading of *H. modjokertensis* to a subspecies.

***Australopithecus africanus robustus* Broom, 1938 (Broom, 1938)** A subspecies of *Australopithecus africanus* introduced by Bernard Campbell (Campbell 1973) for the hypodigm most researchers recognize at the specific level as *Paranthropus robustus*. Even though Bernard Campbell proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies)

retains the name of the author who proposed the species (i.e., *Paranthropus robustus* Broom, 1938). The describer of *P. robustus* is Broom, 1938, and nothing can alter that, not even the downgrading of *P. robustus* to a subspecies.

***Australopithecus africanus tanzaniensis* Tobias, 1980** There is now wide acceptance that *Australopithecus afarensis* is a biologically valid species, but when Don Johanson, Tim White, and Yves Coppens set out the case for recognizing a new species for the hominins recovered from Hadar (Johanson et al. 1978) it met with spirited resistance from Phillip Tobias. In several publications (Tobias 1980a, 1980b) he laid out the detailed case for his claim that the authors had failed to demonstrate the new species was anything other than an East African variant of *Australopithecus africanus*, and thus should be recognized as a junior synonym of that taxon. In one of these publications, Tobias suggested that what was then called the Laetoli (now Laetoli) part of the *Au. afarensis* hypodigm be recognized at the level of a subspecies. He wrote “as we already have two southern African subspecies, *A. africanus africanus* and *A. africanus transvaalensis*, it would perhaps be appropriate to refer to this Tanzanian subspecies as *A. africanus tanzaniensis*” (Tobias 1980b, p. 107).

***Australopithecus africanus transvaalensis* (Broom, 1936)** John Robinson (1954a) proposed that this subspecies of *Australopithecus africanus* should be used to distinguish the australopiths from “Sterkfontein, Makapan and East Africa” (*ibid*, p. 196) from the Taung 1 skull, which he referred to a separate subspecies, *Australopithecus africanus africanus*. Even though John Robinson proposed the subspecies, according to the Principle of Coordination in the **International Code of Zoological Nomenclature** (Article 46.1) a name established for a taxon at either rank in the species group (i.e., species or subspecies) retains the name of the author who proposed the species (i.e., *Plesianthropus transvaalensis* Broom, 1938). The describer of *transvaalensis* is Broom, 1936, and nothing can alter that, not even the downgrading of *transvaalensis* to a subspecies. *See also Australopithecus africanus*; *Australopithecus africanus africanus*.

***Australopithecus anamensis* Leakey et al., 1995** (etym. *see Australopithecus* and

anam = means “lake” in the Turkana language) Hominin species established in 1995 by Meave Leakey et al. to accommodate a left distal humeral fragment, KNM-KP 271, recovered by Bryan Patterson (Patterson and Howells 1967), and cranial remains recovered from *c.*3.9–4.2 Ma localities at Allia Bay and Kanapoi, Kenya [additional fossils from the two sites were described 3 years later (Leakey et al. 1998)]. The authors claim *Australopithecus anamensis* teeth are more primitive than those of *Australopithecus afarensis* (e.g., mandibular canine morphology, the asymmetry of the premolar crowns, and the relatively simple crowns of the deciduous first mandibular molars), but in other respects (e.g., the low cross-sectional profiles and bulging sides of the molar crowns) the teeth of *Au. anamensis* show similarities to *Paranthropus* (see below). Upper limb remains were also recovered and were described as being australopithec-like (Leakey et al. 1998), but a tibia (KNM-KP 29283) attributed to *Au. anamensis*, but not included in the list of paratypes, has features associated with obligate bipedalism. White et al. (2006) reported 31 additional fossils from the Middle Awash study area. One, a maxilla, was found at Aramis, with the remainder coming from three localities at Asa Issie, a collecting area 10 km/6 miles west of Aramis. Biostratigraphic dating suggests an age of *c.*4.2–4.1 Ma for both sets of Middle Awash fossils. Craniodentally (e.g., anterior tooth and postcanine relative tooth size, crown morphology, enamel thickness, etc.) the new material from the Middle Awash is consistent with an attribution to *Au. anamensis* and ASI-VP-5/154, the proximal three-quarters of a right femur shaft, is a slightly more primitive version of the *Au. afarensis* femoral morphology. White et al. (2006) support the proposal made by others (e.g., Ward et al. 1999) that although the hypodigms of *Au. anamensis* and *Au. afarensis* are distinct there is evidence (e.g., relative canine size, upper canine morphology, enamel thickness, femoral shaft morphology, etc.) of the type of morphological continuity that one would expect to see within an evolving lineage, and Kimbel et al. (2006) provide compelling evidence that *Au. anamensis* and *Au. afarensis* are “parts of an anagenetically evolving lineage, or evolutionary species” (*ibid.*, p. 134). Suggestions that *Au. anamensis* might have been a hard-object feeder (e.g., Ward et al. 1999, Teaford and Ungar 2000, Macho et al. 2005, White et al. 2006b) are apparently not supported by dental

microwear evidence (Grine et al. 2006). First discovery KNM-KP 271 (1965). Holotype KNM-KP 29281 (1994). Paratypes KNM-KP 271, 29282–8; KNM-ER 7727, 20419–23, 20427–8, 20432, 22683, 24148, 30202, 30200. Main sites Allia Bay and Kanapoi, Kenya; Aramis and Asa Issie, Ethiopia. *See also* *Australopithecus afarensis*.

***Australopithecus bahrelghazali* Brunet et al., 1996** (etym. *see Australopithecus*, and *bahr el ghazali* = place of discovery) Hominin species established by Michel Brunet and colleagues in 1996 to accommodate a tooth-bearing midline mandible fragment that includes the symphysis and an upper premolar tooth recovered from *c.*3.5–3.0 Ma sediments in the Bahr el Ghazal region, Koro Toro, Chad. The mandibular fragment had been previously assigned to *Australopithecus* aff. *Australopithecus afarensis* (Brunet et al. 1995). The authors claim that it has thicker enamel than *Ardipithecus ramidus*, a more vertically orientated and more gracile symphysis than *Australopithecus anamensis*, more complex premolar roots than *Australopithecus afarensis* and *Australopithecus africanus*, and larger incisors and canines than *Au. africanus*. However, other researchers interpret these differences as geographical variation within *Au. afarensis*. First discovery KT 12/H1 (1995). Holotype As above. Paratypes KT 12/H2, right P³. Main site Bahr el Ghazal, Chad. *See also* *Australopithecus afarensis*.

***Australopithecus boisei* (Leakey, 1959)** (etym. *see Australopithecus*, plus *boisei* to recognize the substantial help provided to Louis Leakey and Mary Leakey by Charles Boise) The genus *Zinjanthropus* was established by Louis Leakey in 1959 to accommodate fossil hominins recovered in 1955 and 1959 in Bed I, Olduvai Gorge, Tanzania. John Robinson (1960) suggested it was a synonym of *Paranthropus*, and Louis Leakey (1963) subsequently sank *Zinjanthropus* into *Australopithecus*. *See also* *Zinjanthropus boisei*.

***Australopithecus garhi* Asfaw et al., 1999** (etym. *garhi* = surprise in the Afar language) Hominin species established by Asfaw et al. (1999) to accommodate a fragmented cranium and two partial mandibles recovered from the *c.*2.5 Ma Hatayae Member of the Bouri Formation at the Bouri, Gamedah, and Matabaietu collection areas,

Middle Awash study area, Ethiopia. *Australopithecus garhi* combines a primitive cranium with large-crowned postcanine teeth. However, unlike *Paranthropus boisei* the incisors and canines are large and the enamel apparently lacks the extreme thickness seen in the latter taxon. A partial skeleton combining a long femur with a long forearm was found nearby, but is not associated with the type cranium (Asfaw et al. 1999) and these fossils have not been formerly assigned to *Au. garhi*. The authors claim that despite its large postcanine tooth crowns its cranium lacks the derived features of *Paranthropus*, and they suggest it may be ancestral to *Homo*, but what little evidence there is from phylogenetic analyses does not support a close link with *Homo*. The morphology of the mandibles reported in the same publication as *Au. garhi* is in some respects like that of *Paranthropus aethiopicus*. If it is demonstrated that the type specimen of *P. aethiopicus*, Omo 18-18, belongs to the same taxon as the mandibles that appear to match the *Au. garhi* cranium, then *P. aethiopicus* would have priority as the name for the *Au. garhi* hypodigm. First discovery GAM-VP-1/1 (1990). Holotype ARA-VP-12/130 (1997). Paratypes None. Main sites Bouri, Ethiopia.

***Australopithecus prometheus* Dart, 1948** (*L. australis* = southern, Gk *pithekos* = ape and *Prometheus* = in Greek mythology the Titan who stole fire from Olympus. Raymond Dart chose this species name because organic chemists had confirmed the presence of carbon in the Makapansgat Cave; Dart 1948, p. 201). Hominin species established by Raymond Dart in 1948 to accommodate MLD 1, a hominin occipital recovered by the Kitching brothers at the Makapansgat Limeworks Dump. Dart (1948) considered the combination of the large size of MLD 1, the separation of **inion** and **opisthocranium**, and its distinctive **suture** pattern, to justify his conclusion that MLD 1 “differs vividly” (*ibid*, p. 200) from *Plesianthropus*. Most researchers interpret the Makapansgat hominin remains as being similar enough to those from **Taung** and **Sterkfontein** Member 4, etc. for *Australopithecus prometheus* to be regarded as a junior synonym of *Australopithecus africanus* Dart, 1925, and Robinson (1954a) suggested that the hominins from Makapansgat be transferred to *Australopithecus africanus* as *Australopithecus africanus transvaalensis*. However, Aguirre (1970) considered the dental mor-

phology of some of the Makapansgat hominins to be sufficiently like that of *Paranthropus robustus* to argue the case for a second hominin at Makapansgat. First discovery MLD 1 (1947). Holotype As above. Paratypes None. Main site Makapansgat, South Africa. *See also* **Makapansgat**; *Australopithecus africanus transvaalensis*.

***Australopithecus ramidus* White et al., 1994** A new species of *Australopithecus* proposed by White et al. (1994) to accommodate 17 fossils recovered from localities at Aramis in the **Central Awash Complex** of the **Middle Awash study area**. A year later, in a corrigendum to the original paper, the same authors made a new genus name, *Ardipithecus*, available along with a diagnosis. They also noted that “in late 1994 a mandible of *A. ramidus* was found at Aramis associated with a partial postcranial skeleton, 50 m north of the holotype specimen, and at the same stratigraphic level. Analysis of this specimen has begun, and will provide further features with which to characterize *Ardipithecus*” (White et al. 1995, p. 88). Presumably White and his colleagues were referring to ARA-VP-6/500 (White et al. 2009a). *See* *Ardipithecus ramidus*.

***Australopithecus sediba* Berger et al. 2010** (*L. australis* = southern, Gk *pithekos* = ape, and Se Sotho *sediba* = fountain or wellspring) A hominin taxon established by Berger et al. (2010) to accommodate two hominin associated skeletons, **MH1** and **MH2**, recovered from **Malapa** in South Africa. These authors suggest that although the lower limb of *Australopithecus sediba* is like those of other archaic hominins, they claim that it has cranial morphology (e.g., more globular neurocranium, gracile face), mandibular morphology (e.g., more vertical symphyseal profile, a weak *mentum osseum*), dental morphology (e.g., simple canine crown, small anterior and postcanine tooth crowns), and pelvic morphology (e.g., **acetabulocrystal buttress**, expanded ilium and short ischium) that is only shared with early and later *Homo* taxa. First discovery MH1 (2008). Holotype MH1. Paratype MH2. Main site Malapa.

***Australopithecus transvaalensis* Broom, 1936** (*L. australis* = southern and Gk *pithekos* = ape; literally the “southern ape of the Transvaal”) Hominin species established by Robert **Broom** in 1936 to accommodate **TM 1511**, the cranium and endocranial cast of a young adult recovered

at Sterkfontein from breccia now referred to as being from Member 4. Broom considered the new cranium “agrees fairly closely with the Taungs ape,” but that “the molar teeth differ in a number of important details” (Broom 1936, p. 488). The species *Australopithecus transvaalensis* was subsequently transferred to the genus *Plesianthropus* as *Plesianthropus transvaalensis* by Broom (1938), but it is now almost universally regarded as a junior synonym of *Australopithecus africanus*. In any event it is doubtful whether Broom’s presentation of the new species complied with the then current (i.e., 1930 revision) version of the Rules of Zoological Nomenclature. First discovery TM 1511 (1936). Holotype As above. Paratypes None. Main site Sterkfontein, South Africa. *See also* *Plesianthropus*; *Plesianthropus transvaalensis*; *Australopithecus africanus*.

***Australopithecus walkeri* Ferguson, 1989**

(*L. australis* = southern and *Gk pithekos* = ape, literally (Alan) Walker’s “southern ape”) Hominin species established by Walter Ferguson in 1989 to accommodate the “black skull” KNM-WT 17000 and named “in honor of its discoverer” (*ibid*, p. 231). Ferguson (1989) argued that shape and size differences between OH 5, belonging to *Paranthropus boisei*, and KNM-WT 17000 were (a) greater than those between “*Australopithecus boisei*” and “*Australopithecus robustus*” (his terminology) and (b) too great to be subsumed within a single species. For example, he suggested the differences in cranial capacity (410 cm³ in KNM-WT 17000 and 530 cm³ in OH 5), both presumed male crania, were beyond what would be expected within one sex in a higher primate taxon. Ferguson’s presentation of the new species complied with the **International Code of Zoological Nomenclature** rules, but his proposal is almost universally ignored because researchers who see the need for a second species for the pre-2.3 Ma megadont archaic hominins from East Africa use *Paraaustralopithecus* or *Paranthropus aethiopicus* as the name for such a taxon. Groves (1999) has pointed out that the taxon name *Australopithecus aethiopicus* is preoccupied by Tobias (1980b), who suggested that *Au. africanus aethiopicus* could be used for the Hadar component of the hypodigm of *Australopithecus afarensis*. First discovery KNM-WT 17000. Holotype As above. Paratypes None. Main site West Turkana, East Africa. *See also* *Paranthropus boisei*; *Paraaustralopithecus aethiopicus*.

Austronesia (*L. australis* = southern and *Gk nesos* = island, literally “southern islands”) An inclusive term used for all the island groups in the Pacific (i.e., **Indonesia**, **Melanesia**, **Micronesia**, and **Polynesia**).

autapomorphic *See* autapomorphy.

autapomorphy (*Gk autos* = self and *morphe* = shape) A term used in **cladistic analysis** for a derived **character state** that is confined to one of the taxa, or **operational taxonomic units**, used in that analysis. Autapomorphies can be used for taxonomic identification, but because the morphology is by definition confined to a single taxon it cannot be used to explore how closely that taxon is related to another taxon. Examples of probable autapomorphies are the enlarged talonid of the mandibular postcanine teeth of *Paranthropus boisei* and the large globular brain case of *Homo sapiens*.

autecology (*Gk auto* = self) The branch of **ecology** that focuses on the interactions between an individual (or a single species) and its environment. Although autecology is a term used infrequently by paleoanthropologists, many ecological studies of hominins are essentially autecological, as some species are represented by a single fossil and in many cases research focuses on a single species.

autopod (*Gk autos* = self and *pod* = foot) The **distal** of the three compartments of a tetrapod, and therefore of a hominin, limb. The proximal compartment is the **stylopod** (the upper arm or the thigh), the intermediate one is the **zeugopod** (the forearm or the lower leg), and the distal one is the autopod (the hand or the foot).

availability *See* available.

available (*L. valere* = to be worthy) In relation to nomenclature a taxonomic name that is available is a name that has been generated according to the rules and recommendations of the **International Code of Zoological Nomenclature**. For example, the rules stipulate that an available name must not have been used in that context before, it must be formed from the 26 letters of the alphabet, and it must not have any commercial connotation. So whereas at the time it was proposed *Plesianthropus transvaalensis* was an available

name, if it was proposed today it would not be available, and for different reasons neither would the taxon names *Homo 2feet* or *Homo bigmacensis*. To be a **valid** as a taxon name, the name must be available, but among many available names for a taxon, only one is valid. *See also* **International Code of Zoological Nomenclature**.

Aves (L. *avis* = bird) The name of the class that contains all bird taxa. Birds are bipedal tetrapod vertebrates; their forelimbs are specialized as wings, although the capability for powered flight has been lost in some lineages (e.g., ratites and penguins). Birds are warm blooded, lay eggs, and have feathers. Birds have a global distribution and there are both resident and migratory species. Bird bones are extremely fragile, having a lightweight structure to make flight less energetically costly. This makes them less durable in death and bird bones are disproportionately destroyed by perimortem, post mortem, and other **diagenetic** processes. Therefore bird osseous true fossils are relatively rare in the fossil record as are bird trace fossils in the form of prints and trails, but fossil egg shell, especially ostrich egg shell, is relatively common in open-air sites in Africa. Structural fragility means that bird remains are unlikely to be transported far from their place of death since they are especially prone to mechanical destruction. When bird remains are found in the fossil record they can be useful paleoenvironmental indicators (e.g., wading birds indicating the nearby presence of water). The most common bird remains found at early hominin fossil sites is probably ostrich egg shell, which can be used for **ostrich egg shell dating** as well as for **paleoenvironmental reconstruction**. *See also* **birds**; **ostrich egg shell dating**; **paleoenvironmental reconstruction**.

Awash River The Awash River runs for approximately 1100 km/700 miles within Ethiopia. It begins in the Ethiopian Highlands west of Addis Ababa, where it shares a watershed with the headwaters of the Blue Nile. It passes south of Addis Ababa and then turns north to run through the Awash National Park which is approximately 240 km/150 miles to the east of the Ethiopian capital. The Awash River then enters the Afar Triangle and runs north–northeast for 320 km/200 miles before turning east and then south–southeast for 120 km/75 miles before coming to an end in the most arid part of the Afar Triangle in Lake Abbé, some 112 km/70 miles west of the deepest part of the

western, landward, end of the Gulf of Tadjoura. The Upper, Middle, and Lower Awash regions are informal divisions of the part of the Awash River valley that runs through the Afar Triangle. *See also* **Middle Awash study area**.

Awash River Basin This refers to the approximately 440 km-/275 mile-long part of the Awash River that passes north, then in a south-easterly direction, through the **Afar Triangle**. Mammalian fossils have been reported in the region since the beginning of the 20thC, but it was not until geologist Maurice Taieb undertook reconnaissance work there in the 1960s that its potential as a source of fossils began to be realized. Taieb, together with Yves **Coppens**, John **Kalb**, and Don **Johanson**, formed the **International Afar Research Expedition** (or IARE) to explore the northern part of the basin in the early 1970s, but thereafter Kalb shifted his attention to the south and in 1975 and 1976 he formed the **Rift Valley Research Mission in Ethiopia** (or RVRME) to explore the region now known as the **Middle Awash study area**. The RVRME's activities focused on the eastern side of the Awash River, but Kalb and colleagues visited the Bouri Peninsula late in 1975, and located fossils and **Acheulean** artifacts at a locality identified as **Dakanihylo**. In the next year they discovered a hominin cranium (**Bodo 1**) in a region on the eastern side of the river at **Bodo**.

Awirs *See* **Engis**.

awl (ME *aul* = pointed tool) A small pointed tool commonly made of bone or metal for engraving or perforating. Awls are, and presumably were, used for a variety of tasks including sewing, leatherwork, basketry, woodworking, and inscribing brittle materials like ceramic and glass. Awls may be used hafted or hand-held. Bone awls, manufactured by longitudinal splitting of long bones and subsequent sharpening of the pointed tip, occur as components of early bone industries, such as found, for example, at **Blombos Cave**, South Africa.

axial digit (L. *axis* = a straight line around which a body or object rotates, or a line around which something is symmetric) The term used for the **reference digit** of the hand (the middle finger), or the reference digit of the foot (the second toe). *See also* **axis**.

axial skeleton Comprises the **skull**, the **vertebral column**, the **ribs**, and the **sternum**. It is the presence of these components of the hard tissue skeleton that defines the vertebrate subphylum. What unites the components of the axial skeleton is that it is what is left of the skeleton after the limbs and limb girdles have been removed or excluded. The components of the axial skeleton are all either in the midline, or they are connected directly, or indirectly, to midline structures.

axis (L. *axis* = a straight line around which a body or object rotates, or a line around which something is symmetric) Four meanings of axis are relevant to human evolution. First, it refers to the midline, or axis, of the body, as in **axial skeleton**. Second, it refers to the straight line, or axis, around which a part of the body rotates. For example, the axis of **pronation** and **supination** of the forearm is a straight line joining the center of the head of the radius and the styloid process of the ulna. Third, it refers to the reference digit of the hand (the middle finger) and foot (the second toe). The fourth meaning refers to the second (C2) of the seven cervical vertebrae. The C2 vertebra is called the axis because it incorporates the odontoid process, which forms the axis around which the atlas [the first (C1) cervical vertebra] plus the cranium, which articulates with the superior aspect of the atlas, rotate.

axon (Gk *axon* = axis) A tubular process that projects from a nerve cell, or **neuron**, and is the way neurons connect to other neurons in a nervous pathway, or with the target structure (e.g., muscle fiber, blood vessel, or sweat gland) or target organ (e.g., heart) being innervated. Axons have diameters that range from 0.2 to 20 μm and they can extend for up to 1 m. Axons are capable of conducting a nerve signal, or action potential, over great distances. Large axons are surrounded by a fatty insulating sheath called **myelin**, which is important for enabling the high-speed conduction of action potentials. The sheath is interrupted at regular intervals by nodes of Ranvier (named after the neuroanatomist Louis Antoine Ranvier who first described them towards the end of the 19thC). Near its end the axon divides into fine branches that have specialized swellings called pre-

synaptic terminals where neurotransmitter molecules are released into the synaptic cleft that lies between the presynaptic terminals and the next neuron, or the structure or organ being innervated. During development, a neuron sends out axons by way of a growth cone. The growth cone appears as an enlargement of the shaft of the axon, and several extensions, called filopodia, project from it and facilitate the migration of the axon through tissue. Maxwell Cowan, Giorgio Innocenti, and their colleagues independently found that neurons send axons to many more targets in the developing brains than are eventually retained in the adult animal, and the projections are focused on discrete areas within the brain (e.g., the **cerebral cortex**) by pruning projections to inappropriate targets.

Azilian A technocomplex that includes small scrapers and distinctive points; the type site is Mas-d'Azil. See **Mas-d'Azil**.

Azokh Cave complex (Location 39°37'09"N, 46°59'19"E, Nagorno-Karabagh, an autonomous region within Azerbaijan in the Lesser Caucasus; etym. named after a nearby village) History and general description The Azokh Cave was discovered in 1960. The initial, 15 year-long, period of excavations at Azokh 1 was brought to an end in 1989, and in that time 2430 m³ out of an estimated 3400 m³ total volume of sediment had been removed from that part of the cave complex. Since 2002 the Azokh Cave Project, an international and multidisciplinary program, has been working at the site. Four more entrances were discovered and two of these, Azokh 2 and Azokh 5, contain fossils and artifacts. A hominin mandible was found at Azokh 1 in 1968. Temporal span and how dated? Five beds have been identified at Azokh 1, with Bed V being dated at *c.*200 ka by **uranium-series dating** and *c.*300 ka by **amino-acid racemization dating** and **electron spin resonance spectroscopy dating**. Archeological evidence found at site In Beds II and II "the lithic assemblages are primarily Middle Paleolithic in character" and Bed V contains "retouched scrapers and unretouched flakes" (Fernández-Jalvo et al. 2010, p. 105). Key references: Geology and dating Fernández-Jalvo et al. 2004, 2010; Hominins Kasimova 2001; Archeology Fernández-Jalvo et al. 2004, 2010.

B

B. A prefix used by the American contingent of the **International Omo Research Expedition** for fossil localities in the Brown Sands group of exposures of the **Usno Formation** (e.g., B. 8). The prefix is also used for fossils found within one of those localities (e.g., B. 8-27).

Ba/Ca ratios *See* strontium/calcium ratios.

baboon The common name for a member of the **Old World monkey** genus *Papio*. The term is also sometimes used more inclusively as the term for a grade that includes the large-bodied **papio-nin** monkeys (including *Papio*, *Theropithecus*, and *Mandrillus* plus a range of extinct genera). After originating most likely in southern Africa and subsequently undergoing an adaptive radiation in the Pleistocene, baboons are now widespread across sub-Saharan Africa, with a small, relatively ancient population also found in Arabia (Wildman et al. 2004). Based on the **phenotype**, most modern authorities classify the *Papio* or common baboons as a single species (*Papio hamadryas*) with multiple subspecies (Jolly 1993) [i.e., the guinea baboon, *P. h. papio*, found in the far west of Africa, the sacred baboon, *Papio h. hamadryas*, found in the Horn of Africa and Arabia, the olive baboon, *P. h. anubis*, found across a wide geographic area, from west to east Africa, the yellow baboon, *P. h. cynocephalus*, found in east and south central Africa, the kinda baboon, *P. h. kindae* (but which some refer to as *Papio cynocephalus kindae*) found in south central Africa, and the chacma baboon, *P. h. ursinus*, found in southern Africa]. However, recent molecular data suggest there are seven major haplotypes that are highly complex genetically, with most likely multiple examples of divergence, reconnection, and hybridization since the origin of the genus (Zinner et al. 2009). Several authors, most notably Jolly (2001), have highlighted the ecological similarities between baboons and hominins (e.g., their **eurytopy**, preference for

open or wooded habitats, terrestriality, and relative abundance in the fossil record). The baboons, as discussed in the *Theropithecus* entry, are thus a popular comparator species for hominins. *See also* *Theropithecus*.

Bacho Kiro (Location 42°56'50"N, 25°25'47"E, Bulgaria; etym. named after a Bulgarian teacher and revolutionary who fought at the nearby Dryanovo Monastery) History and general description This site in eastern Bulgaria is a series of caves in a limestone hill that is a popular tourist attraction for its decorative **speleothems**. It is the type site of an early Upper Paleolithic technology called the Bachokirian. The hominin fossils found at the site have been interpreted by some as a *Homo sapiens*, which has led to the association of this early industry with the very first migration of modern humans into Europe. Temporal span and how dated? **Radiocarbon dating** of the Bachokirian contexts have provided a range of >43–29 ka (uncalibrated). Hominins found at site Several remains were recovered, including a mandibular corpus with dm₁ from the Bachokirian level, and isolated teeth, a right parietal fragment, and a right mandibular corpus with dm₂ and M₁ from the **Aurignacian** level. Most of these have been assigned to *H. sapiens*. Archeological evidence found at site Stone tools assigned to both the Bachokirian and Aurignacian industries. Key references: Geology, dating, and paleoenvironment Jöris and Street 2008; Archeology Kozłowski and Otte 2000; Hominins Churchill and Smith 2000.

Bachokiran *See* **Bacho Kiro**.

backed A term used to describe the blunted or abraded edge of a **microlith**. The blunting, or backing, strengthens the edge so the microlith can be mounted to form a **composite tool**. The opposing edge is usually left unmodified for maximum sharpness.

backed bladelet A type of bladelet with a sharp margin opposite one that has been dulled, or “backed.” Abrasion or percussion may be used to dull the edge to be backed, and backing is often done to facilitate holding of sharp-edge pieces or to strengthen the edge to be inserted into a slot or handle as part of a composite, or multi-part tool.

bacteriophage A virus (or virus-like agent) that infects bacteria. The use of bacteriophages during the development of molecular biology enabled researchers to understand the role DNA plays in heredity. In 1952, the Hershey–Chase experiments confirmed that DNA was the genetic material. These experiments used the T2 bacteriophage labeled with ^{32}P to make the DNA radioactive, and then with ^{35}S to make the protein component radioactive. After the bacteriophages infected the bacteria, Hershey and Chase found that it was the DNA (and not the protein) from the bacteriophage that entered the bacterial cell and infected it.

Bahr el Ghazal (Ar. *Bahr el Ghazal*=river of the gazelles) A collection area approximately 45 km/28 miles east of **Koro Toro**, Chad. More than 17 numbered localities have been identified where there are exposures of **Pliocene** fossiliferous sediments. At one of them, KT 12, researchers recovered the remains of two hominins, one of which is the type specimen of *Australopithecus bahrelghazali*. See also **Koro Toro**; **KT 12/H1**; *Australopithecus bahrelghazali*.

Baia de Fier (Location 45°11'N, 23°46'E, Romania; etym. Romanian for “cave of the old woman”) History and general description The *Petera cu Muierii* is a karstic cave system comprising several galleries. It had been known of since the 1870s, but the initial archeological investigations were not undertaken until 1929, with further excavations carried out in the early 1950s. Excavations in two of the galleries yielded **paleolithic** sequences, including **Middle** and **Upper Paleolithic** remains, and mammal fossil bones. Hominin skeletal remains, thought to represent one individual (*Muierii* 1), were discovered in 1952 in a surface depression at the back of one of these two galleries (the *Galeria Musterian*). Two additional hominin remains (of unknown provenance) have been reported for this site (*Muierii* 2 and 3). Temporal span Middle and Upper Paleolithic, as well as the **Holocene**. The

Mousterian levels of the *Galeria Musterian* yielded a conventional radiocarbon age of $42,560 \pm 1100$ –1300, and a more recent AMS ultrafiltration ^{14}C age of $40,850 \pm 450$ years BP. The hominin remains themselves have yielded AMS ultrafiltration ^{14}C ages of $30,150 \pm 800$, $29,930 \pm 170$, and $29,110 \pm 190$ years BP; all the ages are uncalibrated. How dated? Conventional and AMS ultrafiltration radiocarbon dates on hominin and faunal remains. Hominins found at site Partial cranium, mandible, scapula and tibia (*Muierii* 1), temporal bone (*Muierii* 2), and fibular diaphysis (*Muierii* 3). Archeological evidence found at site **Eastern Charentian** (Cave Mousterian), Upper Paleolithic (possibly evolved **Aurignacian**). Key references: Geology and dating Punesco 2000, Olariu et al. 2003, Soficaru et al. 2006; Hominins Gheorghiu and Haas 1954, Soficaru et al. 2006, Trinkaus 2007, 2008; Archeology Mertens 1996, Punesco 2000, Soficaru et al. 2006. See also *Muierii* 1, 2, and 3.

Baichbal valley See **Hungsi-Baichbal valleys**.

Baise Basin See **Bose Basin**.

balanced polymorphism The simultaneous presence in a population of two or more distinct forms of a phenotypic character (e.g., S and A **hemoglobin**) in proportions well above those resulting solely from recurrent mutation. The determining alleles (in this case the S-type and wild-type alleles of the beta-globin **gene**) are maintained at elevated frequencies by **balancing selection** or frequency-dependent selection.

balanced translocation See **translocation**.

balancing selection A type of selection favoring more than one allele that, because it prevents the fixation of any allele, maintains different alleles in the population. An example in modern humans is the sickle-cell, or S, allele of the beta-globin **gene**. In the **homozygous** form this allele is deleterious since it causes sickle-cell anemia. However, in the **heterozygous** form in regions where malaria is endemic, it *protects* against malaria. In such an environment, homozygotes for the wild-type allele are at a disadvantage because they are more susceptible to malaria. Thus, both alleles are maintained in the population. This

phenomenon, known as **heterozygous advantage**, is also referred to as overdominance.

balancing side *See* chewing.

Balla Barlang (Location 48°02'N, 20°31'E, Hungary; etym. Hu. *balla*=local family name, *barlang*=cave) History and general description This cave, in a limestone outcrop near Répáshuta village, contained a **Gravettian** occupation site with a few hominin remains. Temporal span and how dated? Radiocarbon dating provides an age of 20,000±200 years BP. Hominins found at site Several subadult cranial fragments, including a mandible with three isolated teeth and a partial skeleton, all attributed to *Homo sapiens*. Archeological evidence found at site A Gravettian stone tool assemblage was recovered. Key references: Geology, dating, and paleoenvironment Thoma and Vértes 1971; Archeology Vértes 1967; Hominins Thoma and Vértes 1971.

Balzi Rossi *See* Grimaldi.

Bañolas *See* Banyoles.

Banyoles (Location 42°06'N, 2°45'E, Catalonia, Spain; etym. after the nearby town) History and general description Quarry near the town and lake of Banyoles, about 60 km/35 miles northeast of Barcelona. A hominin mandible was found embedded in travertine at a depth of 4–5 m by the stonemason Lorenzo Roura in 1887. It came into the possession of Don Pedro Alsius, a well-known local pharmacist and naturalist. Alsius himself removed much of the **travertine** matrix from the specimen, and the mandible is still in the hands of the Alsius family. Temporal span and how dated? The travertine matrix stuck to the mandible was dated to 45±4 ka using **uranium-series dating**. Direct uranium-series/**electron spin resonance spectroscopy dating** dating on the tooth enamel gave an age of 66±7 ka. Hominins found at site The Banyoles mandible was originally identified as *Homo neanderthalensis*, but later workers noted the lack of derived **Neanderthal** features (implying that the specimen was **pre-Neanderthal** in character). The more recent date of the specimen, however, makes the pre-Neanderthal attribution unlikely. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Julià and

Bischoff 1991, Grün et al. 2006; Hominins MacCurdy 1915, de Lumley 1971/2, Stringer et al. 1984; Archeology N/A.

Baoussé Rousse *See* Grimaldi.

Bapang Formation (etym. Named after a local village near the type section) General description The younger of the two fossil-hominin-bearing geological formations of Central and East Java, Indonesia. Formerly known as the **Kabuh Formation**, the Bapang Formation is largely a product of local uplift, volcanism, and sedimentary deposition from river and stream activity. Most of the hominin fossil specimens from the **Sangiran Dome** are derived from the Bapang Formation. The lower layers of the Bapang Formation were characterized by high-energy deposition so many of the mammalian fossils, including the hominins, are fragmentary and abraded. In the higher layers the sediments of the Bapang Formation are finer-grained which is indicative of low-energy deposition. The fossils from these strata are better preserved and more complete than those from the lower layers. A coarse-grained **conglomerate** layer rich with fossil bone (formerly known as the **Grenzbank zone**) marks the transition between the younger Bapang Formation and the older **Sangiran Formation**. Sites where this formation is exposed Mojokerto, Ngrejeng, Sangiran, and Sendangbusik. Geological age Argon-argon geochronological analyses have dated the lowermost Bapang hominins to 1.51–1.47 Ma, and later specimens from the same formation to 1.33–1.24 Ma. Most significant hominin specimens Sangiran 2, Sangiran 17, Sangiran 21 (“Mandible E”). Key references: Geology and dating Watanabe and Kadar 1985, Swisher et al. 1994, Larick et al. 2001; Hominins Weidenreich 1944, von Koenigswald 1968, Jacob 1973, Sartono 1976, Pope and Cronin 1984.

Bapaume (Location 50°05'37"N, 2°52'19"E, France; etym. named after the nearby town of Bapaume) History and general description First recognized during road construction in 1966, this large open-air **Lower and Middle Paleolithic** site was further exposed during excavation for a high-speed train line in northern France. Temporal span and how dated? No radiometric dating has been attempted. The site age is based on correlation to **glacial cycles**; the Middle Paleolithic deposit is thought to be early Weichselian [**Oxygen Isotope**

Stage (OIS) 2 or 4], whereas the Lower Paleolithic deposit is dated to the Saalian (possibly OIS 6, 8, or 10). Hominins found at site None. Archeological evidence found at site The exposure of Lower Paleolithic loess, known as les Osiers, produced a variety of late **Acheulean** stone tools, made with the **Levallois** technique, and a few handaxes. The Middle Paleolithic exposures, known as Rencourt-lès-Bapaume, contains several **Mousterian** layers, as well as a late Acheulean layer. Key references: Geology, dating, and paleoenvironment Tuffreau 1976, Tuffreau et al. 1991; Hominins N/A; Archeology Tuffreau 1976, Tuffreau et al. 1991.

BAR Abbreviation for Baringo, and the prefix used for the fossils recovered at **Lukeino**, Tugen Hills, Baringo District, Kenya, from 2000 onwards (e.g., **BAR 1000'00**, the holotype of *Orrorin tugenensis*).

BAR 1000'00 Site **Lukeino**. Locality Kapsomin Surface/*in situ* Surface. Date of discovery 2000. Finder Kiptalam Cheboi. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Lukeino Formation**. Group N/A. Nearest overlying dated horizon Kaparaina Basalts. Nearest underlying dated horizon Kabarnet Trachytes. Geological age *c.*6 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Two fragments of a mandible, plus the left M₂ and left and right M₃; all three teeth are damaged. Enamel thickness at the apex on the **paraconid** is 3.1 mm and is comparable to other hominins with the exception of *Ardipithecus*, which has thinner enamel. Announcement Senut et al. 2001. Initial published description Senut et al. 2001. Photographs/line drawings and metrical data Senut et al. 2001. Detailed anatomical description N/A. Initial taxonomic allocation *Orrorin tugenensis*. Taxonomic revisions N/A. Current conventional taxonomic allocation *O. tugenensis*. Informal taxonomic category Possible primitive hominin. Significance **Holotype** of *O. tugenensis*. Location of original **Kipsaramon Museum**, Baringo District, Kenya.

BAR 1002'00 Site **Lukeino**. Locality Kapsomin. Surface/*in situ* Surface. Date of discovery 2000. Finder Kiptalam Cheboi. Unit N/A. Horizon N/A. Bed/member N/A. Formation **Lukeino Formation**. Group N/A. Nearest overlying dated horizon Kaparaina Basalts. Nearest underlying dated horizon Kabarnet Trachytes.

Geological age *c.*6 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A nearly complete proximal left femur. The femoral head is preserved, but the greater trochanter is not. Announcement Senut et al. 2001. Initial published description Senut et al. 2001. Photographs/line drawings and metrical data Galik et al. 2004. Detailed anatomical description Galik et al. 2004. Initial taxonomic allocation *Orrorin tugenensis*. Taxonomic revisions None. Current conventional taxonomic allocation *O. tugenensis*. Informal taxonomic category Possible primitive hominin. Significance There has been debate about whether this specimen provides compelling evidence for a locomotor mode that involves substantial bouts of bipedal behavior. Many researchers were skeptical that the internal morphology of BAR 1002'00 justified such a conclusion, but the most recent analysis of its external morphology suggests that it does resemble femora attributed to *Australopithecus* and *Paranthropus* (Richmond and Jungers 2008), taxa that were almost certainly facultative bipeds. Location of original **Kipsaramon Museum**, Baringo District, Kenya.

Bar-Yosef, Ofer (1937–) Ofer Bar-Yosef was born in Jerusalem, Israel. His father's family moved to Israel from Morocco around 1850 and his mother's family moved from Latvia in 1891. Bar-Yosef developed an interest in history and archeology as a schoolboy. He conducted his first excavation of an entrance to a Byzantine cistern when he was in the fifth grade, and when he was in the eighth grade he surveyed the ridge on which the Givat Ram campus of Hebrew University would later be built. During his mandatory service in the Israeli Defense Force (1955–8) he spent time in the Negev where two members of his future kibbutz taught him the basics of lithic analysis. In 1957, Bar-Yosef volunteered to work with Moshe Stekelis in **Kebara** cave, and in 1959 Bar-Yosef surveyed an Early Bronze Age (3330–2300 years BCE) mound in the kibbutz located in the Jordan Valley. Before beginning his undergraduate education in the fall of 1959 at Hebrew University, Bar-Yosef worked in the excavation of Nahal Oren Terrace in **Mount Carmel** under the supervision of Stekelis. Bar-Yosef studied at Hebrew University, earning a BA in archeology and geography (1963), an MA in prehistoric archeology (1965), and a PhD in prehistoric archeology (1970). Bar-Yosef's interest in Paleolithic

archeology led him to conduct numerous excavations in the Levant, predominantly at 'Ubeidiya in the Jordan Valley (1960–6 under the supervision of M. Stekelis and in 1967–74 jointly with E. Tchernov) and Kebara Cave, Mount Carmel (1982–90 with Bernard Vandermeersch); excavations in Kebara Cave resulted in the recovery of well-preserved evidence of *Homo neanderthalensis*; he has also participated in fieldwork at sites in Turkey, China, the Czech Republic, and the Republic of Georgia. Throughout his academic career, Bar-Yosef has also maintained active field research programs involving the Neolithic, both in Israel and also, most recently, in China. Since 1988 Bar-Yosef has taught at Harvard University, where he is currently the MacCurdy Professor of Prehistoric Archaeology and head of the Peabody Museum's Stone Age Laboratory.

bare area This term, or more precisely the “bare area of the occiput,” was introduced by Raymond Dart when he described MLD 1, the type specimen of *Australopithecus prometheus* (Dart 1948). He used the term to describe the area on the squamous part of the occipital between lambda and the superior nuchal lines that was not covered by either the temporalis or the nuchal muscles. Because the temporal lines or sagittal crests of extant higher primates nearly always extend posteriorly to intersect the nuchal crests, extant apes seldom have a significant bare area. This contrasts with the megadont archaic hominins in which the sagittal crest tends to be more developed anteriorly and as a result there is often a bare area (e.g., OH 5, MLD 1).

barium/calcium ratios See strontium/calcium ratios.

Barlow, George See Taung; Sterkfontein.

Barma del Caviglione (Location 43°47'00"N, 7°32'08"E, Liguria, Italy; etym. It. *barma*=cave in the local dialect) History and general description One of the caves in the Grimaldi complex, it was primarily excavated by E. Rivière in the early 1870s. Temporal span and how dated? The cave itself has not been directly dated, although direct radiocarbon dating on the biostratigraphically correlated remains from Arene Candide and Barma Grande suggest an age of *c.*24 ka. Hominins found at site BC1, or the “Homme de Menton,” is a fairly complete young adult ceremonial

burial covered with ochre; perforated shells and deer canines ornament the head. However, despite its name, the skeleton appears to be female. Other hominin fossils found at the site include a right cuboid, a right hallucial phalanx, and a fragmentary radius; they and BC1 are anatomically modern *Homo sapiens* and were assigned by Verneau to the “Cro Magnon race.” Archeological evidence found at site In addition from the burial, both Gravettian and Aurignacian assemblages were recovered, but the burial is associated with the Gravettian. A parietal engraving of a horse was discovered in the 1970s. Key references: Geology, dating, and paleoenvironment Alciate et al. 2005; Hominins Rivière 1872, Verneau 1906, Alciate et al. 2005; Archeology Mussi 2001.

Barma Grande (Location 43°47'00"N, 07°32'08"E, Italy; etym. It. *barma*=cave in the local dialect and *grande*=large) History and general description The activity at Grotte des Enfants and Barma del Caviglione in the early 1870s prompted many semi-professionals to explore the other caves in the Grimaldi complex. L. Jullien, an antiquities dealer, discovered the burial of an adult male (Barma Grande 1) in 1884, as well as a number of figurines and artifacts. The skeleton, however, was destroyed a few days after discovery due to a quarrel. Eight years later the owner of the cave, G. Abbo, carried out new excavations that resulted in the discovery of a triple burial (BG 2, 3, and 4). Two more burials were discovered in the rear of the cave in 1894 (BG 5 and 6). Temporal span and how dated? The Barma Grande 6 skeleton was directly dated using radiocarbon dating to 24,800±800 years BP. Hominins found at site The surviving skeletons are fairly complete (BG 6 being an exception), although BG 5 was damaged in WWII. BG 1, 2, 5, and 6 are male, whereas 3 and 4 are most likely female. Archeological evidence found at site The skeletons, like many other Gravettian burials, were lavishly ornamented with flint blades, ivory pendants, deer canines, and ochre. At least two “Venus” figurines were recovered by Jullien in 1884. Key references: Geology and dating Formicola et al. 2004, Hominins Verneau 1908, Formicola 1987, Churchill and Formicola 1997; Archeology Mussi 2001.

Barnfield Pit See Swanscombe.

Barr body Refers to a dense stainable structure (discovered by Murray Barr) that is the inactive X

chromosome in a female cell. This inactivation results in an equal expression of most genes on the X chromosome in both males and females (males have one X chromosome, but females have two). In female mammals, one X chromosome is randomly inactivated early in embryonic development through the initiation of the X-inactivation center (Xic). Since inactivation is random, different areas of the body of a female individual may have different active X chromosomes. If different alleles are present, this genetic mosaic condition can result in a patchy **phenotype** (e.g., the hair color in calico cats). Differential X-chromosome activation may play a role in evolution, including human evolution.

Barranco León One of the sites of the **Orce region**, this area is known for abundant faunal remains dating to the Plio-Pleistocene along with some potential stone tools. *See also* **Orce region**; **Venta Micena**.

basal ganglia A group of **nuclei** at the base of the **forebrain** in vertebrates. The basal ganglia includes the **striatum** (comprising the caudate nucleus and putamen in primates), globus pallidus, substantia nigra (which is in the midbrain), and the subthalamic nucleus. The basal ganglia are involved in a variety of functions (e.g., motor control, **learning**, emotional regulation, and **cognition**) via their recurrent connections through the thalamus to the **cerebral cortex** (syn. basal nuclei).

basal nuclei *See* basal ganglia.

basalt A hard, dense, basic (i.e., between 45 and 52% SiO₂) igneous rock, rich in the minerals plagioclase and pyroxene. It is formed when liquid magma cools either on the Earth's surface as a lava flow or at shallow depths as an intrusion (dyke or sill). Within rift valley sequences basic igneous rocks such as basalts often underly sedimentary rocks, and during the early stages of dating the sediments at **Olduvai Gorge** a layer of basalt beneath Bed I provided a maximum **potassium-argon** age for the fossil-bearing sediments that lay above it.

base *See* base pair; **basicranium**; **cranium**; **mandible**.

base pair The fundamental unit of a DNA molecule. The latter consists of **nucleotides** that

each contain one of four bases – adenine, guanine, cytosine, and thymine – that are joined in pairs by hydrogen bonds to form one of the “rungs” that make up the double-helix “ladder” structure of DNA. The bases are divided into two classes: purines (adenine and guanine) and pyrimidines (cytosine and thymine). In the DNA double helix, guanine always binds with cytosine and adenine always binds with thymine to form what are called base pairs (NB: if you remember the registration number of the late Francis Crick's car, AT GC, then you will have remembered the appropriate pairing). The size of a DNA molecule is expressed as the number of base pairs (or bp) it contains (e.g., 1789 bp). *See also* **RNA**; **uracil**.

basicranium [Gk (and L.) *kranion*=brain case and *basis*=base] This term refers to the part of the bony **cranium** beneath the brain. Its inner or **endocranial** surface is divided into three hollowed areas called cranial fossae. The anterior cranial fossa lies beneath the frontal lobes of the **cerebral cortex**, the middle cranial fossa lies beneath the temporal lobes of the cerebral cortex, and the posterior cranial fossa lies beneath the **cerebellum**. The un-paired bones that contribute to the cranial base are, from front to back, a small part of the frontal, the **ethmoid**, sphenoid, and the **occipital**, except for the occipital squame. Only one paired bone, the temporal, contributes to the cranial base. Except for the squamous parts of the occipital and temporal bones, the rest of the cranial base forms from the **chondrocranium** via a process called **endochondral ossification**. Studies of the cranial base or basicranium usually either consider its midline morphology (i.e., in the sagittal plane; e.g., *see* **cranial base angle**), or its parasagittal morphology (i.e., the morphology that lies either side of the sagittal plane). The latter studies usually concentrate on the bilateral structures that can be seen away from the midline when the cranial base is viewed from above and below; the former view is the endocranial aspect and latter view is called the *norma basilaris*. The cranial base completes its growth and development before the **face** and the **neurocranium**, and thus may constrain their development. *See also* **normal views**. syn. Basicranium is synonymous with the more modern term cranial base.

basin Teeth A depressed area on the surface of the crown of a postcanine tooth bounded by

enamel ridges or cusps (e.g., **talonid** basin) (syn. **fovea**, fossa). **Geology** Basin is used to describe large-scale structural formations that may have formed after the deposition of the strata (structural basins) or may have formed contemporaneously or prior to the deposition strata in response to tectonic processes (e.g., crustal stretching and rifting during rift valley formation). Such sedimentary basins are important as they provide the major locations for deposition and preservation of terrestrial sediments and fossils (e.g., **Turkana Basin**).

Batavia (L. *Batavi*=Germanic tribe whose homeland approximates to the region now known as The Netherlands) In antiquity the name was used for the “Low Countries”, and it was also chosen as the name for the city of Jakarta on the island of Java when the former was the capital of the Dutch East Indies. It features in some of the early articles about *Homo erectus* in Java.

bats See Chiroptera.

Baume Moula-Guercy See Abri Moula-Guercy.

bauplan (Ge. *bau*=architect and *plan*=sketch or drawing) A term used to describe the general organization, or body plan, of a taxon. It is usually used for large taxonomic groups (e.g., the four limbs of tetrapods), but it can be applied to a species (e.g., the flat face, robust mandible, and the large postcanine tooth crowns of *Paranthropus boisei*).

Bayesian methods Bayesian statistical methods trace their roots to the Reverend Thomas Bayes (1701–61), a Presbyterian minister who formulated a rule that described how to calculate the posterior probability of a hypothesis after observing data and after considering one’s prior belief in the hypothesis (i.e., at a time before the data could be observed) (Bellhouse 2004). What is known as Bayes’ rule or Bayes’ theorem states that $P(HD)=P(DH)*P(H)/P(D)$, where $P(HD)$ is the probability of the hypothesis given the data, $P(DH)$ is the probability of the data given the hypothesis (i.e., the “likelihood” of the data), $P(H)$ is the prior probability of the hypothesis, and $P(D)$ is the unconditional probability of the data; that is, the data probability given all possible hypotheses (Bolker 2008). The advantages of Bayesian methods for biological research include the ease with which they can fit complex

models for trait evolution, and their ability to incorporate statistical uncertainty during the estimation of evolutionary models. In evolutionary biology and paleoanthropology, researchers rarely have any good prior information and thus they consider all hypotheses equally probable *a priori*; this condition, also known as “flat priors,” means the conclusion about the alternative hypotheses is driven largely by the likelihood. The likelihood is the probability of the observed data given a hypothesis or model (e.g., the likelihood of the coin flip, TTTTHH, under the model of a fair coin is $0.5^6=0.016$). Because all such exact outcomes in larger problems will be exceedingly small values of probability, they are typically expressed as log-transformed and negative values. Bayes’ theorem is difficult to solve exactly for most real-world problems, and posterior probabilities are often approximated through Monte Carlo Markov chain (or MCMC) procedures. MCMC procedures involve a series of proposals that randomly modify some aspect of an evolutionary model (e.g., a proposal may modify a branch position in a phylogenetic tree, or a rate of character evolution, where characters can be DNA base pairs or presence/absence and multistate morphological data). The software then calculates the likelihood of the data under the new proposal and accepts or rejects the proposal in proportion to its posterior probability. The final set of accepted proposals, usually in the thousands, represents the posterior probability distribution of tree topologies and parameter values. An MCMC for tree inference [using software such as BayesPhylogenies (Pagel and Meade 2004), BEAST (Drummond and Rambaut 2007), or MrBayes 3 (Ronquist and Huelsenbeck 2003)] will include various clades in some trees but not in others. The proportion of accepted trees with a given clade (called “clade credibility”) reflects posterior belief in that evolutionary relationship given the data analyzed. Hypotheses of adaptive trait evolution can also be tested in a Bayesian context by estimating **phylogenetic generalized least squares** (or PGLS) and related models through an MCMC process [using software such as BayesTraits (Pagel and Meade 2007) or the R package MCMCglmm (Hadfield and Kruuk 2010)]. These models share the same goal as **phylogenetically independent contrasts**, but importantly they incorporate estimates of phylogenetic uncertainty by assessing trait correlations across multiple phylogenetic trees. PGLS techniques also allow for many alternative models of trait

evolution (e.g., punctuational versus gradual change) that are difficult to assess with independent contrasts. Bayesian methods are gaining in popularity for phylogenetic tree inference and for examining correlated trait evolution in a phylogenetic context. *See also* **maximum likelihood**; **Monte Carlo**; **phylogenetic generalized least squares**; **phylogenetically independent contrasts**.

BBC Abbreviation for **Blombos Cave** (*which see*).

BC Abbreviation for **Baringo Chemeron and Border Cave**. Prefix used for fossils recovered from the **Baringo Chemeron Formation**, Tugen Hills, Baringo District, Kenya (e.g., **KNM-BC 1**), and for fossils from **Border Cave** (e.g., **BC 1**). *See also* **Border Cave**; **Chemeron Formation**.

$^{10}\text{Be}/^9\text{Be}$ ratio *See* **cosmogenic nuclide dating**.

beam-hardening One of several technical problems involved in the data-acquisition stage of **computed tomography** (or **CT**). Conventional X-ray sources are polychromatic; that is, they encompass a mixture of radiation energies (called their spectrum) and if an X-ray beam passes through matter the lower-energy X-rays (i.e., soft rays) are progressively filtered out so that the average energy of the X-ray spectrum increases. To cope with this problem, clinical CT scanners are calibrated for the different muscle-like tissue thicknesses encountered in patients, but they are not calibrated for fossilized hard tissues. When clinical CT scanners are used to image fossils, inappropriate calibration can cause erroneous "lightening" of tissue boundaries (i.e., elevated gray values), an effect that increases with sample thickness and density. This results in erroneous CT numbers, and/or streak artifacts in the CT image. **Synchrotron X-ray methods** (e.g., **synchrotron radiation micro-computed tomography**, or **SR- μ CT**) avoid these problems by using monochromatic sources.

bed (ME *Bedd*=bed) A layer, or stratum, of rock that can be distinguished from the layers, or **strata**, that lie above it and below it. The bed is the smallest **stratigraphic unit** that is routinely used in the formal geological nomenclature (e.g., **Bed I** at **Olduvai Gorge** can be distinguished from the **basalt** below it and the base of **Bed II** above it).

bedrock A general term for the deep rock layers that beneath a superficial (technically "surficial") stratigraphic sequence, usually **Quaternary** or later **Cenozoic**. The term **bedrock** is also used to refer to lithified or solid rock beneath unconsolidated material such as cemented sandstone beneath loose sand. For example, at **Olorge-sailie** the relatively unconsolidated sedimentary rocks that make up **Beds 1–4**, etc., lie on a **bedrock** of **Pleistocene** lavas.

Beeches Pit (Location $52^{\circ}18'56''\text{N}$, $00^{\circ}38'20''\text{E}$, England, UK; etym. the name of a disused brickpit at the edge of Thetford Forest) History and general description **Beeches Pit**, which is northwest of **Bury St Edmunds** in **Suffolk**, is an **Acheulean** site that also preserves some of the earliest evidence of controlled fire in western Europe. In 1999 artifacts were discovered about 0.5 m beneath the principal artifact horizon. Excavation uncovered archeological sequences in two areas of the northwest part of the disused brickpit, **AF** to the west and **AH** to the east, where vertical sections of up to 5 m are preserved. The sediments in the eastern (i.e., **AH**) trench are stratigraphically older. Here an artifact horizon was exposed across excavations of approximately 75 m², and the evidence suggests there were multiple occupations, probably by the side of a pool. Several thousand **knapped flints** come from an approximately 30 cm-thick horizon within which around 100 **refitting** pieces and **microdebitage** have been found. These artifacts are stratified within clays containing organic material including **microfauna** and molluscs, and they probably come from an occupation on the top of the channel bank in an area later erased by solifluction; only the edge of the distribution is preserved. Temporal span and how dated? The main **Beeches Pit** site preserves an interglacial sequence overlying glacial sediments; the western area, **AF**, records a later sequence within the same interglacial. On the basis of stratigraphy, environmental indicators, and **thermoluminescence dating** and **uranium-series dating** it is inferred that these sediments represent the **Anglian** glaciation (i.e., **Oxygen Isotope Stage 12**) and the following interglacial (**Oxygen Isotope Stage 11**). Hominins found at site None. Archeological evidence found at site The artifacts, which are **Acheulean** but not **Clactonian**, are associated in multiple phases with environmental evidence indicating a temperate environment, sometimes with closed vegetation. The site is also notable for evidence of fire and burning. In area **AH**, in addition to visible

evidence of at least three large hearths, a flint refit set of around 30 pieces is consistent with selective burning. In area AF there is evidence of a similar, but later, event, with localized burning on a sloping bank adjacent to the presumed pond, and at higher levels in AF there is a widespread dark horizon that contains burnt material. The repeated nature of burning concurs with evidence from sites such as **Gesher Benot Ya'akov**, and with the presence of large hearths at **Schöningen**. Key references: Geology and dating Gowlett et al. 2005, Gowlett 2006, Preece et al. 2006; Hominins N/A; Archeology Gowlett et al. 2005, Gowlett 2006.

Behanga See Nyabusosi.

behavioral ecology Behavioral ecology focuses on the evolutionary and ecological factors that influence behavior. Behavioral ecologists might consider, for example, whether the costs of an activity or behavior outweigh its benefits (see **optimization**). Applying behavioral ecological principles to modern humans and to their evolution has, among other things, contributed to debates over the sexual division of labor, foraging, provisioning, and **life history** strategies (e.g., Winterhalder and Alden Smith 2000).

BEL Abbreviation of Belohdelie, Ethiopia. See **Belohdelie**.

BEL-VP Abbreviation of Belohdelie – Vertebrate Paleontology. Prefix used for fossils recovered from **Belohdelie**, Ethiopia (e.g., **BEL-VP-1/1**).

BEL-VP-1/1 Site **Belohdelie**. Locality Belohdelie Vertebrate Paleontology Locality 1 (BEL-VP-1). Surface/in situ Surface. Date of discovery 1981. Finder J. Krishtalka. Unit N/A. Horizon N/A. Bed/member MAK-G1. Formation **Sagantole Formation**. Group Awash Group. Nearest overlying dated horizon Cindery Tuff. Nearest underlying dated horizon Tuff VT-1. Geological age c.3.89–3.86 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The specimen consists of seven vault fragments, three of which comprise most of the frontal bone. Announcement Clark et al. 1984. Initial description Clark et al. 1984. Photographs/line drawings and metrical data Clark et al. 1984, Asfaw 1987. Detailed anatomical description Asfaw 1987, Kimbel et al. 2004. Initial taxonomic

allocation *Australopithecus* aff. *Au. afarensis*. Taxonomic revisions *Australopithecus afarensis* (Kimbel et al. 1994). Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance If confirmed as *Au. afarensis* the Belohdelie frontal would be among the earliest, if not the earliest, fossil evidence for that taxon. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Belohdelie One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous sub-region of the **Middle Awash study area**. It was first explored for its paleoanthropological potential in 1981 by a multidisciplinary team organized by the **Ethiopian Ministry of Culture and Sports Affairs** and led by **Desmond Clark**. A hominin frontal bone, **BEL-VP-1/1**, was recovered during the initial survey. See also *Australopithecus afarensis*.

belowground food resources The terminology used by Hatley and Kappelman (1980) for what are now referred to as **underground storage organs** (or **USOs**). Hatley and Kappelman (1980) reviewed the use of belowground food resources (i.e., bulbs, rhizomes, roots, stem bases, and tubers) by bears and pigs and they also considered the data about the belowground food resources eaten by the ≠Kade San. It is estimated that belowground food resources make up just less than half of the vegetable foods that form the majority of the food intake of the ≠Kade San (Tanaka 1976). Hatley and Kappelman (1980) suggest the digging sticks used by modern humans are the analogs of the claws of the bears and the tusks and snout of pigs, and they suggest that belowground food resources would have provided “security, stability, and independence” from “grazing, fire, and drought” for hominins “seeking a living in **Pliocene** and early **Pleistocene** times” (*ibid*, p. 384). See also **digging stick**; **underground storage organs**.

bending energy See transformation grids.

benthic (Gk *benthos*=deep in the sea) Organisms that live in, on, or close to the sea floor are referred to as benthic. Deep-sea cores are extracted from ocean floors to sample the shells of ancient benthic **foraminifera** within the sediment core. The ¹⁸O/¹⁶O ratios of these shells contain a temporal

record of **deep sea temperatures** and **glacial ice volume**. Any planktonic foraminifera in the cores will provide a record of **sea surface temperature**.

benthic foraminifera *See* foraminifera.

bent-hip bent-knee walking This form of bipedal walking, with flexed hips and knees, was suggested by John Napier (1967) as the type of bipedal gait that archaic hominins might have been capable of. Later Jack Stern and Randall Susman (1983) suggested this form of gait was most likely used by *Australopithecus afarensis* given the skeletal morphology and inferred muscular arrangements seen in A.L. 288. Since then, the nature of gait in *Australopithecus* has become one of the main debates concerning archaic hominins. Currently there is no consensus regarding whether the gait of *Australopithecus* was characterized by a bent hip and bent knee, was similar to that of modern humans, or was unique in other ways.

Berg Aukas (Location 10°30'58"S, 18°15'10"E, Namibia; etym. named after the Berg Aukas vanadium mine) History and general description In 1965 a massive right proximal femur, Berg Aukas 1, was found with other bones in a breccia deposit in level 5 of the mine, 177.4 m below the surface: the source breccia was subsequently destroyed by mining operations. The specimen passed to a private collection, but was acquired by C. Begley and taken to the Museum of Man and Science in Johannesburg in 1968. It was later loaned to Phillip Tobias for study. Temporal span and how dated? **Early to Middle Pleistocene** based on morphological comparison with better-dated specimens. Hominins found at site Berg Aukas 1, a well-preserved and densely mineralized proximal right femur with a massive head, low **neck-shaft angle**, and thick cortical bone. It resembles the presumed *Homo erectus* specimen KNM-ER 736 from Koobi Fora, Kenya, and the massive femoral fragment from **Castel di Guido**, Italy, attributed to *Homo heidelbergensis*. Archeological evidence found at site None. Key references: Geology and dating Grine et al. 1995, Conroy 1996; Hominins Grine et al. 1995, Trinkaus et al. 1999b; Archeology N/A.

Berg Aukas 1 *See* Berg Aukas.

Bergmann's Rule This concept (probably better described as a trend rather than a rule),

attributed to Carl Bergmann (1847), states that animals living at lower average temperatures tend to have larger body sizes overall. Bergmann's Rule (and its "sister" ecogeographic rule, **Allen's Rule**) have not been extensively tested in nonhuman primates, and the studies that have been undertaken show limited support. This could be because for tropical primates temperature is a less important determinant of climate than other factors (such as rainfall) and therefore it has less influence on morphology, but the body sizes and shapes of modern humans and their closest relatives show relatively strong relationships with latitude (Holliday 1999, Ruff 1994, 2002). Bergmann's Rule applies to modern humans with respect to mean body mass (Ruff 2002).

Bernard Price Institute for Palaeontological Research

Dr Bernard Price, a South African industrialist and philanthropist, was so impressed with the research carried out by Robert Broom that in 1945 he provided the funds to establish this institute (or BPI). James Kitching was the first employee of the BPI; he worked there full-time until 1990, remaining associated with the BPI until his death in 2003. The institute is presently part of the School of Geosciences in the Faculty of Science of the University of the Witwatersrand, Johannesburg, South Africa. Its mission is to collect, conserve, study, and interpret the fossil heritage of southern Africa. The BPI houses one of the largest collections of Karoo vertebrates in the world, and in conjunction with the **Institute for Human Evolution** it now curates the faunal fossil collections from **Makapansgat**, **Cooper's Cave A and B**, **Drimolen**, **Gladysvale**, **Sterkfontein**, **Plovers Lake**, etc. It also has extant comparative faunal collections. Hominin fossil collections When the repository at the BPI is completed, it will hold all of the hominins collected at Sterkfontein other than those held at the **Ditsong National Museum of Natural History** (previously the **Transvaal Museum**) (i.e., the material collected by Ron Clarke, Alun Hughes, and Phillip Tobias since 1966 from Members 2–6), and the hominins recovered from Cooper's Cave A and B, Drimolen, and Gladysvale. Comparative collections See above. Contact person Bernhard Zipfel (e-mail Bernhard.Zipfel@wits.ac.za). Street address 1 Jan Smuts Avenue, Johannesburg, South Africa. Mailing address PO Wits, 2050 Wits, South Africa. Website <http://web.wits.ac.za/geosciences/bpi/index.htm>. Tel +27 11 717 6683. Fax +27 11 717 6694.

Bervavölgy (Location 48°00'N, 20°20'E, Hungary; etym. named after the valley in which it is found) History and general description This cave site in the Bükk mountains contains Late Magdalenian deposits. Temporal span and how dated? Comparison of the lithics suggests a Late Magdalenian age (*c.*12 ka). Hominins found at site A mandibular fragment with two teeth attributed to *Homo sapiens*. Archeological evidence found at site Late Magdalenian lithics. Key references: Geology, dating, and paleoenvironment Thoma and Vértes 1971; Hominins Thoma and Vértes 1971.

beta taxonomy (Gk *beta*=the second letter in the Greek alphabet and *taxis*=to arrange or “put in order”) It is common for reference to be made to **alpha taxonomy**, but you very seldom read, or hear, any reference to beta taxonomy. Mayr et al. (1953) is one of the few sources that defines these terms [e.g., they do not appear in the index of Simpson’s (1960) *Principles of Animal Taxonomy*]. Mayr et al. (1953) suggest “the taxonomy of a given group, therefore, passes through several stages. . .informally referred to as alpha, beta, and gamma taxonomy” (*ibid*, p. 19). The distinction made by Mayr et al. is that whereas alpha taxonomy results in species being “characterized and named,” and gamma taxonomy refers to the “analysis of intraspecific variation and to evolutionary studies,” beta taxonomy involves arranging species in “a natural system of lesser and higher categories” (*ibid*, p. 19). So what Mayr et al. (1953) called beta taxonomy includes the process of **phylogeny reconstruction**, which is part of **systematics**. But Mayr et al. (1953) caution that it is “quite impossible to delimit alpha, beta and gamma taxonomy sharply from one another, since they overlap and intergrade” (*ibid*, p. 19). *See also* **systematics**; **taxonomy**.

BHBK Acronym for bent-hip bent-knee. *See* **bent-hip bent-knee walking**.

Biache *See* **Biache Saint-Vaast**.

Biache Saint-Vaast (Location 50°18'54"N, 2°56'55"E, France; etym. named after the town in which it is located) History and general description This open-air site is located in Pas-de-Calais, on an upper terrace along the Scarpe river. The site was discovered during the expansion of a steel mill and was excavated as a salvage operation from

1976 to 1982 by Alain Tuffreau and his team. The site preserved evidence of several episodes of hominin occupation during warm interglacial periods, a large faunal assemblage, and the fragmentary remains of two *Homo neanderthalensis* crania, both from archeological layer IIA. Temporal span and how dated? The **biostratigraphy** suggests that most of the archeological layers were deposited during **Oxygen Isotope Stage 7**, or *c.*240–190 ka. **Thermoluminescence dating** of burned **flints** from the main archeological layer, IIA, suggests an age of 175±13 ka, but thermoluminescence dating using gamma spectrometry on the second hominin cranium suggests an older age of 263+53/–37 ka. **Electron spin resonance spectroscopy dating** of two animal teeth from the same layer also suggests an older age of *c.*272 ka. Hominins found at site Two fragmentary crania were recovered. One, Biache I, was found *in situ*, and includes a portions of the rear of the cranium, parts of the maxillae, and 11 upper teeth belonging to a young, presumably female, individual. The other fossil, Biache II, was found after excavation, during the study of the faunal remains, and consists of a portion of the frontal, and the left parietal and temporal bones. It is thought to be from a young male. Both fossils come from the same thin archeological layer near the base of the site, and are considered to belong to *H. neanderthalensis*, or to a **pre-Neanderthal** hominin. Archeological evidence found at site The abundant lithic assemblage has been characterized as **Ferrassie Mousterian**. Many of the faunal remains show signs of butchery and evidence of marrow extraction. Key references: Geology and dating Huxtable and Aitken 1988, Tuffreau and Sommé 1988, Yokoyama 1989, Bahain et al. 1993; Hominins Rougier 2003, Vandermeersch 1978a, 1978b; Archeology Tuffreau and Sommé 1988.

bias (Fr. *biais*=slant from the Gk *epikarsios*=slanted) A term that refers to several different concepts in statistics and measurement, all of which refer to errors in the estimation of a population parameter. Statistical bias generally refers a difference between the sample estimate of a population parameter (such as the mean) and the value of that parameter in the full population. Such differences can result from different types of bias. For example, selection (also called sampling or ascertainment bias) refers to nonrandom sampling of a population, in which case a variable measured for the sample is a

poor estimate for the actual value for a population. Consider a fossil assemblage that only preserves the largest individuals in a population; in that case, the mean value of any measurement for that sample will be an overestimate of the actual value of the mean for the population from which the sample was drawn. Systematic bias is another source of error and is usually the result of an error in measurement where all measurements are off by the same amount. For example, a set of calipers may be incorrectly zeroed such that the calipers read a measurement of 10 mm when the jaws are completely closed (i.e., a real measurement of zero). In that case, all measurements will be 10 mm too high, and the estimate of the mean will reflect this error. If the systematic bias is truly equal for all measurements, then measures of absolute variation (such as variance and standard deviation) will not be statistically biased, but measure of absolute variation (such as the coefficient of variation) will be. *See also* **ascertainment bias**.

biface (L. *bis*=twice and *facies*=surface) A stone tool that has been worked twice on opposed surfaces, or faces, as opposed to those worked on one side; the latter are termed unifaces. Handaxes are a typical example of a biface.

bifacially worked (L. *bis*=twice and *facies*=surface) A term used in the analysis of stone tools that refers to a piece that is worked (i.e., shaped), on two opposed surfaces, or faces. It contrasts with a piece that is worked (i.e., shaped), on just one surface, or face; such pieces are said to be **unifacially worked**. *See also* **biface**.

Bilzingsleben (Location 51°16'52"N, 11°4'7"E, Germany; etym. named after the village of Bilzingsleben 1.5 km/0.9 miles north of the site) History and general description An open-air hominin site in west central Europe, 35 km/22 miles north of Erfurt, Germany, with controversial evidence of dwelling structures, hearths, and worked bone. The site lies near the base of a sequence of Pleistocene travertine built up by a **karst** spring that flowed into a shallow lake. The first mention of fossil bones and teeth is from 1710 by David Siegmund Büttner. Excavations began in 1922 under the direction of Adolf Spengler. Further excavations, initially directed by Dietrich Mania, began in 1969 and are ongoing. Temporal span and how dated? Biostratigraphy suggests the site is within **Oxygen Isotope**

Stage 11e, and **uranium-series dating** on calcite samples and **electron spin resonance spectroscopy dating** on teeth are consistent with a date between *c.*362 and 423 ka. Hominins found at site Thirty-seven hominin fossils, including 29 cranial fragments (occipital, parietal, and frontal), an edentulous mandible fragment, and nine isolated teeth. At least three individuals are represented, including one juvenile. Archeological evidence found at site The travertine-preserved Pleistocene fauna, molluscs, and flora, as well as hominin-modified bones and Lower Paleolithic lithic material, described as "Micro-Clactonian." In addition, Mania found a circular arrangement of stones that he interpreted as evidence of dwelling structures. The archeological horizon lies in the alluvial deposits by the ancient lake shore and has yielded around 140,000 flint artifacts, and many other tools made of stone, bone, antler, ivory, and wood. Key references: Geology, dating, and paleoenvironment Schwarcz et al. 1988, Jöris and Baales 2003; Archeology Mania 1983, Mania and Vlček 1987, Mania 1989, 1997; Hominins Vlček 1978a, Mania et al. 1993, Stringer 1981, Street et al. 2006. Location of the hominin fossils found at site Landsmuseum für Vorgeschichte, Halle/Saale, Germany (specimens discovered before 1993) and Forschungsstelle Bilzingsleben der Friedrich Schiller Universität Jena, Jena, Germany (specimens collected in 1993 and thereafter).

bimaturism (L. *bi*=two and *maturus*=ripe) Term introduced by Jarman (1983) for the process by which two organisms, or two structures, differ in size because the larger one has grown for longer. Usually it is a sex difference with the males having the longer period of growth (e.g., canine dimorphism in extant hominoids; Schwartz and Dean 2000).

Binford, Lewis (1930–) Lewis Binford was born in Norfolk, Virginia, USA. He began undergraduate studies at Virginia Polytechnic Institute, where he studied wildlife biology and thus began a lifelong scholarly interest in the environment. His education was interrupted by the Korean War, but it was during his military service when he was assigned to be an interpreter for displaced Japanese that he developed an interest in anthropology. Afterwards, he attended the University of North Carolina, where he studied anthropology and archeology. He attended graduate school at the University of Michigan, graduating in 1964

with a dissertation on the archeology and ethno-history of coastal Virginia. Starting in 1961, Binford taught at the University of Chicago, and then at the University of California, first at Santa Barbara, and then at UCLA. His primary academic home, however, was the University of New Mexico, where he taught for 23 years before taking a position at Southern Methodist University in 1991. His magnum opus, *Constructing Frames of Reference*, which used a large database of hunter-gatherer societies and environmental data to create predictive models for prehistory, was published in 2001. In 1962, Binford published *Archaeology as Anthropology*, widely regarded as the foundation of the "New Archaeology" of the 1960s, now known as processual archeology. The call for an archeology relying on scientific methods, including a hypothesis-testing approach, was revolutionary at the time but is *de rigueur* today. Binford took a materialist approach to understanding prehistory, relying on Leslie White's concept of culture as "man's extrasomatic means of adaptation." He helped pioneer ethnoarcheology (with research among the Nunamiut Eskimo and Australian Aborigines), and made fundamental contributions to faunal analysis, taphonomy, and the use of modern ethnographic data to model past behavior. Binford was an outspoken advocate for the development of "middle-range theory," a body of information intended to allow archeologists to make reliable inferences about past dynamics from archeological remains. Binford's involvement with paleoanthropology began early in his career, through a debate with eminent French prehistorian François Bordes over the meaning of variability in stratified Mousterian cave assemblages. Bordes proposed that the assemblages reflected different cultural constructs about appropriate ways to make stone tools, and hence different "tribes" of *Homo neanderthalensis*, but Binford (and Binford) argued that the assemblages reflected different functional uses of a cave. Through his Nunamiut ethnoarcheological research he was later able to demonstrate that the same people did produce different assemblages at different places, and that the same place could be used for different purposes as the settlement system shifted its geographic placement. This work, which appeared first in *Nunamiut Ethnoarchaeology*, led Binford into faunal analysis. This new focus in turn led him to a concern with the inferences that archeologists were making from the faunal remains found in Lower and Middle Paleolithic sites. His efforts in this area appeared in *Faunal Remains from Klasies*

River Mouth Cave and *Bones: Ancient Men and Modern Myths* as well as in a series of articles, mostly published in the 1980s. Binford argued that most paleoanthropologists saw hominins of the Lower Paleolithic as simply modern humans stripped down to bare essentials: hunters of large game who lived in small bands that foraged in much the same manner as Bushmen and other modern hunter-gatherers, with a similar division of labor, settlement pattern (with "base camps"), and technological capacity. Binford asserted that there was no good evidence of large game hunting in the Lower and possibly the Middle Paleolithic at sites such as **Klasies River**, **Zhoukoudian Locality 1**, **Swanscombe**, **Abri Vaufrey**, **Torralba**, **Koobi Fora**, and **Olduvai Gorge**. Instead, he argued from skeletal element representation that most of the faunal remains in association with stone tools was a result of scavenging of low-utility body parts. Binford also argued that the stone tool assemblages of the Lower Paleolithic showed little evidence of the type of planning seen among modern hunter-gatherers. Binford considered the role that tools played in a foraging adaptation and he thought two associations were typical of **Oldowan** and **Acheulean** assemblages: (a) a transported toolkit consisting of heavy-duty core tools such as handaxes or choppers and (b) an expediently produced toolkit consisting of small scrapers and pebble tools; at one point Binford suggested this second toolkit might be produced by children foraging from scavenged carcasses. Binford further argued that the transported toolkits were found in sites that (based on geologic data) were **palimpsests** of artifacts that accumulated in one place slowly over time. These sites were not, he maintained, base camps, but repeatedly revisited foraging stations where hominins extracted and ate food; hence, these sites were not comparable to the residential camps of living foragers. Binford further argued that the transported tools showed little evidence of extensive use and were not "piled up" in particular locations, as if hominins did not remember or know there were already tools at one location. In brief, Binford saw little evidence for extensive "planning depth" until the Upper Paleolithic. Binford's reading of the data suggested to him that Lower and Middle Paleolithic hominins behaved in ways unlike any recent human foragers, thus opening a door onto a world inhabited by foragers that did not necessarily follow familiar modern human patterns. Binford has been criticized for his interpretations, his selection of study samples and his use of data, and he engaged in vigorous debate with researchers whose analyses and

conclusions did not align with his own. His main contributions to paleoanthropology come from leading people to question easy assumptions and to work harder to justify their interpretations. Along with his contemporaries C.K. (Bob) **Brain**, **Glynn Isaac**, and others, Binford helped catalyzed renewed scrutiny of the empirical record. He inspired succeeding generations to make **taphonomy** and the study of site-formation processes central features of Paleolithic research projects. Binford's *Bones: Ancient Men and Modern Myths*, together with Brain's *The Hunters or the Hunted*, are two seminal case studies that demonstrate the value of taphonomy and **actualistic studies** to faunal analysis. Binford's approach to the study of technology as an integral part of foraging systems has become standard in the field and while many of his specific interpretations may not stand the test of time, he nonetheless helped shape paleoanthropology into the more rigorous field it is today.

binomen *See* Linnaean binomial.

binomial *See* Linnaean binomial.

Binshof *See* Binshof, Speyer.

Binshof, Speyer (Location 49°21'48"N, 8°27'03"E, Germany; etym. named after the village of Binshof, 30 km/19 miles west of Heidelberg) History and general description In 1974 an extremely well-preserved cranium was recovered containing most of the facial bones and maxillary teeth. The find became known as "Binshof, Speyer Woman" and was dated to the Pleistocene. The dating of the remains fell into question in 2001 when Thomas Terberger of Greifswald University had some of the fossil samples reanalyzed and the resulting ages were considerably younger. The find is now associated with the downfall of Reiner Protsch who is alleged to have falsified data. Temporal span and how dated? The original **radiocarbon dating** age for "Fra-40" was 21,300±320 years BP, but recent **AMS radiocarbon dating** (OxA-9880) suggests an age of 3090±45 years BP or 1420–1290 years BCE. Key references: Geology, dating, and paleoenvironment Henke 1980, Terberger and Street 2001, Street and Terberger 2002; Hominins Henke 1980.

biochronology (Gk *bios*=life, *chronos*=time, and *ology*=the study of) A **correlated-age**

method of relative dating that uses fossils preserved in a sedimentary rock to determine its age. Many fossil sites cannot be dated using absolute methods because they lack the raw materials needed for absolute dating (e.g., igneous rocks). These sites have to be dated using the fossils they contain. Fossils are matched with those found at other sites that cannot be dated by **numerical-age** and **calibrated-age methods** (e.g., isotopic or radiogenic) of **absolute dating**, as well as fossils from sites that can be dated using such methods. When a taxon is restricted to a particular time period or if their **first appearance datum** (or FAD) or **last appearance datum** (or LAD) is the same across several absolutely dated fossil sites then such a taxon can be used alone, or preferably in combination with other time-delineated taxa, to generate a biochronometric date for the stratum. The use of a single taxon for this purpose is exemplified by the use of the rodents *Mimomys* and *Microtus* in European sites. The vole *Mimomys* predominates in earlier sites, is rare in **Cromerian** sites, and by the **Middle Pleistocene** is replaced by *Arvicola* or *Microtus*. Data from one taxon, or a series of taxa, can be combined to define one, or more, **biozones**. An example of the former is the use of the extinct pig *Metridiochoerus andrewsi* as a marker taxon in East African strata, while an example of the latter is the **European mammal neogene** (or MN) system for dating Miocene and Pliocene sites whose ages range from 24 to 2 Ma. Recently the latter system has been extended below 2 Ma. The MN system is increasingly being used in preference to the classical European mammalian biozonations (i.e. **Vallesian**, **Turolian**, **Ruscinian**, **Villafranchian**, etc.). *See also* **biostratigraphy**; **European mammal neogene**; **geochronology**.

biogenetic law (Gk *bios*=life, plus *genesis*=origin or generation) The biogenetic law, or "ontology recapitulates phylogeny," proposes that during embryonic development animals pass through the adult stages of their ancestors, thus representing a nesting sequence of orthogenesis. This idea was popularized by Ernst Haeckel in the late 19thC, and was supported by comparisons of embryonic morphology from various organisms, identifying stages that represented adult fish, birds, and mammals, moving from earlier embryonic stages to later ones. In this way, one could "read" the entire evolutionary history of an organism by observing its

embryonic development. In this scheme modern humans represented the furthest point on this evolutionary scale, and embryologists endeavored to find examples of adult representatives of all lower life forms in the successive stages of modern human embryonic development. Any malformed fetus was seen as an atavism, or as the result of development that did not progress as far as it should have. The strictest interpretation of the biogenetic law is now understood to be false; that is, evolution does not occur in a linear manner wherein the developmental stages of ancestors are literally compressed into the ontogeny of descendant species. Development itself evolves, rather than just tacking on successive stages to an ancestral template. However, that being said, there are broad similarities in embryonic development among all mammals, and among mammals and reptiles, and among mammals and fish, but these mostly occur early in embryogenesis.

biogeography (Gk *bios*=life, *geo*=earth and *graphein*=to write) The scientific investigation of how and why organisms came to be distributed on the Earth in the way they are. Biogeographers document the spatial distribution of organisms and species and determine the processes that might explain such patterns. Historically, biogeography was an important focus of study for many pre-Darwinian naturalists. The geographic distribution of closely related, but adaptively distinct, species was an important factor leading Charles Darwin to accept the concept of **evolution**, and to propose **natural selection** as a mechanism to explain evolution. Darwin can reasonably be considered the father of evolutionary biogeography. Biogeographic patterns have also influenced the development of ideas about **allopatric speciation**. More recently, the modern development of biogeography as a scientific field is tied to the development and acceptance of plate-tectonic theory insofar as the movement of continental plates can have the effect of opening up or shutting off avenues for the **dispersal** (range change) or **vicariance** (range splitting) of populations (e.g., the separation of two continental plates may split what was formerly a single terrestrial habitat, but in doing so may unite two marine habitats). Some of the most important hypotheses in paleoanthropology concern biogeographic events. These include (a) the possible dispersal of the ancestor of the African ape and modern human **clade** from Europe to

Africa at the end of the **Miocene**, (b) the dispersals of various **australopith** and early *Homo* species within Africa during the Plio-Pleistocene, (c) the earliest dispersal of **hominins** out of Africa, probably comprising early *Homo* or *Homo erectus* near the **Plio-Pleistocene boundary**, (d) the colonization of Europe by hominins, (e) the colonization of Indonesia, (f) a subsequent dispersal out of Africa of modern *Homo sapiens* (or, at least, hominins possessing modern human morphology) during the **Late Pleistocene**, and (g) the colonization by hominins of the New World. Biogeography can be studied by using **phylogeny** as a tool to identify biogeographic events, because when an ancestor and its descendant are found in different regions, then obviously some type of dispersal or vicariance event must have taken place. Hominin biogeography may also be studied by comparing the biogeographic patterns of hominins to those of vegetational zones or other mammalian clades, within a tight temporal and/or climatic framework. Key biographical questions related to paleoanthropology include whether other mammals disperse in the same direction and at the same time as hominins, whether the mammalian dispersals and/or vicariance events provide an insight into how and why hominin populations disperse or split, whether hominin dispersals track the presumed changes in range of vegetational zones, and how, if at all, climate change has affected hominin biogeographic patterns.

biological species One of the many terms used to describe an **extant** species. It will be diagnosed on the basis of evidence of interbreeding, or the lack of any evidence of interbreeding between individuals belonging to that species and individuals belonging to any other species. It contrasts with a **paleospecies** that has to be diagnosed on evidence from the hard tissues alone. See also **species** (syn. **neontological species**, **extant species**).

biological species concept Defined by Ernst Mayr (Mayr 1942) and modified by him in 1982 (Mayr, 1982, p. 273). It is one of the “process” **species** definitions in which species are defined as “groups of interbreeding natural populations reproductively isolated from other such groups.” Note this definition depends on there being at least one additional species. It is a

“relational” and not a “free-standing” species definition. The biological species concept is of limited value in considering extinct hominins because it is impossible to observe direct evidence for interbreeding in the fossil record, and also because modern analogs of closely related primate species (as well as myriad other organisms) suggest that primate speciation can and has occurred even in the presence of gene flow. *See also* **species**.

biomarkers *See* **alkenones**.

biome (Gk *bios*=life) A distinctive regional ecological community of plants and animals adapted to the prevailing climate and soil conditions. Biomes are collections of ecosystems that have similar biotic and abiotic characteristics. Biomes can be (a) terrestrial, (b) freshwater, and (c) marine. There are several schemes for classifying terrestrial biomes (e.g., Holdridge classification scheme, Walter system, Bailey system, and Whittaker’s classification scheme) on the basis of variables such as the amount of precipitation, evapotranspiration potential, mean annual biotemperature and vegetation type. It is conventional to recognize six major terrestrial biomes – **forest**, **grassland**, **woodland**, **shrubland**, semi-desert shrub, and **desert** – each of which can be further subdivided on the basis of climatic conditions and elevation.

biospecies A contraction of biological species; one of the many terms used to describe an extant **species** defined on the basis of criteria such as evidence of interbreeding, or the lack of any evidence of interbreeding between individuals belonging to that species and individuals belonging to any other species. *See also* **biological species**; **species**.

biostratigraphy (Gk. *bios*=life, *stratos*=to cover or spread, and *graphos*=to draw or write) The process of linking rock layers within and among stratigraphic sequences by comparing the fossil assemblages preserved within them. This can be via either the matching of individual taxa (e.g., the rodent *Miomys* in Pleistocene European sites) or by using a system such as the **European Mammal Neogene** (or MN) system, which uses a combination of taxa. The use of the linked rock layers to infer the age of the strata is sometimes called biochronology. *See also* **biochronology**.

biotic (Gk *bios*=life) Describes all the living factors (e.g., competition for food, predator pressure) that affect the evolutionary history of a **taxon**, or of a **clade**.

bioturbation (Gk *bios*=life and *turbe*=turmoil) The displacement and mixing of sediment or soil by **biotic** agents or processes. Bioturbation is caused by plants or animals. In Africa, for example, both **termites** and rodents can burrow during and after the deposition of **artifacts** and **ecofacts** on a land surface. The movement of termites and rodents through the stratigraphic sequence can incidentally transport objects on and within the sediment, removing them from their original context. Their new context is often temporally incongruous, and can create or remove spatial and temporal associations. Detailed sedimentological study can identify strata that have been affected by bioturbation (i.e., they are bioturbated). Any evidence of bioturbation is important when considering the temporal and contextual integrity of a paleontological or archeological site, especially when evidence from the site might be used to develop hypotheses about hominin activity patterns and/or to reconstruct the paleoenvironment.

biozone A series of strata at one, or more, sites all of which sample the same fossil taxon, or suite of fossil taxa. An example would be all the East African strata that sample the extinct pig *Metridiochoerus andremsi*.

biped (L. *biped*=two-footed) A hominin whose resting posture is standing on the feet of the two hind, or lower, limbs, and whose locomotor repertoire involves a significant component of bipedal travel. *See also* **bipedal**.

bipedal (L. *biped*=two-footed) Form of posture or locomotion in which the body is supported exclusively on the feet of the two hind, or lower, limbs. Prost (1980) usefully distinguishes between taxa in which adults are able to travel bipedally, which he calls “facultative bipedalism,” and taxa such as modern human adults for which bipedal gait is the only efficient way for them to move around. Prost (*ibid*, p. 187) refers to the latter as “preeminent bipedalism,” but others have referred to the latter category as “obligate bipeds.” For example, the earliest hominins were most likely facultative bipeds, whereas *Homo neanderthalensis* was almost certainly a preeminent,

or obligate, biped. Prost also makes the point that the possession of some of the morphological traits seen in known bipeds (Prost calls these **bipedal traits**) does not mean the taxon that possesses them was necessarily a biped (i.e., practices “bipedalism”). He cites some bipedal traits that are seen in both vertical climbers and bipeds; thus the possession of these traits should not be equated with bipedalism.

bipedal locomotion *See* bipedal; walking cycle.

bipedal trait A term used by Prost (1980) for a morphological feature found in known bipeds that is functionally related to bipedal posture and/or locomotion. For example, an adducted hallux is a bipedal trait established prenatally that is present in all known hominin bipeds and plays an important role in propulsion at the end of the stance phase of bipedal gait. Some bipedal traits, such as the valgus knee joint, are **epigenetically** sensitive and only develop in bipeds in response to bipedal walking (e.g., Tardieu and Trinkaus 1994). *See also* bipedal.

bipedalism The act of walking or running using only the feet of the two hind, or lower, limbs for support. *See also* bipedal.

bipedalism, facultative *See* bipedal.

bipedalism, obligate *See* bipedal.

bipolar (L. *bi*=two and *polus*=axis) A term used to refer to a specific technological approach for making stone flakes in which the core is rested on an **anvil** and then struck to split the core, or to remove a flake. The flakes produced by this technology are characterized by evidence of percussion from opposite ends, or “poles” (the anvil and hammer ends) of the struck core. Bipolar technology, which is used wherever stone is available in small packages (e.g., pebbles), occurs at **Oldowan** sites such as **Olduvai Gorge** (Jones 1994), and it is also common at many **Later Stone Age** sites in southern Africa (Barham 1987). Chimpanzee populations that crack nuts mostly use bipolar technology when they do so (Haslam et al. 2009).

bipolar percussion (L. *bis*=twice and Gk *polus*=axis, poles are at each end of an axis) Bipo-

lar means “two poles”, so bipolar percussion is a term used for a method of fracturing stone for the production of sharp-edged **flakes**. Percussive forces are initiated on a stone from two opposed directions, or poles. Typically, a small pebble is rested on an **anvil**, and struck from above, and the percussive force splits the pebble in two. Bipolar percussion is a technique seen early in the archeological record (e.g., at **Oldowan** sites). *See also* bipolar.

birds All extant birds and fossil birds found at early hominin sites belong to the Neornithes, the “modern” birds, within the class **Aves**. Bird true fossils are relatively rare in the fossil record, but there are trace fossils of birds (e.g., prints and tracks) as well as evidence from their ontogeny, such as fossil egg shell. However, when the remains or traces of birds are found in the fossil record they can be useful paleoenvironmental indicators (e.g., wading birds indicating the nearby presence of water). The most common bird remains found at open-air early hominin fossil sites is probably ostrich egg shell, which can be used for **ostrich egg shell dating** as well as for **paleoenvironmental reconstruction**. *See also* **Aves**.

Bishop, Walter William (Bill) (1931–77) Bill Bishop graduated from Birmingham University in 1952 with a degree in geography. He stayed at Birmingham for his PhD studies, graduating in 1956, and then left the UK to work as a geologist with the Uganda Protectorate Geological Survey. After a period back in the UK as an Assistant Lecturer at Glasgow University and the Keeper of that University’s Hunterian Museum he returned to Uganda in 1962 as the Director of the Uganda National Museum. From the beginning of his time in Uganda Bill Bishop began to take an interest in paleontology and human evolution and he did field work at many locations including Napak, a volcano mapped by Basil King in 1939. In 1965 Basil King recruited Bishop to join him at Bedford College in the University of London as a Lecturer in Geology, where he became part of Kings’ East African Geological Research Unit (or EAGRU), which was carrying out an ambitious mapping project in the northern part of the Rift Valley in Kenya, in collaboration with the Geological Survey of Kenya and the Department of Geology at what was then University College, Nairobi. This project involved several

graduate students (e.g., Greg Chapman, Andrew Hill, John Martyn, and Martin Pickford) who mapped regions (e.g., the Tugen Hills) that became the focus of several subsequent productive field research projects. For example, Bishop and Chapman (1970) and then Bishop and Pickford (1975) described the sediments and fossils from the Ngorora Formation; Bishop, Chapman, and Hill, together with Jack Miller (Bishop et al. 1971), described the *c.*15 Ma-long succession of vertebrate assemblages in the Tugen Hills and Carney et al. (1971) described the first hominin from the Chemoigut Formation at **Chesowanja** and later Bishop, Pickford, and Hill (1975) reported archeology and a further hominin from Chesowanja. In 1974 Bill Bishop was appointed to the Chair of Geology at Queen Mary College, also in the University of London, and at the time of his unexpected death at the age of 46 he was due to take up the Directorship of the Peabody Museum at Yale University. Bill Bishop was a great advocate of the importance of a sound chronology and he was a skilled synthesizer of information about the fossil record and geochronology. His 1973 review in *Nature*, “The tempo of human evolution,” emphasized the former, as did volumes he edited or co-edited (e.g., *Background to Evolution in Africa*, 1967 with Desmond Clark; *Calibration of Hominoid Evolution*, 1972 with Jack Miller; *Geological Background to Fossil Man*, 1978). At the time of his death Bishop had just begun working as coordinator of the geological studies in David Pilbeam’s project in the Potwar Plateau of Pakistan. Bill Bishop was an amateur singer and he was both noted and notorious for his own (often long) lyrics written to suit the conferences he attended. These usually featured noted conferees and were always set to tunes from Gilbert and Sullivan operettas.

bite force *See* chewing.

BK Acronym for Baringo Kapthurin. It is the prefix used for fossils recovered from the **Kapthurin Formation**, Tugen Hills, Baringo District, Kenya (e.g., KNM-BK 67). It is also an abbreviation of **Blimbingskulon**, and it is used as the prefix for fossils from that site in Java, Indonesia (e.g., **BK 7905**). It is also the acronym for Bell’s Korongo, a site in the side gorge at **Olduvai Gorge**. Excavations at Bell’s Korongo between 1952 and 1958 resulted in the recovery of many artifacts and in 1954 Mary

and Louis **Leakey** recovered two hominin teeth, OH 3, which turned out to be the first evidence to be discovered of the hominin *Zinjanthropus boisei*. *See also* **Blimbingskulon**; **Kapthurin Formation**; **Olduvai Gorge**.

BK 7905 Site Blimbingskulon. Locality Dried tributary of the Brangkal River. Surface/in situ Surface. Date of discovery 1979. Finder Mr Sutanto, a local villager. Unit N/A. Horizon N/A. Bed/member **Grenzbank Zone**. Formation Between the overlying **Bapang Formation** and the underlying **Sangiran Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.60 Ma. Developmental age Late adolescent or young adult. Presumed sex Unknown. Brief anatomical description Fragmentary and heavily mineralized right mandibular corpus preserving the partial roots of M₁ and a complete M₂. Announcement Aziz 1983. Initial description Aziz 1983. Photographs/line drawings and metrical data Kaifu et al. 2005b. Detailed anatomical description Kaifu et al. 2005b. Initial taxonomic allocation “*Meganthropus*” (Aziz 1983). Taxonomic revisions *Homo erectus* (Kaifu et al. 2005b). Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The specimens from Blimbingskulon extend the range of morphological and metrical diversity of early *H. erectus* from Java (see Kaifu et al. 2005b). Location of original Geological Research and Development Center, Bandung, Indonesia. (syn. Sangiran 33, Mandible H).

BK 8606 Site Blimbingskulon. Locality N/A. Surface/in situ Surface. Date of discovery 1986. Finder Mr. Sutanto, a local villager. Unit N/A. Horizon N/A. Bed/member **Grenzbank Zone**. Formation Between the overlying **Bapang Formation** and the underlying **Sangiran Formation**. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*1.51–1.60 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Fragmentary and heavily mineralized right mandibular corpus preserving the distal portion of the P₃ root, the roots of M₁–M₂ and a partial M₃ crown. Announcement Aziz et al. 1994. Initial description Aziz et al. 1994. Photographs/line drawings and metrical data Kaifu et al. 2005a. Detailed anatomical description Kaifu et al. 2005a. Initial

taxonomic allocation *Homo erectus* (Aziz et al. 1994). Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The specimens from Blimbingkulon extend the range of morphological and metrical diversity of early *H. erectus* from Java (see Kaifu et al. 2005b). Location of original Geological Research and Development Center, Bandung, Indonesia (syn. Sangiran 39).

Blaauwbank valley A shallow valley in the limestone hills that form the high veldt in the vicinity of Krugersdorp in Gauteng Province, South Africa. The hills contain many substantial breccia-filled solution cavities and some of these (e.g., Cooper's Cave, Drimolen, Kromdraai, Malapa, Sterkfontein, and Swartkrans) contain fossil hominins. *See also* Cooper's Cave; Drimolen; Kromdraai; Malapa; Sterkfontein; Swartkrans.

Black, Davidson (1884–1934) Davidson Black, born in Toronto, Canada, entered the University of Toronto as a medical student in 1903. After completing his medical degree in 1906 and BA degree in 1909, Black obtained an appointment as an anatomist at Western Reserve University (now Case Western Reserve University) in Cleveland, Ohio, USA. While at Western Reserve, Black was introduced to physical anthropology by Thomas Wingate Todd, who had studied with the prominent Australian neuroanatomist and physical anthropologist Grafton Elliot Smith. In 1914 Black spent a sabbatical leave in Manchester, England, where he worked with Elliot Smith and met Sir Arthur Keith and Sir Arthur Smith Woodward (with whom he visited Piltdown). Black visited the neuroanatomist Cornelius Kappers in Amsterdam (but the impending hostilities of WWI forced him to cut short the visit) before returning to America fired with enthusiasm for human paleontology and neuroanatomy. For much of the early 20thC many anthropologists believed that the first humans had evolved in Asia, not Africa, and for this reason Black became interested in the possibility of searching for hominin remains in Asia. An opportunity arose when Black learned that the newly established **Peking Union Medical College** (or PUMC) in Beijing was looking for faculty. Black obtained a position teaching embryology and neurology at the PUMC in 1918 (but he and his wife did not arrive in China for more than a year) and while his primary duties were to train

Chinese medical students, by 1921 the position offered Black enough free time to pursue his search for hominin fossils together with the Swedish geologist Johan Gunnar Andersson. Even before Black began his explorations, Andersson and the Austrian paleontologist Otto Zdansky had begun collecting **Pleistocene** fossils from sites in China. The most promising site was Choukoutien (now Zhoukoudian) near Beijing, a series of limestone hills where locals had long extracted the limestone and fossils (“dragon bones”), the latter of which were ground into powder for use in traditional medicines. In addition to mammalian fossils Andersson had found crude stone tools at Zhoukoudian, so there was good reason for Black to focus his efforts at this site. In 1926–7 Black made an agreement with Wenhao Weng, the director of the **National Geological Survey of China**, to collaborate on the exploration of China's Cenozoic geology and paleontology. Black obtained funds from the **Rockefeller Foundation** to initiate excavations at Zhoukoudian, which immediately produced a substantial quantity of mammal fossils and then late in 1927 a tooth Black concluded belonged to a new species of hominin. On the basis of this tooth and two others found by Zdansky in the early 1920s, Black (1927) announced the discovery and the new taxon, *Sinanthropus pekinensis* (later reclassified as *Homo erectus*). Zhongjian Yang, a paleontologist, and Wenzhong Pei, a geologist, joined the excavation team in 1928. They soon discovered two lower jaws belonging to *Sinanthropus*, and the large numbers of fossil animals being recovered and the recovery of the additional hominin remains prompted Black and Weng to found the **Cenozoic Research Laboratory** (the forerunner of the **Institute of Vertebrate Paleontology and Paleoanthropology**) in 1929. Then, in December of 1929, Wenzhong Pei found a skullcap, followed by more modern human-like teeth, all of which strengthened Black's interpretation of *Sinanthropus* as a new type of hominin. Black made a trip to Europe in 1930 to discuss the discoveries at Zhoukoudian and he found that most of his colleagues had accepted *Sinanthropus* as a human ancestor. Excavations at Zhoukoudian expanded during the 1930s and produced several skulls and other skeletal material. Researchers soon recognized that the *Sinanthropus* specimens unearthed in China bore many anatomical similarities to the *Pithecanthropus erectus* fossils discovered by the Dutch anatomist Eugène Dubois in Java during the 1890s, and while Black acknowledged some similarities with the Javan

material he was convinced that *Sinanthropus* was more advanced than *Pithecanthropus*. Apparent evidence of *Sinanthropus*' cultural achievements was discovered in 1931 when Pei and Black found charred bones and other evidence they interpreted as showing that *Sinanthropus* used controlled fire (this hypothesis has since been refuted). Moreover, crude quartz tools were recovered, all of which suggested to Black that *Sinanthropus* was not only anatomically, but also culturally, relatively modern human-like. Black and his Chinese colleagues were assembling an impressive collection of hominin fossils, artifacts, and animal fossils, but they were also forming an institutional framework for the study of human origins in China. In the midst of these intensive investigations Davidson Black, who had a congenital heart defect, died unexpectedly in 1934. The German-American physical anthropologist Franz Weidenreich was appointed to replace Black in 1935 and excavations continued at Zhoukoudian until 1937 when war with Japan made excavation impossible. After the end of WWII the excavations at Zhoukoudian were resumed.

blade (OE *blaed*=sharp-edged tool) A term used for a **flake** that is at least twice as long as it is wide. A blade can also be defined as a flake that has parallel edges, or a flake that has multiple flake scars on its outer (or dorsal) surface attesting to previous attempts to remove similar parallel-sided blades from a core. Blade production was most likely invented multiple times, and perhaps by more than one hominin taxon. Blades appear intermittently in stone-tool-making industries globally from the **Middle Pleistocene** onwards, and they are particularly common in **Upper Paleolithic** assemblages (e.g., the upper strata at Kebara; see Bar-Yosef and Kuhn 1999).

bladelet (OE *blaed*=sharp-edged tool and OF *elet*=small) A term used to describe small **blades**. The distinction between blades and bladelets is arbitrary, although some have suggested that a bladelet must be less than 10 mm wide (Bar-Yosef and Kuhn 1999, Inizan et al. 1999). The earliest reported bladelets are those from the coastal cave site of **Pinnacle Point**, South Africa (Marean et al. 2007).

Blanc, Alberto Carlo (1906–60) The son of Gian Alberto Blanc (one of the founders of the Istituto Italiano di Paleontologia Umana), Alberto

Blanc obtained his degree in geology at University of Pisa where he concentrated on prehistoric archeology and the Pleistocene phase of human evolution. He was instrumental in the discovery of the **Saccopastore 2** cranium in 1935 and of the numerous caves on the Monte Circeo promontory, some of which (e.g., the Grotta Guattari) were rich in Paleolithic deposits, and he directed the only excavation carried out at the site. The discovery of Saccopastore 2 prompted the exploration of the basins of the Tiber and Aniene rivers for further sites and this research led Alberto Blanc and his collaborators to identify several periods (the “Cassio,” “Nomentano,” “Flaminio”) when the climate was much colder than at present. In the Pianura Pontina (Pontina Plain) he identified in what is now called Canale delle Acque (Ditch of the Waters) a stratigraphic sequence with fossil fauna and flora and Paleolithic artifacts. Exploration of caves along the coast of the Monte Circeo promontory led to the partly fortuitous discovery of the Grotta Guattari in 1939. In 1954 Alberto Blanc initiated the exploration and subsequent formal excavation of the site of Torre in Pietra and in the same year he founded the journal *Quaternaria*. Blanc held a number of positions during his career, culminating in his becoming professor of Paleolithic and Human Paleontology at the University of Rome as well as Director of the Istituto di Paleontologia in the Faculty of Letters and Philosophy at the University of Rome.

Blimbinkulon (Location 7°20'S, 110°58'E, Indonesia; etym. named after a local village) History and general description Within the **Sangiran Dome**, this is the site of a 1979 surface find of a hominin mandibular fragment (**BK 7905**) from a dry tributary of the Brangkal River; a second hominin mandibular fragment (**BK 8606**) was found nearby in 1986. Both specimens most likely derived from the **Grenzbank zone**, a coarse-grained **conglomerate** between the older **Sangiran Formation** and the younger **Bapang Formation**. Temporal span and how dated? Fluorine analyses support the derivation of these fossils from the Grenzbank zone. The most recent radiometric estimates of the age of this deposit cluster around 1.5 Ma. Hominins found at site BK 7905 is the fragmentary right side of a mandibular corpus with M₂ and a partially preserved root of M₃. BK 8606 is also the right side of a mandibular corpus preserving a partial M₃, the

roots of M₁–M₂ and the distal portion of the P₄ root. These specimens have been attributed to *Meganthropus* and *Homo erectus*. Archeological evidence found at site None. Key references: Geology and dating Aziz 1983, Matsu'ura et al. 1992, 1995b, Kondo et al. 1993, Larick et al. 2001; Hominins Aziz et al. 1994, Kaifu et al. 2005a.

Blind River (Location 27°1'30"S, 33°0'30"E, Eastern Cape Province, South Africa; etym. unknown) History and general description The site of discovery of a hominin femur. It was found by P.W. Laidler 150 m upstream from the river mouth during an archeological survey of the area. Temporal span The site is on a raised beach likely formed during the high sea level of **Oxygen Isotope Stage 5e**, so *c.*127–122 ka. How dated? Optically stimulated **luminescence dating** and geomorphological correlation. Hominins found at site An adult left femur lacking the proximal epiphysis. Archeological evidence found at site No tools in close association. Key references: Geology and dating Laidler 1933, Wells 1935, Wang et al. 2008; Hominins Wells 1935, Wang et al. 2008; Archeology Laidler, 1933.

Blind River femur *See* **Blind River**.

Blombos Cave (Location 34°25'S, 21°13'E, South Africa; etym. Afrikaans for “flowering bush,” named after the local village) History and general description Blombos Cave is situated on the coast approximately 300 km/190 miles east of Cape Town, was formed during the **Plio-Pleistocene** when waves cut away at the base of a cliff, but it is now 35 m above sea level and 100 m from the present shoreline of the Indian Ocean. The approximately 50 m² of sediments in the cave have been excavated since 1991. Temporal span The youngest deposits (*c.*2 ka) preserve evidence of the **Later Stone Age** (or LSA) and some of the earliest evidence of domestic animals in southern Africa. A sterile layer of *c.*70 ka dune sand divides the LSA from the more extensive **Middle Stone Age** (or MSA) deposits below, which constitute three levels, M1–3. Layers M1 and M2 have been dated to *c.*75 ka and *c.*75–105 ka, respectively; M3 is a shell **midden** that is presumed to be >100 ka. How dated? Optically stimulated **luminescence dating** and **thermoluminescence dating**. Hominins found at site Nine isolated teeth. Archeological evidence found at site Blombos is mainly important because of the recovery of the evidence

in MSA layers M1–2 of precociously early symbolic and other advanced behaviors including apparently deliberately fashioned cross-hatch patterns on pieces of **ocher**, more than 40 pierced “Dunker” shells in MSA levels M1–2 that have been interpreted as evidence of symbolic behavior (d’Errico et al. 2005), **bone tools**, and exploitation of deep water fish. All of these behaviors are more commonly associated with the LSA rather than the MSA. Ocher has also been recovered from MSA level M3. Key references: Geology and dating Jacobs et al. 2003, 2006, 2008, Jacobs 2003, Tribolo 2006; Hominins Grine and Henshilwood 2000, 2002; Archeology Henshilwood and Sealy 1997, d’Errico et al. 2001, 2005, Henshilwood et al. 2004, Henshilwood 2007, d’Errico and Henshilwood 2007.

BOD Abbreviation of Bodo. One of the three three-letter prefixes (the others are **DAW** and **HAR**) used for the paleontological evidence collected by the **Middle Awash Research Project**. Each three-letter prefix refers to the geographical area where it was found, followed by VP (for Vertebrate Paleontology), the number of the collecting site within the area, then a final number that places the fossil in the sequence of fossils recovered from that collecting site. Thus BOD-VP-1/1 is the first fossil to be found in the first collecting site to be recognized in the **Bodo** area of the **Middle Awash study area**.

Bodo (Location 10°37.5'N, 40°32.5'E, Ethiopia; etym. named after a local stream, and also known as Bodo D’Ar) History and general description One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area**. Abundant vertebrate fossils and **Acheulean** artifacts attracted prospecting efforts by the **Rift Valley Research Mission in Ethiopia** and its members looked for fossils and conducted archeological excavations at Bodo between 1975 and 1978. During the course of these efforts, a portion of a hominin cranium was discovered and subsequent intensive excavation and screening yielded most of the anterior two-thirds of a hominin cranium. The site was revisited by members of the **Middle Awash Research Project** and additional hominin fragments were recovered in 1981 (BOD-VP-1/1) and 1990 (BOD-VP-1/2). Temporal span Correlations between the Bodo fauna and the fauna from sites in Kenya suggest the site dates from the **Middle**

Pleistocene, and **argon-argon dating** and stratigraphic correlation suggest an age for the site of *c.* 600 ka. How dated? **Biostratigraphy** and argon-argon dating. Hominins found at site Bodo 1, a partial cranium with a massive supraorbital torus and face; BOD-VP-1/1, a left parietal (found roughly 400 m from Bodo 1); and BOD-VP-1/2, a small distal humerus. Archeological evidence found at site Large Acheulean handaxes fashioned of locally available basalt. Key references: Geology and dating Kalb et al. 1980, Clark et al. 1984a, 1994; Hominins Conroy et al. 1978, 2000, Asfaw 1983, White 1986, Adefris 1992, Rightmire 1996; Archeology Kalb et al. 1980, Clark et al. 1994.

Bodo 1 Site Bodo. Locality N/A. Surface/in situ Surface and *in situ* in the top 4–10 cm of loose silt covering the surface. Date of discovery 1976. Finders Alemayehu Asfaw, Craig Wood, Paul Whitehead, and other members of the **Rift Valley Research Mission in Ethiopia**. Unit Upper Bodo Sand Unit (UBSU). Horizon N/A. Bed/member UBSU atop the Upper Bodo (UB) Bed. Formation Wehaietu Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon A volcanic horizon dated to 0.64 ± 0.03 Ma. Geological age **Middle Pleistocene** based on associated fauna, *c.* 600 ka based on **argon-argon dating** and **biostratigraphy**. Developmental age Adult. Presumed sex Male based on its massive brow ridge and large face. Brief anatomical description A partial cranium reconstructed from many fragments. Its face and supraorbital torus are large and the nose is wide. Endocranial volume Approximately 1250 cm^3 and within the range of $1200\text{--}1325 \text{ cm}^3$. Announcement Conroy et al. 1978. Initial description Conroy et al. 1978. Photographs/line drawings and metrical data Conroy et al. 1978, 2000, White 1985, 1986, Adefris 1992, Rightmire 1996, Seidler et al. 1999. Detailed anatomical description Adefris 1992, Rightmire 1996, Conroy et al. 2000. Initial taxonomic allocation Intermediate between *Homo erectus* and *Homo sapiens*. Taxonomic revisions Early archaic *H. sapiens* or *Homo heidelbergensis*. Current conventional taxonomic allocation *H. heidelbergensis*. Informal taxonomic category Pre-modern *Homo*. Significance Bodo 1 resembles **Petralona**, **Arago**, **Kabwe**, and **Saldanha**, and many regard it as consistent with the hypothesis that these specimens all belong to the hypodigm of *H. heidelbergensis*. If that is the case then, if Bodo 1 is *c.* 600 ka, then it is the earliest widely accepted evidence for that taxon. Location of

original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Bodo D'Ar *See* Bodo.

Bodo-Maka The only major fossiliferous sub-region within the **Middle Awash study area** on the east side of the Awash River; the ones on the west side include the **Central Awash Complex**, **Western Margin**, and **Bouri Peninsula**. It is named to represent the narrow sedimentary exposures on the east side of the **Awash River** between the Awash floodplain and the basalt plateau of the **Afar Rift System** floor that are bounded by, and adjacent to, the **Bodo** and **Maka** drainages.

body-mass estimation A wide range of ecological, physiological, and morphological features vary among individuals and among species in association with body size. In general, as similar animals evolve to larger adult body sizes, they have larger brain volumes, larger teeth, thicker bones that support more mass, longer life spans, and occupy larger home ranges, among a large number of other size-correlated attributes. To interpret variation in these size-correlated features, most investigators attempt to use statistical methods to control or adjust for variation “due to” or correlated with body size. Body mass is the most commonly accepted measure of overall body size in paleoanthropology; stature is used less often. A number of issues have been evaluated regarding the process of estimating body mass from fragmentary fossil remains, the three most important being (a) the morphological traits employed for the estimation, (b) the form of the statistical relationship between the trait(s) and body mass, and (c) the composition of the sample used to determine the relationship. Following calculation of an estimation equation between body mass and selected traits in a sample of species or individuals with known body mass, the equation is then applied to the interpretation of the unknown body mass in the fossil specimen; simple ratios cannot be used for this purpose (Smith 2005b). Auerbach and Ruff (2004) examine mechanical criteria for selecting traits, which depend upon functional relationships between body mass and elements of the skeleton that are weight-bearing, and the morphometric methods used in attempts to reconstruct overall body size; these are mostly applicable when relatively complete

specimens are available (Ruff, 2002). Smith (2002) suggests that weight-bearing is not essential to the selection of predictor traits, because predictive equations are not functional equations and others have used non-weight-bearing facial dimensions and teeth to develop equations to estimate body mass (e.g., Aiello and Wood 1994, Kappelman 1996). Most body-mass prediction equations have been simple bivariate relationships, although multiple regression would improve estimation in many cases. Konigsberg et al. (1998) and Hens et al. (2000) have called attention to the difference between an equation in which the trait to be used for estimation is the dependent variable and body mass is the independent variable (classical calibration), which is then solved so that it can be used to estimate body mass, and inverse calibration, in which body mass is the dependent variable. Smith (2009) has reviewed the considerations involved in selecting a line-fitting criterion. **Ordinary least squares regression** rather than **major axis regression** or **reduced major axis regression** is recommended for estimation equations. The species (or individuals) used to calculate the estimation equation determine the species or individuals to which it is appropriate to apply the equation. The subject must be from the same population as the subjects used to generate the equation. The body mass of a fossil hominin might be estimated from a general mammalian data set, from a primate data set, or from an ape data set; although each is valid, it is expected that estimation is improved when the data set is more specific to its intended purpose. It would be invalid to estimate an australopith body mass from a regression equation that had been calculated only with fully modern humans, since australopiths are not members of this population. Phylogenetic relationship is not the only criterion that defines population membership. Extrapolation (e.g., estimating the body mass of A.L. 288-1 from an equation based on great apes and modern humans) is problematic, because the need for extrapolation indicates that by the criterion of size the estimated specimen is not from the same population as the specimens used to determine the equation. In calculating equations specifically for juvenile specimens, Ruff (2007) has identified stage of ontogenetic development as another feature that defines population membership. All body-mass estimates for fossil species should be reported with explicit recognition of the statistical uncertainty involved (e.g., a confidence interval).

body size A linear, area, volume, or mass measurement designed to reflect the overall dimensions of an organism in a single value. Body size usually is measured with some functional and comparative purpose in mind, which determines the appropriate units. For example, wing span may be an appropriate measure of body size for some aerodynamic considerations in birds, and volume may be appropriate for some questions related to displacement in fishes. Most applications in paleoanthropology refer to body mass. Although the terms “mass” and “weight” are sometimes used interchangeably, the correct measurement is mass, which is measured in kilograms, as opposed to weight, which is mass multiplied by the acceleration due to gravity, and which is measured in Newtons (mass \times length \times time $^{-2}$). Living organisms vary over many orders of magnitude in body size, from bacteria to blue whales. Body size is causally related to a variety of physiological, morphological, and ecological features. Many of these causal interactions occur through the square-cube law originally explained by Galileo Galilei in *Discorsi e dimostrazioni matematiche intorno à due nuove scienze* (*Two New Sciences*; 1638), which states that when objects undergo proportional increases in size, volumes increase proportional to the cube of the multiplier and areas increase proportional to the square of the multiplier. Therefore, as organisms increase in size, the ratio of areas to volumes decreases. Many physiological properties take place across areas, exemplified by diffusion across cell membranes. The science of **scaling** examines and seeks to explain much of the functional variation among organisms in relationship to variation in body size (McMahon and Bonner 1983, Schmidt-Nielsen 1984, Jungers 1985, Brown and West 2000, Samaras 2007). Because body size changes during the evolution of the hominin lineage, it is necessary to take body size into account (e.g., when using brain size to judge the evolution of intelligence, tooth size to infer diet, or sexual dimorphism to infer social organization).

Boise, Charles Watson (1884–1964) Charles Watson Boise was the second of six children of Watson and Grace Boise. He was born and raised on a homestead in North Dakota, not far from the Saskatchewan border. He went to college at the University of North Dakota, Grand

Forks, and graduated in 1908 with the degree of Engineer of Mines from the College of Mining Engineering. After graduation Boise followed an elder brother to New Mexico where he worked in a copper mine at Santa Rita. He made the first of many trips to Africa in 1911 where he worked for a time at the Union Miniere in Katanga and he is credited on the photographs in a paper on the economic geology of the Congo published in 1914. In 1919 he led an expedition to Spitzbergen. The narrative of the next part of Boise's career are taken from his obituary in *The Times* of London (November 11, 1964): "In 1920 Boise made the first examination of diamond areas in the Gold Coast (now Ghana), which led to the formation of the Consolidated African Selection Trust, Ltd. In 1925 he was involved with the early exploration of minerals in Northern Rhodesia (now Zambia) that resulted in the formation of copper mining companies that formed part of the Rhodesian Selection Trust Group, and in 1934 he was actively involved in opening up the diamond fields in Sierra Leone. He had a long association with the Selection Trust Group of mining companies (N.B., in the 1934 University of North Dakota Alumni Magazine he is listed as a 'Director', and in the 1936 issue he is referred to as the 'General Manager and part owner') and he was one of the earliest colleagues of their founder Alfred Chester Beatty (later Sir Chester Beatty) and William Selkirk." Boise spent the rest of his career in London, where he was involved in the diamond trade. Boise received an Honorary Degree of Doctor of Science from his alma mater in 1958, and he retired from active business in 1959. In 1927 he purchased Emmetts, a country estate with an extensive garden at Idle Hill, near Sevenoaks, in Kent, England, and became a British citizen in the wake of the Great Depression. Boise continued to develop the house and garden at Emmetts, and on his death in 1964 the fine garden was transferred to The National Trust. Boise's ashes were scattered in the garden at Emmetts. It is likely that Boise first became aware of the activities of Louis and Mary Leakey in the 1930s, but his patronage of their research did not begin until January 1948. Boise was vacationing in Switzerland when he read a report in *The Times* about the results of the first British-Kenya Miocene Research Expedition to Rusinga Island in Lake Victoria in Western Kenya. Boise wrote from his Swiss hotel and offered his assistance to the

Leakeys to ensure the Rusinga research remained "under British auspices," and in February 1948 he mailed the Leakeys a check for £1000. This enabled Louis and Mary Leakey to buy a lorry in which they could travel (and sleep) to and fro to Western Kenya. On October 1, 1948 Mary Leakey discovered the first skull of *Proconsul africanus*, a Miocene ape, and less than a month later, on October 29, she left by flying boat from Lake Naivasha, Kenya, for the UK, to show the new skull to Wilfrid Le Gros Clark. While she was there she also showed it to Boise, who gave the Leakeys further support, which enabled them to buy a motorboat. The next recorded contact between the Leakeys and Boise was in 1950 when they accompanied him on a visit to the Dordogne, where they visited Lascaux and Pech Merle Cave. The following year Boise visited the Leakeys in Africa, and it was during this visit that he pledged to fund their fieldwork, including their renewed exploration and excavations at Olduvai Gorge, for a further 7 years. In 1955 Boise vested a capital sum of £25,000 in the University of Oxford with instructions that a trust fund, the **Boise Fund**, be established to support research "on the antiquity and origin of man and his precursors (with particular emphasis on the continued exploration of appropriate sites in Africa) and on the early migration of paleolithic communities." Among the first research supported by the Boise Fund was that of Louis and Mary Leakey who were given grants in 1960 and 1961 for excavations at Olduvai Gorge, and later for excavations at Fort Ternan in Western Kenya. In recognition of Charles Boise's support for their research, after Mary Leakey had discovered the OH 5 cranium at Olduvai Gorge, in Tanzania, in 1959, they named it *Zinjanthropus boisei*.

Boise Fund A research fund based on a gift from Charles Boise to the University of Oxford to support research on human origins in Africa. The fund was created in 1955 when Charles Boise vested a capital sum of £25,000 in The University of Oxford with instructions that a trust fund, the Boise Fund, be established. The instructions were that the interest on the capital be used to support research "on the antiquity and origin of man and his precursors (with particular emphasis on the continued exploration of appropriate sites in Africa) and on the early migration of paleolithic communities." Charles Boise probably chose Oxford for several reasons. First, although he

was by birth a US citizen by 1955 he had become a UK citizen. Second, since 1948 Boise had been helping to support the research of Louis and Mary Leakey, both at Miocene sites in Western Kenya and later at Olduvai Gorge, and in doing so he would have encountered Wilfrid Le Gros Clark. The latter, an authority on Miocene apes, had become a strong supporter of the Leakey's research, and Le Gros Clark was the Dr Lee's Professor of Anatomy at Oxford University and a Professorial Fellow of Hertford College, Oxford. Le Gros Clark was much involved with the fund when it was first established, and among the first work supported was that of Louis Leakey who was given grants in 1960 and 1961 for excavations at Olduvai Gorge, and later for excavations at Fort Ternan in Western Kenya. However, Le Gros Clark retired from the Dr Lee's Professorship in 1962, and 2 years later, in 1964, at his suggestion, the Council of the University approved a change to the statute and a committee was established with *ex officio* members, namely the Professor of Anthropology, the Professor of Geology, and the Director of the Pitt Rivers Museum (the holders of these posts were to be asked to appoint deputies when their expertise did not fit the Boise remit). From 1964 this committee met to consider applications from researchers working in appropriate subject areas. For a long time the representative from Anthropology (and the chair of the board of management of the Boise Fund) was Geoffrey Ainsworth Harrison. Enquiries at The University of Oxford suggest that support from the Boise Fund is now only available for members of the University of Oxford.

Boker Tachtit (Location 30°50'N, 34°46'E, Israel; etym. He. *Boker Tachtit*="Cowboy's Pit," probably derived from the name of a nearby kibbutz *Sde Boker*=Cowboy's Field) History and general description One of several sites found in the late 1970s during the Central Negev Project, Boker Tachtit is located along the Nahal Zin river. The site was excavated over several field seasons from 1973 to 1980 by A. Marks and his team. Marks and others (see Fox and Coinman 2004) have suggested that Boker Tachtit documents a local transition from Middle to Upper Paleolithic rather than the introduction of a foreign technology (as argued by Bar-Yosef 1999). Temporal span The site is likely beyond the age of radiocarbon dating (>47 ka). How dated? ¹⁴C. Hominins found at site N/A. Archeological evidence found at site Abundant stone tools from the four

main occupation levels supposedly document the Middle to Upper Paleolithic transition. Many of the artifacts could be refitted, allowing a precise reconstruction of the knapping sequence used to produce them. The older layers record a Levallois-based core-reduction strategy and the more recent ones a single-platform core-reduction strategy that resulted in blades. Emireh points, a type of tool unique to the Levantine Middle to Upper Paleolithic transition, were abundant. Key references: Geology and dating Marks 1983; Hominins N/A; Archeology: Marks 1977, 1983.

Bølling-Allerød A warm interval (or interstadial) that followed the abrupt termination of the Last Glacial Maximum. The identification of a Bølling-Allerød-aged sapropel in the eastern Mediterranean indicates that this warm interval was associated with increased precipitation over North-east Africa in the headwaters of the Nile. In records where there is sufficient temporal resolution two separate warming intervals can be recognized: the Bølling *c.*13–12 ka and the μ Allerød *c.*11.8–11 ka. The two warm intervals are separated by the Older Dryas stadial or cold interval 12–11.8 ka and followed by the Younger Dryas stadial or cold interval *c.*11–10 ka (Mangerud *et. al.* 1974).

bone (ME *bon*=bone) Bone is one of the two connective tissues (cartilage is the other) that form the bony skeleton. All connective tissues are made up of cells plus tiny organic fibers, both of which are embedded in a matrix. What makes bone and cartilage harder and stiffer than, say, the fibrous connective tissue of the capsule of a synovial joint, is that the matrix of bone is mineralized. The cells in bone are called osteoblasts, osteocytes, and osteoclasts; osteoblasts make, deposit, and mineralize the matrix, osteoclasts remove it, and osteocytes are what osteoblasts turn into once the matrix they have made matures. The fibers in bone are collagen fibers. These are arranged in flat sheets in immature bone, or in concentric bundles in lamellar, or layered, bone, or in irregular bundles in immature woven, non-lamellar, bone. As bone matures it reorganizes into either compact bone or dense bone, or cancellous bone or trabecular bone. The shafts of a long bone are formed from an outer "skin" or cortex of compact bone, and an inner cavity or medulla of cancellous bone. There are very few spaces in compact bone, and what few there are filled either

with the cells that form bone (see above) or with blood vessels; there are spaces in cancellous bone (it is built like an Aero chocolate bar). These spaces are filled either by fat (yellow bone marrow) or blood-forming tissues (red bone marrow), or a mixture of the two. The minerals in bone matrix are in the form of small (approximately 30 nm×5 nm) crystals of hydroxyapatite $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$. These are mostly in the matrix and among the collagen fibers; they are aligned with their long axis parallel to the long axis of the collagen fibers. It is the combination of the strong collagen fibers and the hard matrix that gives bone its unique properties. If you put a rib in acid and remove the mineral, the rib retains its shape, but it becomes so flexible you can tie a knot in it. If you take a bunsen burner and burn all the organic material out of a vertebra it will retain its shape but when you press lightly on it with your hand it will easily crush down to a small pile made up of the mineral components of hydroxyapatite. *See also fossilization.*

bone breakage patterns Bone breakage, or fracture, occurs when the application of an external force (loading) causes a localized mechanical failure in the bone. Loading can be either static or dynamic and can generate tensile, compressive, shearing, torsion, or bending forces. Static loading involves the application of constant compressive pressure, typically with an even distribution of force, such as the steady pressure on bone from the jaw of a large carnivore. Dynamic loading involves a concentrated and sudden impact, such as that from a hammerstone blow. Various types of bone fractures, breaks, or cracks are known to result from different types of loading on different types of bone (e.g., long bones, vertebrae) in various states (e.g., fresh, wet, dry, weathered, fossilized). On long bones, these can include spiral (radial, oblique, curvilinear) fracture, perpendicular (transverse) fracture, longitudinal fracture, and stepped or columnar fractures. For example, the breakage of fresh bone is often associated with spiral fractures characterized by curved outlines and oblique fracture edges. Conversely, the breakage of dry bone is associated with transverse fractures and perpendicular fracture angles. Thus, the study of bone breakage patterns in an archeological assemblage can inform on whether bones were broken while fresh, possibly during carcass processing, or while dry, long after discard. Bones can be fractured by numerous taphonomic agents and

processes, including hominins, carnivores (i.e., chewing), large mammals (i.e., trampling), falling rocks (i.e., within cave sites), and sediment compaction. Identifying the taphonomic agent responsible for the fractured bones involves a detailed study of bone breakage patterns. For example, in zooarcheological contexts, it has been suggested that notches along fracture surfaces show different morphologies depending on whether loading was static or dynamic. Dynamic loading associated with hammerstone percussion is thought to produce notches that are broader and shallower in cortical view than those created by the static loading of carnivore teeth. In turn, the study of these particular fracture morphologies can provide insight into whether bones were fractured by hominins or carnivores. Determining the identity of the agent responsible for bone fracture is best accompanied by a study of bone surface modifications (e.g., percussion marks, carnivore tooth marks).

bone density Measured as the average value for whole bones, or as a more accurate value at a standardized location on the same bone (e.g., the calcaneum at the heel is one of the sites clinicians use to screen for and diagnose osteoporosis). Photo densitometry gives accurate values at a standard location, but **computed tomography** provides more reliable average values for bones with complex shapes and/or cavities. Bone density is used in **zooarcheology** to study its influence on differential bone preservation at fossil and archeological sites (see Lam et al. 2003).

bone remodeling (L. *re*=in a different way and *modus*=a measure) Refers to internal reorganization within a **bone** that does *not* result in a net change in mass or in any change of external shape; also called Haversian remodeling. It involves osteoclasts resorbing existing bone, and osteoblasts laying down an equivalent mass of new secondary osteonal or Haversian bone. The surfaces of a bone where bone resorption is occurring have a distinctive morphology (e.g., Howship's lacunae) and this enables researchers to characterize parts of the surface of bones as either areas of bone resorption or of bone deposition. Bromage (1989) and Rosas et al. (2010) have utilized this distinctive morphology to explore whether there are consistent differences among taxa in the sites where bone resorption is taking place. Note that "modeling" is the equivalent term used when bone is modified so that its mass and/or its external shape *are*

changed (e.g., during growth and as the result of excessive use). See also **ossification**.

bone strength In material science the strength of a material is its ability to withstand an applied stress without failure. There are two common types of failure: yielding and fracture. Yielding, which is defined by the material's yield strength, occurs when the material undergoes macroscopic permanent deformation. A material with an applied stress value less than the yield strength of the material will not be permanently deformed upon unloading. Fracture is defined by the ultimate strength of the material, which is the largest absolute value of applied stress the material can withstand without fully fracturing. Since yielding occurs at an applied stress less than the applied stress that produces full fracture, the yield strength of a material is always less than its ultimate strength. The type of loading (e.g., tensile, compressive, or shear) also influences failure; thus there are corresponding types of material strength (e.g., ultimate tensile strength, ultimate compressive strength, and ultimate shear strength). However, bone is not a homogeneous structure made of single material; it is a heterogeneous composite structure. One can measure the strength of a bone (such as the femur) by loading it to failure, but this is a measurement of its structural strength and not of the bone tissue. Strictly speaking, bone tissue strength is a material property and not a structural property and therefore should be measured at the tissue level. This means one should measure the strength of compact bone, or the component individual trabeculae of cancellous bone, most likely via micro-indentation. Conversely, one can infer bone tissue strength via a coupled *in vitro* and *in silico* testing. This involves physically testing the bone structure to determine the failure load and location and also developing a finite element model of the same bone specimen loaded and constrained as in the physical experiment. The finite element model is used to provide the stress state of the tissue at the critical failure load and failure location. The appropriate measure of stress predicted by the model, such as maximum principal stress, minimum principal stress, maximum shear stress, or von Mises' or equivalent stress at the failure location is then taken as the tissue strength.

bone tool Any osseous (i.e., bone) object used during the performance of a task. Objects made of osseous materials used by hominins to assist in

carrying out tasks. The first category of bone tools is exemplified by the *c.*1–1.8 Ma bone tools found in Members 1–3 at **Swartkrans**, South Africa (Backwell and d'Errico 2001). They have been interpreted as implements used to extract **termites** from mounds and they were probably bones or bone fragments whose shape was modified through use rather than by being deliberately shaped prior to their use. The second category comprises bones that are carefully shaped through cutting, grinding and/or polishing. For example, some bones at **Olduvai Gorge**, Tanzania, were deliberately modified and shaped through flaking (the technique is similar to that used for stone tool production) to make handaxe-like pieces (Backwell and d'Errico 2004a). The **Middle Stone Age** levels at **Blombos Cave**, South Africa provide another good example of deliberately fashioned bone tools (Henshilwood et al. 2001), and at **Katanda**, Democratic Republic of Congo, bone harpoons, presumably for fishing, have been dated to *c.*90 ka (Yellen 1998). Many purportedly deliberately shaped bone tools at **Lower and Middle Paleolithic** sites in Eurasia such as **Torrvalba** and **Ambrona** have been shown to be bones that were shaped by natural causes (Villa and d'Errico 2001). Bone tools are common in **Upper Paleolithic** and **Later Stone Age** sites.

Bonferroni correction A method that addresses the problem of identifying the appropriate significance level when multiple significance tests are performed. For example, a significance level of $\alpha=0.05$ is typically used to identify a statistically significant result. This means that we accept that 5% of the time a result that appears as significant as this could happen by random chance even if the **null hypothesis** is true (i.e., no significant difference between groups or significant relationship between variables actually exists). However, suppose one were to conduct 20 significance tests in the course of an analysis. Even if no significant relationships existed in any of those 20 tests, by random chance we would expect that 5% of the tests, or 1 out of 20, would yield a statistically significant result even though no real relationship exists. The Bonferroni correction recognizes this problem and adjusts the α value (the value at which a result is deemed statistically significant) downwards to compensate for multiple tests. In the traditional application of the Bonferroni method, α is set to α/n for all tests when n significance tests have been preformed. For

example, if P values are calculated for four separate correlations of stature and four different skeletal variables, then to accept a result as significant at 0.05, α must be set equal to 0.05 divided by four, or 0.0125. Only those correlations which have P values equal to or less than 0.0125 would be considered significant. However, it has been argued that this correction is overly conservative, and Holm (1979) suggests a modification which is widely used. The P values for all tests are ordered from smallest to largest. If the smallest P value is less than α/n then the test associated with that P value is found to be significant. The next smallest P value is then compared to $\alpha/(n-1)$, and if P is smaller it is found to be significant. The next smallest P is compared to $\alpha/(n-2)$, and so on. If at any point the P value is not smaller than the adjusted α value, then that test and all others with higher P values are considered non-significant.

bonobo Susman (1984) and Groves (2008) review the possible etymology of “bonobo.” As Susman (1984) suggests it is most likely a “mispronunciation of the word Bolobo, which is a town on the Zaire River, between Kinshasa and Lukolela” (*ibid*, p. xix). *See also Pan paniscus*.

bony labyrinth (Gk *labyrinthos*=complex of cavities) Complex of **periosteum**-lined cavities in the **petrous** part of the **temporal** bone. It has three regions, a central vestibule, the cochlea anteriorly, and the semicircular canals posteriorly. It contains the **membranous labyrinth** (ML). The space between the walls of the bony labyrinth and the ML is filled with **perilymph**. It is this complex of cavities that is visualized using **computed tomography**. *See also semicircular canals*.

bootstrap A **resampling** procedure that can be used to calculate a confidence interval and/or the degree of bias for sample statistics (e.g., mean, variance, median, correlation coefficient, regression slope, etc.). The bootstrap is used when equations do not exist to calculate the confidence interval of interest (e.g., for the median), or when data are not normally distributed, and/or when sample sizes are small. Consider a statistic that is calculated for some sample (e.g., the median cranial capacity for 10 crania). A sample of size equal to the full sample is subjected to random **sampling with replacement**. In this example, 10 endocranial capacities are selected at random from the 10 measurements, but each time

all 10 measurements have an equal probability of being selected, so some measurements may be selected more than once and other measurements not at all. The statistic, in our example the median, would be calculated for the resulting randomly sampled 10 measurements. This procedure is repeated many times to generate a distribution of values for the statistic of interest (in this case, the median). The total number of unique samples that can be drawn from a sample of size n is equal to $(2n-1)!/[n!(n-1)!]$, where the exclamation point is the **factorial** symbol. For our example of 10 measurements, this corresponds to 92,378 possibilities. Whereas it is theoretically possible to cycle through all possible samples (this would be an example of an **exact test**), the number of possibilities is usually prohibitively high. Instead, it is more usual to randomly choose a large number of the possibilities (typically 5000 or more) to stand in for the full set of possibilities (this is an example of a **Monte Carlo** method). In either case, the resulting distribution of values for the statistic of interest, in this case the median, is the bootstrap distribution. There are several ways to calculate a confidence interval for the statistic of interest using the bootstrap distribution, but the simplest and most common is the percentile bootstrap. In this technique, the values in the bootstrap distribution are sorted from highest to lowest. To generate a 95% confidence interval, the largest 2.5% and the smallest 2.5% of values are discarded, with the remaining maximum and minimum values giving the limits of the confidence interval. One can also check for bias in the bootstrap estimate by comparing the mean of the bootstrap distribution with the original statistic from the full sample. The difference between the two is the bias. For other methods of calculating confidence intervals for the statistic of interest and for ways to remove bias from the confidence interval generated by the bootstrap see Manly (2007).

Border Cave (Location 27°01'19"S, 31°59'24"E, Kingdom of Swaziland, South Africa, 365 m from the border with South Africa; etym. named after its location overlooking the border) History and general description Initial investigations directed by Raymond **Dart** in the 1930s and by Basil **Cooke** in the 1940s were followed by more extensive excavations by Peter Beaumont in the 1970s. Border Cave was formed when an **agglomerate** layer within lava flows was preferentially weathered. The more than 4.5 m sequence of sediments exposed in the >60 m² of excavated

area consist of alternating deposits of brown wind-blown sandy silts and **reworked** white-black hearth ash. These span the **Middle Stone Age** to the **Iron Age**. The Stone Age sequence is divided from bottom to top into MSA 1, MSA 2 (Howieson's Poort), MSA 3a, MSA 3b, and the early **Later Stone Age (ELSA)**. The finds include several hominins including a controversial early infant burial. Temporal span and how dated? Border Cave has been dated by a number of methods, including **electron spin resonance spectroscopy dating** (or ESR) of mammalian teeth and **Bayesian** estimates of age boundaries as well as **amino acid racemization dating** (or AARD) of ostrich egg shell. Ostrich egg shell and wood charcoal have been **radiocarbon dated** by traditional and AMS methods, and the site served as an initial test case for the acid-dichromate oxidizing solution pretreatment method. Combined AARD and ESR age estimates suggest an age range from >100 ka to 227 ± 11 ka for MSA 1, with an age range of 82–56 ka for MSA 2 (Howieson's Poort). ESR, AARD, and radiocarbon age estimates suggest a range of 69–53 ka for MSA 3a, 56–41 ka for MSA 3b, with the ELSA dating to *c.*38 ka. Hominins found at site BC 1 (a calvaria) and BC 2 (a partial mandible) derive from commercial digging in the cave for guano, they are both possibly from the MSA 1 levels, but their **provenance** is uncertain. BC 3 was discovered in the 1941 excavations, and is an infant skeleton buried with a *Conus bairstowi* shell from coastal sources at least 80 km/130 miles away, with the lip of the grave shaft at the base of the MSA 2 levels; BC 4, a complete skeleton except for the cranium, dates to the Iron Age; BC 5 is a nearly complete lower jaw. Additional hominin remains from contexts disturbed by early excavations and thus of uncertain provenance include BC 6 (humerus), BC 7 (proximal ulna), and BC 8a and BC 8b (both metatarsals). Bone crystallinity studies suggest that BC 3 and BC 5 may be **intrusive** burials from overlying (perhaps Iron Age) strata, but ESR dating of a tooth fragment from BC5 has produced an age of 74 ± 5 ka. Archeological evidence found at site In addition to well-preserved organic remains, the archeological sample includes more than 69,000 stone artifacts, and a substantial macromammalian fauna. As in many other southern African sites, the production of elongated **flakes** is common throughout the MSA strata, with the MSA 1 further characterized by

bifacial points, MSA 2 by the **backed pieces** characteristic of the Howieson's Poort, with the MSA 3 levels also including backed pieces and basally thinned points. The early LSA shows an informal flaked **lithic** assemblage as well as rare ground stone pieces, ostrich egg shell beads, and polished pointed pieces of bone and warthog tusk. Stone tools are predominantly of local **lavas** or **chalcedony**, the latter from an unknown source not in the immediate vicinity of the site. The frequency of the use of fine-grained chalcedony increases as one goes up the Stone Age sequence, from approximately 6% at the base to roughly 84% in the upper strata. The fauna suggest environmental conditions similar to those found at the site today for much of the occupation of the cave, and the sample includes at least two extinct species, the "giant Cape horse" (*Equus cf. capensis* in MSA 3) and the bovid *Antidorcas bondi* (MSA 3 and ELSA strata). Bose Basin (Location approximately 23°66'N, 106°37'E, Guangxi Zhuang Autonomous Region, China) History and general description Bose is a large basin, roughly 800 km²/309 square miles, located north of Nanning, the capital city of Guangxi Zhuang Autonomous Region, southern China. The Mandarin transcription of the basin was "Baise," but the current spelling follows the local spelling "Bose"; researchers have used both terms. The Youjiang River cuts through the basin from northwest to southeast. Seven river terraces have been identified in the basin with Paleolithic and Neolithic archeological remains surface collected and excavated from the first four terraces (T1–T4). Bifacially worked Paleolithic stone implements were initially discovered in 1973 in T4 and many more have since been identified. **Australasian strewn-field tekites** have also been excavated and surface collected from T4. To date, about 80 Paleolithic open-air sites have been identified, the best known of which are Damei, Fengshudao, and Gaolingpo. Cave sites have been identified and excavated in the Bose Basin, but the cave deposits have been tentatively

dated to the terminal Pleistocene and Holocene. Temporal span and how dated? Fission-track and $^{40}\text{Ar}/^{39}\text{Ar}$ dating on Australasian strewn-field tektites have produced dates of $c.732\pm 39$ and $c.803\pm 3$ ka, respectively. Some have questioned these dates based on the suggestion that the tektites were not found in their original context, but hundreds of tektites have been excavated from T4 and only T4, suggesting that T4 is the stratigraphic level where the tektites were originally deposited, and although some of the tektites are rounded, probably from fluvial activity, the majority of them still display sharp edges, suggesting rapid deposition and that T4 was their original context. Thus, it is generally accepted that T4 dates to the Early–Middle Pleistocene transition. Hominins found at site No hominin fossils dating to the Pleistocene have been reported, but there are Neolithic modern human burials. Archeological evidence found at site The reason why Bose receives the attention it does is because of the presence of bifacially worked stone tools in T4. In particular, 129 handaxes and similar “large cutting tools” were surface collected and excavated from the Fengshudao site, whereas lower frequencies of these large bifacially and unifacially worked implements were found at other sites in the Bose Basin. The evidence of handaxes in Bose has been used, primarily by Chinese Paleolithic archaeologists, to refute the idea of the **Movius’ Line**. Detailed morphological and statistical analyses of the bifaces and other large cutting tools suggest that although there are differences between those from Bose and those found in India and in East Africa, the Bose artifacts manifest similar flaking capability and technological efforts as Acheulean tool kits from other Early Pleistocene sites. Paleolithic artifacts have also been identified in T2 and T3, stratigraphic layers that are younger than T4, but the T2 and T3 assemblages do not include bifacially worked implements or Australasian tektites. Furthermore, variation appears to be present in the composition of the lithic assemblages and the morphology of the artifacts from T2 and T3 when compared with the materials from the handaxe-bearing T4 level. There are Neolithic deposits, including modern human burials, in at least one cave in the area that divides the Bose Basin and **Bubing Basin**, but is geographically located on the Bose side and there may be Pleistocene deposits beneath the Neolithic layers. Boskop (Location $26^{\circ}34'S$, $27^{\circ}07'E$, Gauteng Province, South Africa; etym. Afrikaans for a bush- or brush-covered head or hill) History and general description The open-air site was discovered in 1914 by F.W. Fitzsimons in a field belonging to the Kolonies Plaas farm on the east bank of the Mooi River in the southwest of what is now Gauteng Province. The remains recovered included a calvaria that attracted intense interest at the time because of its large size and endocranial volume (approximately $1700\text{--}1950\text{ cm}^3$). Some inferred it to have substantial antiquity, but later authors cast doubt on its antiquity and emphasized its similarity to a variety of other large-brained crania from the **Holocene** of the Cape. Temporal span Pleistocene. How dated? Archeological association, degree of mineralization and **fluorine dating**. Hominins found at site Boskop 1, a calvaria, a left mandibular ramus and highly fragmentary partial skeleton. The calvaria was made the holotype of *Homo capensis* Broom, 1918 Archeological evidence found at site One **Middle Stone Age** artifact. Key references: Geology and dating Fitzsimons 1915, Tobias and Wells in Oakley and Campbell 1967; Hominins Haughton 1917, Thomson 1917, Broom 1918, Galloway 1937, Dreyer 1938, Wells 1959, Tobias 1959, Singer, 1958, 1961; Archeology van Riet Lowe 1954.

Boskop 1 *See* Boskop.

bottleneck A bottleneck (as in a population or genetic bottleneck) is an evolutionary event during which **genetic diversity** is reduced due to a severe decrease in population size. A population bottleneck increases **genetic drift** (since the latter is a stronger force of evolution in smaller populations) and it also increases inbreeding. Some researchers have suggested that modern humans have undergone one, or more, population bottlenecks, possibly in connection with natural disasters, disease or migrations (e.g., Rogers and Harpending 1992, Sherry et al. 1994, Hammer 1995, Ambrose 2003, Amos and Hoffman 2009).

BOU Abbreviation of Bouri Peninsula. It is the prefix used for localities in the **Bouri Peninsula, Middle Awash study area**, Ethiopia. *See also Bouri.*

BOU-VP-2/66 Site Daka. Locality Dakanihylo Member, Vertebrate Paleontology Locality 2. Surface/in situ *In situ*. Date of discovery December 27, 1997. Finder Henry Gilbert. Unit N/A. Horizon Silty sand layer in the section of Vertebrate Paleontology Locality 2. Bed/member Dakanihylo “Daka” Member. Formation **Bouri Formation**. Group N/A. Nearest overlying dated horizon Paleomagnetic sample PMMA 97-5 shows reversed polarity, and is assumed to belong to the **Matuyama chron**. Nearest underlying dated horizon Pumiceous unit at the base of the Dakanihylo Member $c.1.04 \pm 0.01$ Ma. Geological age Lower Pleistocene by faunal correlations and absolute dates (see above). Developmental age Adult. Presumed sex Unknown. Brief anatomical description A well-preserved calvaria of *Homo erectus* that retains much of the basicranium except for the sphenoid and ethmoid. It bears a series of parallel scratches and may have been defleshed perimortem. Endocranial capacity 986 cm^3 (Asfaw et al. 2008). Announcement Asfaw et al. 2002. Initial description Asfaw et al. 2002. Photographs/line drawings and metrical data Asfaw et al. 2002, 2008. Detailed anatomical description Gilbert et al. 2003, Asfaw et al. 2008. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The Daka calvaria presents a mix of characters often associated with *Homo ergaster* and *Homo erectus*, supporting the conclusion the two are conspecific. The specimen also shows some morphological features such as more vertical parietal walls that foreshadow **Middle Pleistocene** specimens of *Homo heidelbergensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

BOU-VP-12/130 Site Bouri. Locality Bouri Vertebrate Paleontology Locality 12. Surface/in situ Surface. Date of discovery November 20, 1997. Finder Yohannes Haile-Selassie. Unit N/A. Horizon Maoleem Vitric Tuff. Bed/member Hatayae Member. Formation **Bouri Formation**. Group N/A. Nearest overlying dated horizon See information for horizon. Nearest underlying dated horizon See information for hor-

izon. Geological age $c.2.5$ Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description Associated cranial fragments consisting of the frontal, parietals, and maxilla with a complete and well-preserved dentition. The teeth show little occlusal wear, with dentin exposure limited to the occlusal edges of the incisors and canine, and pin-hole-sized areas of dentin exposure on the cusps of the M^1 . Announcement Asfaw et al. 1999. Initial description Asfaw et al. 1999. Photographs/line drawings and metrical data Asfaw et al. 1999. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus garhi*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Au. garhi*. Informal taxonomic category Megadont archaic hominin. Significance **Holotype** of *Au. garhi*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

BOU-VP-16/1 Site Herto. Locality Bouri Vertebrate Paleontology Locality 16. Surface/in situ *In situ*. Date of discovery 1997. Finder David DeGusta. Unit N/A. Horizon N/A. Bed/member Upper Herto Member. Formation **Bouri Formation**. Group N/A. Nearest overlying dated horizon Waidedo Vitric Tuff, which caps the Upper Herto Member, correlates with an unnamed tuff at **Konso** that lies 6 m below the Konso Silver Tuff, which dates to 154 ± 7 ka by **argon-argon dating**. Nearest underlying dated horizon Lower Herto Member, 260 ± 16 ka by argon-argon dating. Geological age “On the basis of the combined stratigraphic, geochemical and radioisotopic evidence the Upper Herto archeological and paleontological remains are therefore securely constrained to be between 160 ± 2 and 154 ± 7 kyr old” (Clark et al. 2003). At the least the cranium can be considered to be **Middle Pleistocene**. Developmental age Adult. Presumed sex Male. Brief anatomical description A well-preserved, large cranium that lacks the left side of the face and part of the left side of the cranial vault. The preserved tooth crowns show substantial occlusal wear. The BOU-VP-16/1 cranium is long, the distance between the articular eminence and the occlusal plane is substantial, the upper and lower scales of the occipital meet at a more acute angle than is the case in most modern human crania, and the external occipital protuberance is exceptionally rugged compared with most modern human crania. The vault bones are described as “thick” (*ibid*, p. 742).

Endocranial volume Approximately 1450 cm³ (by doubling the volume of the better-preserved right side of the endocranial cavity). Announcement Gilbert et al. 2000. Initial description. White et al. 2003. Photographs/line drawings and metrical data White et al. 2003. Detailed anatomical description Gilbert and Asfaw 2009. Initial taxonomic allocation *Homo sapiens idaltu*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance The BOU-VP-16/1 cranium is the **holotype** of the subspecies of *H. sapiens*, *Homo sapiens idaltu*. The cranial vault is long and high, as in modern humans, and the supraorbital torus, while robust, is modern human-like. The molars decrease in size from M¹ to M³. Although its non-metrical morphology is closest to that of modern humans, BOU-VP-16/1 (and the other hominins recovered from Herto) can readily be distinguished metrically from living modern humans, and it is this that prompted their classification as a subspecies of *H. sapiens*. Until the redating of **Omo I** and **Omo II** from Omo-Kibish, the BOU-VP-16/1 cranium was the earliest evidence of *H. sapiens* in Africa; it is still the best preserved among the early well-dated occurrences of modern human cranial anatomy. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

BOU-VP-16/5 Site Bouri. Locality BOU-VP-16. Surface/in situ Surface. Date of discovery 1997. Finders N/A. Unit N/A. Horizon N/A. Bed/member Upper Herto Member. Formation Bouri Formation. Group N/A. Nearest overlying dated horizon Waidedo Vitric Tuff, which caps the Upper Herto Member, correlates with an unnamed tuff at Konso that lies 6 m below the Konso Silver Tuff, which dates to 154±7 ka by argon-argon dating. Nearest underlying dated horizon Lower Herto Member, 260±16 ka by argon-argon dating. Geological age “On the basis of the combined stratigraphic, geochemical and radioisotopic evidence the Upper Herto archeological and paleontological remains are therefore securely constrained to be between 160±2 and 154±7 kyr old” (Clark et al. 2003). At the least the crania can be considered to be **Middle Pleistocene**. Developmental age Immature: the provisional chronological age estimate is 6–7 years. Presumed sex Unknown. Brief anatomical description The cranium, which has been restored from >180 small

fragments, preserves much of the cranial vault, little of the cranial base and much of the upper face. There is also a partial dentition that is reported to include both left deciduous molars, the germs of a canine and premolars and a permanent first molar with a wear facet. Announcement White et al. 2003. Initial description White et al. 2003. Photographs/line drawings and metrical data White et al. 2003. Detailed anatomical description Gilbert and Asfaw 2009. Initial taxonomic allocation *Homo sapiens idaltu*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Until the redating of **Omo I** and **Omo II** from Omo-Kibish, this immature cranium was part of the earliest evidence of *H. sapiens* in Africa, and it is the oldest immature *H. sapiens* specimen. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Bouffia Bonneval (Fr. *bouffia*=the word for cave in the local dialect and *Bonneval* is the name of the family who own the land on which the cave is situated) The name of the cave, and the name used in the national site register, for the site better known as **La Chapelle-aux-Saints** (*which see*).

Boule, Marcellin (1861–1942) Marcellin Boule who was born in Montsalvy, France, entered the University of Toulouse in 1880 to study science where encounters with the archeologist of prehistory Émile Cartailhac and the paleontologist Louis Lartet influenced his decision to study human paleontology. Boule completed his degree in the natural and physical sciences in 1884 and in 1886 he moved to Paris where he studied geology with Ferdinand Fouqué and paleontology with Albert Gaudry. Boule became the latter’s assistant at the **Muséum National d’Histoire Naturelle** (National Museum of Natural History) in 1894 and in 1902 he succeeded Gaudry as Professor of Paleontology at the museum. In addition to this position at one of France’s premier scientific institutions, Boule was also appointed the Director of the **Institut de Paléontologie Humaine** (Institute of Human Paleontology), which had been established by Prince Albert I of Monaco in 1914. Boule’s positions at the Museum and the Institute gave him access to substantial collections of anatomical material, both fossil and recent, and these proved invaluable in his paleoanthropological

researches. His prestigious appointments also gave him a measure of scientific authority that gave added weight to his later ideas about human evolution. Besides these powerful institutional affiliations, Boule also served as an editor of the journal *L'Anthropologie* from its creation in 1893 until 1930, and he founded two other journals, the *Annales de paléontologie* (in 1906) and the *Archives de l'Institut de Paléontologie Humaine* (in 1920). Boule concluded early in his career that the best way to approach the study of human prehistory was through a combination of geological, paleontological, and archeological perspectives where each was used to help interpret and inform the other. He rejected the linear progressive conception of human cultural development advocated by some prehistorians and believed that cultural development, like biological evolution, should be viewed as being like a tree with many branches rather than like a ladder. This image of biological evolution had a significant impact on Boule's theories about human evolution and especially his interpretation of the hominin remains from **La Chapelle-aux-Saints**. This largely complete hominin skeleton evidently resembled previously known *Homo neanderthalensis* remains and because of its significance the skeleton was sent to Boule at the Museum of Natural History. Boule's meticulous study of the La Chapelle-aux-Saints hominin skeleton was published in four parts in the *Annales de paléontologie* between 1911 and 1913. Boule concluded from his analysis that Neanderthals shared more features in common with the apes than with modern humans. His influential reconstruction of the skeleton depicted Neanderthals as slouching rather than standing fully upright. He also emphasized the "bestial" appearance of the face and the low sloping skull to suggest that Neanderthals possessed minimal intelligence, a conclusion that was strengthened, he argued, by the crude **Mousterian** tools found at other Neanderthal sites in Europe. For Boule, the evidence was overwhelming that the Neanderthals had not evolved into modern humans. He concluded that the geological evidence suggesting a relatively short period separating Neanderthal deposits and early **Cro-Magnon** *Homo sapiens* deposits did not provide enough time for Neanderthals to have evolved into modern humans. Indeed, there seemed to be evidence the two species had co-existed in some parts of Europe, a possibility that corresponded well with Boule's conception of evolution where

there are numerous branches to the evolutionary tree, many of which are dead ends. The Neanderthals, for Boule, represented just such a dead end. Moreover, he considered the *Pithecanthropus* and *Sinanthropus* (now *Homo erectus*) fossils from Indonesia and China to possess greater similarities to the Neanderthals than to modern humans, which suggested that neither group were ancestral to modern humans. Boule's assessment of the La Chapelle-aux-Saints Neanderthal was widely accepted and had a profound impact on the way subsequent Neanderthal specimens were interpreted and upon the popular perception of Neanderthals as unintelligent brutes. Boule expanded upon these ideas in his major monograph *Les Hommes Fossiles*, published in 1921 and the English translation, *Fossil Men*, appeared in 1923. In that textbook Boule examined the available evidence of hominin evolution from the first primates to modern humans. Again the *Pithecanthropus* and Neanderthals are relegated to a side branch of human evolution, with the ancestors of modern humans evolving along a separate branch. Indeed, Boule accepted as evidence of this theory the fossils attributed to *Eoanthropus dawsoni* unearthed in Sussex, England, between 1908 and 1915. Unfortunately for Boule and many others, it was not until much later, in 1953, that Piltdown Man was demonstrated to be a hoax. Boule's interpretation of the Neanderthals was the dominant one until the middle of the 20thC when some paleoanthropologists began to reassess Boule's reconstruction of the La Chapelle-aux-Saints skeleton. It is now clear that Boule allowed his preconceptions to affect his research, and that some features of the bones that had influenced his "brutish" depiction of the skeleton were in fact the result of the fact that the La Chapelle-aux-Saints was an aged individual with severe osteoarthritis. Boule received numerous scientific honors and remained at the Muséum National d'Histoire Naturelle until his retirement in 1936. *See also La Chapelle-aux-Saints; Piltdown.*

Bourgeois-Delaunay *See La Chaise.*

Bouri (Location approximately 10°15–18'N, approximately 40°30–34'E; etym. named after a village at the northern end of the Bouri Peninsula) History and general description The name given to the Bouri Fault Block, a peninsula in the **Middle Awash study area**. The long

axis of the Bouri Fault Block trends northnorthwest–southsoutheast. It has the Awash River on its eastern margin, around the tip of the peninsula and on the southern part of its western margin, and Lake Yardi (into which the Awash River discharges) on the northern part of its western margin. Its sediments were initially explored by the **Rift Valley Research Mission in Ethiopia** (Kalb et al. 1982), and were assigned to the Wehaitu Formation (Kalb 1993). However, they were subsequently mapped in more detail in 1981 and thereafter by members of the **Middle Awash Research Project**. Three members of the **Bouri Formation** are exposed on the peninsula, from oldest to youngest these are the Hata Member (an abbreviation of Hatayae), the Daka Member (an abbreviation of Dakanihylo), and the Herto Member. The Hata Member is contemporary with the sediments exposed at **Gona** approximately 100 km/60 miles to the north. Research at Bouri has resulted in the recovery of the type specimen of *Australopithecus garhi*, hominin postcranial remains, isolated **Mode I** artifacts and cut-marked and percussed mammal bones from the Hata Member, **Acheulean** artifacts and hominins including the **BOU-VP-2/66** calvaria from the Daka Member, and the **Herto** crania from the Herto Member. Temporal span *c.*2.5 Ma for the Hata Member, *c.*1.0 Ma for the Daka Member, and *c.*150–200 ka for the Herto Member. How dated? **Argon-argon dating**, incremental laser heating, **tephrostratigraphy**, and **lithostratigraphy** Hominins found at site The type specimen of *Australopithecus garhi*, the Daka (BOU-VP-2/66) cranium, three femoral shaft fragments, one with the base of the neck preserved (BOU-VP-1/75) and one with part of the distal articular surface preserved (BOU-VP-19/63), a proximal tibia (BOU-VP-1/109), a talus (BOU-VP-2/95), and the Herto crania. Archeological evidence found at site Isolated Mode I artifacts and cut-marked and percussed mammal bones from the Hata Member, **Acheulean** artifacts from the Daka Member, and “Acheulian and Middle Stone Age technocomplexes” from the Herto Member. Key references: Geology and dating de Heinzelin et al. 1999; Hominins Asfaw et al. 1999, 2002, 2008, White et al. 2003; Archeology: de Heinzelin et al. 1999, 2000, White et al. 2003.

Bouri calvaria *See* BOU-VP-2/66.

Bouri Formation (etym. Named after a village at the northern end of the Bouri Peninsula) General description The approximately 80 m-thick Bouri Formation is exposed in the southern two-thirds of the **Bouri** Peninsula. It consists of three members, and from oldest to youngest these are the Hata Member (an abbreviation of Hatayae), the Daka Member (an abbreviation of Dakanihylo), and the Herto Member (de Heinzelin et al. 1999). Sites where the formation is exposed The fossiliferous localities within the Bouri Formation are designated BOU-VP. Geological age *c.*2.5 Ma for the Hata Member, *c.*1.0 Ma for the Daka Member, and *c.*150–200 ka for the Herto Member. Hominin evidence The type specimen of *Australopithecus garhi* (ARA-VP-12/130) from the Hata Member, the Daka (**BOU-VP-2/66**) calvaria, three femoral shaft fragments, one with the base of the neck preserved (BOU-VP-1/75) and one with part of the distal articular surface preserved (BOU-VP-19/63), a proximal tibia (BOU-VP-1/109), and a talus (BOU-VP-2/95) from the Daka Member, and the Herto crania from the Herto Member. Archeological evidence Isolated **Mode I** artifacts and cut-marked and percussed mammal bones from the Hata Member, and **Acheulean** artifacts from the Daka Member. Key references: Geology and dating de Heinzelin et al. 1999, WoldeGabriel et al. 2000; Hominins Asfaw et al. 1999, 2002, 2008, White et al. 2003; Archeology de Heinzelin et al. 1999, 2000, White et al. 2003.

Bouri Peninsula One of the major fossiliferous subregions within the **Middle Awash study area** (others include the **Central Awash Complex**, **Western Margin**, and **Bodo-Maka**). The Bouri Peninsula is in the southeastern portion of the Middle Awash study area and is situated between the **Awash River** and Yardi Lake. The peninsula is an approximately 10 km/6 miles long and 4 km/2.5 miles wide **horst** that was uplifted and tilted westward along a major NW-SE trending transverse **fault**.

bovid The informal name for the artiodactyl family, the **Bovidae**, comprising the antelopes and their allies. Bovid remains are found at many early hominin sites. *See also* **Bovidae**.

bovid size classes African faunal assemblages are often dominated by **bovid** remains. Although bovid teeth and horn cores are readily identifiable to

tribe, genus, and/or species, their postcrania are extremely difficult to identify to taxon, particularly when fragmented or if multiple species are represented. For this reason, faunal analysts typically assign bovid remains to one of several size classes proposed by Bob Brain. They are: bovid size class I, <23 kg (e.g., duikers and dwarf antelopes); bovid size class II, 23–84 kg (e.g., springbok and Grant’s gazelle); bovid size class III, 84–296 kg (e.g., wildebeest and hartebeest) and bovid size class IV, >296 kg (e.g., eland and buffalo); Richard Klein has added bovid size class V (>900 kg) to accommodate the extinct giant buffalo *Pelorovis antiquus*. Faunal analysts are increasingly utilizing these body size classes as analytical units for all mammal remains, particularly as it relates to studies of skeletal-element representation or bone-surface modifications that often include specimens that cannot be identified beyond the class Mammalia. Ethnographic and experimental observations indicate that an animal’s body size can influence a number of behavioral and/or taphonomic factors, including butchery patterns, carcass transport strategies, and carnivore ravaging.

Bovidae One of the artiodactyl families whose members are found at many hominin sites. The group is almost certainly **monophyletic** (Gatesy et al. 1997, Hernández-Fernández and Vrba 2005). A commonly used taxonomy recognizes the eight subfamilies listed below (the modern taxa in those subfamilies are given in parentheses): the Bovinae (cattle and buffalo), Antilopinae (dik-diks and gazelles) Cephalophinae (duikers), Reduncinae (kob), Aepycerotinae (impala), Caprinae (ibex and musk ox), Hippotraginae (antelopes and oryx), and the Alcelaphinae (wildebeest, topi, etc.). Bovids are recognized on the basis of their cranial morphology and particularly the size and shape of the bony horn cores (the horns themselves are made of keratin and do not survive, but horns have a bony core that does fossilize). *See also Artiodactyla.*

bovine (L. *bos*=cow) The informal name for the artiodactyl subfamily, the Bovinae, comprising the cattle and buffalos, within the family **Bovidae**. *See also Bovidae.*

Boxgrove (Location 50°51’N, 0°43’E, England, UK; etym. name of nearby village) History and general description The site is in a quarry 7 km/4 miles east of Chichester and 10 km/6 miles from the current English Channel shoreline. Excavations began in

1982 and continue to the present. A hominin tibia, **Boxgrove 1**, was found in 1993, and two hominin isolated incisors were recovered in 1996. Temporal span **Oxygen Isotope Stage 13 and 12.** How dated? Biostratigraphy (Cromerian mammal fauna), comparative geomorphology, optically stimulated **luminescence dating**, and **electron spin resonance spectroscopy dating.** Hominins found at site The tibial shaft of an adult and two isolated incisors, attributed to *Homo heidelbergensis*. Archeological evidence found at site **Acheulean.** Key references: Geology and dating Roberts et al. 1994, Roberts and Parfitt 1999; Archeology Roberts and Parfitt 1999; Hominins Roberts et al. 1994, Stringer et al. 1998, Trinkaus et al. 1999, Hillson et al. 2010.

Boxgrove 1 Site **Boxgrove.** Locality Quarry 1 (Q1-B). Surface/in situ *In situ.* Date of discovery 1993. Finder Roger Pedersen. Unit Approximately 40 m at the base of the “calcareous silts and gravels” (Roberts et al. 1994, p. 311). Horizon “Higher-energy correlatives of the upper part of the Slindon silts” (*ibid.*). Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*500 ka/**Oxygen Isotope Stage 13.** Developmental age Adult (Streeter et al. 2001). Presumed sex Unknown. Brief anatomical description A left hominin tibial shaft (approximately 294 mm) broken near the midshaft. Its morphology includes a “medially placed nutrient foramen, a well marked soleal line and a particularly prominent vertical line” (Roberts et al. 1994). Announcement Roberts et al. 1994. Initial description Roberts et al. 1994. Photographs/line drawings and metrical data Roberts et al. 1994. Detailed anatomical description Given the nature of the specimen a detailed anatomical description is unnecessary, but Trinkaus et al. (1999) provide a comprehensive analysis of its cross-sectional geometry. Initial taxonomic allocation *Homo cf. heidelbergensis.* Taxonomic revisions None. Current conventional taxonomic allocation *H. heidelbergensis.* Informal taxonomic category Pre-modern *Homo.* Significance This specimen only preserves the shaft, or diaphysis, of what is presumed to be an adult tibia, but early **Middle Pleistocene** postcranial hominin fossils are few and far between, so this specimen makes a significant contribution to what (little) we know about the limb morphology of *H. heidelbergensis*. The cortical bone area is modest, but the shaft is robust overall (i.e., externally thick for its length) and the specimen suggests that the overall

skeletal proportions of this individual are consistent with an adaptation for cold conditions. Location of original Natural History Museum, London, UK. *See also Homo heidelbergensis.*

BP Abbreviation of “before the present”. Used in absolute dating techniques particularly in radiocarbon dating although it has been applied to absolute dates derived from other techniques, typically for relatively recent dates (e.g., the last few thousand years). To standardize radiocarbon dates the “Present” is formally assigned to the arbitrary date of January 1, 1950 (Stuiver and Polach 1977). Thus a date given as 5000 years BP refers to a date 5000 years before 1950.

bp Acronym for **base pair** (*which see*).

BPI Abbreviation of the **Bernard Price Institute for Palaeontological Research** (*which see*).

BPT Acronym for the **Black Pumice Tuff** in the **Koobi Fora Formation, West Turkana, Kenya**.

brachial index (L. *brachium*=arm) Ratio of the lengths of the radius and humerus, calculated as $100 \times (\text{radius length} / \text{humerus length})$, that measures the relative length of the forearm. Like the **intermembral index**, the brachial index varies among primates with different locomotor strategies. In primates with long arms, the forearm tends to contribute disproportionately to the length of the arm (possibly due to developmental constraints), so that suspensory primates (e.g., orangutans) with long upper limbs also have high brachial indices. The brachial index also distinguishes arboreal and terrestrial quadrupeds because the latter have long limbs relative to their body size. Disproportionately elongated distal elements (e.g., forearm), which increases speed and efficiency on the ground, also increases the lengths of the parts of the forelimb that have the least mass. This contrasts with what happens in above-branch arboreal quadrupeds for which having their trunk closer to the branch improves balance. Climate also influences the brachial index, as part of a trend described in **Allen’s Rule**. Limbs typically become narrower distally, and this increases their surface-area-to-volume ratio. The ability to lose or retain heat is proportional to relative surface area, and this explains why primates (includ-

ing modern humans) that inhabit hot, dry environments have elongated distal limb elements (high brachial indices), while those in cold, humid habitats tend to have relatively short distal elements (low brachial indices). That is most likely why the high brachial index of *Homo ergaster* in Africa (as seen in **KNM-WT 15000**), and the low brachial index of *Homo neanderthalensis* are at, or surpass, the ends of the range of brachial index among modern human populations. *See also Allen’s Rule.*

brachiationist model *See* climbing hypothesis.

Brachystegia *See* miombo woodland.

Brain, Charles Kimberlin (Bob) (1931–) C.K. (Bob) Brain was born in Salisbury, Southern Rhodesia (now Zimbabwe), and graduated from the Pretoria Boys High School in 1947. He entered the University of Cape Town in South Africa where he completed his BSc in geology and zoology in 1950. Brain continued at the University of Cape Town for his graduate work and in 1951 he began to study the complex stratigraphy of the cave deposits in the Transvaal where Robert **Broom** and John **Robinson** had found numerous hominin fossils. While working with Robinson at **Sterkfontein** in 1956, Brain found stone **artifacts** in **breccia** deposits where **hominin** fossils at the time assumed to belong to **australopiths** had previously been recovered. These discoveries apparently offered the first evidence that at least some australopiths may have made stone tools. Brain’s research on the formation and structure of the australopith-bearing (then called australopithecine-bearing) deposits at **Sterkfontein, Swartkrans, Kromdraai, and Makapansgat** formed the basis for his PhD in geology from the University of Cape Town in 1957. The results were published as a monograph *The Transvaal Ape-man Bearing Cave Deposits* in the *Transvaal Museum Memoir* series in 1958. In 1963 Robinson resigned his position as the head of the Department of Vertebrate Palaeontology and Physical Anthropology at the **Transvaal Museum** in Pretoria and in 1965 Brain was appointed to succeed him. The discovery of australopith fossils along with **ungulate** fossils by Raymond **Dart** at Makapansgat in the 1950s, and Dart’s assertion that some of the ungulate bones had been modified

for use as **bone tools**, prompted Brain to re-examine the fossil collections in the Transvaal Museum and to begin new excavations at Swartkrans. Brain's work at Swartkrans continued until 1986 and the main results were published in 1993 (see below). He collected over 200,000 bone fragments, including several hundred hominin fossils, from Swartkrans in an attempt to assemble as complete a fossil assemblage as possible. Brain developed field and laboratory techniques to try to understand how the deposits had been formed and he investigated the effects of weathering and of carnivore gnawing on bones to show that these processes could modify bones in ways that resembled human modification. He also gathered ethnographic data on animal butchering and the disposal of bones by indigenous people of the Namib Desert as a way of testing the notion that animal fossils found in cave deposits could have been the remains of game animals eaten by hominins. Brain's research made a major contribution to cave **taphonomy**. By the early 1970s Brain had come to understand how animal bones and other debris were deposited in caves. Significantly, by studying the eating habits of carnivores and other living African animals Brain concluded that many of the bones found at Swartkrans and other cave sites had been accumulated by predators such as leopards, and by scavenging animals such as porcupines. Brain presented these conclusions at a **Wenner-Gren Foundation for Anthropological Research**-sponsored conference on "Taphonomy and Vertebrate Paleocology: with Special Reference to the Late Cenozoic of Sub-Saharan Africa" co-organized by Brain in 1976. Brain also argued that a juvenile *Paranthropus* cranium from Swartkrans that had two perforations at the top of the brain case was evidence that leopards had preyed upon australopiths, the perforations resulting from the canines of the leopard biting into the skull as it carried its prey away to be eaten. Whereas Dart had argued that the bone accumulations at Makapansgat were evidence that the australopiths were hunters, Brain argued that they were likely the prey of carnivores and had not gathered the bones found in cave deposits. Instead, Brain suggested that at least some of the hominin bones found in these deposits had been brought there by predators. To test his ideas he conducted experiments feeding carcasses to large predators to see what affect they had on the bones. He also collected animal bones left by carnivores

in their lairs or by owls in caves to determine the types and quantity of bones that accumulated there. These original investigations led to many publications that culminated in *The Hunters or the Hunted? An Introduction to African Cave Taphonomy*, published in 1981. In addition to unraveling the processes that formed the bone-bearing deposits in southern African caves, Brain also discovered numerous hominin fossils and a large quantity of stone artifacts at Swartkrans as well as some fossil **antelope** bones that do appear to have been used as tools. Brain also found burnt bones at Swartkrans suggesting that campfires were maintained at the cave. Brain retired from the directorship of the Transvaal Museum in 1991. The first edition of his most recent book, *Swartkrans: A Cave's Chronicle of Early Man*, was published in 1993, and a second, revised, edition was published in 2004.

brain (OE *braegen*=brain, most likely from the Gk *bregma*=the front of the head) The brain is defined as the part(s) of the central nervous system that lie within the **endocranial cavity**. The central nervous system develops from the dorsal ectoderm germ layer (i.e., a long strip of ectoderm in the middle of the back of the embryo). This strip of ectoderm rolls up along its long axis into a tube called the neural tube that for all but a small section of its length (between the hindbrain and the midbrain) is normally sealed at the back. The caudal (i.e., towards the tail) part of the neural tube, which is the majority of its length, becomes the **spinal cord**. The cranial part of the neural tube initially develops as three swellings, or vesicles, and it is these vesicles that give rise to the brain. The **caudal** swelling (i.e., the one that connects with the spinal cord at the level of the **foramen magnum**) is called the hindbrain (or rhombencephalon), the middle swelling is called the midbrain (or mesencephalon), and the cranial of the three swellings is called the **forebrain** (or prosencephalon). The hindbrain develops into the medulla oblongata, the pons, and the cerebellum; the **cerebellum** is a dorsal outgrowth from the same embryonic brain subdivision that contains the pons. The forebrain comprises the **thalamus** (the diencephalic part of the forebrain vesicle), which lies close to the midline, and the two **cerebral hemispheres** (the telencephalic part of the forebrain vesicle), which are more laterally situated. It is the external surfaces of the cerebral

hemispheres that are visible when the cranial cavity is opened by removing the roof of the cranium (i.e., the **calotte**). The **basal ganglia** (i.e., the **striatum**, globus pallidus, substantia nigra, and subthalamic nuclei) develop during ontogeny deep in the wall of the part of the expanding forebrain that comes to rest up against the thalamus. In primates, but especially in the great apes and particularly in modern humans, it is the forebrain that undergoes the most expansion during ontogeny. This is an extension of the trend seen across a range of mammals, wherein increases in **brain size** are generally accompanied by a positive **allometry** of forebrain components, particularly the **neocortex** and the **striatum** (Finlay and Darlington 1995). *See also* **brain size**; **brain volume**.

brain mass The average specific mass or density of 78 adult modern human brains was 1.032 g/cm³ (Zilles 1972). Thus, brain mass=brain volume (cm³)×1.032. European researchers tend to refer to “brain weight,” whereas US-based researchers generally refer to “brain mass.” Count (1947) suggested that brain mass=endocranial volume/1.14. *See also* **brain size**.

brain size The size of the brain can be expressed either in terms of its volume or its weight (or mass). Brain size is equal to the **endocranial volume** (also called cranial capacity) minus the volume (or weight) of the meninges, the extracerebral cerebrospinal fluid (i.e., the cerebrospinal fluid outside the ventricles), the intracranial (but extracerebral) vessels, and the cranial nerves within the cranial cavity. *See also* **endocranial volume**.

brain size evolution, molecular basis of

The genes involved in regulating brain size may also be among the molecular mechanisms underlying brain evolution within the hominin clade. Several genetic loci associated with primary microcephaly, a genetic disorder characterized by an extreme reduction in the size of the cerebral cortex, have undergone a high rate of nonsynonymous amino acid substitutions within the primate lineage, and especially within the hominin clade. Primary microcephaly has been mapped to six regions of the modern human genome (i.e., *MCPH1* to *MCPH6*, microcephaly, primary autosomal recessive 1–6) and null mutations have been

identified at four loci: microcephalin (aka *MCPH1*), *CDK5RAP2* (*CDK5* regulatory-subunit-associated protein 2; aka *MCPH3*), *ASPM* (abnormal spindle-like, microcephaly-associated; aka *MCPH5*), and *CENPF* (centromeric protein J; aka *MCPH6*). The microcephaly related genes *ASPM* and *MCPH1* are involved in regulating brain size through mitotic spindle activity and cell cycle progression, respectively. All primary microcephaly genes (i.e., *MCPH1* to *MCPH6*) function in cell-cycle control, and their ability to influence brain size likely stems from their role in regulating the proliferation of neural precursor cells during embryogenesis. *ASPM* has been shown to have undergone positive selection throughout the primate lineage, including at the stem of the hominid clade (i.e., great apes and modern humans) and in the hominin clade. One variant of the *ASPM* gene seems to have undergone a recent **selective sweep** (i.e., a sharp reduction in variation as the favored variant quickly spreads) around 14 ka and one common variant of the allele might have entered the modern human gene pool via admixture with archaic *Homo sapiens*, perhaps even *Homo neanderthalensis*, c.37 ka. Microcephalin shows a strong indication of positive selection primarily at the base of the hominid clade, whereas both *CDK5RAP2* and *CENPF* show higher rates of nonsynonymous substitutions in primates than rodents, and *CDK5RAP2* shows especially high rates in the hominin and panin clades. Another gene involved in neural precursor proliferation, *ADCYAP1* (adenylate cyclase-activating polypeptide 1), which helps regulate the transition from proliferative to differentiated states during neurogenesis, has also been found to bear signatures of accelerated protein-sequence evolution in the hominin clade. Examples of genes with critical roles in determining the relative size of areas within the cerebral cortex include *Emx2*, *Pax6*, and *COUP-TFI* (*Nr2f1*) and variation in some of these genes among modern humans leads to cognitive deficits.

brain specific mass The average specific mass, or density, of the central nervous system within the cranial cavity. *See also* **brain mass**.

brain tissue volume The volume of the brain itself (i.e., brain volume minus the volume of the cerebrospinal fluid within the cavities, or ventricles, of the brain and the volume of any

meninges and cranial nerves that may adhere to the brain).

brain volume Usually defined as the sum of the volume of the **brain tissue**, the **cerebrospinal fluid** within the ventricles of the brain (i.e., the intracerebral cerebrospinal fluid), and any cranial nerves and **meninges** that may adhere to the brain. In practice adult brain volume is approximately 85% of the **endocranial volume** or cranial capacity.

brain weight *See* brain mass.

branch length The lengths of the branches of a **phylogenetic tree** are sometimes scaled according to the numbers of character-state changes or time intervals that separate the tree's nodes. Because the nodes of a phylogenetic tree represent taxonomic units, when branch lengths are employed the length of the branch that separates two nodes indicates either the amount of evolutionary change that has taken place since the ancestral taxon gave rise to the descendant taxon, or the amount of time that has elapsed since the ancestral taxon gave rise to the descendant taxon. A phylogenetic tree whose branch lengths represent the numbers of character-state changes between nodes is known as a phylogram, whereas one whose branch lengths represent the time intervals between nodes is referred to as a chronogram.

branchial arches (Gk *branchion*=gill) System of arches (also called pharyngeal arches) from which the side of the head and neck is formed. Each arch comprises a branchial arch **cartilage**, a dominant nerve and branchial muscle(s); some arches also have a branchial arch artery that persists into adulthood. The structures they give rise to are covered externally with skin or modified skin, and internally they are lined by a layer of epithelium moistened by mucus, called mucosa. On the outside the region in the embryo between two contiguous branchial arches is called a branchial cleft; on the inside it is called a branchial pouch. For example, the cleft between the first and second branchial arches (the first pharyngeal cleft) is the external ear, and the equivalent pouch (the first pharyngeal pouch) is the **auditory tube**; the tympanic membrane is all that prevents the first branchial cleft communicating with the first branchial pouch. The first branchial can serve as an example. Its arch cartilage is **Meckel's cartilage**; this gives rise, from medial to lateral

respectively, to the **incus**, the **malleus**, the anterior ligament of the malleus, the **sphenomandibular ligament**, and the **lingula**. The **mandible** develops in membrane *around* (not from) the lateral extension of Meckel's cartilage. The muscles of the first branchial arch comprise the **muscles of mastication**, the tensors of the palate and the tympanic membrane, the mylohyoid, and the anterior belly of the digastric. The first branchial arch motor nerve, the motor part of the mandibular division of the trigeminal, supplies all of these muscles (syn. pharyngeal arches).

Bräuer, Günter (1949–) Born in Altena, Germany, Günter Bräuer attended the University of Mainz, and was awarded a Diploma in Biology in 1975 and a Dr. rer. nat (PhD) in 1976. Following his PhD research he moved to the University of Hamburg, becoming Professor of Physical Anthropology in 1985. His PhD dissertation research focused on the **Later Stone Age** skeletal remains from **Mumba Cave** and from other localities along the shores of Lake Eyasi in Tanzania, and his subsequent field work and anatomical studies have focused on African Middle and Late Pleistocene–Holocene hominin fossils. His Habilitation in 1983 was a detailed assessment of the evidence for the origin of modern humans in Africa. In 1982 he proposed a version of the **out-of-Africa hypothesis** of modern human origins called the Afro-European Sapiens hypothesis (Bräuer 1984), which favors a gradual, mosaic-like, process of anatomical modernization in Africa over about half a million years. He was also one of the first researchers to recognize the importance of the hominin remains from **Klasies River Mouth** in South Africa (Bräuer et al. 1992a), and his research in Europe suggested there was only minimal evidence for interbreeding between *Homo neanderthalensis* and the modern humans who eventually supplanted them. Günter Bräuer has been a major figure in the debate between those who advocate one or other version of the out-of-Africa hypothesis and those who preferred one or other versions of the **multiregional hypothesis** for the origin for modern humans. Working with Richard Leakey and Emma Mbua, he described the **Middle Pleistocene** cranial remains from **Eliye Springs** and the **KNM-ER 3884** cranium from **Koobi Fora**. His morphological studies on *Homo erectus*, which focused on the origin and evolution of *H. erectus* in Africa and Asia, led to his support for *Homo erectus sensu lato* and his

rejection of *Homo ergaster* (Bräuer 1994). He is co-editor (with Fred Smith) of *Continuity or Replacement – Controversies in Homo sapiens evolution* (1992). He is currently Professor of Human Biology and Physical Anthropology at the University of Hamburg.

breccia (Ge. *brechhan*=to break, or It. *breccia*=rubble) A rock containing angular fragments that have been cemented together in a fine-grained **matrix** (e.g., soil or cave earth) hardened with a mineral cement such as calcium carbonate. The fragments have not been subjected to prolonged water transport and thus because their edges have not been rolled and rounded by water action they are still sharp. Nearly all the early **hominins** from southern Africa have been extracted from breccia-filled limestone caves (e.g., **Drimolen**, **Sterkfontein**). The breccia and speleothem that adheres to many of these fossils can be removed mechanically (e.g., precision drills) or chemically (e.g., by immersion, under strictly controlled conditions, in 10% acetic acid).

bregma (Gk *brechein*=moist) The name given by Aristotle to the part of the **cranium** of a newborn that is moist and membranous. This is because in the newborn the frontal and parietal bones have not fused, and in that region beneath the skin there is a soft diamond-shaped patch of **dura mater** called the anterior fontanelle. It is now used as the name for the midline landmark where the sagittal suture between the two parietal bones meets the coronal suture, which separates the frontal from the parietal bones.

bristle-cone pine *See radiocarbon dating.*

Brno (Location 49°11'N, 16°39'E, Czech Republic; etym. named after the city of Brno, in or near which the sites are located) History and general description This name is applied to three hominin specimens discovered near Brno in 1885 (Brno 1), 1891 (Brno 2), and 1927 (Brno 3). The latter two specimens are burials. Brno 3 was destroyed by fire in 1945. Temporal span and how dated? Brno 1 has uncertain dating; Brno 2 is suggested to be Pavlovian (**Gravettian**) by cultural association, and Brno 3 was initially thought to be **Upper Paleolithic**, but this attribution has been questioned. Hominins found at site All three are *Homo sapiens*. Brno 1 consists of a calotte,

maxilla, and fragmentary postcrania. Brno 2 consists of a calvaria, partial face, partial mandible, and fragmentary postcrania. Brno 3 was an associated skeleton. Archeological evidence found at site Brno 1 was found in a horizon with **Aurignacian**-like tools, but it is unclear how they are associated with the fossil remains. Brno 2 was buried with mammoth bone and ivory, a figurine, and perforated shells, which suggest a Pavlovian (Gravettian) context. Brno 3 was not associated with any archeological remains. Key references: Geology, dating, and paleoenvironment Smith 1982; Hominins Vlček 1971, Smith 1982.

Brno-Bohunice (Location 49°10'N, 16°34'E, Czech Republic; etym. named after the suburb of Brno in which it is located) History and general description This open-air site near the city of Brno in Southern Moravia is the type site of the Bohunician transitional technocomplex. Valloch collected stone tools exposed in bulldozer trenches in the 1970s, and performed limited excavation. The site was re-excavated in 2002. Temporal span and how dated? **Radiocarbon dating** suggests a range of 40–35 ka (calibrated). **Thermoluminescence dating** gives an age of *c.*48 ka, but optically stimulated **luminescence dating** provides a large range of dates: 30.9±3.1, 58.7±5.8, and 104.3±10 ka. Hominins found at site None. Archeological evidence found at site The recovered stone tools are from an early **Upper Paleolithic** industry that Valloch initially described as a kind of **Szeletian**, but was later renamed the Bohunician. It is marked by the use of **Levallois** with a significant proportion of blades and, like the **Châtelperronian** in France, it is a transitional industry with many similarities to both Middle and Upper Paleolithic technologies, but which is usually attributed to *Homo neanderthalensis*. Key references: Geology, dating, and paleoenvironment Svoboda 2003, Richter et al. 2009; Archeology Svoboda 2003.

broad-sense heritability (H or H^2) Defined as the genetic variance divided by the **phenotypic variance**. This value is considered the broad-sense (as opposed to the narrow-sense) heritability since it reflects *all* of the possible genetic contributions to the phenotypic variance. *See also heritability.*

Broca's area (etym. Named after Paul Broca) A region of the inferior frontal gyrus of the

cerebral cortex that in modern humans is important for the production of **speech**, the processing of **syntax**, lexical retrieval, the organization of hierarchically ordered movements of the face and hands, and the processing of rules relating to **recursion**. This cortical region is named after the French physician and anthropologist Paul Broca (1824–80), who discovered its function by studying the post-mortem brains of patients with aphasia, a profound speech impairment. Broca found that lesions that included the left inferior frontal gyrus were often observed in these cases. Broca's area is generally thought to include **Brodmann's** cytoarchitectonic areas 44 and 45. In modern humans, different parts of the inferior frontal gyrus are typically associated with different cytoarchitectonic components of Broca's area. The ascending (vertical) ramus of the **lateral fissure** usually separates the pars opercularis (area 44) from the pars triangularis (area 45), and the anterior ramus divides the pars triangularis from the pars orbitalis (area 47). Because approximately 95% of modern humans show **left-hemispheric dominance** for language, numerous studies have investigated macrostructural asymmetry in Broca's area of modern humans using the sulcal landmarks listed above to subdivide the region. Results from these macrostructural studies, however, have differed markedly depending upon methodology and anatomical definitions and it is not clear whether the gross anatomical structure of inferior frontal gyrus in modern humans displays lateral asymmetry. Histological studies of Broca's area of modern human brains, however, have revealed several significant asymmetries. Volumetric cytoarchitecture-based studies have shown that area 44, but not area 45, is leftward dominant (Galaburda 1980, Amunts et al. 1999). In addition, leftward asymmetries have also been reported in terms of the dendritic branching of **pyramidal cells**, and the **grey-level index**. Based on connectivity, **cytoarchitecture**, and function, homologues of Brodmann's areas 44 and 45 have been identified in macaque monkeys and great apes. The region equivalent to Broca's area in the inferior frontal cortex of macaques has been shown to be activated during the perception of species-specific vocalizations and facial expressions, and, in addition, when this region is electrically stimulated in macaques it results in orofacial movements. When the equivalent region in the inferior frontal cortex of chimpanzees is stimulated movements of

the larynx and tongue are evoked and **positron emission tomography** neuroimaging experiments have shown activity in the left inferior frontal gyrus during the production of communicative vocalizations and hand gestures. As with modern humans it is unclear whether gross morphological asymmetries are present in the inferior frontal gyrus of chimpanzees. Cytoarchitecture-based studies, furthermore, indicate that Brodmann's areas 44 and 45 are *not* asymmetric in terms of volume or neuron numbers in chimpanzees (Schenker et al. 2010). This differs from the documented leftward asymmetry of area 44 in modern humans. When compared to the other cortical areas that have been measured in both modern humans and chimpanzees on the basis of a cytoarchitectonic definition of boundaries (including areas 10, 13, and 17), area 44 and area 45 on the left side are among the most enlarged in the modern human brain.

Brodmann's areas Numbered regions of the **cerebral cortex**. They are named after Korbinian Brodmann who, after studying sections of the cerebral cortex, subdivided it according to what he interpreted were differences in the neuronal morphology, cell packing density, and relative thickness of the six main cortical layers. For example, the primary **motor speech areas** of the cerebral cortex are given the numbers 44 and 45, and the primary **visual** cortex is numbered 17.

Broken Hill *See* Kabwe.

Broom, Robert (1866–1951) Robert Broom was born in Paisley, Scotland, and entered the University of Glasgow in 1883. He completed his medical degree in 1889, and emigrated in 1892 to Australia where he lived for 4 years before settling in South Africa in 1897. Initially Broom practiced medicine in Cape Province, but in 1903 he was appointed Professor of Zoology and Geology at Victoria College (now Stellenbosch University). The fossil-rich deposits of the Karoo located at the outskirts of Cape Province provided Broom with the opportunity to pursue paleontology and he quickly became an expert on therodonts, the topic of his University of Glasgow DSc thesis in 1905; thus began Broom's long interest in the evolutionary origin of the mammals from mammal-like reptiles. In 1910, Broom was dismissed from his position at Victoria College, possibly because of his support of the idea of evolution,

which was a controversial subject in the conservative cultural environment of South Africa at the time. Broom returned to Britain during WWI and worked in a London hospital, but in 1916 he returned to South Africa. He continued to practice medicine and to pursue his paleontological researches, but the emphasis of his research changed when he learned of Raymond Dart's discovery of *Australopithecus africanus*. Late in 1924 Dart, who was Professor of Anatomy at the newly founded University of Witwatersrand in Johannesburg, recognized the juvenile skull of a previously unknown species intermediate between the anthropoid apes and modern humans and an evolutionary ancestor to modern humans among the fossils from a lime quarry in Taungs (now called **Taung**). Accounts of Dart's discovery were published in *Nature* and in a local newspaper in Johannesburg during the first week of February 1925, and within 2 weeks of learning of the discovery Broom traveled to Johannesburg to inspect the fossil for himself. Broom immediately recognized the importance of Dart's "discovery" and agreed with the latter's assessment that *Au. africanus* represented an evolutionary link between our ape-like ancestors and modern humans. But Dart's discovery received a mixed response among European anthropologists, and few accepted Dart's conclusion that *Australopithecus* was ancestral to modern humans. Broom, however, acted quickly to defend Dart's interpretation of the fossil by writing two papers about it. The first, entitled "Some notes on the Taungs skull," was published in *Nature*, and the second paper, entitled "On the newly discovered South African man-ape," was published in *Natural History*; both appeared in 1925, but Broom's support did little to convince his European and American colleagues. There were several reasons for this. First, most anthropologists at that time believed that humans had evolved in Asia, not Africa, and the discovery of *Pithecanthropus erectus* by Eugène Dubois in Java in the 1890s and of *Sinanthropus pekinensis* in China by Davidson Black in the late 1920s only strengthened this conviction. Second, the *Australopithecus* specimen discovered by Dart was of a juvenile and it was known that apes during their infancy can resemble the morphology of modern humans, acquiring their more distinct ape-like features as they mature. Lastly, since the geology of southern Africa was poorly understood, there was skepticism about the geological antiquity that Dart

and Broom claimed for *Australopithecus africanus*. Broom realized that *Australopithecus* would not be accepted as an evolutionary link between early anthropoids and modern humans until further, more complete, adult specimens were discovered. His experience in paleontology provided Broom with the knowledge necessary to search for additional specimens and his appointment in 1934 as curator of paleontology at the **Transvaal Museum**, in Pretoria, gave Broom the time and resources to devote all his efforts to the search. The discovery of fossil baboon skulls in cave deposits at **Sterkfontein**, near Johannesburg, in 1936 by Harding le Riche and Trevor Jones, who were students working with Dart, prompted Broom to visit the site. There he met the local quarry manager, George Barlow, who gave Broom several fossil baboon skulls and a partial fossilized brain cast that clearly was from an "ape-man." Broom recovered portions of the skull belonging to the **endocast** several days later, and he considered the specimen to be closely related to Dart's *Australopithecus*. He originally named it *Australopithecus transvaalensis*, but he later renamed it *Plesianthropus transvaalensis* (it is now considered to be conspecific with *Au. africanus*). Broom collected teeth and small pieces of bone from Sterkfontein over the next 2 years, but his next major discovery occurred in 1938 when Broom received teeth and portions of a skull from a **hominin** that seemed to differ from both *Australopithecus* and *Plesianthropus*. The specimen, found at a cave site called **Kromdraai** in the same valley as Sterkfontein, had larger postcanine teeth and a larger mandibular body than *Australopithecus*, so Broom referred the specimen to a new taxon, *Paranthropus robustus*. Broom now had fossils from several adult australopiths, and because the outbreak of WWII had stopped excavations in South Africa, this allowed Broom and his assistants to study the fossils. This resulted in the publication in 1946 of *The South African Fossil Ape-Men: The Australopithecinae* by Broom and G.W.H. Schepers, the second in the *Transvaal Museum Memoir* series. Broom resumed excavations at Sterkfontein in 1947 together with John **Robinson**, who had just been appointed to Broom's department at the Transvaal Museum. Over the next few years they recovered more skeletal material there, but in 1948 at a recently discovered site called **Swartkrans** they unearthed another robust hominin mandible, which they

assigned to yet another new species called *Paranthropus crassidens*. A year later, also at Swartkrans, they found several fossils of a much less robust type that they believed belonged to a species intermediate between “ape-men” and modern humans. Broom and Robinson named this new species *Telanthropus capensis* and by 1952 several additional specimens had been discovered there. In 1950 Broom, Robinson, and G.W.H. Schepers published *Sterkfontein ape-man, Plesianthropus*, the fourth volume in the *Transvaal Museum Memoir* series, and in 1952 the sixth volume in the series, *Swartkrans ape-man, Paranthropus crassidens*, was published, this time by Broom and J.T. Robinson. This was Broom’s last publication. In addition to making major discoveries of hominin fossils, Broom also wrote on theoretical issues concerning the mechanism and operation of biological evolution. While discussing vertebrate evolution and the origin of mammals in *The Origin of the Human Skeleton* (1930), Broom criticized both the Neo-Lamarckian and the Darwinian conceptions of evolution. He repeated these criticisms in *The Coming of Man: Was It Accident or Design?* (1933), where he argued that mutationist, Neo-Lamarckian, and Darwinian mechanisms do not adequately account for what we know about the fossil record and the evolution of humans. Broom instead argued that an intelligent spiritual agent must operate in biological evolution, and moreover he believed that evolution had reached its completion in modern humans. He wrote a popular account of his discoveries on paleoanthropology entitled *Finding the Missing Link*, which was published in 1950, and he continued his paleontological research and remained curator of paleontology at the Transvaal Museum until his death in 1951. Broom was elected a Fellow of the Royal Society in 1920 and was awarded its Royal Medal in 1928.

brow ridge (ME *brow*=eyelash) An informal inclusive term that applies to either discrete thickening of the bone above each superior orbital margin (e.g., *Homo neanderthalensis*) or to a continuous bar of thickened bone that extends from the lateral end of one superior orbital margin across the midline to reach the lateral end of the superior orbital margin on the other side (e.g., **Trinil 2**). The term brow ridge is usually not applied to the compound structure seen above each

orbital opening in *Homo sapiens*, which consists of the **superciliary eminence** medially and the **supraorbital trigon** laterally.

brown breccia See Sterkfontein; Swartkrans.

Brown Sands One of two hominin-bearing localities in the **Usno Formation** in the **Lower Omo Valley** (the other one is called **White Sands**). Fossils found in the Brown Sands locality have been given the prefix “B” for Brown Sands. See also **Usno Formation**; *Australopithecus afarensis*.

brown striae Less common term used to refer to **long-period incremental lines** in enamel; the term is derived from the common appearance of these structures as brown lines when viewed using transmitted light microscopy. See also **striae of Retzius**.

brown striae of Retzius See **striae of Retzius**.

Brown, Francis H. (1943–) Francis Brown was born and raised in northern California, USA. In 1965 he graduated from the University of California, Berkeley with a BA in geology. He stayed there for his graduate studies, which addressed the petrology of kalsilite-bearing lavas in Toro-Ankole, Uganda; he was awarded his PhD in 1971. He began stratigraphic work on the **Shungura Formation** in 1966, and between 1967 and 1974 Brown joined the **International Omo Research Expedition** in Ethiopia where he worked with **Jean de Heinzelin** and **Paul Haesaerts** on the stratigraphy of the Usno and Shungura Formations, and between 1972 and 1974 he collaborated with **Ralph T. Shuey** to determine the geomagnetic polarity of the Shungura and Usno Formations; his study of tephra (volcanic ash layers) of the Shungura Formation also began in the 1970s. After fieldwork in southern Utah and at Sahabi, Libya, in 1980, Brown, at the invitation of **Richard Leakey**, began reviewing the stratigraphy at **Koobi Fora** and this began a long association with the **Koobi Fora Research Project** and by 1986 the stratigraphic framework of the Koobi Fora had been revised in collaboration with **Craig Feibel**; work on the **Nachukui Formation**, west of Lake Turkana, began in 1981. In conjunction with **Thure Cerling**, Brown pioneered **tephrostratigraphy** (i.e., the use of tuffs as lithostratigraphic markers) at hominin sites in East Africa. By 1982, the first correlations

were established between the **Hadar** study area and Koobi Fora, and by 1985 links were established with the deep sea record in the Gulf of Aden. During the same period, together with Harry Merrick, he began analysis of Kenyan obsidians to determine sources of archeological material, and more recently has worked on obsidians from Ethiopia. Fieldwork with Bereket Haileab in 1985 and 1986 formed the basis for tephra correlations throughout the Turkana Basin, and also to other sites, such as **Gadeb** and the **Middle Awash study area** (also with Bereket Haileab), Baringo (with Fulbert Namwamba), and the Suguta Valley (with Benson Mboya). In 1980 Brown began a long-term association with Ian McDougall (Australian National University), and together they have provided secure ages for many Miocene sites in the region as well as ages for the many tephra in the Pliocene and Pleistocene **Omo Group**, and on two tephra in the Pleistocene Kibish Formation; Brown's long-term fieldwork on the Nachukui and Shungura Formations continued until 2010. His important role in the Koobi Fora Research Project was recognized by his lead-authorship of the paper that announced the recovery of **KNM-WT 15000** from **West Turkana** (Brown et al. 1985). Brown is currently Dean of the College of Mines and Earth Sciences at the University of Utah, where he is also a Distinguished Professor of Geology and Geophysics.

browser An animal that feeds on above-ground vegetation (e.g., leaves, fruits, and shoots in bushes and trees). *See also* **browsing**.

browsing (OF *broust*=shoot or twig) The consumption of leaves, fruits, and shoots of usually dicotyledonous plants (flowering plants with two embryonic seed leaves or cotyledons) that grow above ground level. This term is often used in paleoanthropology to refer to the inferred diets of the **herbivores** whose remains are found at many archeological and paleoanthropological sites. A browsing diet in extinct animals is usually inferred through studies of tooth and jaw morphology (e.g., a narrow snout and evidence of **hypsodonty**) or from studies of **stable isotopes**. Plants that browsers feed on (i.e., shrubs, trees, and non-grass herbs) use the C_3 photosynthetic system and they are depleted in ^{13}C (i.e., have less ^{13}C) relative to plants that use the C_4 and **CAM** photosynthetic systems; thus the bones of browsing animals have bones and enamel that are depleted in ^{13}C (i.e., have less ^{13}C) relative to the bones of grazing

animals that consume plants that use the C_4 photosynthetic system. Modern giraffes and elephants are browsers and the same dietary adaptation has been suggested for many of their extinct fossil relatives. Like all forms of herbivory, browsing can be considered a form of predation in which an organism predate on plants, in which case browsers are primary consumers in the **ecosystem**. *See also* C_3 and C_4 ; $^{13}C/^{12}C$; **stable isotopes**.

Brunet, Michel (1940–) Michel Brunet was born in Southern Vienne, France, in the midst of WWII and spent his early childhood in the village of Poitou, near Poitiers. After the end of the war Brunet completed his early education at Versailles and in 1962 he entered the Sorbonne in Paris to study paleontology. Brunet completed his thèse d'Université in paleontology in 1966, then he moved to the University of Poitiers to study Paleogene mammals, and it was there he completed his Natural Sciences State Doctorate in 1975. In 1989 Brunet accepted a position as Professor of Paleontology at the University of Poitiers. His early research dealt with the paleontology of mammals, but the focus of his research changed to primate and hominin paleontology in 1976 after he learned of efforts to find new specimens of *Ramapithecus* or other early hominoid fossils in Pakistan. During the late 1970s Brunet and Emile Heintz, a paleontologist at the Centre National de la Recherche Scientifique (National Center of Scientific Research) conducted excavations in Afghanistan and Iraq searching for fossil apes, but they had to abandon their search in 1980 due to the dangerous political situation in both countries. Brunet then turned his attention to Africa, but rather than focusing in the eastern or southern regions of Africa where fossil hominins had already been found Brunet decided to explore western Africa for ape and hominin fossils. Brunet, along with David Pilbeam, began explorations in Cameroon in 1984 and although research continued there throughout the late 1980s no fossil apes were found. Brunet was also hopeful about finding fossils in Chad, especially since French paleontologist Yves Coppens had found fossil mammals there during the 1960s. In 1993 Brunet received a research permit from the government of Chad to conduct excavations in the **Chad Basin** (also known as the Djurab Desert) in what had once been the bed of Lake Chad. He established

the **Mission Paléanthropologique Franco-Tchadienne** (French-Chadian Paleoanthropological Mission, or MPFT), a scientific collaboration between the University of N'Djamena, the University of Poitiers, and the Centre National d'Appui à la Recherche, whose purpose was to research the origin and evolution of early hominins and their environment in western-central Africa. In 1994 Brunet and his team began exploring the sediments of the Lake Chad basin for fossils and in the following year Brunet found a hominin mandibular fragment at a site called **Koro Toro** that he biochronologically dated at 3.5 Ma. He considered the specimen to be a new species of *Australopithecus* that he named *Australopithecus bahrelghazali* (nicknamed “Abel” in honor to the memory of Abel Brillanceau, a colleague and close friend who died while working in the field). This fossil was important evidence that hominins were also present in central Africa, but even more intriguing was the fact that in 1997 Brunet's team was discovering mammal fossils from the late **Miocene** deposits at **Toros-Menalla** that were biochronologically dated to between 6 and 7 Ma. Then in 2001 Ahounta Djimdoumalbaye, a Chadian student from the University of N'Djamena working on Brunet's team, found a largely complete but crushed and distorted hominin cranium from the *c.*6–7 Ma deposits. The fossil, named “Toumai” (meaning “hope of life” in the Goran language) by the Chadian authorities, was assigned by Brunet and his colleagues to a new genus and species, *Sahelanthropus tchadensis*. Because it possesses what are interpreted to be derived hominin characters Brunet considers this species to represent the stem hominin, and it would be the earliest hominin fossil yet found. More recently Brunet has been conducting field surveys to look for fossil mammals and primates in Libya, and since 2004 he has served as the director of the **Mission Paléontologique Franco-Libyenne** (Franco-Libyan Paleontological Mission, or MPFL), a scientific collaboration between the University of Poitiers and the Al Fateh University of Tripoli. Brunet was appointed a professor in the Faculté des Sciences Fondamentales et Appliquées at the University of Poitiers in 1989, and from 1992 he was also the head of the Laboratoire de Géobiologie, Biochronologie, et Paléontologie Humaine (Laboratory of Geobiology, Biostratigraphy, and Human Paleontology), which was integrated into the Centre National de la Recherche

Scientifique in 2000 (the laboratory has since been renamed the Institut International de Paléoprimatologie et Paléontologie Humaine, Evolution et Paléoenvironnements, CNRS UMR 6046). He is also the director of the Mission Paléanthropologique Franco-Tchadienne. In 2007 Brunet was appointed a Professor in the College de France.

Brussels Natural History Museum *See* Royal Museum for Central Africa.

BSC Acronym for the **biological species concept** (*which see*).

BSN49/P27 Site **Gona**. Locality BSN49. Surface/in situ Surface. Date of discovery February 12, 2001. Finders Ali Ma'anda Dato and team. Unit N/A. Horizon Maoleem Vitric Tuff. Bed/member Hatayae Member. Formation **Busidima Formation**. Group N/A. Nearest overlying dated horizon Silbo Tuff (*c.*0.751±0.022 Ma). Nearest underlying dated horizon Base of the Clr polarity chron (*c.*1.778 Ma). Geological age Given the measured sedimentation rates in the Busidima Formation, the “likely age” is “0.9–1.4 Ma” (Simpson et al. 2008, p. 1089). Developmental age Adult. Presumed sex Female. Brief anatomical description Most of the right side and a substantial part of the left side of a pelvis, plus the associated sacrum and the last lumbar vertebra. The pelvic brim is preserved except for the medial end of the right pubic ramus. Announcement Simpson et al. 2008. Initial description Simpson et al. 2008. Photographs/line drawings and metrical data Simpson et al. 2008. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance Exceptionally well preserved pelvis that provides evidence about the size of the birth canal of a “short-statured *H. erectus* adult female” (Simpson et al. 2008, p. 1090), but Ruff (2010) suggests that the size of the pelvis as assessed from the diameter of the acetabulum is more consistent with it belonging to an archaic hominin, possibly *Paranthropus boisei*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Bubing Basin (Location approximately 23°25'N, 107°00'E, Guangxi Zhuang Autonomous Region, China) History and general description Bubing is a small basin located to the southwest of the larger **Bose Basin**. Bubing Basin is 16 km/9.9 miles long by 2 km/1.2 miles wide and runs in a northwest to southeast direction. Bubing comprises Paleozoic limestone hills that uplifted at different stages during the **Neogene** and **Quaternary** periods. More than 50 caves have been identified in Bubing, between 140 and 215 m above sea level; the older caves are situated at higher elevations and the younger caves are located along the floor of the basin. The best-known caves in the basin are Chuifeng, Cunkong, Dingmo, Lower Pubu, Luna, Mohui, Upper Pubu, Wuyun, and Zhongshan. Evaluation of the vertebrate paleontological fossils from Bubing has resulted in a greater appreciation of variation in the *Ailuropoda-Stegodon* fauna, a category that has often been considered representative of the southeast Asia, including southern China. For example, *Stegodon* and *Ailuropoda* are absent from Cunkong Cave, which dates to the Holocene, but in the Late Pleistocene Lower Pubu Cave *Ailuropoda* is present, but *Stegodon* is absent. *Elephas maximus* is present in Lower Pubu and *Equus* was also identified in Chuifeng and Lower Pubu. Some link these differences with the amounts of open grassland in the region. Temporal span and how dated? **Biostratigraphy, uranium-series dating, electron spin resonance spectroscopy dating, and AMS radiocarbon dating** suggest that the caves in the Bubing Basin date from the Early Pleistocene to the Holocene. Biostratigraphic evidence places the caves in the following chronological order: Chuifeng and Mohui *c.*2 Ma, Wuyun and Upper Pubu *c.*280–76 ka, Luna Cave to 70–20 ka, and Zhongshan to 12–6 ka. Hominins found at site Two hominin teeth excavated from Mohui have been allocated to *Homo cf. erectus*; two anatomically modern human teeth were excavated from Luna Cave along with an anatomically modern human partial skull that appears to have been pathological. Many nonhominin primates (e.g., *Presbytis*, *Macaca*, *Pongo*) have been recovered from the caves [e.g., Chuifeng yielded the largest collection of *Gigantopithecus* teeth ($n=92$) found in one locality except for the type site Liucheng (where more than 1000 teeth and three partial mandibles were found)]. Archeological evidence found at site Surface collections of Paleolithic artifacts plus excavated evidence from cave and open-air sites (e.g., eight core and flake tools were excavated from Mohui Cave, but six of these were excavated from disturbed deposits and

the relationship between the hominin teeth and the remaining two artifacts is not clear). Dingmo Cave has evidence of rock art, although the age of the art needs to be ascertained. Surface survey of the area in front of Dingmo resulted in the recovery of Paleolithic-like stone flakes. A systematic study of the archeological residues surface collected and excavated in Bubing is under way. Repository Natural History Museum of Guangxi Zhuang Autonomous Region, China; Tiandong Museum, Guangxi, China. buccal (L. *bucca*=cheek) Refers to the cheek. It is used to describe the outer, or lateral, aspect of the premolars and molars. The equivalent term for the canine and the incisors is **labial**, because the lateral aspect of these teeth faces the lips, not the cheek. The measurement of the breadth of a premolar or molar tooth that is taken at right angles to its long, or mesiodistal, axis is referred to as its buccolingual breadth (i.e., the measurement runs from the outer, buccal, aspect of the tooth crown, to the inner, tongue-side, or **lingual** aspect of the crown).

buccostyle A term used by Tobias (1967a) for an enamel feature more commonly referred to as a **paramolar tubercle** (*which see*).

Buia (Location approximately 14°49'N, 39°50'E, Eritrea; etym. unknown) History and general description In 1994–5 geological and paleontological exploration of the Danakil Depression by an Italian team headed by Ernesto Abbate led to the recognition of the Dandiero Group, an about 1000 m thick succession, previously attributed to the Danakil Formation or the Red Series. This group includes three main unconformity-bounded units (Abbate et al. 2004): the Maebele Synthem, the Curbelu Synthem, and the Samoti Synthem. The Maebele Synthem is divided into six formations that sample **fluvial**, **deltaic**, and **lacustrine** environments with late **Early to Middle Pleistocene** faunas. In the lower portion of the Maebele Synthem, the Alat Formation yielded six hominin fossils preliminarily attributed to *Homo erectus*. Temporal span The sedimentary succession covers from *c.*1.3 to 0.6 Ma. How dated? **Fission track dating** on volcanic glasses from an ash layer

approximately 80 m below the *Homo*-bearing sediments ($c. 1.3 \pm 0.3$ Ma). Rocks of normal polarity correlated with the Jaramillo subchron (C1r.1n) and associated late Early to Middle Pleistocene mammal fauna. Hominins found at site A nearly complete cranium (UA 31), two permanent upper incisors (UA 222, an upper left I^2 , and UA 369, a lower left I^1), two conjoined pelvic fragments, a right iliac blade (UA 173 *s.s.*), and a right acetabulum and partial ischium (previously reported as UA 405), forming an incomplete adult hip bone (UA 173) and a pubic symphysis (UA 466). Archeological evidence found at site Acheulean handaxes, cleavers, choppers, and flakes. Key references: Geology and dating Abbate et al. 1998, Albanielli and Napoleone 2004, Bigazzi et al. 2004, Martínez-Navarro et al. 2004, Ghinassi et al. 2009; Hominins Abbate et al. 1998, Macchiarelli et al. 2004a, Bondioli et al. 2006; Archeology Abbate et al. 1998, Fiore et al. 2004, Martini et al. 2004.

Buia pubis See UA 466.

Bukuran (Location $7^\circ 20' S$, $110^\circ 58' E$, Indonesia; etym. named after a local village) History and general description Within the **Sangiran Dome** and less than 1 km/0.6 miles west of the village of **Sendangbusik**, this is the site of a 1989 surface find of 16 hominin cranial fragments of a single individual named **Hanoman 1**. These specimens were derived from upper levels of the **Sangiran Formation** (NB: there is no **Grenzbank zone** between the older Sangiran and younger **Bapang Formations** at Bukuran). Temporal span and how dated? The most recent radiometric estimates of the age of nearby Upper Sangiran Formation deposits cluster around 1.5 Ma. Hominins found at site Hanoman 1 includes 16 cranial vault fragments including portions of the frontal, parietal, and occipital bones. This specimen has been attributed to *Homo erectus*. Archeological evidence found at site Two heavily rolled siliceous flakes from the overlying Bapang Formation. Key references: Geology and dating Widiyanto et al. 1994, Larick et al. 2001; Hominins Widiyanto et al. 1994.

bulk strategy See economic utility index.

Bulletin of Zoological Nomenclature The name of the journal that carries the opinions of the

International Commission on Zoological Nomenclature (or ICZN; *which see*).

bunodont (Gk *buno*=hill and *dont*=teeth) Teeth with low, conical crowns, as opposed to hypsodont (i.e., high crowned) teeth. **Hominin** teeth are relatively bunodont, and among hominins the teeth of *Paranthropus boisei* are the most bunodont, for they have a large crown base and curved buccal and lingual surfaces.

Bura Hasuma One of the designated subregions of **Koobi Fora**. It includes localities where some of the oldest sediments in the Koobi Fora and the **Kubi Algi Formations** are exposed. *See also* **Koobi Fora**.

Burg Wartenstein International Symposium Program In 1958 The **Wenner-Gren Foundation for Anthropological Research** acquired Burg Wartenstein castle in Austria as a gift from Axel Wenner-Gren. Between 1959 and 1980 Burg Wartenstein was the Foundation's European headquarters and the primary venue for its International Symposium Program. International Symposia were (and still are) meetings of intensive discussion that aim to include international scholars with broad interests. During the 1960s and 1970s the Foundation hosted almost 2000 scholars at 86 symposia held at the castle and elsewhere during the summer months. The titles of landmark meetings that focused on paleoanthropology are given below with the year in which they were held (the publication date and the organizer(s) are given in parentheses): "Social Life of Early Man," 1959 (1961, Washburn), "Early Man and Pleistocene Stratigraphy in the Circum-Mediterranean Regions," 1960 (1962, Blanc and Howell), "African Ecology and Human Evolution," 1961 (1963, Howell and Bourlière), "Classification and Human Evolution," 1962 (1963, Washburn), "Background to Evolution in Africa," 1965 (1967, Bishop and Clark), "Man the Hunter," 1966 (1968 Lee and DeVore, held in Chicago), "Calibration of Hominoid Evolution: Recent Advances in Isotopic and Other Dating Methods as Applicable to the Origin of Man," 1971 (1972, Bishop and Miller), "Earliest Man and Environments in the Lake Rudolf Basin," 1973 (1976, Coppens, Howell, Isaac, and Richard Leakey, held in Nairobi and Lake Rudolf, Kenya), "After the Australopithecines," 1973

(1975, Butzer and Isaac), and “Early Hominids of Africa,” 1974 (1978, Jolly, held at The Wenner-Gren Foundation, New York). The results of these meetings were published through the Foundation’s **Viking Fund Publications in Anthropology**, as well as through special arrangement with publishing houses (such as Aldine Publishers) and various university presses. *See also* **Wenner-Gren Foundation for Anthropological Research**.

burin (Fr. *burin*=a term used by engravers and printmakers for an elongated metal chisel) This term was borrowed by archeologists to describe stone tools made on **flakes** that are particularly common at some European **Upper Paleolithic** sites. Burins have a distinctive chisel-like edge or tip and were originally considered to function as tools for engraving, bone, antler, wood, or similar media (e.g., de Sonneville-Bordes and Perrot 1954–6, Debénath and Dibble 1994). Burins are “flaked flakes,” in which the relatively thick chisel-like edge is made by removing an elongated flake (called a burin spall) along one or more edges of a flake. Some suggest burins may have served a wider range of functions than originally conceived (see Barton et al. 1996). This includes their use as **cores**, and under this interpretation, it is the thin elongated flake (the burin spall) rather than the burin that was used as a tool.

burin spall *See* burin.

bush pig The vernacular name for the taxa within the genus *Potamochoerus*. *See also* **Suidae**.

bushland Biomes that are dryer than **woodland** forests, receiving 250–600 mm mean annual rainfall. Due to lower levels of rainfall and poorer-quality soils in terms of nutrients and drainage, bushlands are dominated by small trees between 3 and 9 m in height with multiple stems. By definition 40% or more of bushland is covered by bushes. Most bushlands have some degree of grass cover. More open habitats, such as bushland and shrubland biomes, have been suggested to have been the major biomes for *Paranthropus* and early *Homo* between 2.5 and 2.0 Ma.

Bushmen *See* San.

Busidima Formation [Location <10°55′–11°15′N, 40°20′–40°35′E, Ethiopia; etym. Busidima is the local Afar (Danakil) name for the ephemeral stream central to outcrops of the Busidima Formation] History and general description A wedge-shaped basin (half-graben) of sediments adjacent to the foothills of the western escarpment of the Ethiopian Rift near the **Gona Paleoanthropological study area**, the **Dikika study area**, and **Hadar**. The strata from which archeological evidence has been recovered at Gona were originally assigned to the upper Kada Hadar Member of the **Hadar Formation** (Semaw et al. 1997), but more recent stratigraphic work has recognized a significant angular unconformity between the Hadar Formation and the overlying sediments. This required redefining the Busidima Formation as those sediments that overlie the unconformity and fill the half-graben structure up to a prominent paleosol surface, the Halalalee Bed (Quade et al. 2004, Quade and Wynn 2008). The Busidima Formation is not further subdivided, but contains several prominent tuffs exposed throughout the region that can be used as stratigraphic markers. Temporal span and how dated? The lowest dated tuff in the Busidima Formation is an unnamed tuff dated to 2.69 Ma and the youngest is a correlate to the Waidedo Vitric Tuff, dated to 0.16 Ma. The sediments have been dated using the **argon-argon dating** method, **magnetostratigraphy**, **tephrostratigraphy**, and **biostratigraphy**. Hominins found at site Fossil hominins recovered from the Busidima Formation have been assigned to early *Homo* and *Homo erectus*. Archeological evidence found at site The Busidima Formation includes evidence of **Oldowan**, **Acheulean**, and **Middle Stone Age** sites. Key references: Geology, dating, and paleoenvironment Quade et al. 2004, Quade and Wynn 2008; Hominins Kimbel et al. 1996, Simpson et al. 2008; Archeology Corvinus and Roche 1976, Kimbel et al. 1996, Semaw et al. 1997. *See also* **Gona Paleoanthropological study area**; **Hadar Formation**.

Buxton Limestone *See* Taung.

C

c. Abbreviation of *circa* (L. *circum*=around) meaning ‘about’ or ‘approximately’ the true value.

$^{13}\text{C}/^{12}\text{C}$ A ratio of **stable isotopes** in bone collagen used for **diet reconstruction** and to reconstruct the **paleoenvironment**. The system works on the basis that the levels of ^{13}C in the bone collagen and bioapatite and enamel bioapatite of herbivores reflect the types of plants they consumed (e.g., C_3 , C_4 , or CAM) and the levels of ^{13}C in the bones and enamel of carnivores reflects the diets of the herbivores preyed on by those carnivores. For example, animals that eat plants, such as most shrubs, trees, herbs, and cool-season grasses, that use the C_3 photosynthetic pathway should have carbon isotope ratios that are depleted in $\delta^{13}\text{C}$ (i.e., have less $\delta^{13}\text{C}$) relative to animals that consume plants such as succulents, sedges, and warm-season grasses that use the C_4 and CAM photosynthetic pathways. Carbon isotope ratios can indicate whether or not a particular environment was open (e.g., grassland or wooded savannah) or closed (e.g., forest) (van der Merwe and Medina 1989). Within closed environments, carbon isotope ratios can indicate if an animal was consuming foods close to the ground or up in the canopy due to the **canopy effect** (Cerling et al. 1999). Carbon isotope ratios have also been found to be correlated with temperature, and negatively correlated with relative humidity, rainfall, and elevation.

C_3 and C_4 Two groups of plants, C_3 plants and C_4 plants, show minimal overlap in $^{13}\text{C}/^{12}\text{C}$ ratios (commonly represented as $\delta^{13}\text{C}$ values parts per thousand, as in the ‰ notation). The C_3 plant group, which consists of trees, herbaceous plants, and cool-season grasses and constitutes the vast majority of plants, uses the C_3 photosynthetic system and has lower $\delta^{13}\text{C}$ values (global mean -27‰). The C_4 plant group, which includes warm-season grasses such as the vast majority of native grasslands in the Great Plains of the USA and many tropical grass species such as maize, uses the C_4 photosynthetic

system and has higher $\delta^{13}\text{C}$ values (global mean approximately -13‰). A third photosynthetic pathway, CAM, is used by **CAM plants**, which includes cacti and other succulents. Depending on environmental conditions, CAM plants exhibit $\delta^{13}\text{C}$ values ranging from those typical of C_3 to those typical of C_4 plants. Fauna eating either C_3 and C_4 plants or some mixture of the two record those diet sources in their tissues (DeNiro and Epstein 1978). Dietary isotope ratios are passed on to consumers with some **enrichment**. For example, carbon isotope ratios in herbivore keratin tend to be about 3–4‰ higher than those in their diets (see data in Kellner and Schoeninger 2007). **Marine** animals have $\delta^{13}\text{C}$ values in their flesh that are higher than most C_3 plants and they can overlap the values for C_4 plants (Schoeninger and DeNiro 1984). Therefore, in regions where modern humans eat maize *and* have access to marine foods, bone collagen $\delta^{13}\text{C}$ values are not useful in reconstructing the amount of marine food in diet (Schoeninger et al. 1990). *See also* $^{13}\text{C}/^{12}\text{C}$; **diet reconstruction**.

C_3 and C_4 proxies Several proxies from the geological record can be used to reconstruct the relative proportion of C_3 plants and C_4 plants in a region. These include the $^{13}\text{C}/^{12}\text{C}$ isotope ratio of soil carbonates, **flowstones**, plant leaf wax biomarkers, and indices of **phytolith** types.

C_3 foods These are either plants that use the C_3 photosynthetic pathway, such as trees, herbaceous plants, and cool-season grasses, or animals that browse or graze on C_3 plants. *See also* C_3 and C_4 ; C_3 plants.

C_3 plants Plants that use the C_3 photosynthetic pathway such as most trees, herbaceous plants, cool-season grasses, and the vast majority of other plants that have relatively low $\delta^{13}\text{C}$ values. *See also* C_3 and C_4 .

C₄ foods These are either plants that use the C₄ photosynthetic pathway such as many tropical grass species (e.g., maize), or animals that feed or graze on C₄ plants. *See also* C₃ and C₄; C₄ plants.

C₄ plants Plants that use the C₄ photosynthetic pathway such as warm-season grass species and many tropical grass species (e.g., maize) that have relatively high $\delta^{13}\text{C}$ values. *See also* C₃ and C₄.

C5 A term commonly employed for an accessory cusp on the crown of a maxillary molar. The term has also occasionally been used for the mandibular molars where it refers to the fifth main cusp (i.e., the **hypoconulid**); syn. **distal accessory tubercle** (*which see*).

C6 A term introduced by Hellman (1928) for an accessory cusp on the crown of a mandibular molar that others call a **tuberculum sextum** (*which see*); syn. **tuberculum sextum**.

C7 A term introduced by Hellman (1928) for an accessory cusp on the crown of a mandibular molar originally described as the **tuberculum intermedium** (*which see*).

Cabezo Gordo *See* Sima de las Palomas.

CAC Abbreviation of the **Central Awash Complex** (of sites), Western Margin, Middle Awash study area, Ethiopia.

caenotelic (Gk *kainos*=recent and *telikos*=end, so "towards a purpose") *See* **palimpsest evolution**.

calcarine sulcus (L. *calx*=heel or spur and *sulcus*=fissure) The calcarine sulcus is the most conspicuous sulcus on the medial aspect of the occipital lobe of the **cerebral hemisphere** in primates. The **primary visual cortex** lies largely within this sulcus. The representation of the central, high-acuity, part of the visual field is in the posterior portion of the calcarine sulcus and the representation of the peripheral visual field is located in the more anterior portion of the sulcus.

calcification The process of calcium deposition that occurs during the development of hard tissues such as teeth and bones. Typically during this process an organic framework is replaced by calcium (and other associated minerals); this

part of the process is referred to as **mineralization**. During **enamel development** the calcium pumped into a developing tooth is incorporated into the crystalline structure of the **enamel prisms** by displacing the enamel matrix proteins.

calcite *See* **calcium carbonate**.

calcium carbonate Calcium carbonate (CaCO₃) is a solid abundant natural mineral and is a component of many sedimentary rocks but is particularly abundant in chalk and limestones. Calcium carbonate has two polymorphs **aragonite** and its more stable form **calcite**. Water seeping through cave bedrock carries dissolved calcium carbonate. When this solution reaches an air-filled cave, the de-gassing of carbon dioxide alters the water's ability to hold minerals in solution, causing its solutes to precipitate and accumulate to form **speleothems**, of which **flowstone**, **stalactites**, and **stalagmites** are all examples. Stalactites are icicle-shaped mineral deposits which grown *down* from cave roofs, whereas stalagmites are conical mineral deposits fed from drip waters above that grow *up* from cave floors. Flowstones, which are formed by water flowing on the floor or walls of a cave, are generally horizontal, finely laminated layers of calcium carbonate that may found between breccia deposits in caves, and some of the fossil hominins in the southern African cave sites are preserved in flowstones (e.g., **Stw 573**). Stalagmites and flowstone can be dated with **uranium-series dating** and they are also important sources of paleoenvironmental information. The terms **travertine** and **tufa** are commonly used in older literature to describe finely crystalline, usually white, calcium carbonate formed by the precipitation of carbonate minerals from geothermally heated hot springs and from ambient-temperature water bodies such as lakes, springs, and rivers, respectively, but today speleothem or flowstone are the preferred terms.

calibrated-age methods *See* **biostratigraphy**; **geochronology**.

calibrated radiocarbon age *See* **radiocarbon dating**.

calibration (Gk *kalapous*=shoemaker's last) An adjustment made to a measurement by comparing it to a more reliable standard. For example,

this is the process used to correct radiocarbon dates to allow for the changes that have occurred over time to the levels of radiocarbon in the atmosphere. *See also* **radiocarbon dating**.

calotte (Fr. *calota*=skullcap worn by a Roman Catholic priest or by an observant member of the Jewish faith) So called because it is the part of the **cranium** covered by a skullcap. The unpaired bones making up the calotte are the frontal and the squamous part of the **occipital**; the paired bones are the parietals and the squamous parts of the temporal bones. The calotte is one of the three parts of the cranium; the others are the **face** and the **cranial base**.

calvaria (L. *calvus*=bald) Literally, the part of the **cranium** that is exposed when a person loses their hair (NB: it has to be long hair). It is the cranium minus the **face**. The word calvaria is Latin feminine singular; the proper plural is **calvariae**. Note that the singular term calvarium (plural calvaria) is incorrect, but this has not prevented its widespread use. *See also* **cranium**.

calvariae (L. *calvus*=bald) The Latin feminine plural version of calvaria. *See also* **calvaria**; **cranium**.

calvarium (L. *calvus*=bald) This term is a neologism and should not be used. The correct term is calvaria. *See also* **calvaria**; **cranium**.

CAM Acronym for the crassulacean acid metabolism photosynthetic pathway. *See also* **C₃** and **C₄**; **CAM plants**.

CAM plants Plants, such as cacti and other succulents, that use the crassulacean acid metabolism (or CAM) photosynthetic pathway. Depending on environmental conditions such as water availability, CAM plants exhibit $\delta^{13}\text{C}$ values ranging from those in **C₃** plants to those in **C₄** plants. Whereas CAM plants are a small fraction of global vegetation they may be locally important components of **flora** in some tropical seasonal forests and drylands, such as southern Africa. *See also* **C₃** and **C₄**.

camelid The informal name for the artiodactyl family, **Camelidae**, comprising the camels and their allies, whose members are found at some hominin sites. *See also* **Artiodactyla**.

Camelidae One of the artiodactyl families whose members are found at some hominin sites. *See also* **Artiodactyla**.

canalization (L. *canalis*=conduit, hence “to channel”) A term introduced by Conrad H. Waddington (1942) to describe the tendency for **development** to produce a similar **phenotype** despite different genetic and environmental influences. Waddington developed the concept of canalization to explain the results of his **genetic assimilation** experiment. In this experiment, Waddington exposed *Drosophila* to ether, which caused a proportion of individuals to develop the bithorax phenotype. For several generations, he selected for the bithorax phenotype in the presence of ether and eventually produced populations in which the bithorax phenotype appeared *even in the absence of the exposure to ether*. To explain this, he argued that selection for the bithorax phenotype had stabilized this state by acting on modifier **genes** to the extent that the phenotype appeared without the original stimulus; he referred to this process of stabilization as “canalization”. Gunter Wagner et al. (1997) have formalized the population genetic definition of canalization. They distinguish between environmental and genetic canalization. Environmental canalization is the reduction in the genotype-specific environmental variance, whereas genetic canalization is the reduction in the average effect of mutations, or genetic variants.

cancellous bone (L. *cancellus*=lattice; ME *bon*=bone) (syn. trabecular bone). *See* **bone**.

candelabra model The term candelabra was introduced by William White **Howells** in *Mankind in the Making* (1959). He used it to describe the polycentric theory of German physical anthropologist Franz **Weidenreich**, which he suggested was representative of what he referred to as the “**polyphyletic** or Candelabra School” of thought. In a diagram portraying Weidenreich’s theory, Howells indicated that modern Australasians, Mongoloids, Africans, and Eurasians had evolved from populations represented by *Pithecanthropus*, *Sinanthropus*, Rhodesian Man, and **Cro-Magnon** respectively. However, although Weidenreich (1946) had argued that a kind of racial continuity existed in geographically separated populations of hominins as they evolved over time into modern

humans, he also made it clear that his model assumed a certain degree of interbreeding had occurred between these populations and that this genetic exchange ensured that these geographical “races” belonged to one species. In this sense, then, Howells misrepresented Weidenreich’s views when he used a candelabra metaphor, although other polyphyletic theories of human evolution proposed in the late nineteenth and early twentieth centuries were strictly consistent with Howells’ metaphor. For example, the candelabra metaphor was entirely appropriate for the views of Carleton Coon. In his *The Origin of Races* (1962) Coon had assembled fossil, ethnographic, and linguistic evidence to support the view that the five major modern human races he identified (Caucasoid, Negroid, Capoid, Mongoloid, and Australoid) had existed for more than half a million years. Coon argued that modern human races had evolved separately from geographically separate subspecies of *Homo erectus*. Coon also believed that the races of modern humans had evolved at different rates, which explained why they had achieved such different levels of cultural development. For Coon, therefore, modern humans are a **polytypic** species consisting of separate geographical populations that differ from one another, and if the geographical barriers separating these populations are large enough and the populations remain isolated for long enough periods then they can actually become distinct species. Given the political and social conditions of the 1960s, Coon’s conception of modern human races generated considerable controversy and Coon himself complained that some of his ideas were misconstrued by others. Coon’s extreme manifestation of the candelabra model of human evolution garnered few supporters, but since the 1990s it has been more common for paleoanthropologists to use the candelabra analogy (even though it may be inappropriate) to describe Weidenreich’s polycentric theory and Milford Wolpoff and Alan Thorne’s **multiregional hypothesis** (Thorne and Wolpoff 1981, Wolpoff et al. 1984, Wolpoff 1989).

canid The informal name for the **Canidae** (dogs), one of the **caniform** families whose members are found at some hominin sites. *See also* **Carnivora**.

Canidae The family that includes wild dogs and their close relatives, and it is one of the **caniform** families whose members are found at some hominin sites. *See also* **Carnivora**.

caniform Informal term for taxa within the suborder **Caniformia**, one of the two suborders in the order **Carnivora**. *See also* **Carnivora**.

Caniformia One of the two suborders in the order **Carnivora**. Common caniform families at hominin sites include the **Ursidae** (bears), **Mustelidae** (weasels and otters), and the **Canidae** (dogs). *See also* **Carnivora**.

canine buttress (*L. canis*=dog) *See* **anterior buttress**.

canine dimorphism *See* **sexual dimorphism**.

canine eminence (*L. canis*=dog) Rounded area of bone that covers the anterior, or facial, aspect of the root of the canine; syn. canine jugum.

canine fossa Hollowed area posterior to the **canine eminence** that covers the anterior, or facial, aspect of the root of the upper canine tooth. Its superior and anterior boundary is the **transverse buttress** that runs inferiorly from the infra-orbital foramen to blend with the canine eminence.

canine jugum Rounded area of bone covering the anterior, or facial, aspect of the root of the canine; syn. canine eminence.

Cann, Rebecca L. (1951-) Rebecca Cann attended the University of California at Berkeley where she completed her PhD in anthropology in 1982. While at Berkeley Cann worked in the laboratory of Australian biochemist Allan Wilson. During the 1970s Wes Brown had conducted research on **mitochondrial DNA** (or mtDNA) taken from mothers of different ethnic groups and he had concluded that the surprisingly small amount of variation in their DNA, caused by the accumulation of mutations over time, indicated that modern human populations arose recently from a relatively small aboriginal population. Cann collaborated with Wilson and Mark Stoneking to collect mtDNA from 147 women from Europe, Asia, and the South Pacific, and because there were difficulties in obtaining samples from Africans, they obtained samples from African-American women instead. Cann and Stoneking used a computer program to analyze the variations in the mtDNA samples to construct a phylogenetic

tree by grouping together samples with the fewest differences. The resulting tree had two main branches, one containing only African-American populations and the other containing populations from every part of the world. Since the two branches diverged close to the base of the tree Cann and her colleagues concluded that all the mtDNA in living human populations descended from a woman who had lived in Africa and Cann, Stoneking, and Wilson estimated that all modern humans were descended from a woman who lived in Africa about 200 ka (Cann et al. 1987). This hypothetical female common ancestor was soon given the nickname “Mitochondrial Eve” and Cann and colleagues’ research generated considerable interest, but for methodological reasons it was also controversial. *See also* **mitochondrial DNA**.

canonical (L. *canon*=rule) In relation to **multivariate analysis** it refers to a standard or criterion. Canonical analysis is a form of multivariate analysis that captures the **variation** subsumed in a large number of variables and summarizes it in a smaller number of canonical axes. The axes are orientated at right angles to each other (this relationship is also called **orthogonal**), and the amount of variation represented in each axis can be inferred from the sum of the variable loadings on each axis. *See also* **canonical analysis**; **canonical axis**; **multivariate analysis**.

canonical analysis (L. *canon*=rule) A form of **multivariate analysis** also known as canonical variates analysis and canonical correlation analysis. Canonical analysis divides a data set into two groups of variables and finds a set of functions that maximizes the correlation between groups. For example, a variety of cranial and postcranial measurements may be collected for all specimens in a skeletal collection of modern humans. Canonical analysis can be used to find functions that generate new pairs of variables, or canonical variates, which maximize the correlation between cranial and postcranial variables. Similar to **principal components analysis**, the first pair of canonical variates account for the highest possible correlation between the two groups of variables, the second pair account for the highest possible correlation in the remaining variation in the two groups, and so on. The loadings of the original variables in the canonical variates can then be used to identify the relative contribution of

variables in the two groups to the overall correlation. For example, out of 10 cranial variables and 10 postcranial variables, eye orbit height and eye orbit width may contribute the most to the cranial canonical correlate, which is highly correlated with a postcranial canonical correlate mainly influenced by humeral head diameter, femoral head diameter, and tibial plateau width. In this way, canonical analysis can be thought of as a form of **multiple regression** in which there is more than one dependent variable.

canonical axis (L. *canon*=rule) Multivariate analysis summarizes the **variation** subsumed in a large number of variables in a smaller number of canonical axes that are orientated at right angles to each other. The amount of variation represented in each axis can be inferred from the sum of the loadings on each axis; the greater the loading associated with a variable, the greater the influence that variable has on a particular canonical axis. *See also* **canonical analysis**.

canonical correlation analysis *See* **canonical analysis**.

canonical variates analysis *See* **canonical analysis**.

canopy effect The canopy effect occurs when some of the CO₂ released during respiration by soil microbes is trapped beneath the forest canopy and is fixed by understorey plants (Medina and Minchin 1980, van der Merwe and Medina 1989). Because this CO₂ results from the breakdown of plant material, it has δ¹³C values that are similar to the C₃ plants from whence it came (e.g., approximately -27‰) rather than atmospheric CO₂ (approximately -8‰). This results in lower δ¹³C values in understorey leaves. Carbon isotope ratios in leaves and other vegetative plant parts tend to be more negative (¹³C-depleted) than those in reproductive parts such as fruits and flowers (Cernusak et al. 2009).

Carabelli('s) anomaly *See* **Carabelli('s) trait**.

Carabelli('s) complex *See* **Carabelli('s) trait**.

Carabelli('s) cusp *See* **Carabelli('s) trait**.

Carabelli('s) structure *See* **Carabelli('s) trait**.

Carabelli('s) trait The term refers to an enamel feature on the mesiolingual face of a maxillary molar tooth crown between the tip of the **protocone** and the **cemento-enamel junction**. It ranges in expression from a pit to a well-developed accessory cusp. Its name derives from Georg Carabelli (1842) who provided the first description of the character, although he actually used a different term (**tuberculum anomalus**) for it [syn. Carabelli('s) anomaly, Carabelli('s) complex, Carabelli('s) cusp, Carabelli('s) structure, Carabelli('s) tubercle, entostyle, tuberculum anomalus, protostyle, pericone].

Carabelli('s) tubercle *See* Carabelli('s) trait.

carbon An element commonly used for **absolute dating** and **stable isotope biogeochemistry**. There are three naturally occurring isotopes of carbon: ^{14}C , ^{13}C , and ^{12}C . ^{13}C and ^{12}C are stable and do not decay; they are used in stable isotope biogeochemistry. The carbon isotope ^{14}C is not stable and decays to ^{14}N at a regular rate with a **half-life** of 5730 years. *See also* $^{13}\text{C}/^{12}\text{C}$; **radiocarbon dating**; **stable isotope**.

carbon dating *See* radiocarbon dating.

carbon isotope analysis *See* isotope ratio mass spectrometry.

carcass acquisition strategy Refers to the method used to acquire animal remains (e.g., **hunting**, **confrontational scavenging**, **passive scavenging**). In hominin evolution, identifying carcass acquisition strategies helps characterize the ecological niche and behavioral capabilities of our hominin ancestors. Hunting refers to the active pursuit and capture of animal prey and is generally understood to be a basic constituent of modern human behavior. Confrontational scavenging, also known as “power” or “aggressive” scavenging, is defined as the capture of a nearly complete animal carcass from nonhominin predators that are actively consuming it. Modern hunter-gatherers, such as the **Hadza** of northern Tanzania, have been observed to occasionally obtain meat through confrontational scavenging. Passive scavenging includes the culling of small amounts of meat or marrow from heavily ravaged animal carcasses abandoned by their initial predators. Ethnographic studies document opportunistic passive scavenging by some hunter-gather groups (e.g., the

Hadza), but no modern human populations have a carcass acquisition strategy characterized by obligate passive scavenging of terrestrial mammals. The emergence of hunting in the hominin behavioral record is a particularly controversial issue (i.e., the hunting-scavenging debate), much of which has focused on the **FLK** site in **Olduvai Gorge**. The timing of the appearance of hunting as a carcass acquisition strategy is particularly important because hunting falls within the realm of modern human behavior and implies the presence of relatively complex social interactions and cooperation within hominin groups.

carcass transport strategy A term that refers to decisions made by foragers when transporting animal remains from the point of carcass acquisition (e.g., the kill site) to the point of consumption. Ethnographic observations of **hunter-gatherers** in sub-Saharan Africa (e.g., the **Hadza**, the Kua [San], the !Kung), the Arctic (e.g., the Nunamut), and elsewhere indicate that carcass transport strategies are influenced by constraints including the number and size of carcasses to be transported, transport distance, transport mode, the number of carriers, and even the time of day and season of prey acquisition. Decisions are presumably mediated by recognition of the nutritional/energetic value associated with different skeletal parts. In archeology, carcass transport strategies are often evaluated by examining the relationship between estimates of **skeletal part frequency** in a fossil assemblage and their corresponding energetic return, often calculated using an **economic utility index**. For example, at **Olduvai Gorge**, studies of skeletal part frequencies and the carcass transports strategies inferred from them have been used to evaluate the timing of hominin access to prey (i.e., primary or secondary access) and to determine whether individual fossil assemblages represent kill sites or consumption sites. Carcass transport strategy also refers to the method used to acquire animal remains, such as **hunting**, **confrontational scavenging**, or **passive scavenging**. In hominin evolution, identifying carcass acquisition strategies helps characterize the ecological **niche** and behavioral capabilities of our hominin ancestors. Ethnographic studies document opportunistic passive scavenging by some hunter-gatherer groups (e.g., the Hadza), but no modern human populations have a carcass acquisition strategy characterized by obligate passive scavenging of terrestrial mammals. The emergence of hunting in

the hominin behavioral record is a particularly controversial issue (i.e., the hunting-scavenging debate), much of which has focused on the **FLK-Zinjanthropus** site in Olduvai Gorge. The timing of the appearance of hunting as a carcass acquisition strategy is particularly important because hunting falls within the realm of modern human behavior and implies the presence of relatively complex social interactions and cooperation within hominin groups.

cardioid foramen magnum (Gk *kardia*=heart) This is the expression used by Tobias (1967) to describe the shape of the foramen magnum of **OH 5**. He described the anteriorly truncated foramen magnum as “more or less heart-shaped, with a blunt point posteriorly” (*ibid.*, p. 59). *See also foramen magnum.*

Carnegie Institution for Science *See Carnegie Institution of Washington.*

Carnegie Institution of Washington

Founded by Andrew Carnegie in 1902 as an organization for scientific discovery, the Carnegie Institution of Washington is an endowed, independent, nonprofit institution. Its headquarters is in Washington DC, but the scientific staff work in five scientific departments (plant biology, developmental biology, Earth and planetary sciences, astronomy, and global ecology) on the west and east coasts of the USA. Although it remains officially and legally the Carnegie Institution of Washington, in 2007 it adopted a new name, the Carnegie Institution for Science. The Carnegie Institution of Washington provided crucial support for Ralph von Koenigswald’s work in Java. In 1930 von Koenigswald had been employed by the Geological Survey of Java as a mammalian paleontologist and despite his success at identifying actual and potential fossil sites the project was abandoned, and his salary and support from the Survey ceased, in December 1934. However, soon after Teilhard de Chardin visited Java on his way to China, and it was he who brought von Koenigswald’s predicament to the attention of John Merriam, a well-known paleontologist and President of the Carnegie Institution of Washington at the time. Merriam arranged for some temporary support for von Koenigswald and he invited him to a meeting about fossil man held in Philadelphia early in 1937. Shortly thereafter, von Koenigswald was appointed a Research Associate of the Carnegie Institution of Washington, and according to von

Koenigswald at Merriam’s instigation “a considerable sum was placed at my disposal to pursue the search for fossil man in Java” (von Koenigswald 1956, p. 93).

Carnivora (L. *carn*=flesh and *vora*, from stem of *vorare*=to devour) The order of mammals so named because its members principally consume meat. The proper informal term for members of this order is **carnivoran**, but the term usually used is **carnivore**. The carnivoran order is **speciose** and widely distributed. There are two suborders of Carnivora: the **Feliformia** (cat-like) and the **Caniformia** (dog-like) carnivorans. Common feliform families at hominin sites are the **Felidae** (cats), **Hyenidae** (hyenas), **Viverridae** (civets and their relatives), and **Herpestidae** (mongooses and relatives). Families within the Caniformia include **Ursidae** (bears), **Mustelidae** (weasels and otters), and the **Canidae** (dogs). The aquatic carnivorans of the superfamily Pinnipedia are also subsumed within the Caniformia. Carnivorans first appear in the fossil record in the Paleocene epoch.

carnivoran (L. *carn*=flesh and *vora*, from stem of *vorare*=to devour) The proper informal term for members of the order Carnivora, but the term usually used in its place is **carnivore**. *See also Carnivora* (syn. carnivore).

carnivore (L. *carn*=flesh and *vora*, from stem of *vorare*=to devour) The proper informal term for members of the order Carnivora is **carnivoran**, but the term usually used in its place is **carnivore**. *See also Carnivora* (syn. carnivoran).

carnivore guild A carnivore **guild** is a group of mammalian carnivores that garner faunal resources using similar predation strategies and dental adaptations. For example, at the **Miocene** hominoid site of Pasalar, in Turkey, four carnivore guilds have been identified on the basis of dental morphology: hypercarnivores, including bone crushers, main-carnivores (that may also have included some bone crushers), omnivores, and invertebratevores (including insectivores) (Viranta and Andrews 1995). More carnivore guilds, such as those comprising sabre- and dirk-toothed cats, existed in the past. It has been suggested, both on the basis of archeological data and also on the rather unusual evidence of **tapeworms** evolution,

that hominins may have entered a carnivore guild during the **Plio-Pleistocene** (Hoberg et al. 2001).

carnivore modification *See* carnivore ravaging.

carnivore ravaging Also known as carnivore modification, this is the spatial disturbance and modification, or destruction, of skeletal remains by **carnivores**. Archeological bone assemblages, particularly those from open-air sites, frequently show tooth marks or other signs of alteration by carnivores. Because carnivore ravaging can alter the post-depositional integrity of a bone assemblage, it is important that it be identified and corrected for when making informed decisions on hominin behavior or past environments. **Actualistic studies** indicate that carnivores, especially **hyenas** and **canids**, readily destroy grease-rich, low-density skeletal elements, such as long-bone epiphyses, ribs, pelvis, and vertebrae. When examining **carcass transport strategies**, the observation that carnivore ravaging can alter skeletal part frequencies, and even mimic the **schlepp effect**, should be taken into account. Evidence of carnivore ravaging can be unambiguously detected through the identification of carnivore tooth marks on bone. *See also* **skeletal element survivorship**.

carnivory (L. *carn-*=flesh plus *vorous*, from the stem of *vorare*=to devour) The consumption of flesh, or other animal tissues. Although members of the order **Carnivora** are popularly viewed as being exclusively meat eaters (i.e., **carnivores**), many of them eat plant food as well, and some (e.g., the grey wolf) are most accurately described as **eclectic feeders**. Many primates are known to engage in at least occasional meat-eating, and many more are carnivorous in the wider sense of including some animal tissues (from throughout the animal kingdom) in their diets, either regularly or opportunistically. In paleoanthropology, the examination of carnivory as a hominin subsistence strategy is a primary research question. Chimpanzees, our closest living relatives, are known to hunt and consume small mammals, so this capability might also have been present in early hominins. With the advent of stone tool manufacture (*c.*2.6 Ma) hominin-faunal interactions can be demonstrated through **cutmarks** and the breakage patterns of fossil bones. Exactly when, and in what context, hominins began to consume more meat than contem-

porary chimpanzees remains a topic of lively debate in paleoanthropology. *See also* **Dikika**; **expensive tissue hypothesis**.

carrying capacity The fixed population size above which a population will decrease in size and below which it will increase in size. The carrying capacity represents a stable equilibrium population size in the **logistic population growth model**.

Cartesian coordinates A system invented in the 17thC by René Descartes that specifies a point uniquely in a plane by a pair of numbers, or **coordinates**, which are the distances from the point to two fixed perpendicular lines, measured in the same units. The same principle can be used to specify the position of any point in three-dimensional space by three Cartesian coordinates, its signed distances (i.e., using positive and negative numbers) to three mutually perpendicular planes (or, equivalently, by its perpendicular projection onto three mutually perpendicular lines). In general, one can specify a point in a space of any dimension *n* by use of *n* Cartesian coordinates. Geometric shapes can be described by Cartesian equations that involve the coordinates of the points lying on the shape. *See also* **coordinate data**; **geometric morphometrics**.

cartilage (L. *cartilago*=gristle) Cartilage is one of the two connective tissues (**bone** is the other) that form the skeleton. All connective tissues are made up of a combination of cells and microscopic organic fibers, both of which are embedded in a cellular matrix. There are three types of cartilage: hyaline, fibro-, and elastic cartilage. Chondrocytes, the cells that form the matrix, are the predominant cell type in hyaline and elastic cartilage; fibroblasts are also found in all three types, but they are especially common in fibrocartilage. Collagen fibers (produced by fibroblasts) are found in all three types of cartilage, but only elastic cartilage contains yellow elastic fibers in any significant numbers. The first manifestation of the skeleton during ontogeny is made of hyaline cartilage and the bones that form the bulk of the adult skeleton develop within that cartilaginous template by a process called endochondral **ossification**. In adults, hyaline cartilage covers the surfaces of synovial **joints** and the tips of the ribs. It is also the basis of structures such as the xiphoid and most of the cartilages of the larynx. The matrix, also known as ground substance, consists of mainly water, together with dissolved salts,

proteins, and glycoproteins, all held in a network of molecules called proteoglycans. Hyaline cartilage is particularly stiff, but it is also elastic and its elasticity helps it to dissipate stress.

CAS Acronym for the **Chinese Academy of Sciences** (*which see*).

Casablanca *See* Sidi Abderrahman; Thomas Quarry.

Casal de'Pazzi (Location 41°56'N, 12°44'E, Italy; etym. It., named after the neighborhood in Rome in which it is located; *Casal*=variant of farmhouse or castle; *Pazzi*=the name of a family which developed the land) History and general description This is an open-air site on the middle terrace of the Aniene river in the suburbs of Rome. The sedimentation of the lower Aniene valley has produced a number of other Pleistocene sites in fluvial deposits, such as **Sedia del Diavolo** and **Saccopastore**. The site was discovered in 1981 during surveys commissioned by the Soprintendenza Archeologica di Roma. The hominin parietal fragment was discovered in 1983. Temporal span and how dated? Amino acid racemization dating on *Bos* teeth suggests an age of *c.*360 ka. Hominins found at site The right parietal fragment, known as Casal de'Pazzi 1, displays affinities of both *Homo sapiens* and *Homo erectus*. Manzi et al. (1990) conclude that the chronology and morphology of the specimen indicate it being part of an archaic variant of *Homo*, "tend[ing] increasingly towards the Neanderthal form." Archeological evidence found at site A stone tool technology similar to the early -Mousterian, called the "proto-Pontinian," has been recovered from the site. Key references: Geology, dating, and paleoenvironment Bietti 1985, Belluomini et al. 1986; Hominins Passarello et al. 1989, Manzi et al. 1990; Archeology Bietti 1985.

Castel di Guido (Location 41°53'59"N, 12°16'33"E, Italy; etym. It., named after the neighborhood in Rome in which it is located; *castel*=variant of home or castle; *Guido*=the name of the duke of Spoleto who defeated the Saracens in a battle in this area) History and general description This open-air site on a low hill along the Aurelian Way in the outskirts of Rome was discovered in 1976 and systematically excavated from 1980 to

1990 by A.M. Radmilli from the University of Pisa. The top agricultural level of humus and silt lies above a layer of lacustrine tuffaceous sands, which itself overlays a rich paleosurface that may have been a butchering site. Temporal span and how dated? Technostratigraphic and Biostratigraphic comparisons with other Italian sites suggests that the site was deposited during Oxygen Isotope Stage 9. Hominins found at site Seven fragmentary hominin bones have been recovered, both from the surface (CdG-1-4) and from the tuffaceous sands (CdG-5-7). The remains appear to show a mixture of *Homo erectus* and *Homo neanderthalensis* features, and have been interpreted as being "intermediate" between the two. Archeological evidence found at site More than 5800 stone and bone artifacts were found. The assemblage is characteristic of the Italian **Acheulean**. Bifaces and choppers have been recovered, along with a microlithic pebble and flake industry. Many of the bone implements were made from fragments of elephant bone. Key references: Geology, dating, and paleoenvironment Mariani-Constantini et al. 2001; Hominins Mallegni et al. 1983, Mallegni and Radmilli 1988, Mariani-Constantini et al. 2001; Archeology Radmilli and Boschian 1996.

CAT Acronym for both computer-assisted tomography and computerized axial tomography. *See* **computed tomography**.

Catalogue of Fossil Hominids Quenstedt and Quenstedt (1936) was probably the first attempt at a comprehensive list and bibliography of the hominin fossil record. Vallois and Movius' *Catalogue des Hommes Fossiles* (Vallois and Movius 1953) was the next attempt to survey the hominin fossil record, but the first comprehensive attempt to collate information about both the hominin fossil record *and* its context came in the late 1960s with the publication of the first volume (Part I) of the British Museum (Natural History) *Catalogue of Fossil Hominids*. The first volume, *Part I: Africa*, edited by Kenneth Oakley and Bernard Campbell, was published in 1967. Subsequent volumes covered fossil hominin discoveries from Europe (Oakley et al. 1971), and Asia (Oakley et al. 1975), but only Part I ran to a second updated edition (Oakley et al. 1977). Unfortunately (but understandably given the work involved to assemble a resource such as this in a non-electronic format and on a rapidly enlarging hominin fossil

record) the series was discontinued and it has long been out of print. In the *Catalogue of Fossil Hominids* the fossil evidence for human evolution was organized by country and then by site. Within the entry for each site the fossils are grouped according to their preserved morphology (crania, mandibles, teeth, postcranial bones) and references were provided for publications relating to the morphology, taxonomy, and dating of the regional morphological groups of specimens. A more recent attempt to take up the challenge of providing a comprehensive catalogue of the fossil evidence for hominin evolution has been the initiative by Orban and her colleagues, entitled *Hominid Remains – an up-date*. This is distributed as part of a general series of publications called the *Supplements au Bulletin de la Societe Royale Belge d'Anthropologie et de Prehistoire*. The first volume in this series of separates was published in the beginning of 1988, and publication has continued thereafter. The early issues were organized by an Editor (Orban) and Associate Editors (e.g., Slachmuylder, Semal, and Alewaeters). The individual entries are put together by experts who are familiar with one, or more, temporal phases of the hominin fossil record from that country, or countries. Each slim volume covers one, or more, countries. The *Hominid Remains – an up-date* series is in effect an updated version of the *Catalogue of Fossil Hominids*, and it retains the latter's format. In 2005, and published as a supplement to the *Journal of Anthropological Sciences*, Alciati et al. (2005a, 2005b) published a two-part inventory of fossil hominins from Italian sites. Note that the *Catalogue of Fossil Hominids* was current at a time when the term hominid was routinely used for the what many now refer to as the hominin clade.

catch-up growth In cases where an infant is born prematurely or a child experiences prolonged nutritional deficiency, disease, or severe psychological stress, normal growth patterns may be disrupted and growth in various dimensions affected. Once the source inhibiting growth is removed (or after birth, in premature infants) catch-up growth facilitated by a marked increase in growth velocity can serve to return the child to age-appropriate size. Catch-up growth may occur through rapid gains in height, weight, and head circumference. Depending on when catch-up growth occurs there may or may not be permanent deficits in the growth of certain tissues, especially the brain. Whereas indi-

viduals who do not experience catch-up growth in many cases end up as smaller adults and may show compromised cognitive development, individuals who do go through catch-up growth can incur a greater risk of obesity and related metabolic problems later in life.

catfish Catfish bones, in particular those of *Clarias*, a large, air-breathing catfish, are often associated with early and late **Pleistocene** hominin sites, especially in Africa. While many fish bones are naturally washed into sites, *Clarias* bones with cut and/or tooth marks have been recovered from early hominin sites at **Koobi Fora** (Pobiner 2007, Braun et al. 2010) and **Olduvai Gorge** (Stewart 1994, in press). The importance of *Clarias* as a food source continues into the late Pleistocene, with the occurrence of dozens of archeological sites along the Nile and other rivers that contain hundreds of thousands of *Clarias* bones (Van Neer 1986). These were apparently procured seasonally during annual spawning runs. Similarly, *Clarias* is known historically as a valued food in Egypt and elsewhere and today sustains many groups as a staple in the dry season. *Clarias* is readily caught with bare hands or with spears in shallow waters in the food-scarce dry season and is even more accessible and predictable in the rainy season, when groups spawn in shallow floodplains. Further, *Clarias* is adapted to low water and drought conditions, in that it burrows into mud (hence the informal name “mudfish”), often for long periods, until water returns. There are anecdotal reports of bonobos digging in mud for fish, probably for *Clarias*. Many other predators, including hyenas, baboons, and large cats, hunt *Clarias* seasonally. A major attraction of *Clarias* is its nutritional value: it is an excellent source of high-quality fats, and this source is critically important in the dry season when other animals are fat-depleted and vegetation is scarce.

caudal (L. *cauda*=tail) The anatomical term used to refer to structures in the axial skeleton that are “towards the tail”: in upright hominins this means it refers to structures that are inferior. Thus, the axis vertebra (or C2) is caudal to the atlas vertebra (or C1), and the first lumbar (or L1) vertebra is caudal to the twelfth thoracic (or T12) vertebra. The opposite of caudal is **cranial**.

Caune de l'Arago (Location 42°50'22"N, 2°45'18"E, France; etym. *caune*=local dialect for cave and *Arago*=name of the valley over which

the cave is located) History and general description This cave site is located at the eastern end of the Pyrenees overlooking the Tautavel plain (which has led to the fossils being called “l’Homme de Tautavel” or “Tautavel Man”). The cave has been excavated since 1964 under the direction of Henry de Lumley. It is large and deep and consists of three main stratigraphic complexes. Temporal span and how dated? Several dating methods, including biostratigraphy, uranium-series dating, thermoluminescence dating, electron spin resonance spectroscopy dating, fission track dating, and amino acid racemization dating have been attempted, but the results are not consistent. However, recent uranium-series dates on a stalagmitic floor that immediately overlies that hominin-bearing levels have provided a date of more than 350 ka for the hominin layers, which is consistent with the uranium-series date on the Arago XXI face of *c.*400 ka. Hominins found at site More than 100 human remains belonging to 26 individuals have been found in layer G of the Middle Stratigraphic Complex. Many of the fossils (about 50%) belong to adolescents. These individuals have several traits that align them with *Homo neanderthalensis*, but their generally primitive features and their apparent age have led to their being considered pre-Neanderthals or assigned to *Homo heidelbergensis*. The most important among these fossils are the Arago XXI face, the Arago II mandible, and the Arago XLVII parietal. Archeological evidence found at site Several tens of thousands of stone flakes and retouched tools were recovered, mostly from the Middle Stratigraphic Complex, made on a variety of raw material including quartz, quartzite, flint, and hornfels. Many faunal remains were also recovered. Key references: Geology, dating, and paleoenvironment Falguères et al. 2004, Yokoyama and Nguyen 1981; Hominins de Lumley and de Lumley 1973, de Lumley 1982; Archeology Byrne 2004.

Cave of Hearths (Location 24°08'25"S, 29°12'00"E, South Africa; etym. named after the numerous hearths and presumed hearths throughout the stratigraphic sequence) History and general description The Cave of Hearths, formed in limestone deposits in the Makapansgat Valley, was first investigated by C. van Riet Lowe in 1937. In 1947 G. Gardiner and J. Kitching collected fauna (including hominin remains) that had fallen into a sinkhole, and large-scale excavations direc-

ted by Revil Mason were conducted in 1953–4. Mason removed more than 1800 tons of calcite-hardened breccia and calcite blocks, and exposed a 7 m-thick sequence with archeological evidence that spanned the period between the **Early Stone Age** and the **Iron Age**. Temporal span and how dated? No radiometric dates are available for the Cave of Hearths, but the Acheulean-like artifacts are >780 ka and may be >500 ka reported fauna and the artifact typology are consistent with a **Middle Pleistocene to Holocene** age estimate. Hominins found at site An *in situ* juvenile hominin mandible, Cave of Hearths 1, which has a thick corpus, large teeth, and congenital absence of the M₃ and was originally attributed to *Homo sapiens rhodesiensis*, was recovered from **Acheulean** Bed 3. A proximal radius showing a mosaic of primitive and modern human features was recovered from a swallow hole and hence has poor provenance; it is assumed to be **Middle Stone Age** or **Early Stone Age** in age. Archeological evidence found at site The archeological sequence is divided into 11 beds numbered from bottom to top: beds 1–3 contain **Acheulean**-like artifacts with variably shaped **handaxes** and **cleavers**, and beds 4–9 contain **Middle Stone Age** artifacts that become smaller as one goes up the section. They include **flake-blades**, **Levallois** and other **cores**, rare **points**, and **ochre**. Beds 10 and 11 are **Later Stone Age** and **Iron Age**, respectively. It has been suggested that some of the “hearths” in the lower strata may be deposits of bat guano that were ignited by lightning strike. Key references: Geology and dating Latham and Herries 2004, Mason 1988, Herries and Latham 2009; Hominins Tobias 1971, Pearson and Grine 1997, Curnoe 2009; Archeology Mason 1962, 1988, McNabb et al. 2004, McNabb and Sinclair 2009.

Cave of Scladina *See* Scladina.

Caverna delle Fate (Location 44°11'45"N, 8°22'03"E, Italy; etym. It. Cave of the Fairies) History and general description This cave is located about 5 km/3 miles northeast of Finale in Liguria and was originally excavated by Gian Battista Amerano in the late 19thC. The rediscovery of three hominin bone fragments among the faunal assemblage in the early 1980s revived interest in the site and new excavations were carried out between 1984 and 1988. This work led to the recovery of more hominin remains, but they were recovered from the

spoil heaps of the old excavations so their stratigraphic position cannot be established. Temporal span and how dated? Gamma-ray spectrometry dating of the remains and electron spin resonance spectroscopy dating on the stalagmitic floor of the cave suggest an age of between 60–80 ka. Hominins found at site The three “original” remains found by Giacobini include a fragmentary immature frontal (Fate I), a nearly complete immature mandible (Fate II) and a fragmentary adult mandible (Fate III). Archeological evidence found at site A **Mousterian** industry was recovered, along with faunal remains, including a large number of cave bear bones. Key references: Geology, dating, and paleoenvironment Falguères et al. 1990; Hominins Giacobini et al. 1984; Archeology Amerano 1889.

Caviglione *See* Barma del Caviglione.

CB Abbreviation for Central Basin, the term used for the persistent, central, part of the paleo-Lake Olduvai. *See also* **Olduvai Gorge**.

CBA Abbreviation for cranial base angle. *See* **basicranium**; **cranial base angle**.

cdNA *See* complementary DNA.

CEJ Acronym for **cemento-enamel junction** (*which see*).

cemento-enamel junction The junction between the inferior (lower teeth) or superior (upper teeth) limit of the enamel cap of the crown of a tooth and the **cementum**, the tissue that covers the external surface of its **root** (syn. cervix).

cementum [L. *caementum*=rough (pre-dressed) stone] One of the three hard tissues (along with **enamel** and **dentine**) that make up a tooth. There are two kinds of cementum: acellular and cellular. The initial cementum that forms against the root dentine is acellular but cementocytes get trapped in the later-forming dentine as it grows in an appositional fashion. Cementum contains fibers that run from the periodontal ligament into the tooth root. Cementum deposition at the apex of a tooth root is a response to axial tooth movement and new cementum forms over resorbed root surfaces (Nanci 2003). Cementum is believed to show an annual incremental feature known as cementum annulations (Kay et al. 1984) and at certain latitudes its microstructure may

respond to seasonal environmental changes. These responses have been used by zooarcheologists to infer the season at death of fauna found at hominin fossil sites (Lieberman 1994).

Cenozoic (Gk *kainos*=new and *zoe*=life) The term for the youngest (and current) **era** of the Phanerozoic eon. Cenozoic refers to a unit of geological time (i.e., a **geochronologic unit**) that spans the interval from 65.5 Ma to the present. The onset of the Cenozoic is marked by the **Cretaceous–Paleogene** event that saw the mass extinction of numerous faunas, including the non-avian dinosaurs. Compared to the previous Mesozoic era, the Cenozoic is noted for a worldwide decline in temperatures. Although mammals were numerous and diverse throughout the previous era, the extinction of the dinosaurs allowed them to flourish and become the dominant large fauna of the Cenozoic. Historically the Cenozoic was subdivided into the **Tertiary** and **Quaternary** periods, but today most geologists opt to subdivide the former Tertiary into two separate periods, the Paleogene and **Neogene**. The International Union of Geological Sciences recently ratified the Quaternary as the third period in the Cenozoic, although opinion is divided on this issue. *See also* **Plio-Pleistocene boundary**.

Cenozoic Research Laboratory The Cenozoic Research Laboratory (or CRL) was established in 1929 to facilitate the collection and study of geological and paleontological material relevant to the problem of human origins in China. In 1926 the Canadian anatomist Davidson **Black** approached Weng Wenhao, the director of the **National Geological Survey of China**, about a collaborative research program to study the **Cenozoic** deposits outside of Beijing, and the value of a formal institution became apparent when excavations at Choukoutien (now **Zhoukoudian**) led to the discovery in 1927 of a tooth that Black claimed belonged to a hitherto unknown species of hominin he named *Sinanthropus pekinensis* (now *Homo erectus*). The Cenozoic Research Laboratory was established as a department within the Geological Survey of China, but it was also associated with the newly established **Peking Union Medical College** where Davidson Black was the Professor of Anatomy. The new laboratory received its funding from the **Rockefeller Foundation**, which also funded the excavations at Zhoukoudian, but the laboratory was a Chinese institution run by the director of the Geological

Survey of China. Reports of any geological and paleontological discoveries made under the auspices of the Cenozoic Research Laboratory were to be published in the journal of the Geological Survey of China, *Paleontologia Sinica*. Chinese scientists who became prominent members of the Cenozoic Research Laboratory's staff over the years included the paleontologist Yang Zhongjian, geologist Pei Wenzhong, and paleontologist Jia Lanpo. During the 1930s Black and his colleagues discovered a substantial quantity of *Sinanthropus* fossils as well as faunal remains and stone tools that were curated by the Cenozoic Research Laboratory. After Davidson Black's premature death in 1934 the German anatomist Franz Weidenreich was invited to replace him and Weidenreich and his Chinese colleagues continued excavations at Zhoukoudian until 1937 when the Japanese invasion of China made further excavation impossible. Weidenreich remained in China until 1941, but it became unsafe for him to remain so Weng Wenhao, Weidenreich, and Pei Wenzhong decided that photographs and plaster casts of all the "Peking Man" remains should be made and the fossils themselves were prepared to be taken out of the country, since it was feared that the Japanese would remove the fossils to Japan. Weidenreich left China with the photographs of the fossils, but the original fossils were entrusted to a group of US Marines who were also evacuating China, but the fossils were lost and their fate is still a mystery. Pei Wenzhong became the director of the Cenozoic Research Laboratory after Weidenreich's departure and he spent the war years at the laboratory. After the creation of the People's Republic of China in 1949 the Cenozoic Research Laboratory was reorganized and renamed the **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP) in 1953 and became part of the **Chinese Academy of Sciences**: the IVPP has conducted archeological and paleoanthropological excavations throughout China.

census size *See* population size.

center of mass The experimentally determined, or estimated, location within an object of the center of its mass. This term is usually used in the sense of the center of mass of the whole body, but it can refer to the center of mass of a segment of part of the body, or a segment of a limb.

centimorgan *See* linkage.

Central Awash Complex (or CAC)

One of the major fossiliferous subregions within the **Middle Awash study area**; the others include the **Western Margin**, **Bouri Peninsula**, and **Bodo-Maka**. The Central Awash Complex is a dome-like structure that lies on the west side of the **Awash River** and it extends to within 25 km/15.5 miles of the western escarpment of this section of the **Afar Rift System**. It rises approximately 200 m above the surrounding rift floor and it is dissected by the **Amba**, **Urugus**, **Sagantole**, and **Aramis** drainages. Collecting areas within the CAC that have yielded hominins include **Amba East**, **Aramis**, and **Asa Issie**.

central facial hollow A term used by Phillip Tobias (1967, p. 209) to refer to the depressed central part of the face, relative to the forwardly positioned zygomatic bones, of **OH 5**. Similar-shaped faces are seen in other specimens of *Paranthropus boisei*, and to a lesser extent in the faces of *Paranthropus robustus* crania (syn. *dished face*).

central fissure The term used by Weidenreich (1937) for a tooth crown feature that others call the **central fovea (maxillary)**. *See also* **central fovea (maxillary)**.

central fossa (mandibular) The term used by Robinson (1956) for a tooth crown feature that others call the **central fovea (mandibular)** (*which see*).

central fossa (maxillary) The term used by Robinson (1956) and Korenhof (1960) for a tooth crown feature that others call the **central fovea (maxillary)** (*which see*).

central fovea (mandibular) A depressed triangular area on the occlusal surface of the crown of a mandibular molar that is bounded by the **protoconid**, **metaconid**, **hypoconid**, **entoconid**, and **hypoconulid** (syn. **central fossa**, **central pit**, **fovea centralis**, **postfossid**, **taloid basin**).

central fovea (maxillary) The term used by Tobias (1967a) and White (1977) for the depressed triangular area on the occlusal surface of the crown of a maxillary molar that is bounded by the **paracone**, **metacone**, and **paracone** (syn. **central fissure**, **central fossa**, **central pit**, **fovea centralis**, **profossa**, **protocone basin**, **trigon basin**).

central nervous system *See* brain.

central pit (mandibular) *See* central fovea (mandibular).

central pit (maxillary) The term used by Kraus et al. (1969) for a feature on the crown of a maxillary molar that others call the central fovea (maxillary). *See also* central fovea (maxillary).

central place foraging *See* home base hypothesis.

central sulcus (L. *sulcus*=furrow or groove) A prominent morphological landmark located on the lateral surface of the cerebral hemispheres of most anthropoid primates. Originally called the Rolandic fissure after Luigi Rolando, the central sulcus defines the border between the parietal lobe and frontal lobe. The primary motor cortex is located along the anterior wall of the central sulcus and the primary somatosensory cortex is situated along the posterior wall of the sulcus.

Centre for Prehistory and Palaeontology
See National Museums of Kenya.

centric fusion *See* Robertsonian translocation.

centroid The average of a multivariate data set, usually calculated as either the mean or median of all variables in the data set.

centromere *See* chromosome.

Ceprano (Location 41°31'42"N, 13°54'16"E; Italy; etym. named after the nearest town) History and general description The region in which Ceprano is located for some time has been recognized as an area of geological and archeological interest, but in March 1994 a hominin calvaria was recovered during road construction. The discovery of the calvaria was brought to the attention of the archeologist, I. Biddittu. It was recovered by a team of the Istituto Italiano di Paleontologia Umana directed by A.G. Segre. New excavations in the area of Campogrande started in 2001 under the direction of I. Biddittu e G. Manzi, which drove to a reconsideration of both the paleo-environmental history and chronological succession at Campogrande. Temporal span and how dated?

Tephrostratigraphy and biostratigraphy suggest an age of *c.*400 ka (i.e., Oxygen Isotope Stage 11). Hominins found at site Ceprano 1, a well-preserved (i.e., undistorted) calvaria. Archeological evidence found at site No artifacts are directly associated with the hominin, but **choppers** and **flakes** have been recovered from an underlying layer and **Acheulean** artifacts have been found in overlying deposits. Key references: Geology and dating Ascenzi *et al.* 1996, 2000, Muttoni *et al.* 2009, Basilone and Civetta 1975, Manzi *et al.* 2010; Hominins Ascenzi *et al.* 1996, 2000, Clarke 2000, Ascenzi *et al.* 1996, 2000, Manzi *et al.* 2001, Mallegni *et al.* 2003, Bruner and Manzi 2005, 2007, Muttoni *et al.* 2009. Archeology Ascenzi *et al.* 1996, Manzi *et al.* 2010.

Ceprano 1 Site Ceprano. Locality Campogrande. Surface/in situ *In situ*. Date of discovery March 13, 1994. Finders Construction workers and I. Biddittu. Unit Fourth Ensemble, upper part of Unit D. Horizon Muddy/sandy lake margin deposit. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Local leucitic tephra layer. Nearest underlying dated horizon N/A. Geological age *c.*400 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description A well-preserved (i.e., undistorted) calvaria that lacks much of the left parietal and most of the base. Announcement Ascenzi *et al.* 1996. Initial description Ascenzi *et al.* 1996. Photographs/line drawings and metrical data Ascenzi *et al.* 1996, Manzi *et al.* 2001, Bruner and Manzi 2005, 2007. Detailed anatomical description Ascenzi *et al.* 1996, Manzi *et al.* 1996, Manzi *et al.* 2001, Mallegni *et al.* 2003, Bruner and Manzi 2005, 2007. Initial taxonomic allocation "Late" *Homo erectus*. Taxonomic revisions *Homo cf. antecessor* (Manzi *et al.* 2001), *Homo cepranensis* (Mallegni *et al.* 2003) or *Homo heidelbergensis* (Bruner and Manzi 2005, 2007). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance Some suggest the morphological affinities of Ceprano 1, especially after the reconstruction by Clarke (2000), are with *H. erectus*, but other researchers have suggested it should be assigned to *Homo heidelbergensis*, *Homo mauritanicus*, *Homo antecessor*, or to a novel taxon, *Homo cepranensis*. Bruner and Manzi (2005) suggest Ceprano 1 "represents the best available candidate for the ancestral phenotype of the cranial variation observed among Middle Pleistocene fossil samples in Africa and Europe" (*ibid*, p. 643).

Location of original Soprintendenza Archeologica del Lazio, Rome, Italy.

cercopithecoid An informal term for the Cercopithecidae, one of the two families within the superfamily Cercopithecoidea, also known as Old World monkeys. *See also* Cercopithecidae.

Cercopithecidae (L. *cercopithecus* from the Gk *kerkos*=tail and *pithekos*=ape; i.e., an ape with a tail) One of the two families (the extinct family the Victoriapithecidae is the other) that make up the Cercopithecoidea, the Old World monkey superfamily. The Cercopithecidae is further divided into two subfamilies, the Cercopithicinae or cercopithecines, and the Colobinae or colobines. Genetic data suggest the two subfamilies diverged around 16 Ma.

cercopithecini An informal term for the tribe Cercopithecini, one of the two tribes within the subfamily Cercopithicinae. *See also* Cercopithecini.

Cercopithicinae (L. *cercopithecus* from the Gk *kerkos*=tail, and *pithekos*=ape; i.e., an ape with a tail) A subfamily of the family Cercopithecidae. The cercopithecines comprise two tribes: the Papionini or papionins (baboons and macaques) and the Cercopithecini or guenons. The paucity of late Miocene fossil remains obscures the early stages of cercopithecine evolution but molecular evidence indicates that they split at 11.5 ± 1.3 Ma (Tosi et al. 2005). These sister clades share many features, but they can be distinguished because cercopithecines lack a hypoconulid on their lower third molars (Szalay and Delson 1979).

cercopithecine An informal term for the subfamily Cercopithicinae. *See also* Cercopithicinae.

Cercopithecini (L. *cercopithecus* from the Gk *kerkos*=tail, and *pithekos*=ape; i.e., an ape with a tail) A tribe of monkeys within the subfamily Cercopithicinae. The Cercopithecini, informally referred to as guenons, includes the genera *Cercopithecus*, *Chlorocebus*, *Erythrocebus*, *Allenopithecus*, and *Miopithecus*. The guenons have a poor fossil record, and they are only known from Koobi Fora and a handful of other African Pliocene and Pleistocene sites in very small numbers, insufficient to properly determine the evolutionary history of the tribe. However, genetic data have filled

some of the gaps in knowledge. The divergence of *Allenopithecus* and *Miopithecus* is inferred to have been in the late Miocene (Tosi et al. 2005). The terrestrial guenons (the vervet, patas, and L'Hoest's monkeys) and major arboreal groups (*Cercopithecus mona*/*Cercopithecus neglectus*/*Cercopithecus diana* and *Cercopithecus mitis*/*Cercopithecus cephus*) diverged in the Pliocene (*ibid*) and speciation within the arboreal groups probably happened rapidly during the Plio-Pleistocene (*ibid*).

cercopithecoid An informal term for members of the primate superfamily Cercopithecoidea, also known as the Old World monkeys. *See also* Cercopithecoidea.

Cercopithecoidea (L. *cercopithecus* from the Gk *kerkos*=tail, and *pithekos*=ape; i.e., an ape with a tail) Members of this primate superfamily are referred to informally as cercopithecoids or Old World monkeys (or OWMs). The OWMs diverged from the Hominoidea *c.* 23–25 Ma, and the extant members of the Cercopithecidae are widely distributed across Africa and Asia. The OWMs can be distinguished from the New World Monkeys (or NWMs) of South and Central America because of differences in their dental formulae (OWMs have two premolars per quadrant, whereas NWMs have three premolars per quadrant), molar crown morphology (OWM molars are dominated by two crests, or lophs, that run across the crown; hence the term bilophodont), and their nasal anatomy (the NWMs have broader noses than OWMs; hence the names platyrrhine for the NWMs and catarrhine for the latter). The OWM superfamily comprises two families: one extinct, the Victoriapithecidae, and one extant, the Cercopithecidae. The cercopithecoid fossil record is sparse but towards the end of the early Miocene there is evidence for the presence of two genera within Africa *c.* 19 Ma, *Prohylobates* and *Victoriapithecus*, both belonging to the family Victoriapithecidae. OWMs are relevant to paleoanthropology for two main reasons. First, they are prevalent at Plio-Pleistocene paleoanthropological and archaeological sites, so they can be used to help reconstruct the paleohabitat at those sites. Second, they have been used in comparative models (Jolly 1972, 2001, Elton 2000, 2006, Elton et al. 2001, Hughes et al. 2008) that have been devised to help explain the events and patterns observed within human evolutionary history.

cerebellum (L. diminutive of *cerebrum*=brain; so “little brain”) The part of the central nervous system that occupies the most posterior part of the **endocranial cavity** called the posterior cranial fossa. The cerebellum has a central midline component called the vermis and two paired cerebellar hemispheres. Its main function is the coordination of motor activity, but the lateral hemispheres have also been shown to play a significant role in **language** and **cognition**. The volume of the lateral part of the cerebellar hemispheres in hominoids is greater than that predicted by allometric extrapolation based on the observed relative size relationships in monkeys (MacLeod et al. 2003).

cerebral cortex (L. *cerebrum*=brain and *cortex*=bark; thus the “outer covering”) The outer layer of the **cerebral hemispheres** and unless the cerebral hemispheres are sectioned, either actually or virtually by imaging, it is the only part of the cerebral hemispheres that can be inspected externally and it is the only part whose surface morphology can be seen on natural and researcher-prepared endocasts. It is mainly made up of the cell bodies of **neurons** and **glial** cells and because this region of the brain does not contain a significant amount of myelin the unstained cerebral cortex is gray-colored (hence the term gray matter). In modern humans the adult cerebral cortex is deeply folded. The crest of a fold is called a **gyrus** and a fissure between two gyri is called a **sulcus**. The sulci and gyri are named according to their location (e.g., the superior temporal gyrus) or shape (e.g., the **lunate sulcus**). The cerebral cortex is also subdivided into functional areas. Anatomical mapping of the cerebral cortex using **cytoarchitecture** (the microstructure of the cerebral cortex shows distinct layers of neuronal cell bodies that vary in size and shape) and **chemoarchitecture** also reveals distinct areas that are associated with different functions. The main subdivisions of the cerebral cortex of mammals include the **neocortex** (also called the isocortex) and the **allocortex** (comprised of the archicortex and the paleocortex). The neocortex is distinguished by a six-layered horizontal arrangement of cells, whereas allocortical areas have fewer than six layers. The allocortex includes parts of the cerebral cortex concerned with the processing of olfaction (i.e., the piriform cortex or paleocortex), as well as memory and spatial navigation (i.e., the **hippocampus**, also

called the archicortex). Most regions of the cerebral cortex have a distinctive pattern of the cell layers and a widely used system of cerebral cortical areas proposed by Korbinian Brodmann (1909) is based on these patterns (e.g., the **motor speech area** comprises Brodmann’s areas 44 and 45). *See also* **Brodmann’s areas**.

cerebral hemispheres (L. *cerebrum*=brain, Gk *hemi*=half and *sphaira*=surround) The cerebral hemispheres are a major component of the telencephalon, which itself forms the majority of the fore-brain (or prosencephalon). Each hemisphere consists of an outer surface layer, the **cerebral cortex**, which is made up of the cell bodies of neurons. Beneath the cerebral cortex is mainly white matter consisting of the myelin-covered processes (called dendrites and axons) of the cortical neurons. There are clusters of neuronal cell bodies buried in the white matter; the biggest of these are the basal nuclei. The cerebral hemispheres also contain a cerebrospinal fluid-filled cavity called the lateral ventricle. Named fissures or sulci separate the major **frontal**, **parietal**, **occipital**, and **temporal lobes** of the cerebral hemispheres. The paired hemispheres occupy the anterior and middle cranial fossae and they are connected by a substantial bundle of fibers called the **corpus callosum**.

cerebral petalia *See* petalia.

cerebrospinal fluid (or CSF) Clear and straw-colored fluid the composition of which resembles that of extracellular fluids; it is secreted by the choroid plexuses in the walls of the ventricles. The total volume of this fluid (approximately 150 cm³ in an adult modern human) is divided into two main compartments, called intracerebral and extracerebral. The intracerebral CSF compartment consists of the ventricles (a pair of lateral ventricles and the third and fourth ventricles in the midline) plus the small channels that connect them. The extracerebral CSF compartment occupies the space between the arachnoid and pia (the subarachnoid space). Most of the extracerebral CSF is in well-defined spaces called cisterns; the rest is in the form of a thin film of fluid between the arachnoid and the pia. The volume of the extracerebral compartment of the CSF comprises most of the difference between the volume of the brain and **endocranial volume** (or ECV), which is the volume of the cranial cavity.

cervid (L. *cervus*=deer) The informal name for the artiodactyl family, the Cervidae, that comprises deer, reindeer, and moose. Mostly known from fossil and archeological sites in the northern hemisphere. *See also* Cervidae.

Cervidae The artiodactyl family that comprises deer, reindeer, and moose. All male (and, in a few taxa, the female) cervids have keratin-derived antlers that are shed annually. *See also* Artiodactyla.

cervix (L. *cervix*=neck, or a narrow region between two wider regions) On the outside of the tooth, it is the narrow part of a tooth where the crown and the root meet.

cf. A term used in taxonomy to suggest that incompleteness or damage make the allocation of a specimen to a taxon problematic. Thus, a small fragment of the crown of a tooth with evidently thick enamel might be assigned to “*Paranthropus cf. P. boisei*.”

CF-bf Acronym for the Cromer Forest-bed Formation. *See* Pakefield.

CFT *See* crown formation time.

Chad Basin The Chad Basin is presently occupied by the Djurab Desert and it is there that the **Mission Paléoanthropologique Franco-Tchadienne** (French-Chadian Paleoanthropological Mission, or MPFT) has located several “fossiliferous areas” (e.g., **Kollé**, **Kossom Bougoudi**, **Koro Toro**, and **Toros-Menalla**). Each area has a different prefix – KL, KB, KT, and TM respectively – followed by a number for each locality within that area; further numbers are used to identify each specimen (e.g., TM 266 is the locality where **TM 266-01-060-1**, the type specimen of *Sahelanthropus tchadensis*, was discovered).

chaîne opératoire Literally translated as “operational sequence,” this refers to the analysis of technological action sequences, especially in the case of stone tool production. The approach has its intellectual roots in the ethnology of Marcel Mauss (1935), who argued that bodily techniques (e.g., ways of walking or sitting) are culturally conditioned and can thus provide a window on non-discursive elements of thought and culture. André Leroi-Gourhan (1993, originally 1964)

extended these ideas and applied them in an evolutionist analysis of human technological development, coining the term *chaîne opératoire* to refer to the sequences of technical “gestures” said to be characteristic of particular technologies. The approach applies to any technology, but has been most enthusiastically adopted in **lithic analysis** where it refers to the entire sequence of behaviors involved in tool production, use, and discard (Inizan et al. 1999). In this sense, it is very close to the American concept of a lithic reduction sequence (Shott 2003). Both focus on the sequential transformation of artifacts by hominin behavior, and represent improvements over previous, typological approaches. However, the intellectual origins of the *chaîne opératoire* approach are reflected in a much greater emphasis on the cognitive and cultural interpretation of tool-making behavior. *Chaîne opératoire* analysis aims to decipher the intentions of tool makers through piece-by-piece refitting and/or mental reconstruction of action sequences based on the technological expertise of the analyst (Pelegrin 2005). Results are commonly expressed in terms of operational flowcharts intended to reflect the normative “technological choices” characteristic of a particular prehistoric social group (Bar-Yosef and Van Peer 2009). In contrast, reduction sequence analysis more typically proceeds through the use of experimentally derived quantitative models to interpret assemblage level variation in terms of production stages, intensity of re-sharpening, and evidence of transport across the landscape (e.g., papers in Andrefsky 2008). This reflects a theoretical interest in reconstructing the behavioral ecology, as opposed to cognitive capacities, of prehistoric populations.

chalcedony (Gk *khalkedon*=a mystical stone) A microcrystalline variety of silica, often white or translucent, with a fibrous, cryptocrystalline, structure that typically forms as a secondary deposit in igneous and other rocks. Chalcedony is fine-grained and percussion results in a **conchoidal fracture**. When available chalcedony is widely used in artifact production as in the many **Howieson’s Poort** sites (e.g., **Klasies River**) in southern Africa.

Changyang () (Location 30°15’N, 110°50’E, central China; etym. named after the local county) History and general description The cave site of

Longdong (or Dragon Cave) is located on the southern slope of Guanlao Hill near the village of Xiazhongjiawan, 45 km/27.9 miles southwest of Changyang City, Changyang County, Hubei Province. A hominin maxilla was collected by non-specialists and sent to the **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP) for analysis in the fall of 1956, and an isolated lower tooth, along with mammalian fossils, was found by an IVPP team in 1957. Temporal span and how dated? A mean **uranium-series** age of 195 ka is derived from fossil mammal teeth. Hominins found at site A fragment of a small left maxilla with C, P⁴, M² (PA 76), and an isolated left P₄ (PA 81). Archeological evidence found at site None. Repository Institute of Vertebrate Paleontology and Paleoanthropology, Beijing, People's Republic of China. Key references: Geology and dating Yuan et al. 1986; Hominins Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995.

Chaohu *See* **Chaoxian**.

Chaoxian () (Location 31°32'55"N, 117°51'51"E, eastern China; etym. named after the local county) History and general description A breccia-filled fissure in Yinshan (Silvery Hill) located southeast of the town of Yinping and west of Yuxihe (Yuxi River), 6 km/3.7 miles south of Chaohu City, Chaoxian County, Anhui Province. Acting on reports of mammalian fossil finds, researchers from the **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP) organized two field seasons of excavation in 1982 and 1983. Two groups of fossiliferous deposits, Locus A and Locus B, were identified at the site. The hominin fossils were discovered in layer 2 (of four layers) at Locus B. Temporal span and how dated? Based on nine fossil animal teeth and bones Chen et al. (1987) report an age range of 200–160 ka based on **uranium-series dating**. Subsequent sampling of stalagmites and animal bones collected from the upper part of layer 2 produce uranium-series ages older than 310 ka. To constrain the chronological position of Chaoxian, Shen Guan Jun and colleagues collected additional calcite samples in 2006 and 2008. Their new **thermal ionization mass spectrometry** uranium-series dates suggest the fossils may be between 360 and 310 ka. Hominins found at site A cranial fragment (female?) including a large part

of the occipital squama was discovered in 1982. The occipital has been described as having a weak occipital torus, lacking an external occipital protuberance and possessing a distinct supratoral sulcus. It is also said to possess a “depression similar to fossa supratoralis” (Xu et al. 1984, p. 209), which Wu and Poirier describe as a “small fovea corresponding to the suprainionic [*sic*] fossa above the middle of the torus” (*ibid*, p. 134). And yet, the estimated large occipital angle and thin bone are said to resemble most closely that of “early” *Homo sapiens* (Xu et al. 1984). A maxillary fragment with lateral incisors and right P³–M¹ and three isolated left teeth (P⁴, M¹, and M²) were discovered in 1983. Bailey and Lu (2010) concluded that the occlusal morphology of the maxillary dentition differs from that seen in *Homo neanderthalensis*. Archeological evidence found at site None. Repository Institute of Vertebrate Paleontology and Paleoanthropology, Beijing, People's Republic of China. Key references: Geology and dating Chen et al. 1987, Shen et al. 1994, 2010; Hominins Xu et al. 1984, 1986, Xu and Zhang YY 1989, Pope 1992, Wu and Poirier 1995, Bailey and Liu 2010.

character (ME *caractere*=to describe) A unit of the genotype or the phenotype used to describe and compare taxa: sometimes also called a **trait**. The condition of a character in a taxon is referred to as its **character state**. For example, the character “root system of the first mandibular premolar tooth” has four states among the hominins: (a) a single root (1R), (b) one root divided for part of its length (1/2R), (c) one main distal root and a second mesiobuccal accessory root (2R: MB+D), and (d) two main roots (2R: M+D). Characters can be qualitative (e.g., a sharp or a rounded boundary between the nasal cavity and the face) or they can be derived from continuous measurements.

character conflict (ME *caractere*=to describe) When the branching pattern of a **cladogram** generated using the states of one character differs from the branching pattern of a cladogram generated by the states of a second character or by a number of other characters.

character evolution The pattern by which characters evolve (i.e., change state between ancestors and descendants) in a **phylogeny**. It is not always appreciated that the pattern of character

evolution implied by a **cladogram** is logically equivalent to the tree topology of that cladogram. Thus, the most parsimonious tree implies a pattern of character evolution; therefore it is illogical to accept the phylogenetic hypothesis of the cladogram, but reject the hypothesis about the pattern of character evolution.

character state (ME *caractere*=to describe) Character states are different versions of a **character**. For example, if the character is the root system of the first mandibular premolar tooth, among archaic hominins and *Homo* the states would be a single root (1R), one root divided for part of its length (1/2R) (also called a Tomes' root), one main distal root and a second mesiobuccal accessory root (2R: MB+D), and two main roots (2R: M+D). *See also* **cladistic analysis**; **character**.

character state data matrix Takes the form of a table in which the rows represent **taxa** or **operational taxonomic units**, the columns represent **characters** and the cells of the table record the **character states** seen in each of the taxa (e.g., the state of the character **chin** in *Homo sapiens* is "present" while the state of the same character in *Homo neanderthalensis*, *Homo habilis*, and *Paranthropus boisei* is "absent"). The construction of a character state data matrix is the first step in any form of **phylogenetic analysis**.

Charentian (etym. Named after the French department of Charente, where sites such as **La Quina** are located) A group of lithic assemblages within the **Mousterian** tradition as defined by Francois Bordes. Charentian assemblages are rich in **scrapers** (particularly side-scrapers) that may account for more than 50% of the **retouched** pieces, but there are few denticulates. The Charentian is divided into two types: Quina and Ferrassie, distinguished by a greater number of scrapers with typical steep, scaled Quina-type retouch in the former and a greater proportion of Levallois flakes and cores in the latter. The Charentian and other Mousterian variants, or facies, have figured prominently in debates about the implications of different archeological assemblages that have been interpreted as different cultures (Bordes and de Sonneville-Bordes 1970), time-successive entities (Mellars 1996), activity variants (Binford 1969), or the outcomes of different amounts of tool reduction prior to discard (Dibble 1991).

Charnov's "dimensionless numbers" (or DLNs) These measures, introduced by and named for the evolutionary ecologist Eric Charnov, are used in the analysis of life history. They simplify the description of relationships by describing the value of the ratio of variables, rather than the values of individual variables. It has been argued that the use of DLNs allows researchers to identify cases where the DLNs are invariant and then explore the possible reasons for their invariance. Examples include (a) exponents derived from the analysis of the relationship of life history traits to **body size**, (b) measures of reproductive effort, and (c) sex ratios.

Châtelperron (Location 46°23'N, 3°38'E, France; etym. named after the nearby village) History and general description This cave site, originally called the Grotte des Fées de Châtelperron, lies in the Massif Central of France. It was discovered during railway construction in the late 1800s and it was excavated by A. Poirrier in the 1840s, G. Bailleau between 1867 and 1872, and by Henri Delporte between 1951 and 1955. The relatively poor archeological material was determined by the Abbé Breuil to be distinctive, and he gave it the name **Châtelperronian**. Recent reanalyses of the site by several researchers have led to very different interpretations. Paul Mellars and colleagues (Gravina et al. 2005, Mellars 2005, Mellars et al. 2007) argue that there is a small **Aurignacian** deposit at Châtelperron that is interstratified with the Châtelperronian layers (this is based on the **radiocarbon dating** of the layers) and they claim this is evidence that modern humans were in the area and that they exposed Neanderthals to the Upper Paleolithic culture. Zilhão et al. (2006, 2008) have argued that the levels from which the dates come are actually from intermixed backfill from the excavations in the 1800s and cannot therefore be evidence of interstratification. Riel-Salvatore et al. (2008) come to a similar conclusion, concluding that the Aurignacian determination of the deposit relies on a very small number of Aurignacian-type tools, a percentage that is within the range of Aurignacian-type tools found at other Châtelperronian deposits. Both the latter research groups suggest that *Homo neanderthalensis* acquired the wherewithal to make this Upper Paleolithic technology independently. Temporal span and how dated? Radiocarbon dating of the layers results in a range of 41–34 ka (uncalibrated). Hominins found at site Although a calvaria

was reported as coming from the Grotte des Fées, the hominin linked with Châtelperron is from a different open-air site in the area and is not from the Grotte des Fées; its age and taxonomic status are unknown. Archeological evidence found at site The approximately 217 retouched tools are consistent with a Châtelperronian assemblage; Gravina et al. (2005) identified 10 Aurignacian-type artifacts. Key references: Geology, dating, and paleoenvironment Gravina et al. 2005, Zilhão et al 2006, 2008, Mellars et al 2007; Hominins Lacaille and Cave 1947, Montagu 1952. Archeology Breuil 1910, Riel-Salvatore et al. 2008. *See also Châtelperronian.*

Châtelperronian (Fr. after the site of Châtelperron) A western European technocomplex from the early Upper Paleolithic that includes many aspects of what is usually considered modern human behavior, including bone tools, composite tools, and beads, but which is associated with sites with *Homo neanderthalensis* fossils. Some authors have suggested that the Châtelperronian and other so-called transitional technocomplexes are evidence that Neanderthals adopted the behavior of the first modern humans that had migrated into Europe; Mellars (1999, 2005) supports this acculturation model. Other researchers suggest that *H. neanderthalensis* individuals developed these techniques independently (e.g., d’Errico et al. 1998, Riel-Salvatore et al. 2008). Some see continuity between the Châtelperronian and later Upper Paleolithic cultures, and argue that this is evidence that Neanderthals either evolved into, or were assimilated into, modern human populations. *See also Châtelperron.*

Cheboit (Location 00°46’N, 35°52’E, Kenya; etym. Tugen name for the area) History and general description Site within the **Lukeino Formation** in the eastern foothills of the Tugen Hills, Baringo District, Kenya. Temporal span c.6–5.7 Ma. How dated? Magnetostratigraphy, argon-argon, and potassium-argon dating. Hominins found at site The only specimen recovered to date is **KNM-LU 335**, a left lower molar, either an M₁ or an M₂, but probably an M₁, discovered by Martin Pickford in 1973 and now assigned to *Orrorin tugenensis*. Archeological evidence found at site None. Key references: Geology and dating Sawada et al. 2002; Hominins Pickford 1975; Archeology N/A.

Chellean *See Chellean man.*

Chellean man This term was used by Louis Leakey to describe the population that included the individual **OH 9** whose calvaria was found at **Olduvai Gorge** in December 1960 (Leakey 1961). The term Chellean was introduced by the French prehistorian Gabriel de Mortillet, the curator of the Musée des Antiquités nationales (Museum of National Antiquities) at Saint-Germain-en-Laye, near Paris, France. He subdivided John Lubbock’s **Paleolithic** period into a series of distinct “industries” named after sites in France. The final version of this scheme was published in his book titled *Le préhistorique: antiquité de l’homme* (C. Reinwald, Paris, 1883). Gabriel de Mortillet identified four industries: **Chellean**, **Mousterian**, **Solutrean**, and **Magdalenian**. He had earlier used the term **Acheulean** to refer to what he was now proposing to call Chellean, but for complicated reasons he changed the type site from St. Acheul (in the Somme Valley) to Chelles (near Paris). There were debates at the beginning of the 20thC over the existence of “Tertiary Man” (linked to supposed eoliths) but there were also supposed to be distinct races of early humans that corresponded to each archeological industry. Thus, there was an “Aurignacian Man” (often considered to be Cro-Magnon), a “Mousterian Man” (usually *Homo neanderthalensis*), and a hypothetical “Chellean Man.” [NB: both Leakey (1961) and Tobias (1967c) use lower case for “man.”]

Chemeron Formation (Location 00°47’N, 36°5’E, Kenya; etym. named after the Chemeron River that runs through and exposes part of the formation) History and general description The Chemeron Formation, previously referred to as the Chemeron Beds (Martyn and Tobias 1967), lies immediately above the Kaparaina Basalts and it is separated by an **unconformity** from the overlying **Kapthurin Formation**. It is part of the Tugen Hills succession and in the mid-1960s the **East African Geological Research Unit** was conceived to analyze and map the geology in and around the Tugen Hills. It is exposed at several locations and fossil hominins have been found at several locations (e.g., **Tabarin**, the Chemeron Formation Site, etc.). In 1965 John Martyn was mapping the area when a Kenyan field assistant, John Kimengich, discovered the **KNM-BC 1** temporal. The potential of the site was drawn to the

attention of Louis and Mary **Leakey**, and subsequently Richard **Leakey** and Margaret Cropper found an elephant skeleton at site BPRP#23, and recovered evidence of two new species of fossil monkeys, *Paracolobus chemeroni* and *Papio baringensis*, at site BPRP#97. Since 1981 the **Baringo Paleontological Research Project**, headed now by Andrew Hill, has worked in the Chemeron Formation. Temporal span 5.6–1.6 Ma. How dated? Argon-argon dating and biostratigraphy. Hominin evidence The Chemeron Formation is best known for **KNM-TH 13150**, a fragment of >4.15 Ma from the right side of a mandibular corpus recovered from Tabarin, KNM-BC 1745, a >4 Ma proximal left humeral fragment from Mabaget, and KNM-BC 1, a c.2.4 Ma well preserved but isolated right temporal bone. The former may, with hindsight, prove to be the earliest evidence for *Ardipithecus ramidus* and the latter is among the fossil evidence proposed as the earliest evidence for the genus *Homo* (but see Kimbel et al. in press). Archeological evidence Despite sustained survey efforts (McBrearty and Tryon, pers. comm.) no archeological evidence has been found. Key references: Geology and dating Martyn and Tobias 1967, Deino et al. 2002, Deino and Hill 2002; Hominins Martyn and Tobias 1967, Hill 1992, Wood 1999, Sherwood et al. 2002, Kimbel et al. in press.

chemoarchitecture (*L. alchymista*=alchemist and *architectus*=builder) The term used to describe the microanatomical organization of the cerebral cortex as revealed by staining for biochemical substances using techniques such as immunohistochemistry and enzyme or lectin histochemistry. These techniques allow researchers to define the borders of areas in the neocortex and nuclei in the thalamus. Additionally, chemoarchitectural information can provide insight into how cortical areas may differ in their neurochemical makeup across species. These techniques have been used to reveal several unique specializations of neocortical organization in great ape and human evolution. *See also cerebral cortex; neocortex.*

Chenjiawo *See* Lantian Chenjiawo.

chert A sedimentary rock consisting primarily of microcrystalline to cryptocrystalline quartz. Generally it takes the form of a light-colored variety of cryptocrystalline silica (SiO₂), but trace

amounts of impurities impart color variations to a rock that is otherwise mostly white or translucent. Chert can be in the form of nodules, or it may be more widespread as in the beds of ancient lakes or seas, and it may contain trace fossils diagnostic of the age or location of its formation. Chert is globally perhaps the most abundant raw material used to make stone tools. This is because it is fine-grained, relatively hard, and homogeneous, thus it has excellent fracture properties (i.e., it shows **conchoidal fractures** when percussed) (Luedtke 1992). Many **Middle Paleolithic** assemblages from Europe, the Levant, and Africa (e.g., **Porc-Epic Cave** in Africa and **Tabun** in Israel) are made almost exclusively from chert. **Flint** is a variety of dark-colored chert that has formed in marine environments.

Chesowanja (Location 36°12'E, 0°39'N, Kenya; etym. unknown) History and general description A Lower Pleistocene locality/site east of Lake Baringo, Kenya. Hominins, bovids, suids, and other fossils were first recovered from the site in 1970 by John Carney during mapping as part of **East African Geological Research Unit**. The geological record at Chesowanja is complex, as many of the sediments formed as fluvial cut-and-fill deposits, the fossil-bearing strata dip steeply as a result of post-depositional folding, and all of the outcrops are poorly exposed as a result of low topographic relief. Subsequent fieldwork by W.W. (Bill) **Bishop**, Andrew Hill, and Martin Pickford focused on clarifying the geological sequence, whereas excavations by John Gowlett and Jack **Harris** targeted Pleistocene-Holocene artifacts found in the area. Temporal span **Early and Middle Pleistocene** c.>1.42±0.07 to 0.78 Ma. How dated? Potassium-argon dating and magnetostratigraphy. Hominins found at site The remains of at least two individuals have been recovered from the site: **KNM-CH 1**, a partial cranium, **KNM-CH 302**, a partial right M¹ or M² crown plus other crown fragments consistent with them being from maxillary postcanine tooth crowns, and **KNM-CH 304**, five fragments of a hominin calotte. These derive from the **Chemoigut Formation**, the basal geological formation at Chesowanja. Archeological evidence found at site **Choppers**, polyhedrons, and **discoids** attributed to the **Developed Oldowan** occur in the Chemoigut Formation, as does purported evidence for the controlled use of fire. This includes a concentration of baked clay

fragments washed into a stream channel. Some magnetic tests suggest that these fragments were heated at temperatures beyond that found in wildfires. However, the absence of clear evidence of a **hearth** (e.g., a ring of stones) and the unclear association of the artifacts and fossils with the burnt fragments makes Chesowanja an unreliable first appearance datum for the hominin control of fire. **Acheulean handaxes** have been recovered from the overlying sediments of the Chesowanja Formation, and the latter is overlain by a "non-biface" industry in the limited exposures of the Karau Formation. The uppermost strata in the Karau Formation show reversed magnetization, suggesting an age greater than the Middle Pleistocene (i.e., the Brunhes-Matuyama boundary at *c.*780 ka). Holocene pottery-bearing sites unconformably overlie Karau Formation sediments. Key references: Geology and dating Carney et al. 1971, Bishop et al. 1975, Bishop 1978, Hooker and Miller 1979; Hominins Carney et al. 1971, Bishop et al. 1975, Gowlett et al. 1981; Archeology Gowlett et al. 1981, Isaac 1982, Gowlett 1999.

chewing (ME *cheuan*=chew) Chewing is the cyclic application of bite forces to a food item, but the specific kind of chewing employed by mammals is called **mastication**. The primitive condition for primate mastication involves an anteriorly, superiorly, and (most distinctively) medially (i.e., lingually) directed power stroke. In animals (including many primates) in which the upper and lower jaws are not the same width (i.e., they are anisognathous), the distances between a tooth and its **antimere** in the upper and lower tooth rows are different, with the equivalent teeth in the mandible being closer together than those in the maxilla. In anisognathous animals bite forces can only be applied on one side at a time. The side where the bite force is applied is called the "working side;" the other side is referred to as the "balancing side." Mastication gape cycles are usually characterized by four phases, defined using a plot of either vertical gape distance or gape angle against time (a gape time plot). During the initial, *slow*, component of the open phase, the lower jaw is slowly depressed from a closed (or minimum gape) position while the tongue is protruded and elevated to make contact with the food item. During the ensuing fast component of the open phase the jaws are then depressed more rapidly while the

tongue is retracted and depressed in order to transport and/or reposition the food item between the teeth for the ensuing power stroke. Starting from their maximally depressed position, or the position of maximum gape, the jaws are then rapidly elevated in the *fast* component of the close phase until the teeth contact the food item. This tooth–food–tooth contact slows the jaws, and initiates the *slow* component of the close phase of the gape cycle. The slow close phase is also referred to as the "power stroke" because this is when bite force is applied as the teeth move through the food. The slow close phase of the chewing cycle ends at minimum gape. It used to be thought that the primate power stroke consisted of two phases: phase I being the last part of slow close phase, and phase II being the start of the slow open phase. However, it is now clear that in primates little or no bite force is generated after minimum gape; thus the primate power stroke is equivalent to just phase I. Tetrapod chewing, including mastication, evolved from and was integrated with the intra-oral transport behaviors. Tongue-based intra-oral transport is evolutionarily primitive and functionally fundamental for tetrapods because, once they moved out of the water, tetrapods were unable to use intra-oral fluid movements to move prey items through the oral cavity. Instead, coordinated movements of tongue and jaws move prey items from the mouth to the pharynx for swallowing. Chewing evolved as biting behavior was added on to these cyclic jaw and tongue movements. Single bites to kill prey items would not qualify as chewing, but once animals were applying multiple bites in a cyclical fashion to the food item, chewing, as we presently understand it, would have evolved. Many tetrapods chew, but only mammals employ the cyclic, rhythmic, medially directed power strokes characteristic of mastication.

chewing cycle *See* chewing.

chi-square test A statistical test used to identify whether a set of observed frequencies differs significantly from a set of expected or theoretical frequencies. This test is most commonly used to determine whether proportions differ between groups. For example, two cave sites each contain fossils, some of which have cutmarks and some of which do not. A chi-square test (or χ^2 test) can be used to answer the question "does the proportion

of cutmarks differ significantly between the two sites?” Note that from a statistical perspective the answer to this question is identical to the answer of the question “does the proportion of bones at each site differ between cutmarked and non-cutmarked fossils?” Data for a chi-square test can usually be laid out in an $n \times m$ table where observations can be apportioned into one of n groups (e.g., 1 to n cave sites) and one of m categories (e.g., 1 to m types of bone modification). In the example given above this corresponds to a 2×2 table, although the table can be larger. Each cell of the table contains the number of observations that fall into that combination of group and category. For example, one cell of the table in the example above will contain the number of cutmarked fossils at site A, another cell will contain the number of cutmarked fossils at site B, a third cell contains the number of non-cutmarked fossils at site A, and the final cell contains the number of non-cutmarked fossils at site B. The counts in the data are used to calculate expected frequencies within each cell, and then squared differences between the observed and expected counts are summed to get the chi-square value. A significantly high value of chi-square indicates that observed frequencies are very different from expected values, indicating a significant difference in proportions between groups (alternatively, it can be thought of as a significant difference between categories; both interpretations are equally valid). Chi-square tests are generally robust at high sample sizes, but should not be used when the expected count in any cell of the table is less than five.

childhood (OE *cild*=child or infant plus *-had*=condition or position) Childhood, lasting from approximately 3 to 7 years, has been proposed to be a unique life history stage in modern human ontogeny, inserted between infancy and the juvenile stage. During this time there is a leveling off of the postnatal growth rate following the precipitous decline in growth velocity that characterizes the infant stage. This stage is also characterized by post-weaning dependency; that is, while modern human children are weaned by the beginning of this stage, they are still highly dependent on other members of their social group to assist in procurement and preparation of food resources. This is because their dentition is still immature, and because of their low growth rate they are small and are not able to compete effectively at sites of food resource; the first perma-

nent tooth, usually one of the first molars or central incisors, erupts toward the end of this stage. Furthermore, children are neurologically and cognitively immature; brain growth is still rapid, but decreases in velocity toward the end of childhood. It is difficult to ascertain whether childhood is truly present in other primates (e.g., chimpanzees are weaned at approximately 4 or 5 years of age and begin foraging for themselves). However, analyses of primate growth trajectories have shown that chimpanzees, like modern humans, have much longer pre-adolescent periods of growth than would be predicted for their size. Because the presence of the childhood stage is associated with relatively shortened interbirth intervals in modern humans (e.g., children are weaned relatively early and remain dependent on other adults in the group, freeing up mothers for further reproduction) it is an adaptation that increases fitness. Estimates for the first appearance of the childhood stage in the hominin fossil record extend back to *c.*2 Ma although evidential support for this and other such claims is weak at best.

chimpanzee *See Pan.*

chimpanzee archeology This is the name proposed by Carvalho et al. (2008) to describe the study of **chimpanzee** tool manufacture and use (Boesch and Boesch 1990, McGrew 1992). However, tool manufacture and tool use in non-human primates is emphatically not confined to chimpanzees, so a more inclusive term was needed and in a multi-authored review Haslam et al. (2009) proposed the term **primate archeology** as a more inclusive term to describe the study of the “past and present material record of all members of the order Primates” (*ibid*, p. 339).

chin *See* true chin.

China Fund *See* Johan Andersson.

Chinese Academy of Sciences (or CAS) Founded in 1949 and set up under the administration of the State Council as a government institution for the management of the nation’s scientific

research. It superseded the *Academia Sinica* and the Peiping Academy of Sciences. Currently it comprises five Academic Divisions, over 200 science and technology enterprises, more than 20 supporting units, and 108 scientific research institutes. The **Institute of Vertebrate Paleontology and Paleoanthropology** (or IVPP) is one of the CAS's scientific research institutes, and the former is the repository of many of the hominin fossils found in China prior to regional administrations insisting that hominin fossils stay in regional museums.

Chiroptera (Gk *cheir*=hand and *pteron*=wing) The order of mammals comprising the bats. Bat wings are formed by a membrane of skin stretched over modified manual digits and all bats are capable of powered flight. Bats are widespread in their distribution; however, they are relatively rare in the terrestrial fossil record of open-air hominin fossil sites, but they have a better chance of preservation within cave deposits. Chiropterans are phylogenetically close relatives of the primates.

Chiwondo Beds (etym. Named after Lake Chiwondo, northern Malawi) History and general description The ancient lake deposits of northern Malawi were first described as Chiwondo and Chitimwe Beds by Dixey (1927). The Chiwondo Beds (70 km/43 miles north–south and 10 km/6 miles east–west) are an uplifted sedimentary succession of fossil- and artifact-bearing lacustrine and fluvial deposits derived from the paleo-Lake Malawi and river flows and they are situated in the Karonga District of northern Malawi on the northwest shore of the modern Lake Malawi. Desmond Clark (1995) provides a history of the mapping and exploration of the Chiwondo Beds, their sedimentology and stratigraphy are described by Kaufulu et al. (1981), Ring and Betzler (1995), and Betzler and Ring (1995), and their paleoanthropological significance is reviewed by Bromage et al. (1995). They were the focus of the fieldwork of the **Hominid Corridor Research Project** (or HCRP) that resulted in the recognition of more than 145 fossil localities, two of which, **Uraha** (U18) and **Malema** (RC11), have each yielded a single hominin specimen (**HCRP UR 501** and **HCRP RC 911**, respectively). Sites where the beds are exposed Malema, Uraha, and many other localities. Geological age Four biostratigraphic time periods (units/biozones) are represented in the

Chiwondo Beds, unit 2 >4 Ma, unit 3A-1 3.75–2.7 Ma, unit 3A-2 2.7–1.8 Ma, and unit 3B 1.74–0.6 Ma (Kullmer 2008). Most significant hominin specimens recovered from the beds The mandibular corpus HCRP UR 501 from Uraha, and a maxillary fragment HCRP RC 911 from Malema. Archeology Although Kaufulu and Stern (1987) reported artifacts from the Chiwondo Beds, subsequent geological work has shown these to be reworked and intrusive from younger strata. Key references: Geology and dating Ring and Betzler 1995, Betzler and Ring 1995, Kullmer 2008; Hominins Bromage et al. 1995, Kullmer et al. 1999. Chokier See Schmerling, Philippe-Charles (1790 or 1791–1836).

chondroblasts See cartilage.

chondroclasts See ossification.

chondrocranium (Gk *khondros*=cartilage and *kranion*=brain case) The part of the **cranium** formed from cartilage by the process called **endochondral ossification**. In the second month of intrauterine life, symmetrical foci of hyaline cartilage appear beneath the developing **brain**. From posterior to anterior they are (a) four pairs of occipital cartilages that give rise to all of the adult occipital bone except for the occipital squame, (b) a pair of parachordal cartilages that lie on either side of the anterior end of the notochord that eventually contribute to the body of the sphenoid, (c) a pair of otic cartilages that surround the **inner ear** and later develop into the **petrous** component of the temporal bone, (d) a pair of hypophyseal cartilages that surround the pituitary that also eventually contribute to the body of the sphenoid, (e) two pairs of laterally situated sphenoid cartilages: the orbitosphenoids form the lesser wings of the sphenoid and the alisphenoids form the greater wings of the sphenoid, (f) two pairs of trabecular cartilages that eventually contribute to the **ethmoid** and to the nasal skeleton, and (g) a final pair of components that contribute to the presphenoid. All the cartilages anterior to and including the orbitosphenoids derive from neural crest cells, whereas all the paired cartilaginous elements posterior to and including the hypophyseal cartilages derive from mesoderm in the form

of **somites**. The bony equivalent of the chondrocranium is the **basicranium**. Bone formation, or **ossification**, begins at the caudal (i.e., the posterior or inferior) end of the chondrocranium and most of the occipital bone, the petrous part of the temporal bone, and most of the sphenoid, and ethmoid bones derive from the chondrocranium. The rest of the cranium, the **desmocranium**, develops from connective tissue by a process called intramembranous ossification. *See also ossification.*

chondrocytes *See cartilage.*

Chongokni (Location 38°00'42"N, 127°03'52"E, Kyunggi Province, South Korea; named after the town where the artifacts were discovered) History and general description Chongokni is an open-air site located in the Imjin/Hantan river basins (IHRB) in Kyunggi Province, South Korea, bordering the demilitarized zone separating modern-day North and South Korea. The IHRB is a region where more than 30 open-air Paleolithic sites have been identified, including Chongokni, Kumpari, Chuwoli, and Kawoli. Chongokni, the best known of the IHRB sites, came to the attention of the broader international scientific community in 1978 following the discovery of Acheulean-like bifacially worked stone implements. This evidence has been used by some researchers to refute the **Movius' Line** hypothesis. Temporal span and how dated? Fission-track dating, potassium-argon dating, thermoluminescence dating, infrared and optically stimulated luminescence dating, AMS radiocarbon dating, and presence/absence of AT and K-Tz tephra which originated from two separate volcanic explosions on Kyushu, Japan, have all been used to date the site. However, these analyses have resulted in a wide range of ages, with the age of the earliest Chongokni stone tools placed between 350 and 300 ka (i.e., the Middle Pleistocene). Hominins found at site None reported. Due to the acidity of the soil in Korea, bone preservation at open-air sites (except shell middens) is almost non-existent. Archeological evidence found at site More than 5000 stone artifacts have been collected through surface surveys and excavations at the IHRB sites. The most common raw materials are locally available poor-quality quartz and quartzite river cobbles. The Chongokni lithic assemblage comprises core and flake tools. Although most of the bifacially worked handaxes and cleavers were surface finds some came from excavations. The bifacially worked implements represent less than 5% of the total number

of lithic implements, leading one of the principal investigators of the IHRB (Kidong Bae) to suggest these types of assemblages should be referred to as "Chongoknian." Through systematic excavations at sites like Chongokni, the Korean researchers were able to collect small waste flakes (i.e., debitage), indicating at least some of these sites should be considered places where stone knapping occurred. Most of the bifacially worked artifacts differ morphologically from typical **Acheulean** handaxes found west of Movius' Line, although a small minority of researchers suggest a number of similarities. Repository Hanyang University Museum, Korea National Museum, Kyounghee University Museum, Seoul National University Museum, Yonsei University Museum, and Chungnam University Museum (all in South Korea). Chonyogul *See Turubong.*

chopper A term used to describe flaked Mode I stone tools particularly common in Bed I at **Olduvai Gorge** and other early archeological sites. As defined by Mary Leakey (1971), a chopper is a rounded cobblestone or angular stone block of stone with a unifacially or bifacially flaked edge along part of its circumference. Although the original terminology suggests their use as tools, more recent work (e.g., Toth 1985) suggests that choppers defined in this way may have functioned as **cores** for the production of sharp-edged **flakes**.

Choukoutien *See Zhoukoudian.*

chromatin *See chromosome.*

chromosome (Gk *chroma*=color and *soma*=body) A single, very long strand of **nuclear DNA**, plus its associated **protein** scaffolding. In **eukaryotes**, the chromosomes are found in the **nucleus** of the cell, they are typically linear, and they are packaged into a condensed structure referred to as **chromatin**. Chromatin can itself be packaged

either tightly as heterochromatin (which stains darkly in Giemsa-stained **karyotypes**) or more loosely as euchromatin (which stains lightly in Giemsa-stained karyotypes). Heterochromatin is found in regions with limited gene **transcription** and is only present in eukaryotes, whereas euchromatin is typically rich in genes that are actively transcribed and is present in both prokaryotes and eukaryotes. Organisms differ in their **chromosome numbers**. Each chromosome is linear, with a centromere (a heterochromatic region containing the **tandemly repeated sequences** involved in cell division) that separates the long (q) arm from the short (p) arm of the chromosome. Chromosomes are classified by size and by the location of the centromere. Chromosomes with centromeres in the center of the chromosome are referred to as metacentric while those with centromeres closer to one end are referred to as submetacentric and categorized further as acrocentric (p arm is still present) or telocentric (no real p arm is present). Chromosome replication occurs during interphase in both **mitosis** and **meiosis**. The evolution of chromosome structure is studied using karyotypes.

chromosome banding *See* karyotype.

chromosome painting *See* karyotype.

chromosome number Modern humans have 23 pairs of chromosomes (22 pairs of autosomes and one pair of sex chromosomes: XX in females and XY in males) whereas chimpanzees and gorillas have 24 pairs of chromosomes (23 pairs of autosomes and one pair of sex chromosomes). A **Robertsonian translocation** may have been responsible for producing the modern human chromosome 2 from two ape chromosomes (Yunis and Prakash 1982).

chron (Gk *kronos*=time) This term is an abbreviation of “polarity chronozone,” and it refers to a substantial period in the history of the Earth’s geomagnetic **polarity** (subdivisions of chrons are called **subchrons**). Chrons are numbered and these numbered chrons have replaced the eponymously named **epochs** (e.g., Gauss, Gilbert, etc.) that were used in older geomagnetic polarity timescales. The most recent chron is 1, and the numbers increase going back in time. A capital-letter postfix is used to identify chrons that have been added since the scheme was adopted (e.g., chron 3A). A chron can have both

normal and reversed components identified by a lower case ‘n’ or ‘r’ (e.g., 3An and 3Ar). Subchrons within a chron are also numbered and their magnetic direction is identified using the same abbreviation system (e.g., the first reversed subchron in chron 3An is 3A.1r). Some schemes mix the old and the new terminology (e.g., the “Matuyama chron”). *See also* **geomagnetic dating**; **geomagnetic polarity time scale**.

chronocline *See* cline.

chronogram *See* branch length.

chronospecies (Gk *kronos*=time and *eidos*=form or idea) One of several terms used for a temporally distributed group of fossils all of which belong to the same **lineage**, or lineage plexus (*sensu* Westoll 1956). For example, all the fossils attributed to *Paranthropus boisei*, from its first appearance in the fossil record to its last appearance, would make up a chronospecies. Some, but not all researchers, claim *Paranthropus aethiopicus* should be included in the same chronospecies, whereas others would include it in a separate chronospecies in the same lineage. *See also* *Paranthropus boisei*; **species** (syn. **paleospecies**, paleontological species).

chronostratigraphic units (Gk *kronos*=time and L. *stratum*=cover or layer) Intervals of rock accumulated through Earth’s history. The geologic time scale has a dual character in which intervals of time share terms with the sequence of rock (strata) deposited in that interval. However, chronostratigraphic unit subdivisions are sequential (e.g., thus they have the prefix Lower, Middle, and Upper), whereas **geochronologic units** are time-referenced, and thus their subdivisions are temporal (e.g., thus their prefixes have different names, as in Early, Middle, and Late). In the hierarchy of terminology for the geologic time scale, chronostratigraphic units are (from the largest to the smallest) called Eonothems, Erathems, Systems, Series, and Stages (e.g., *Australopithecus afarensis* fossils from **Laetoli** derive from strata of the **Pliocene Series**).

CHS Acronym for Chad’s Hominid Site. *See* **Omo-Kibish**.

Chuwolli *See* **Chongokni**.

CI Acronym for **consistency index** (*which see*).

“Cinderella” Nickname given by Louis and Mary Leakey to OH 13 from Olduvai Gorge.

cingulum (L. *cingulum*=girdle) A bulging of the enamel just above the base of the enamel cervix (**cemento-enamel junction**, or CEJ). In some teeth this bulging is so well-marked that it is given the name “style” with an appropriate prefix and suffix (e.g., **protostylid** is the part of the cingulum related to the **protoconid** in mandibular lower molars).

Cioclovina *See* **Petera Cioclovina Uscata**.

Cioclovina calvaria Site Petera Cioclovina Uscat. Locality Cioclovina cave. Surface/in situ Probably *in situ*. Date of discovery 1941. Finders Phosphate miners. Geological age Direct AMS ¹⁴C uncalibrated **radiocarbon dating** suggests an age of *c.*28 ka (ultrafiltration pretreatment) for the hominin remains. Developmental age Adult. Presumed sex Disputed. Brief anatomical description A calvaria, missing much of the face and parts of the **basicranium**. Announcement Rainer and Simionescu 1942. Initial description Rainer and Simionescu 1942. Photographs/line drawings and metrical data Rainer and Simionescu 1942, Harvati et al. 2007, Soficaru et al. 2007. Detailed anatomical description Harvati et al. 2007, Soficaru et al. 2007. Initial taxonomic allocation *Homo sapiens*. Informal taxonomic category Modern human. Significance Among the earliest securely dated modern human specimens in Europe. Location of original **University of Bucharest, Department of Paleontology**. *See also* **Petera Cioclovina Uscat**.

Ciota Ciara *See* **Monte Fenera**.

circadian (L. *circum*=around and *dies*=day) An intrinsic biological rhythm with an approximately 24 hour cycle (see Smith 2006 for a review). The development of **enamel** and **dentine** is under the influence of a circadian cell rhythm, which manifests as **short-period incremental lines** that can be seen in both tissues. These take the form of fine dark **cross-striations** in enamel viewed microscopically that run at approximate right angles to the long axis of the prisms. The equivalent fine markings in predentine as well

as dentine are called **von Ebner’s lines**. *See also* **incremental features**.

circaseptan (L. *circum*=around and *septem*=seven, thus “around seven”) A term used to describe the time interval in days between long-period incremental markings (i.e., striae of Retzius) in enamel. The temporal repeat interval of the striae of Retzius (also known as their periodicity) is assessed by counting the number of short-period incremental markings (i.e., daily cross-striations) between consecutive striae. The range observed in modern humans is 6–12 days; the mean and median value is 8 days. The range in *Pan* is 5–9 days; the mean and median value is 7 days (Smith 2004). A long-period incremental marking analogous to striae of Retzius exists in dentine (called Andresen lines) and within the same organism its temporal repeat interval has been found to match that in enamel. *See also* **Andresen lines**; **striae of Retzius**.

CISC Acronym for the **Coimbra Identified Skeletal Collection** (*which see*).

Ciutarun *See* **Monte Fenera**.

clade (Gk *clados*=branch) This term, introduced by Julian Huxley (1958b, p. 27), refers to what Willi Hennig later called a **monophyletic group**. This is a grouping of two or more **taxa** that contains all (no more and no less) of the descendants of their most recent common ancestor. A clade is analogous to a *make* of car (all Rolls-Royce cars share a recent common ancestor not shared with any other make of car), whereas a **grade** is analogous to a *type* of car (luxury cars made by Mercedes, Jaguar, and Lexus are functionally similar, yet they have different evolutionary histories and therefore have no uniquely shared recent common ancestor). The smallest clade consists of just two taxa, called **sister taxa**; the largest includes all living organisms. It is conventional to indicate the structure of a clade by a series of parentheses, each of which represents a sister taxon relationship. So the shorthand way of expressing the relationships of the taxa in the clade that contains *Homo sapiens* and *Homo neanderthalensis* is (*H. sapiens*, *H. neanderthalensis*), and for the taxa in the clade that contains *Homo*, *Pan*, and *Gorilla* it would be ((*Homo*, *Pan*) *Gorilla*) (syn. monophyletic group).

cladistic (Gk *clados*=branch; i.e., a branching pattern) A pattern of relationships among **taxa** based on taxa sharing recently evolved (i.e., **derived**) features, called **characters**, of the **phenotype** or **genotype**. Phenotypic characters are either discrete morphological features (e.g., a sharp nasal sill), or a particular range of values of a measurement. *See also* **cladistic analysis**.

cladistic analysis (Gk *clados*=branch, so-called because it is an analysis that results in **taxa** being related in a tree-like branching pattern) A method devised by Willi Hennig (1966) that uses shared **derived** features to generate hypotheses about the relationships among taxa that conform as closely as possible to the phylogenetic history of the group. The term cladistic analysis was not used by Hennig, who instead called his approach to classification and phylogeny reconstruction **phylogenetic systematics**. The taxa used in a cladistic analysis are called **operational taxonomic units** (or OTUs). In the case of cladistic analysis applied to the phenotype, the nature of the taxa must be decided beforehand on the basis of **alpha taxonomy**. Cladistic analysis of the phenotype works by breaking morphology down into discrete features called **characters**. Characters can be described either non-metrically [e.g., the form of the root(s) of a mandibular premolar] or metrically (the cross-sectional area of the mandibular corpus), but the assumption is that they are inherited independently (i.e., they are not redundant sources of information about relationships). The different forms each of the characters takes (e.g., the different ways nasal bones articulate with the frontal bone, or the different sizes of a tooth crown) are called **character states**. Several methods can be used (e.g., using an **outgroup** or **ontogenetic criterion**) to generate hypotheses about how to order the states of each character from the most **primitive** (shared by the most taxa) to the most **derived** (shared by the least number of taxa, or found in just one taxon). The taxa are then arranged in a branching diagram that is consistent with the distribution of the states of each character. The branching pattern that is supported by the greatest number of characters (called the **consensus cladogram**) becomes the null hypothesis for the relationships among those taxa. That hypothesis can be tested by finding new characters, and then comparing their distribution with the consen-

sus cladogram. Any morphology shared by two taxa, but which was not inherited from their most recent common ancestor, will support a hypothesis of relationships that is not consistent with their phylogenetic history. This type of similarity is called **homoplasy** and any shared character states not inherited from a recent common ancestor are called homoplasies (syn. **phylogenetic analysis**). *See also* **character**; **character state**.

cladistics *See* **cladistic analysis**.

cladogenesis (Gk *clados*=branch and *gena*=birth or origin) The formation of two new **species** when one species splits, or bifurcates, into two. The splitting process is called vicariance if a geographical barrier is responsible for initiating the split. *See also* **speciation**; **vicariance**; **vicariance biogeography**.

cladogram (Gk *clados*=branch and *gramma*=a letter or something written or drawn) A tree-like diagram, in which the branching is usually dichotomous, indicating the relationships among **taxa** (i.e., one old taxon splits into two new taxa). The detail of the branches is determined by the distribution of shared **derived character** states (or **synapomorphies**) and it is usually based on the assumption of **parsimony**. The cladogram that results is conventionally the most parsimonious tree (i.e., the pattern of branching requiring the fewest evolutionary changes). *See also* **cladistic analysis**.

Clarias *See* **catfish**.

“classic” Neanderthals *See* **pre-Neanderthal hypothesis**.

Clark, John Desmond (1916–2002) Desmond Clark was born in London, England, and he claimed he became interested in archeology because as a boy he explored the hill forts and castles in nearby Buckinghamshire. He entered Christ’s College, Cambridge University, in 1934 where he studied archeology and anthropology with Miles Burkitt and Grahame Clark, and history. While at Cambridge, Clark joined the excavations at the Iron Age hill camp at Maiden Castle conducted by Mortimer Wheeler, then Keeper of Archaeology at the Museum of London. Clark took his BA in

anthropology and archeology in 1937, but the lack of professional positions in the UK led him to accept a position as curator of the David Livingstone Memorial Museum and secretary of the Rhodes-Livingstone Institute for Social Anthropology in the Northern Rhodesian (now Zambian) town of Livingstone. When Clark arrived in Livingstone in 1938 there were only a handful of archeologists working in Africa and little was known of Africa's prehistory. Clark began to expand the museum's archeological and ethnological collection and in 1938 he collaborated with geologist Basil Cooke on excavations of deposits along the Zambezi River that produced numerous stone implements and animal fossils. The following year Clark decided to re-examine the site of **Mumbwa** in the Kafue valley, which had first been excavated by a team of Italian scientists in 1930. His careful excavation of the site uncovered a remarkable archeological sequence that extended from the **Middle Stone Age** to the Iron Age. With the outbreak of WWII Clark joined the Field Ambulance Unit of the Northern Rhodesia Regiment in 1941 and was sent to Ethiopia and Somalia where the Allies were fighting the Italians. Clark used whatever opportunities he could to look for prehistoric artifacts and by the end of the war he had learned enough to allow him to publish *The Prehistoric Cultures of the Horn of Africa* in 1954. He also met Louis and Mary **Leakey** in Nairobi, where the Headquarters of the British East Africa Command was located, a meeting that formed the basis for a long professional relationship. When Clark was discharged from the army in 1946 he returned to Livingstone to resume his duties at the museum, which was now housed in a new building and renamed the Rhodes-Livingstone Museum in 1951. While exploring Africa's prehistoric ruins during the war Clark recognized the growing threat to archeological sites from farming, treasure hunting, and settlement. Thus, in order to preserve archeological sites Clark established the Northern Rhodesia National Monuments Commission and served as its first secretary. Clark also became active in African archeological institutions such as the South African Archaeological Society and in 1947 he participated in the **First Pan-African Congress on Prehistory and Quaternary Studies**, which was organized by Louis Leakey and held in Nairobi, Kenya. Clark served as the president of the prehistory section of the **Second Pan-African Congress on Prehistory** held in Algiers in 1952 and he organized the third congress, which met in Livingstone in 1955. Clark began

new excavations in the Zambezi River Valley near Victoria Falls in 1948, where he worked out the stratigraphic sequence of stone tool industries found there. Clark returned to England in 1950 to complete his PhD with Miles Burkitt at Cambridge using the archeological materials he had collected in the Horn of Africa and in the Zambezi gravels, but after completing his degree in 1951 Clark returned to Livingstone. In 1953 he explored the archeological potential of the Kalambo River, near Lake Tanganyika, and found an archeologically rich site at **Kalambo Falls**. He conducted a brief excavation in 1955 but large-scale work began in 1956 when Clark received financial support from the **Wenner-Gren Foundation**. Over the next decade Clark unearthed a wealth of archeological material from a succession of deposits containing **Acheulean hand-axes** in the earliest levels to artifacts from the Middle Stone Age and ending with material from the Iron Age. Although no hominin and few animal fossils were found at Kalambo Falls, Clark did learn a great deal about the climate and environmental conditions that prevailed during the different periods represented at the site. Clark also used the newly devised **radio-carbon dating** method to obtain absolute dates for the different levels, and although these dates were later found to be inaccurate they did mark a major contribution to the understanding of the chronology of African prehistory. Excavations at Kalambo Falls continued until 1966 and Clark's painstaking investigation of the immense quantity of material recovered from the site was published in *The Kalambo Falls Prehistoric Site*, the first volume of which appeared in 1969, the second volume in 1974, and the third in 2001 just before Clark's death. Clark expanded into new territory in 1959 when a Portuguese diamond mining company invited him to excavate sites in northern Angola where their mining operations had uncovered numerous artifacts. Clark subsequently published the results of these excavations as *Prehistoric Cultures of Northeast Angola and their Significance in Tropical Africa* (1963) and *The Distribution of Prehistoric Culture in Angola* (1966). By 1960 Clark had become a world-renowned specialist in African prehistory, had dramatically expanded the collections of the Rhodes-Livingstone Museum, and had added two young British archeologists to the museum's staff, Ray Inskeep and Brian Fagan, who would go on to have distinguished careers of their own. In 1960 Clark received an invitation to join the Department of Anthropology at the University of California at Berkeley. Sherwood

Washburn, an American physical anthropologist whom Clark met at the Third Pan-African Congress on Prehistory in 1955 when Washburn was studying baboons in southern Africa, had just joined the department at Berkeley and was putting together a program in paleoanthropology. Clark joined the department in the autumn of 1961, Glynn **Isaac** was recruited in 1964, Clark **Howell** in 1970, and later still **Tim White**; this team of researchers would make Berkeley the premier center for the study of African prehistory and paleoanthropology over the next few decades. Before leaving for Berkeley, Desmond Clark participated in a symposium sponsored by the Wenner-Gren Foundation as part of the **Burg Wartenstein International Symposium Program** held in Burg Wartenstein, Austria, on African Ecology and Human Evolution. The 20 participants from varying disciplines discussed the implications of new evolutionary, primatological, and ecological discoveries for the study of human origins. The success of this symposium led Clark, **William (Bill) Bishop** and Clark Howell to organize a follow-up symposium in 1965 that resulted in the publication of *Background to Evolution in Africa* (1967), which helped to shape the developing field of paleoanthropology. Clark's fieldwork continued with excavations at a **Lower Paleolithic** site in the Orontes Valley in Syria (1964–5) and he supervised excavations of lake-bed deposits in the **Karonga** region of Malawi (1965–8) that brought together archeologists, paleontologists, and geologists. From 1970 to 1973 Clark investigated the origins of agriculture in Neolithic sites in the central Sahara and the Sudanese Nile valley. He also published his influential *Atlas of African Prehistory* (1967) that contained maps showing the distribution of archeological sites throughout Africa in different geological periods in relation to topography, vegetation, climate, and other factors. Publications such as *The Prehistory of Africa* (1970) emphasized his encyclopedic knowledge of that continent and the later *From Hunters to Farmers: The Causes and Consequences of Food Production in Africa* (Clark and Brandt 1984) further showed his interest in the full time range of the African past. In 1974 Desmond Clark led an international team of researchers from a variety of disciplines to explore the Paleolithic sites in Ethiopia. In the **Gadeb** Plain in central Ethiopia the team discovered **Oldowan** and **Acheulean** tools in deposits dated at 1.5 Ma. This was followed by the discovery in 1980 of **Oldowan** and **Acheulean** tools in deposits along the Middle Awash River in Ethiopia. Plans to

begin large-scale excavations the following year were interrupted by rebel fighting in the country but Clark was able to return with **Tim White** of the University of California at Berkeley and a team of researchers in 1990. Clark remained a member of the research team that explored the Middle Awash study area and discovered several new hominin taxa, including *Australopithecus ramidus* (later *Ardipithecus ramidus*) in 1994 and *Australopithecus garhi* between 1996 and 1997 (see de Heinzelin et al. 2000). Desmond Clark retired from the University of California at Berkeley in 1986, but he continued to be active as a field worker and as an analyst well into his retirement. Throughout his professional life Desmond Clark was supported by his wife Betty whose skills as an illustrator and editor did much to enhance the impact of his publications.

Clarke, Ronald J. (1944–) Born in Wokingham, England, Ron Clarke's longstanding interest in antiquities took him first to a course in their conservation, and in 1963 he was awarded Diploma in the Conservation of Antiquities and Works of Art from the University of London. From 1963 to 1969 Ron Clarke worked as technical officer and archeological and palaeontological assistant to **Louis Leakey** at the Centre for Prehistory and Palaeontology that was attached to what in 1963 was the Coryndon Museum and which from 1964 became known as the Kenya National Museum. His work included cleaning, reconstructing, and casting Miocene, **Pliocene**, and **Pleistocene** fossils, including early East African hominins. From 1969 to 1972 Clarke attended the University of London and he was awarded a BSc in 1972 and from 1973 onwards he was a graduate student at the University of the Witwatersrand in Johannesburg, South Africa. His thesis, entitled "The cranium of the Swartkrans hominid SK 847 and its relevance to human origins," was awarded in 1977. From 1978 to 1980 Clarke worked as a fossil conservator at the Transvaal Museum, but in 1981 he moved to the National Museum, Bloemfontein, where he was Senior Professional Officer in palaeontology and responsible for the excavations at **Florisbad**. From 1984 to 1986 he was Senior Research Officer in the **Palaeo-Anthropology Research Unit** within the Department of Anatomy at the University of the Witwatersrand Medical School; thereafter he returned to work in England as a freelance conservator. For a year in 1990–1 Clarke worked as Senior Exhibitions Assistant in the Department of Vertebrate Paleontology at

the **American Museum of Natural History**, New York, before returning to South Africa in 1991 to the Palaeo-Anthropology Research Unit as its Senior Research Officer and its Deputy Director; it was at this time that Clarke took over the day-to-day running of the excavations at **Sterkfontein**. In January 1999 Clarke moved to Frankfurt am Main, Germany, to be the Director of Research at the Institut der Anthropologie und Humangenetik für Biologen, Johann Wolfgang Goethe-Universität, but he remained Deputy Director of the **Sterkfontein Research Unit**. In 2002 he returned to South Africa to work at the University of the Witwatersrand where he is now a professor and the Director of the Sterkfontein Research Unit. His main contributions to paleoanthropology are his management and then direction of the research at the Sterkfontein site and his recognition of the importance of the isolated hominin foot bones that were the key to the eventual discovery and recovery of the Stw 573 associated skeleton from the Silberberg Grotto. *See also Silberberg Grotto*; SK 847; Stw 573.

classification (L. *classis*=the name of the units used to subdivide the Roman army fleet, etc.) **Systematics** is the inclusive term used for (a) assembling individual organisms into groups, (b) formalizing those groups as Linnaean **taxa**, (c) giving formal names to the taxa, (d) allocating the taxa to taxonomic categories, and (e) assembling the taxa into a hierarchical scheme, or classification: classification subsumes the activities involved in (c) and (d). Classification schemes generally try to reflect the evolutionary history of a taxon, but they also need to be relatively stable. This explains why there was so much resistance to revising classifications based on the results of applying **cladistic** analytical methods to the hominin **clade**. Strictly speaking you cannot classify an individual fossil. It has to be assigned to an existing taxonomic group, or if its morphology is novel, to a new taxon, and then, and only then, can you proceed to classify the taxonomic group to which the fossil has been assigned. *See also nomenclature*; **systematics**; **taxonomy**.

clast (Gk *klastos*=broken) A piece, or fragment, of a rock that results from a larger rock fragment being broken or reduced in some way into smaller pieces. Clasts can be as large as a boulder or as small as a grain of sand. Clastic rocks are formed from rock fragments, or clasts.

clastic *See* **clast**.

clavicle, evolution in hominins An S-shaped bone lying superior to the first rib and articulating medially with the sternum and laterally with the acromion process of the scapula. When viewed from above the modern human clavicle has two main curvatures: an anterior and inferior curve at the medial end and laterally a superior and posterior curve. The conoid tubercle on the inferior aspect of the lateral curve is the attachment site for the coracoclavicular ligament (an important stabilizing ligament connecting the clavicle and the coracoid process of the scapula). Modern humans share the pronounced S shape with *Pan* and *Pongo*, but not all apes have this same sigmoid-shaped clavicle. *Gorilla* has a more pronounced posterior curvature laterally, and a relatively straight medial portion, whereas in *Hylobates* the lateral part is straight and the medial section is curved (Voisin 2006). In posterior view, modern humans are unique in having just one inverted U curvature. In contrast, apes have two curvatures that reflect the relative height of the shoulder girdle relative to the thorax; the relatively low position of the modern human shoulder has been associated with this single dorsal curve (Voisin 2006, Larson 2007). Most early hominin clavicles are fragmentary, and it is not always clear whether they display the two curves and an oblique orientation, or the presumed derived modern human condition, which would imply a more modern human-like thorax configuration (Larson 2007). The 1.8 Ma OH 48 clavicle from **Olduvai Gorge** is incomplete and there are conflicting reports as to how derived its morphology is. The clavicle of **KNM-WT 15000** is more derived in the direction of modern humans, but it is shorter than would be expected for modern humans, and this has led to the suggestion that a shorter clavicle may be the primitive condition for the great apes. Since modern humans and orangutans share relatively longer clavicles, it is possible that long clavicles were independently derived in these lineages (Larson 2007). It is important to note that pathology has not been ruled out in KNM-WT 15000 and some diseases (e.g., hypoplastic clavicle syndrome) do result in shorter clavicles. However, if KNM-WT 15000 is an accurate representation of the clavicular morphology of early *Homo*, Larson (2007) suggests the following evolutionary transformation of the shoulder. If the ape-like condition of short clavicles and a superiorly facing scapula

positioned dorsally on the thorax was the primitive condition, early *Homo* would have maintained these shorter clavicles and possibly accommodated a more laterally oriented shoulder joint with a scapula that was more laterally situated on the thorax. From this configuration, elongation of the clavicle would have resulted in a more dorsal position of the scapula on the thorax while maintaining a laterally oriented glenohumeral joint (i.e., the *Homo sapiens* condition). It has been suggested that this configuration would have allowed for more range of motion behind the head, thus increasing leverage for overhand throws (Larson 2007).

clay Sedimentary materials defined primarily on the basis of particle size (i.e., a mean diameter of <4 m). Loose (unlithified) sediment in this range is referred to as clay, whereas consolidated or cemented (lithified) examples would be termed claystone. Clays are produced when deposition occurs in standing water (e.g., lakes) and they are also the active components of most soils. The term clay also designates a class of minerals (typically occurring as clay-sized particles) defined by their chemical structure of inter-layered silicate sheets. Clay minerals often form through the chemical weathering of other geological materials (e.g., the formation of smectite clay from the alteration of volcanic glass in an alkaline environment). The lacustrine deposits exposed in **Olduvai Gorge** include a wide range of clays that reflect complex fluctuations in the water chemistry of paleo-Lake Olduvai.

claystone *See* clay.

cleaver (OE *cleofan*=to split) A stone tool common among **Acheulean** assemblages. Cleavers are similar to handaxes in size and in some manufacturing details. The lateral margins of cleavers may be uniaxially or biaxially **retouched**, but cleavers are distinguished from handaxes by having an unretouched distal end. This distal end (the cleaver part) forms a sharp cutting edge sub-perpendicular to the long axis of the tool. Cleavers are almost always made on large flakes; thus the form of the cleaver is determined at the time of flake removal (Inizan et al. 1999). Cleavers are particularly abundant at the site of **Isonya**, Kenya, and experimental evidence suggests they were used for butchery (Jones 1980, Schick and Toth 1993).

Cleveland Museum of Natural History

In the 1830s Cleveland's first natural history collections were kept in a small, two-room wooden building on Cleveland's Public Square called the Ark. Its creators, the "Arkites," were amateur natural scientists, and in 1845 they joined Dr Jared Potter Kirtland, a doctor and natural scientist, to create the Cleveland Academy of Natural Science. The new Academy was in effect a museum with specimens donated by Kirtland and by some of the Arkites and it became a place where local natural historians could discuss scientific matters of the day. During the Civil War the Academy was dormant, but in 1869 members of the Academy created the Kirtland Society of Natural History (later called the Kirtland Society of Natural Science). The Kirtland Society, whose purposes were to study natural history and create a museum, lasted for 20 years, but it became dominated by lawyers and businessmen who supported it because it was good for the community, not because they had any personal interest in natural history. Eventually, with interest waning, the Kirtland Society turned its collections over to the Case School of Applied Science and Western Reserve College (in 1967 the two institutions merged to form Case Western Reserve University). In 1920, the Cleveland Museum of Natural History (or CMNH) was founded by a group of lawyers, businessmen, and scientists, and via Henry Wood Elliott, the only surviving member of the Kirtland Society of Natural Science, the Kirtland Society was incorporated into the new Museum. The CMNH has played an important role in paleoanthropology for two reasons: its links with field research in Ethiopia and the Hamann-Todd Osteological Collection. The collection, which consists of more than 3100 human skeletons and over 900 primate skeletons, includes the largest collection of lowland gorilla skeletons in the world as well as one of the largest collections of common chimpanzees in the western hemisphere. The collection was begun in 1893 by Carl August Hamann and his work was enlarged and vigorously expanded on by T. Wingate Todd until the latter's death in 1938. The collection was originally housed in its own museum facility in the Western Reserve College Medical School, but after Todd's death it was put into storage. Finally, after prolonged negotiations, it was transferred to the CMNH in several stages between 1950 and 1969. It was the Hamann-Todd Osteological Collection that attracted Donald

Johanson to the CMNH when he came as a student in 1968 to study the dentition of the collection's chimpanzees for his PhD dissertation. He was invited to join the **International Omo Research Expedition** for the 1970 and 1971 field seasons, and while working in the Omo Johanson met French geologist Maurice Taieb, who invited Johanson to join him to examine some promising deposits located in the Afar Triangle region in northeast Ethiopia. It was when Taieb, Johanson, French paleoanthropologist Yves Coppens, and American geologist Jon Kalb explored the region in 1972 that they realized the potential of the study area now known as **Hadar**. The first large-scale expedition to Hadar in 1973 resulted in the recovery of a large quantity of mammal fossils along with an early hominin knee joint, and in the following year Johanson and Tom Gray recovered the **A.L. 288-1** associated skeleton. In the meantime, in 1972 Johanson had accepted a position as a member of the CMNH's Department of Physical Anthropology and in 1974, the year he completed his PhD at the University of Chicago, he became Curator of Physical Anthropology. The original Hadar hominin fossils had been brought to the CMNH and it was there that Johanson and his team became convinced that all the Hadar remains belonged to one, novel, species of *Australopithecus* and in 1978 they proposed the Hadar hominin fossils should be referred to a new taxon, *Australopithecus afarensis*. In 1981 Johanson left his position at the CMNH and founded the **Institute of Human Origins** in Berkeley, California. Currently the CMNH is still involved with fieldwork in Ethiopia via Yohannes Haile-Selassie's research in the Woranso-Mille study area. Hominin fossil collections N/A. CLIMAP Acronym for the Climate: Long range Investigation, Mapping and Prediction research consortium, formed in 1971 to study past ocean climates. A major achievement was the reconstruction of **sea surface temperatures** across the world at the **Last Glacial Maximum** (CLIMAP

Project Members 1976). *See also* **sea surface temperature**.

climate (Gk *klima*=which refers to the slope of the Earth's surface, is the origin of L. *clima*=referring to climate, or latitude) Climate is the time-averaged (>30 years) description of the Earth's weather or the average weather in a particular region (e.g., East Africa, Antarctica) of the globe. Weather, and therefore climate, is usually described in terms of four variables: temperature, precipitation (rainfall, snowfall), wind speed, and wind direction. There are local records of how these variables have changed over the course of the last few hundred years and before that climatic conditions have been recorded in literature and in painting, but once you get beyond the previous millennium nearly all information about past climate come from **proxies** that must take the place of direct observations of the four climate variables. These proxies can be divided into two main categories: **biotic** and **geochemical**. The climate experienced in any region is the result of interactions among component climate systems (e.g., the **El Niño Southern Oscillation**, **thermohaline circulation**, etc) and the global climate system is the product of interactions among these regional climate systems. The component climate systems have their own internal dynamics, as does the Earth's climate system, but these dynamics can be influenced, or "forced," by external factors such as changes in the way the Earth is inclined relative to the sun, changes in the shape of the Earth's orbit around the sun, massive volcanic eruptions, and changes in the Earth's atmosphere that affect the intensity of the sun's rays that reach the Earth (i.e., insolation). Regional climates are also influenced by the shape, or topography, of the Earth's surface (e.g., regional precipitation is influenced by rain shadow phenomena, and regional temperature by altitude). *See also* **climate forcing**; **insolation**; **paleoclimate**.

climate forcing (Gk *klima*=which refers to the slope of the Earth's surface, is the origin of L. *clima*=climate, latitude, and L. *fortis*=strong) One of the definitions of "force" is the ability to affect the rate of progression of normal processes (e.g., as in "forcing" the growth of plants by changing their environment). A number of physical processes (e.g., fluctuations in the shape of the Earth's orbit, and in the degree of tilt and amount of wobble of the Earth's axis, changes to ocean

circulation, variations in atmospheric gases, etc.) can affect the dynamics of and thus force regional and global climate systems. In paleoanthropology there is considerable interest in climate forcing as a mechanism for environmental change, thereby potentially functioning as a catalyst for evolutionary change. Climate forcing has been linked to environmental change at some Pliocene East African hominin localities and to hominin speciation events (Kingston et al. 2007), including the emergence of *Homo erectus* (Lepre et al. 2007).

climate models *See* general circulation model; models of intermediate complexity; paleoclimate.

climate systems *See* climate; El Niño Southern Oscillation.

climbing hypothesis This hypothesis summarizes several separate but related models introduced to explain the origin and evolutionary history of upright posture and **bipedal** locomotion within the hominin clade. All the models regarding the evolutionary stages preceding the origin of hominin bipedalism have relied heavily on existing ideas about the phylogenetic relationships of modern humans and other higher primates. In this context, Sir Arthur **Keith** (1903, 1923), followed by William King Gregory (e.g., 1928, 1930), offered the first explicit hypothesis of the locomotor behaviors preceding hominin bipedalism. They proposed three stages prior to the appearance of hominin bipedalism: (a) a **prono-grade** (horizontal-bodied) arboreal monkey (like modern catarrhines) stage, (b) a gibbon-like, “hylobatian” small-bodied **orthograde** (upright-bodied) ape stage, and (c) a large-bodied, “troglo-dytian” ape stage. It is from this stage that (d) hominin bipedalism evolved. Keith and Gregory surmised that the earliest hominin bipeds retained orthograde adaptations in the trunk and upper limbs from their large-bodied ape ancestors and maintained this upright posture when traveling on the ground. A variation of this model was proposed by Morton (e.g., 1924), who suggested that the earliest hominins evolved directly from small-bodied apes that like modern gibbons habitually employed bipedal locomotion when traveling arboreally. This model became known as the **brachiationist model** for its emphasis on the orthograde behaviors requiring considerable upper-limb

weight support, but this term has been largely abandoned. **Brachiation** now refers to the pendulum-like arm-swinging locomotion commonly practiced by gibbons. Russell Tuttle (1974) built on Morton’s hylobatian model by arguing that bipedalism on large branches, like that observed in modern hylobatids, could be preadaptive for hominin bipedalism from a small-bodied ape. In the same paper Tuttle provides an excellent summary of the early hypotheses seeking to explain human origins (Richmond et al. 2001 provide a more up-to-date review). A more recent hypothesis to focus on the concept of **preadaptation** is the **vertical climbing hypothesis**. Following work by Stern (1976), Cartmill and Milton (1977), and especially Prost (1980), and elaborated by Fleagle et al. (1981), this hypothesis is based principally on experimental studies of modern humans, apes, and other primates. Fleagle et al. (1981) noted that forelimb muscles that are large or unique in orthograde primates are more active in climbing than in pendular brachiation, suggesting that climbing more likely underlies the orthograde adaptations shared among apes and modern humans. Indeed, when apes climb vertical supports the movements of the hindlimb are similar to those observed when modern humans walk bipedally. Moreover, compared with quadrupedal walking, bipedal walking and vertical climbing are closer kinematically (Prost 1980) and involve more similar muscle recruitment patterns. Finally, the **ground reaction forces** produced by climbing primates when they walk bipedally are more similar to those produced by modern humans than they are to those produced by non-climbing primates. Thus, primates that habitually climb vertical supports when traveling arboreally might be expected to adopt bipedal locomotion when forced to travel terrestrially and would have fewer functional anatomical obstacles in an evolutionary transition to habitual bipedal walking. Thorpe et al. (2007) argue that instead of vertical climbing it was arboreal bipedalism on flexible branches that was preadaptive for hominin bipedalism because they observe that orangutans use extended knee and hip postures on flexible branches that resemble the extended limb postures used by modern humans walking on the ground. They argue that this extended-limbs arboreal bipedality was present in the great ape and modern human **most recent common ancestor** (or MRCA), and was subsequently lost independently in *Gorilla* and

Pan. The current climbing hypotheses are based on the concept of preadaptation and a key prediction implicit in all of them is that the ancestors of the earliest hominins were predominantly arboreal and they lacked adaptations for traveling on the ground in any way other than bipedally. The hypothesis that the pre-bipedal ancestor had an upper limb too specialized to evolve any terrestrial style other than bipedalism is no longer tenable under our current understanding of phylogeny because the MRCA of chimpanzees/bonobos and modern humans gave rise to both bipedal hominins and climbing/knuckle-walking panins. Recent analyses of fossil hominins and living apes by Richmond and Strait (2000) and Richmond et al. (2001) have revived the hypothesis originally proposed by Sherwood Washburn (e.g., 1968) that modern humans are descended from knuckle-walking ancestors. If true, hypotheses based on preadaptation could still explain why bipedalism evolved from an African ape-like MRCA because living African apes display the biomechanical similarities between climbing and bipedalism, but would complicate evolutionary scenarios requiring the MRCA to be exclusively arboreal because such hypotheses would need to explain why an ape that was already a terrestrial knuckle-walker would switch to travelling bipedally when on the ground. *See also* **bipedal**.

clinal variation *See* **cline**.

cline (Gk *klinein*=to lead, or bend) A gradual change in a feature as one moves across a given geographic region (geocline) or over time (chronocline). Clinal variation is found in morphology, genetics, and behavior. Clines occur either because dispersed populations may have slightly different adaptations in response to local conditions, or because two separate populations have been “merged” through **gene flow**. A stepped cline occurs when there is an abrupt change in a feature; stepped clines are often observed at **hybrid zones**. In modern humans there are multiple examples of clinal variation, many of them genetic, and some have argued that the majority of modern human variation is clinal (Lawson-Handley et al. 2007).

clock model Models introduced by Gould (1977) to address deficits encountered by other attempts to visualize **heterochronic** transformations in bivariate space. A vertical bar representing

age forms the base of a semicircular clock composed of two arcs (one representing shape, and one representing size). Two clock hands are set in the midline, calibrated to the age representing the developmental stage of the ancestor of interest for a given analysis. The hands of the clock are then moved in either direction to demonstrate how shape and size in the descendant vary in relationship to the ancestor, and a marker on the vertical age bar is moved to demonstrate whether an adult morphology is achieved earlier, later, or at the same age as the ancestor.

closed basin lakes Lakes with no inflow or outflow. They are useful for **paleoenvironmental reconstruction** because they represent the equivalent of a “rain barrel” in that any change in lake level can be attributed solely to variations in the amounts of meteoric precipitation and evaporation, without the complication of variations in stream flow. Two examples are the **Tswaing Impact Crater** in southern Africa and Lake Bostumtwi in West Africa (Partridge et al. 2007, Scholz et al. 2007).

Clovis Currently the earliest well-documented culture in the Americas. The culture is named after the town of Clovis, New Mexico, which is close to the site of Blackwater Locality No. 1, where the first artifacts assigned to the Clovis culture were discovered in 1929. Clovis sites date to c.13,480–12,440 years BP using calibrated **radiocarbon dating** (Hamilton and Buchanan 2007, Haynes et al. 2007) and are found throughout most of the contiguous USA and parts of southern Canada. In terms of archeological visibility, the key Clovis artifact is a distinctive **projectile point**. Clovis points are bifacially flaked and usually have a flute (a flake scar that runs from the base part way towards the tip). They are frequently described as being **lanceolate** in shape, but recent work has shown that they can also be elliptic, linear, and deltoid (Buchanan and Collard 2009). It has been suggested on the basis of similarities between certain Clovis and **Solutrean** artifacts that Clovis Paleoindians were descended from people who migrated from Europe to North America via an “ice bridge” (Bradley and Stanford 2004). However, this hypothesis has not been widely accepted and the consensus is that the Clovis Paleoindians were descended from people who migrated to North America from Beringia

via an ice-free corridor between the Laurentide and Cordilleran ice sheets or along the northwest coast (Straus et al. 2005, Buchanan and Collard 2007). With regard to subsistence, the available evidence suggests that Clovis Paleoindians hunted a wide range of large mammals, including mammoth, mastodon, and ancient bison (Waguespack and Surovell 2003).

CMCK Acronym for the **Cultural and Museum Centre, Karonga** (*which see*).

CNV Acronym for **copy number variation** (*which see*).

CO Prefix for fossils recovered from Cooper's Cave. The prefix CO is followed by a capital letter indicating locations (A, B, C, etc.) within the cave (e.g., COB), which is then followed by the number of the fossil (e.g., COB-101). *See also* Cooper's Cave.

Coale and Demeny model life tables

This series of **life tables** was first published in 1966 by Ansley J. Coale and Paul Demeny and later updated in 1983. The 1966 life table categorized age as 0–1 year, 1–4 years (with an implied end of the interval at 4.997; i.e., up to 4 years and 364 days), and then progressed in 5-year intervals, ending with an open interval of 80+ years. The second edition added two more 5-year intervals at the end of the life table, bringing the final open interval to 90+ years. The addition of these older age intervals in the second edition was made so that the models would be "particularly useful in applications to populations with low mortality" (Coale and Demeny 1983, p. 1). As anthropological demography typically does not focus on low-mortality populations, the 1966 models suffice. The model life tables were constructed based on a large number of historical life tables, and were grouped into four families referred to as North, South, East, and West. The West model life tables are the ones most often used in anthropological demography. This follows from a statement in the first edition (and repeated in the second edition) that, "The four families of model tables will also provide a basis for estimating life tables in populations outside of the ones that underlie the model tables themselves. We would suggest utilizing the 'West' family in the usual circumstances of underdeveloped countries where there

is no reliable guide to the age pattern of mortality that prevails" (Coale and Demeny 1966, p. 29). Within each family the model life tables are numbered by level such that level 1 has a **life expectancy** at birth of 20 years and each higher level has the addition of 2.5 years of life expectancy at birth. Thus the highest numbered level in the first edition (level 24) has a life expectancy at birth of 77.5 years while the second edition's highest level (level 25) has a life expectancy at birth of 80 years. These round levels only apply to the "female" life tables, as the "male" tables are adjusted for differences in mortality between the sexes. Because the Coale and Demeny model tables were formed from historical census data, there has been considerable question as to whether they are applicable in **paleodemography** and in anthropological demography: **Weiss' model life tables** are probably more appropriate in paleodemography.

coalescence (L. *co*=together and *alescere*=to grow) Used in **molecular evolution** to describe the observation that all copies of a **gene** can be traced back to a single ancestral gene called the **coalescent**. Thus, the evolutionary histories of all the copies of a gene are said to coalesce at this ancestral gene. *See also* **coalescent theory**.

coalescent (L. *co*=together and *alescere*=to grow) The ancestral **gene** that gave rise to all the copies found in subsequent generations. *See also* **coalescent theory**.

coalescent theory (L. *co*=together and *alescere*=to grow) A retrospective model used in **molecular evolution** to trace all the **alleles** of a specific **DNA sequence** back to a single ancestral sequence called the **most recent common ancestor** (or MRCA). Thus, the evolutionary histories of all the lineages of a sequence are said to coalesce at this ancestral sequence. The coalescent process is affected by population size and structure, and coalescent theory can be used to infer the demographic or selective processes that produced the resulting **gene genealogy**. For example, compared with the coalescent produced under a neutral model, growing populations show a gene genealogy with long terminal branches and populations undergoing positive selection of one lineage (a **selective sweep**) or those populations that have undergone a bottleneck show a shorter **coalescent time** since older lineages are lost.

It is possible to distinguish between selection and **demography** as the cause of shortened terminal branches by looking at multiple loci: demography affects all loci while selection only affects a single locus.

coalescent time (L. *co*=together and *alescere*=to grow) The age of the ancestral sequence (called the **most recent common ancestor** or MRCA) that gave rise to all the copies in subsequent generations. Self-evidently each DNA sequence potentially has its own coalescent time, so the coalescent time of one sequence should not be interpreted as providing information about the timing of the evolutionary history of a species. For example, the coalescent time for mitochondrial DNA often differs from that of a nuclear DNA sequence (i.e., it is much shorter) because of the difference in **effective population size** (NB: the effective population size of mitochondrial DNA is one-fourth that of nuclear DNA) between these two types of DNA.

Cobb Collection Taxon *Homo sapiens*. History William Montague Cobb, a student of T. Wingate Todd, took over from Todd as Professor of Anatomy at Howard University in 1932. Cobb, emulating his mentor (see **Hamann–Todd Collection**), began to collect the skeletons of dissecting room cadavers. The collection now numbers around 700 modern human skeletons representative of the mid-19thC through to about 1969. The collection is located in the Cobb laboratory within the Anthropology Department at Howard University. Contact department Department of Sociology and Anthropology. Cobb Mountain subchron See geomagnetic polarity time scale.

cochlea (Gk *kochlias*=snail) Snail-shaped anterior part of the membranous and bony labyrinths. The cochlea has a central bony spine (called the modiolus) and a spiral canal that consists of two and three quarter turns. The lumen of the canal is partly divided by a shelf of bone to which is

attached the part of the membranous labyrinth called the **cochlear duct**. The endolymph-filled cochlear duct (called the scala media) subdivides (except at the apex of the cochlea) the perilymph-filled part of the cochlea into two channels, the scala vestibuli and the scala tympani. Compared to the semicircular canals, which form the posterior part of the labyrinth, the cochlea part of the bony labyrinth is relatively invariant among living higher primates. See also **bony labyrinth**.

cochlear duct One of the components of the endolymph-filled **membranous labyrinth**. Part of its wall consists of the Organ of Corti, the specialized linear arrangement of hair cells that interprets the relative movement of the hair cells as sound.

codon See genetic code.

coefficient of determination (or r^2) The square of the **correlation coefficient** (r). It is a measure of how much of the total variation in one variable, y , can be explained, or determined, by variation in a second variable, x . For example in the case of two variables, if $r=0.8$ then $r^2=0.64$, so knowledge about one of the variables provides the researcher with information that explains approximately 64% of the variation in the value of the other. This is a useful measure, especially when combined with **regression**, which describes the manner in which y changes with changes in x . More broadly, for any predictive model including one or more independent variables, the coefficient of determination indicates the proportion of variation in the dependent variable that can be explained or accounted for by variation in the independent variable(s). See also **correlation**.

coeval (L. *coevus*=of the same age) The term used for fossils that are to all intents and purposes the same geological age. For example, hominin fossils recovered from different localities in the same stratigraphic interval in the Turkana Basin (e.g., KNM-ER 406 and KNM-ER 732) are considered to be coeval.

cognition Refers to the mental process of “knowing:” awareness, perception, reasoning, and judgment are traditionally subsumed within cognition. Cognition also involves the ability to learn and subsequently use the knowledge that has been

acquired in ways that are appropriate and adaptive. Researchers refer to different types of cognition as different types of **intelligence**. Among primatologists three types of intelligence (technical, ecological, and social) have received the most attention, and these also seem most relevant to the evolution of modern human behavior. Technical intelligence refers to knowledge about physics and causality, with a special emphasis on knowledge relevant to object and tool-use. Ecological intelligence refers to knowledge about the environment and other members of the ecological community, such as the seasonal availability of foods and the behavior of predators. The third type of intelligence of particular relevance to human evolution is **social intelligence**. It refers to an individual's knowledge of relationships with kin and non-kin, and with the behaviors and dispositions of conspecifics. *See also intelligence*.

Cohuna (Location 35°55'S, 144°15'E, Australia; etym. named after a local town) History and general description Cohuna 1, a young male's cranium, was recovered in the red loam of an alluvial formation during canal excavations in November 1925. Temporal span and how dated? Presumed **Late Pleistocene** age, but no radiometric dates are associated with the fossil. Cohuna's physical proximity to, and morphological similarity with, **Kow Swamp** suggest that Cohuna 1 is very likely contemporary with, and may even be a member of, the Kow Swamp population. Hominin found at site The Cohuna 1 skull is robust and morphologically similar to the Kow Swamp series found just to the east, displaying a long, flattened frontal with a well-developed supra-orbital torus. Archeological evidence found at site None. Key references: Geology and dating Thorne and Macumber 1972; Hominins MacIntosh 1972, Thorne and Macumber 1972, Thorne 1976.

Cohuna 1 *See* Cohuna.

COHWHS Acronym for the **Cradle of Humankind World Heritage Site** (*which see*).

collagen (Gk *kola*=glue and *genes*=born, for when collagen is boiled it forms gelatin, which is a glue) Collagen is the dominant protein in animal bone and connective tissue (e.g., tendons, ligaments). Collagen molecules form aggregates called

collagen fibrils. Collagen fibrils contain three polypeptide alpha chains twisted together to form a right-handed triple helix (Orgel et al. 2006, Perumal et al. 2008) and the helices are held together by hydrogen bonds. With the aid of specialized proteins, collagen fibrils bundle together to form a collagen fiber. There are at least 29 types of collagen, but Types I, II, III, and IV are the most common types in mammals. Type I collagen is the most abundant and is the main collagenous component of bone. Collagen in bone can be isolated and used for **radiocarbon dating** or **stable isotope biogeochemistry**.

collecting areas *See* Koobi Fora.

Colobinae (L. *colobus* from the Gk *kolobos*=maimed, referring to the short thumbs that characterize the genus *Colobus*) One of the two subfamilies (the other is the **Cercopithecinae**) of Old World monkeys within the **Cercopithecidae**, one of the two families within the superfamily **Cercopithecoidea**. Members of this subfamily are commonly referred to as colobines. Colobines are commonly split into Asian and African forms and genetic evidence suggests the two groups diverged *c.*11 Ma (with a confidence limit of between 9.6 and 12.3 Ma). The earliest fossil colobine currently known is *Microcolobus*, recovered from Kenya and dated to between 9 and 8.5 Ma. By the late **Miocene** colobines had dispersed into Eurasia, with the extinct *Mesopithecus* recovered from sites in Greece, the Ukraine, Macedonia, Iran, Afghanistan, and Italy and the smaller colobine *Presbytis sivalensis* found in some terminal Miocene deposits in the Siwaliks. Colobines radiated in Eurasia during the **Pliocene** and **Pleistocene**. *Dolichopithecus*, a terrestrial colobine associated with wooded paleoenvironments, emerged in the Pliocene. Like *Mesopithecus*, it became extinct *c.*2.5 Ma. Compared to Africa and Europe, relatively little is known about the fossil record of colobines in Asia. However, it is clear that some modern genera were present in south and central Asia at least from the Pliocene and in southeast Asia from the latest Pliocene and Pleistocene (Jablonski 2002). The African fossil record of colobines between 7 and 9 Ma is generally poor, so little is known about colobine evolution on that continent in the late Miocene. However, by the time of the **Plio-Pleistocene**, African colobines were much more diverse than they are today. Unlike

modern forms, which are relatively small (ranging in size from around 8 to 13 kg), arboreal, and restricted to primary or secondary forest, several extinct African colobines were large and terrestrial. The body masses of fossil *Paracolobus*, *Rhinocolobus*, and *Cercopithecoides* from East Africa were probably in the range of 20–50 kg (Delson et al. 2000), but even these three taxa contain a range of locomotor adaptations. For example, whereas *Cercopithecoides williamsi* was terrestrial, exploiting open environments (Birchette 1982, Elton 2006), *Paracolobus* may have been capable of a mix of terrestrial (Ting and Ward 2001) and arboreal locomotion (Elton 2000). In addition to these large-bodied colobines, smaller-bodied species, including some that are closely related to modern African forms, were also present in the Pliocene and Pleistocene fossil record of East Africa.

colobines The informal name for the Colobinae, one of the two subfamilies within the Cercopithecidae. *See also* Colobinae.

Columnata (Location 35°28'48"N, 1°16'12"E, near Sidi Hosni, Algeria) History and general description A collapsed rock-shelter/cave site in inland western Algeria best known for its “cemetery” with an extensive collection of modern human remains and the presence of a transitional Epipaleolithic tool industry known as the Columnatian. The latter, which is characterized by a high proportion of microliths and bone tools of Iberomaurusian tradition, was excavated by Cadenat (1948, 1957, 1966) and Brahim (1972). Temporal span and how dated? **Radiocarbon dating** of charcoal and shell provided Late Pleistocene through the Early Holocene dates, specifically 10,800–5200 years BP. Hominins found at site Many modern human skeletons (minimum number of individuals, >60), classified as Mechta-Afalou, were recovered from what has been interpreted as the cemetery area at the site; one mandible reported from the site may have been used as a ritual item. Demographic markers suggest a healthy and growing population during the course of the site's habitation. Archeological evidence found at site The stratified sequence spans the Iberomaurusian (Oranian) through the Neolithic. The Iberomaurusian deposits are dated to 10,800 years BP but also appear to be laterally bedded with the Columnatian deposits (8200 years BP), rather than underlying them; this is interpreted as evidence that the Columnatian inhabitants removed the materials left behind by the previous Iberomaurusian

inhabitants. Above the Columnatian layers, deposits identified to the Capsian Mesolithic industry have been dated to 6750 years BP; the uppermost Neolithic layer dates to 5200 years BP. Key references: Geology, dating, and paleoenvironment Lubell 2001; Hominins Chamla et al. 1970; Archeology Lubell et al. 1976.

COM Acronym for **center of mass** (*which see*).

Combe-Capelle (Location 44°45'14"N, 0°51'00"E, France; etym. Fr. *combe*=valley or hollow; *Capelle*=name of the family that owned the farm) History and general description This site in the Dordogne region of France has several distinct archeological areas, including the Plateau de Ruffet, Roc du Combe-Capelle, Combe-Capelle haut (also called Abri Peyrony), and Combe-Capelle bas. On the Plateau de Ruffet, stone tools were uncovered by plowing. Roc du Combe-Capelle and Combe-Capelle haut are two rockshelters along the steep face of the plateau. Combe-Capelle bas is a deep and extensive deposit stretching from the base of the plateau towards the Couze River and is the main archeological area. Much of the site was first explored by amateur archeologists in the early 20thC including the Swiss Otto Hauser who in 1909 found the only hominin burial in the **Perigordian** layers of Roc de Combe-Capelle. Professional excavations were initiated in 1910 by D. Peyrony and his colleague Henri-Marc Ami in Combe-Capelle haut and bas and continued for several years under their direction. Combe-Capelle bas was revisited in the late 1980s by a team led by Harold Dibble and Michel Lenoir. Temporal span and how dated? Burned stone tools from the lower portion of Combe-Capelle bas have been dated using **thermoluminescence dating** to *c.*51 ka, but some of the stone tool technologies found in the Peyrony and Ami excavations suggest that the site may also have been inhabited much earlier, since *c.*100 ka. Hominins found at site The Perigordian modern human skeleton was buried with several grave goods, including a shell necklace and flint artifacts. It was sold by O. Hauser to the Museum für Vor- und Frühgeschichte in Berlin and the postcrania were burned during the bombing of the museum in WWII. The skull was damaged and misidentified until 2002 and only it and the shell necklace remain; it was dated using accelerator mass spectrometry radiocarbon dating to *c.*7 ka. In addition, a small fragment of a frontal bone also from *Homo*

sapiens was recovered in 1914. Archeological evidence found at site With the exception of Roc de Combe-Capelle, the site contains predominantly Mousterian layers, with some late Acheulean assemblages in the lower layers. There is some debate about the kinds of Mousterian technologies present and their ordering within the site, which would influence interpretations of local cultural evolution within this area of France. Roc de Combe-Capelle has an Upper Paleolithic sequence including Perigordian (Châtelperronian or Gravettian), Aurignacian, and Solutrean layers. Key references: Geology, dating, and paleoenvironment Peyrony 1943, Valladas et al. 2003, Dibble and Lenoir 1995; Hominins Ambrose and Bouvier 1973, Hoffmann and Wegner 2002; Archeology Mellars 1969, Peyrony 1943, Valladas et al. 2003, Dibble and Lenoir 1995.

Combe-Capelle bas *See* Combe-Capelle.

Combe-Capelle haut *See* Combe-Capelle.

Combe-Grenal (Location 44°48'N, 1°13'E, France; etym. Fr. *combe*=small valley) History and general description This cave and talus deposit was discovered in 1817, but was extensively excavated much later by François Bordes between 1953 and 1965. It was at this site that Bordes formulated the original concept of the distinctive Mousterian tool typologies, and the Mousterian facies (e.g. Denticulate Mousterian, Typical Mousterian, etc.) that he believed represented individual tribes or ethnicities. Others have since debated these interpretations, but the site remains an important reference site for the Mousterian. Temporal span and how dated? Geostatigraphic correlation suggested an age range of Oxygen Isotope Stage (OIS) 5e or 6 through late OIS 3. Hominins found at site Several fragments were recovered from the Mousterian levels, all of which have been attributed to *Homo neanderthalensis*. Several of the recovered fragments have marks that have been interpreted as evidence of intentional defleshing. Archeological evidence found at site Bordes recognized 64 layers, 54 of which he identified as Mousterian. Key references: Geology, dating, and paleoenvironment Bordes 1955, 1972, 1973, Bordes et al. 1966, Dibble et al. 2009a; Hominins Le Mort 1989, Genet-Varcin 1982; Archeology Bordes 1955, 1972, 1973, Bordes et al. 1966, Dibble et al. 2009a.

communality analysis A method of deciding which state of a character is **primitive** and which is **derived**. In communality analysis, the states exhibited by a range of **taxa** beyond those being investigated are examined. The state that occurs most frequently in the comparative sample is the one that is deemed to be primitive. This course of action is defended on the grounds of the principle of **parsimony**. *See also* **cladistic analysis: outgroup criterion**.

communication (L. *communicare*=to share) The term refers to the process by which information in the form of a message is passed from one individual to another. The various means of communication – visual, tactile, olfactory, gustatory, and auditory – correspond to the major sensory modalities. Communication has three components: (a) encoding, (b) transmission, and (c) decoding, or translation. According to the most liberal definitions of communication, all living things (including plants and animals) communicate. In this view, communication need not be intentional. That is, the encoding, or codification process need not be designed with a specific appreciation or understanding of the audience. Rather, codification may be the result of selection, whereby specific messages are favored because they enhance the sender's fitness (e.g., estrus swellings in many non-human primates). The decoding process may be similarly shaped by selection, so that the individuals attuned to certain messages are favored over those that are not. More conservative or anthropocentric conceptualizations of communication argue that **intentionality** is critical. In this view, the codification of messages and their perception is premised on mutual understanding between the individual sending the message (i.e., the sender) and the individual that is the focus of the message (i.e., the receiver). This is certainly the case for a uniquely modern human mode of communication, **language**.

comminution (L. *comminuere*=to reduce) A term used to describe the reduction in the particle size of food that takes place during the process of **mastication**.

community ecology (L. *communis*=common and Gk *oikos*=house) A community is a group of organisms that live together in the same area and **ecology** refers to all the interactions between an organism and its environment. Community ecology

is therefore concerned with the interactions and features of co-existing populations of different types of organism. Although individual species may stay the same, the nature of the overall community (i.e., the total number and types of species) is likely to change over time or across space, influenced by the external physical environment as well as the other community members. Studying the competition between organisms is a key aspect of community ecology, as is understanding their ecological **niches**, diversity, species composition, and **predation**. Paleontologists have developed numerous qualitative and quantitative ways for measuring the influence of these factors in extinct communities. Community ecology studies help to reconstruct the environments inhabited by extinct hominins, and they can also be useful for increasing our understanding of speciation and extinction events. *See also* ecology.

compact bone *See* bone.

competitive exclusion This principle, also known as **Gause's rule**, states that two species cannot stably occupy an identical **niche** within the same **ecosystem**. Competitive exclusion leads either to local extinction of a species or to adaptation as one species moves into a different niche (i.e., character divergence). The competitive exclusion principle is best known in paleoanthropology because it underpinned the **single species hypothesis**. Wolpoff (1968) suggested that human culture is such a specialized ecological niche that "no more than one culture-bearing hominid could have arisen and been maintained" (*ibid*, p. 477). Thus, once culture had been acquired there could only ever have been one **synchronic** hominin species. In fact the competitive exclusion principle does not necessarily mean that two closely related species cannot co-exist: in guenon monkeys, for example, two or more species may live closely together but avoid direct and sustained competition by foraging on a different mix of resources or exploiting different areas of the canopy. Behavioral and morphological adaptations assist such differentiation. It has been argued (e.g., Banks et al. 2008) that competitive exclusion may have caused the extinction of *Homo neanderthalensis* in Europe.

complementary DNA (or cDNA) DNA that is synthesized using reverse transcriptase from messenger RNA. Because cDNA is synthesized from the mature mRNA, it does not contain the intron sequences present in the original DNA copy

of the gene. Studies of gene expression include creation of a cDNA library so that the genes expressed in a given tissue can be identified and quantified. *See also* gene expression.

complex trait *See* epistasis; heritability; quantitative trait locus.

composite section (L. *compositus*=to put together) A diagram summarizing the **stratigraphy** of several localities within a fossil site, or several subregions within a site complex (e.g., Koobi Fora). It is assembled by using **marker beds** that are defined lithologically or chemically to correlate shorter sections from individual localities or subregions into a longer composite section.

composite tool (L. *compositus*=to put together) Any tool made of more than one component (e.g., a spear consisting of a stone point mounted on a wooden shaft, bound together by leather, sinew, or resin). Composite tools make their first appearance in the **Middle Stone Age** and **Middle Paleolithic** at sites such as **Twin Rivers** and **Königsau** (Clark 1988, Koller et al. 2001).

compound sagittal crest *See* sagittal crest.

compound temporal-nuchal crest A term introduced by John Robinson (1958) to describe the feature that results when the **temporal crest** fuses with the **superior nuchal line** or **nuchal crest**. Because the temporalis muscles of the extant higher primates, and especially the gorilla, are largest posteriorly, in many large gorilla males the temporal crest fuses with the nuchal crest to form a compound temporal-nuchal crest. Because the temporalis muscles are largest more anteriorly in the megadont archaic hominins, most of them do not display a compound temporal-nuchal crest, but a few do. Among hominins it is especially common in *Australopithecus afarensis*, in which the temporalis muscles are inferred to have been especially well developed posteriorly. It is given the prefix "compound" because what may look like a single crest actually consists of two elements, the temporal and the nuchal crests.

compound (T/N) crest Abbreviation for **compound temporal-nuchal crest** (*which see*).

computed axial tomography *See* **computed tomography**.

computed tomography (or **CT**) (Gk *tomos* = section and *graphein*=to write) An X-ray-based radiological imaging method. In paleontological and paleoanthropological applications it is mainly used to nondestructively visualize the inside and surface of modern and fossil bones and teeth. Compared to **plain film radiography**, CT (aka computed axial tomography or **CAT**) has three advantages: (a) no parallax distortion, (b) no superimposition of underlying structures, and (c) a higher contrast resolution. Medical CT scanners have an X-ray source and an array of detectors that rotate about a static specimen (the patient/specimen being examined). As X-rays pass through the specimen their absorption and scatter (attenuation), which depend on the local density properties, are detected and converted into an electronic signal. If this is repeated from many different angles the spatial distribution of the attenuation values in a cross-sectional slice can be computed and reconstructed as a 2D grayscale image consisting of a matrix of picture elements or pixels. Each pixel is assigned a CT number proportional to the degree that the X-ray beam is attenuated by the object (attenuation coefficient). The pixel size depends on the area to be scanned per axial section, also known as the field of view (or **FOV**). Since every slice has a given thickness, each pixel corresponds to a small cube known as a volume element or voxel. Medical CT systems can collect cross-sectional images slice by slice (sequential mode) or by acquiring a “corkscrew” of measurements from which slices are calculated afterwards (helical or spiral mode). The latter mode has the advantage that the acquisition time is much shorter compared to sequential CT scanning, but the reconstructed images may show small distortions. Modern CT scanners often have multiple lines of detectors that speed up the scanning process. Medical CT images have a spatial resolution typically between 0.2 and 0.5 mm (in the scan plane) and 0.5 and 1.0 mm (between slices). Industrial **micro-computed tomography** (or **micro-CT** or **μCT**) uses the same basic principles as medical CT, but the specimen is rotated on a turntable while the source/detector system remains static. Moreover, the cross-sectional images are calculated from a large series of digital radiographs obtained by projecting an X-ray cone beam onto a flat detector, rather than using a collimated X-ray fan beam and one or more lines of detectors as with medical CT systems.

The spatial resolution of **μCT** typically ranges between 1 and approximately 200 μm depending on the size of the specimen, but scanning of small objects at sub-micrometer resolution is possible as well. **Synchrotron radiation micro-computed tomography** (or **SR-μCT**) uses X-rays produced by a **synchrotron**. The monochromatic, high-energy, and parallel X-ray beam provides a better image quality than can be obtained with regular **μCT** scanners. Medical CT has adequate spatial resolution to reliably visualize internal skull morphology such as that of the paranasal sinuses, the endocranial surface, the inner ear, tooth roots, or the cross-sectional geometry of long-bone diaphyses. Moreover, it can provide a surface model of the external bone surface for use in the virtual reconstruction of a fossil or for morphometric analysis. With its better spatial resolution, **μCT** can also be used to examine structures with finer detail such as trabecular bone and the enamel-dentine junction of teeth. **SR-μCT**, especially in combination with propagation phase-contrast techniques, can visualize microscopic interfaces within structures, including the dental microstructure required to determine the age at death in juvenile fossil hominins. Persistent problems encountered when applying CT to fossil specimens include (a) density artifacts when scanning highly mineralized fossils because of the limited CT scale range of medical CT, (b) **beam-hardening artifacts**, (c) **lack-of-signal artifacts** in large and/or highly mineralized fossils, and (d) stitching artifacts due to the cone beam projection in **μCT**.

computer-assisted tomography *See* **computed tomography**.

conceptual modeling (L. *conceptus*=to conceive and *modus*=standard) One of two types of behavioral modeling suggested by Tooby and DeVore (1987). In conceptual modeling the model is not directly based on “real” observations, but on general principles developed from observations of a wide range of animals (e.g., bees) not just those closely related or analogous to the referent. Therefore, for example, baboon behavior could be used as a literal **referential model** or observations on baboons could be just one component of the information used to generate a conceptual model. *See also* **modeling**.

conchae (L. *concha*=shell) Used in two senses with respect to morphology. The first refers to the

skin-covered expanded lateral end of the cartilaginous part of the external ear. The second refers to three (superior, middle, and inferior) scroll-like bones, also called turbinates, attached to the lateral wall of the nose. The superior and middle are parts of the ethmoid bone; the inferior concha is a separate bone. They are very delicate and are seldom preserved in the hominin fossil record.

conchoidal fracture (etym. This descriptive term refers to an analogy between the broken surface of a stone and the smooth inner surface of a shell) Describes how brittle, homogenous (glass-like) material breaks when the crack does not follow any natural plane of separation. It is a desirable feature of a lithic raw material that allows it to be made into tools, because the material fractures in a controllable fashion and can be made into a variety of shapes. Materials that have conchoidal fracture include siliceous rocks (**flint**, **chert**, **chalcedony**), bone, and some igneous rocks (**obsidian**, fine-grained **basalt**) (Whittaker 1994).

condylar position index The index introduced by Wilfrid Le Gros Clark (1950a) as a variation on Raymond Dart's **head-balancing index**. The center of the convexity on the occipital condyles is projected onto the **Frankfurt Horizontal** and then the distance between the projected point and **opisthocranium** (CD) is divided by the maximum length of the cranium (CE) (i.e., the distance between **prosthion** and **opisthocranium** projected onto the Frankfurt Horizontal), multiplied by 100. The more posterior the occipital condyles, as in *Pan* compared to modern humans, the lower the value of the condylar position index.

confocal microscopy In a conventional light microscope the observer can see into a solid object as far as light can penetrate, but they see a confused image because information from multiple depths is superimposed. The optics of a confocal microscope are designed so that out-of-focus information is eliminated and only information from a specified depth, called the "plane of interest," is collected to form the image. There are various types of confocal microscopes (e.g., light, fluorescence, laser scanning), but the one that has been used in paleoanthropology is the confocal scanning light microscope (or CSLM). Alan Boyde and colleagues pioneered the use of tandem scanning

reflected light microscopy (or TSRLM) to investigate dental tissues (Boyde et al. 1985, Boyde and Martin 1987) and Tim Bromage and colleagues have developed a confocal scanning light microscope that is portable enough to take to museums yet can still see **enamel prisms** in a dense solid structure such as dental enamel up to a depth of 50µm (Bromage et al. 2005). *See also* **portable confocal scanning optical microscope**.

confocal scanning light microscope *See* **confocal microscope**.

confrontational scavenging Also referred to as power scavenging or aggressive scavenging, this is a **carcass acquisition strategy** defined as the capture of a nearly complete animal carcass from the nonhominin predators still engaged in consuming it. Modern **hunter-gatherers**, such as the **Hadza**, have been observed to occasionally practice confrontational scavenging.

congener (L. *congener*=of the same race) Strictly interpreted it refers to another **species** in the same **genus**, but some use "congener" in a more general sense to refer to members of the same taxonomic category, whatever that category's level in the Linnaean hierarchy, although they should not do so.

conglomerate (L. *glomus*=ball) A rock made of large, rounded fragments (pebbles, gravel) that may be cemented together by a fine-grained matrix or mineral cement.

Congo Museum The name of the museum now known as the **Royal Museum for Central Africa**.

Congress of the Pan-African Association of Prehistory and Related Studies The Pan-African Congress on Prehistory and Quaternary Studies was inaugurated in Nairobi in January 1947 and it met thereafter in Algiers (1952), Livingstone (1955), Leopoldville (1959), Santa Cruz de Tenerife (1963), Dakar (1967), Addis Ababa (1971), Nairobi (1977), and Jos (1983). At the Jos meeting the name of the congress was changed to the Congress of the Pan-African Association of Prehistory and Related Studies, and the **Pan-African Association of Prehistory and Related Studies** has organized the later

congresses in this series in Harare (1995), Bamako (2001), Gaborone (2005), and Senegal (2010). *See also* **Pan-African Congress on Prehistory and Quaternary Studies**.

connective tissue *See* bone; cartilage.

consensus cladogram *See* cladistic analysis; cladogram.

consistency index (or CI) Developed by Kluge and Farris (1969) as a measure of the goodness of fit between a **cladogram** and a **character state data matrix**. The CI for a single **character** is calculated as m/s , where m is the minimum number of character state changes required by any possible cladogram and s is the number of character state changes required by the cladogram being investigated. To compute the CI for a group of characters used in a **cladistic analysis**, the m values for the characters are summed and then divided by the sum of the s values for the characters (M/S). The values for CI can range between 1 and 0. A CI of 1 indicates that the character state data matrix is perfectly congruent with the cladogram (i.e., the cladogram requires no changes due to **homoplasy**). Homoplasy levels increase as the CI decreases toward 0. The CI value is affected by the number of taxa or the number of characters included in a character state data matrix, whereas the retention index was designed so that it is not influenced by either the number of taxa or the number of characters included in a character state data matrix. *See also* **cladistic analysis**.

contagion *See* social enhancement.

contingency (L. *contigens*=to touch, but contingency now refers to an unintended event) An evolutionary perspective that stresses the effects of earlier factors or events (usually random or near random) in influencing subsequent evolutionary outcomes. For example, in small populations in the absence of countervailing factors, **genetic drift** will ultimately lead to the elimination or fixation of alleles, thereby reducing the population's genetic variation. But which of a pair of alleles is fixed and which lost is due to chance, but the population's subsequent evolution will be determined by (i.e., be contingent upon) the pattern of random fixation and loss. This is a micro-

evolutionary example, but in recent years, influenced by punctuational theory, and especially by the writings of Stephen J. Gould, workers have considered the possible role for contingency at the macroevolutionary level. In ascribing most evolutionary change to speciation, **punctuated equilibrium** identifies many more speciation and extinction events than **phyletic gradualism**. The isolation that promotes speciation does not of itself necessarily result in enhanced fitness or improved adaptation, and many species, especially when originating as clusters, will be of identical or near-identical fitness. Their continuation or extinction may therefore be strongly influenced by chance: those that do persist provide the starting points for subsequent evolutionary diversification, which is thus contingent on the fortuitous pattern of species survival. For example, Gould has argued that the survival of only a small number of forms from the extraordinarily diverse Burgess Shale fauna, most of which became extinct in the Middle-Late Cambrian, predetermined subsequent metazoan evolution in general and arthropod evolution in particular (Gould 1990). Any other pattern of Burgess fauna survival would have meant other starting points and so very different patterns of post-Cambrian evolution. Possible examples of contingency in hominin evolution include (a) differences of detail in the locomotor systems of East and southern African *Australopithecus*, (b) the initial appearance of several early *Homo* species (*H. habilis*, *H. rudolfensis*, and *H. erectus/ergaster*) with differing morphologies and then the extinction of all save the last, (c) the evolution of *Homo neanderthalensis* morphology from later *Homo heidelbergensis* populations in higher-latitude Eurasia around the Middle/Upper Pleistocene boundary, possibly associated with population bottleneck(s) during Oxygen Isotope Stage 6, and (d) the evolution of *Homo floresiensis* in Southeast Asia. In this last case, **founder effect**, genetic drift, transience event(s) that mitigate the adverse impacts of disadvantageous recessive alleles exposed as homozygotes, and endemic dwarfing were probably all involved, illustrating that chance factors can interact with other evolutionary processes. It is also possible that the fixation of some or all of the characteristic morphology of *Homo sapiens* (e.g., globular neurocranium, retracted face, gracile mandible with a chin, pronounced basicranial flexion, slender limb-bones, etc.) results from random factors influencing diversity in later Middle

Pleistocene African populations. The spread of *H. sapiens* would then reflect subsequent behavioral, technological, and/or reproductive or demographic innovations of some *H. sapiens* populations compared with other later-Pleistocene *Homo*, rather than any enhanced fitness resulting from the morphology *per se*, which nonetheless becomes ubiquitous. See further explanations and examples in papers by Stephen J. Gould, Chris Paul, Robert Foley, and Alan Bilsborough in *Structure and Contingency: Evolutionary Processes in Life and Human Society* (Bintliff 1999).

conule (L. *conule*=diminutive of cone) A small accessory cusp of a maxillary (upper) postcanine tooth that is not one of the four main cusps (i.e., not the **proto-**, **para-**, **meta-**, or the **hypocone**). For example, the **metaconule** is an accessory cusp between the metacone and protocone. *See also* **accessory cusp**.

conulid (L. *conule*=diminutive of cone) A small accessory cusp of a mandibular (lower) postcanine tooth (hence the suffix “-id”) that is not one of the five main cusps (i.e., not the **proto-**, **ento-**, **meta-**, or **hypoconid**, or the **hypoconulid**). For example the **tuberculum intermedium** is an extra distal cusp between the metaconid and the entoconid. *See also* **accessory cusp**.

conventional radiocarbon dating *See* radiocarbon dating.

conventional radiography *See* plain film radiography.

convergence (L. *convergere*=to incline together) When a character shared by taxa has not been inherited from their **most recent common ancestor** (i.e., the taxa have evolved the same character independently). Convergence is a common cause of homoplasy. For example, are the coronally rotated petrous bones seen in *Homo* and *Paranthropus* inherited from their most recent common ancestor, or are they an example of convergence? *See also* **homoplasy**; **convergent evolution**.

convergent evolution Convergent evolution is the independent origin of similar **traits** in distantly related taxa (e.g., the acquisition of thick-enameled teeth in orangutans and cebus monkeys).

Parallel evolution is the independent origin of similar traits in closely related taxa. For example, the coronally rotated petrous bones seen in *Homo* and *Paranthropus* may not have been inherited from their most recent common ancestor, in which case they would be an example of convergence in the form of parallel evolution, or if bipedalism evolved independently in *Australopithecus afarensis* and *Australopithecus africanus*, then this would also be an example of parallel evolution. Simpson (1950) was most likely the originator of these terms, or, if not, he certainly was among the first to formalize them (Simpson 1960). He suggested “there is no really fundamental difference between” them (*ibid*, p. 181), and inevitably whether a trait in two taxa that are not in the same clade qualifies as an example of convergent or parallel evolution (i.e., whether the taxa are “distant” or “close”) is a subjective decision. Convergent and parallel evolution both result in **homoplasy**: the appearance of similar morphology in two taxa that is not seen in the most recent common ancestor of those taxa. “Deep” convergent evolution (e.g., similar body form in whales and fishes) is relatively easy to recognize because only a minority of features is affected. Parallel evolution in closely related taxa is more difficult to distinguish from characters inherited from the most recent common ancestor because the taxa involved are more similar overall and are likely to have responded to common selection pressures in similar ways. *See also* **homoplasy**.

Coobool Creek (Location 35°12'S, 143°45'E, Australia) History and general description An ancient cemetery near the Coobool Crossing of the Wakool River between Swan Hill and Deniliquin in southern New South Wales where G.M. Black collected a series of hominin skeletal remains in 1950. Temporal span and how dated? A preservative applied to the hominin remains upon their collection unfortunately precludes direct radiocarbon dating of the skeletons. Based on morphological similarities to the robust hominins that comprise the **Kow Swamp** sample, and on distinctions from the more gracile mid-Holocene specimens from **Green Gully** and **Lake Nitchie**, the Coobool Creek series is presumed to belong to *Homo sapiens* and to be of Late Pleistocene age. Hominins found at site The Coobool Creek crania are robust and morphologically similar to those from Kow Swamp, **Cohuna**, and **Naccurie**. The anterior skull vault shows

evidence of artificial cranial deformation, and the faces are large, robust, and sub-nasally prognathic. The Coobool Creek mandibular sample displays the greatest average dimensions (e.g., height of the symphysis, and height and breadth of the corpus and the buccolingual dimensions of many of the teeth) among all of the hominin samples found at Australian sites. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Brown 1989; Hominins Brown 1989, 2010, Durband 2008.

Coobool Crossing *See* Coobool Creek.

Coon, Carleton Stevens (1904–81) Carleton Coon was born in Wakefield, Massachusetts, USA. He entered Harvard University to study Egyptology with George Reisner, but he changed to anthropology after taking classes with Earnest Hooton. Coon graduated from Harvard in 1925 and remained there for his graduate studies, which involved conducting fieldwork in North Africa studying the Rif Berbers of Morocco. Coon completed his PhD in anthropology in 1928 and his dissertation, *Tribes of the Reef*, was published in 1931. Coon accepted a position as a lecturer at Harvard in 1928 and continued to conduct anthropological research, spending a period from 1929 to 1930 studying the people of northern Albania and traveling to Ethiopia and Yemen in 1933–4. Coon was appointed an instructor at Harvard in 1935 and became a Professor of Anthropology there in 1938. In 1939 he published a reworked version of William Z. Ripley's *The Races of Europe*, a work originally published in 1899, in which Coon used craniometry to examine the physical anthropology of the people of Europe. Coon took a leave of absence from Harvard in 1941 and in 1942 he was sent to German-occupied Morocco with a mission to mobilize Riffian tribesmen in preparation for the landing of Allied troops in Africa. After the war Coon returned to teaching at Harvard, but in 1948 he accepted a position as Professor of Anthropology at the University of Pennsylvania, as well as curator of ethnology at the University of Pennsylvania Museum. In addition to conducting research into the physical anthropology of current populations, Coon also conducted archeological excavations. During one of his first excavations in Morocco in 1939 he unearthed what was then thought to be a *Homo neanderthalensis* maxillary bone from a cave in

Tangier. From 1948 to 1949 he participated in excavations in Iraq and Iran, and during the mid-1950s he excavated sites in Afghanistan and Syria, where he explored an archeological record that spanned the Paleolithic and the Neolithic. In 1950 Coon published, in collaboration with anthropologist Stanley Garn and evolutionary biologist Joseph Birdsell, *Races: A Study of the Problems of Race Formation in Man*, which used Darwinian ideas of adaptation, especially in response to climate, to explain modern human racial variation. Coon also published a general overview of recent discoveries and theories in archeology and physical anthropology in *The Story of Man* (1954). However, Coon's most extensive and controversial treatment of the idea of human racial diversity was *The Origin of Races* (1962) in which he argued that the five major human races (Caucasoid, Negroid, Capoid, Mongoloid, and Australoid) have a deep evolutionary history. According to Coon, human racial diversity was already present in *Homo erectus* and he argued that the different modern human races evolved separately from geographically separate subspecies of *H. erectus* into *Homo sapiens*. Moreover, he believed these races had evolved at different rates, which explained why the modern human races have attained such different levels of cultural development. This model of human evolution is often referred to as the **candelabra model** and differs from the so-called **multiregional model** of human evolution originally espoused by Franz **Weidenreich**, and more recently by Milford **Wolpoff** and Alan **Thorne**. According to Coon, the candelabra model suggests that the various geographical races evolved independently from one another (polygenism), while the multiregional model argues that the distinct geographical populations evolved into modern humans in only relative isolation, maintaining their regional identity, but with some **gene flow** between these populations, and thus did not evolve independent of one another (polycentrism). Coon's ideas were controversial and in later years he backed away from them. Sherwood **Washburn** and Ashley Montagu, both of whom had written on the question of race from the perspective of physical anthropology, used new ideas derived from the **modern evolutionary synthesis** and population genetics to criticize Coon's interpretations. Scientific and political attitudes of the time were turning against the scientific racism of the 19thC and early 20thC, yet Coon's work did

demonstrate that human racial diversity was a subject that could be studied using evolutionary theory and the hominin fossil record. Coon published a less controversial, but valuable, study of modern human racial diversity titled *The Living Races of Man* in 1965. He later included new biological and anthropological discoveries, especially evidence from molecular biology, in *Racial Adaptations* (1982), which expanded upon his earlier work. Coon retired from the University of Pennsylvania in 1963, and in 1981 he published his autobiography *Adventures and Discoveries*.

Coopers See Cooper's Cave.

Cooper's Cave [Location 26°00'46"S, 27°44'45"E, South Africa; etym. a cave in the Sterkfontein Valley named after R.M. Cooper. **Broom** (in Broom and Schepers 1946) refers to a "Mr. R. M. Cooper" who "owns the Sterkfontein Caves" and also refers to Cooper giving Broom "every facility to collect ... on his farm" (p. 144). Some publications refer to it as "Coopers Cave", but Cooper's Cave is correct] History and general description A cluster of breccia-filled caves in Pre-Cambrian dolomite in the Blauwbank Valley, Gauteng, South Africa, between Sterkfontein to the west and **Kromdraai** to the east. A single hominin tooth was discovered in 1939 and since then hominins have been reported in 1995, 2000, and 2009. Temporal span and how dated? **Biostratigraphy** (1.9–1.6 Ma) and **uranium-series dating** (U-Pb) (1.5–1.4 Ma) for Locality D. Hominins found at site Hominins have been recovered from three spatially distinct infills (A, B, and D) at Cooper's. From Cooper's A there is an upper incisor (COA-1), and a squashed face (COB-101). From Cooper's B there is an upper third molar (TM 1514), but the original was lost during the 1980s and only a cast remains. The hominins recovered from Cooper's D include four isolated teeth, three deciduous molars and a permanent molar (CD 1634, 1638, 5774 and 22619), two mandibular fragments (CD 6807 and 17796) and a thoracic vertebra (CD 5773). All have been assigned to *Paranthropus robustus*, except COA-1, which has been assigned to *Homo sp.*; only the hominins from Cooper's D are known to be from that location. The hominins from Cooper's A and B were found in boxes in the **Transvaal Museum**, not at the site. The fossil prefixes were assigned by staff at the

museum and do not refer to the lettered infills referred to above. Archeological evidence found at site Possibly early **Acheulean**. Key references: Geology and dating Brain 1958, Berger *et al.* 2003, de Ruiter *et al.* 2009; Hominins Berger *et al.* 1995, 2003, Steininger and Berger 2000, Steininger *et al.* 2008, de Ruiter *et al.* 2009. Collections prior to 1998 are at the **Ditsong National Museum of Natural History** (formerly the **Transvaal Museum**), but the hominins recovered after 1998 are kept at the **Bernard Price Institute**.

coordinate In mathematics, a coordinate is one of a set of numbers that specifies where a point is located in space. See also **geometric morphometrics**; **Cartesian coordinates**.

coordinate data The **Cartesian coordinates of landmarks**. Bookstein (1991, p. 2) defines landmarks as loci that are homologous across individuals in a sample (i.e., the landmarks have the "same" location in every other member of the sample being investigated). These coordinate data can be one-, two-, or three-dimensional. 2D coordinates are usually captured using a digitizing tablet or by measuring an image on the computer. 3D data can be captured directly using a coordinate digitizer such as a Microscribe or Polhemus, or may be measured on surface or volumetric scans. Volumetric data are based on image slices from **computed tomography** (CT or μ CT) or **magnetic resonance imaging** (MRI or μ MRI) or, more recently, optical projection tomography. These slices contain grayscale values that correspond to tissue densities and are concatenated to obtain a 3D representation of an object. Surface scanners provide high-resolution 3D representations of an object's surface using either laser or more traditional optical technology and may also include texture information, and virtual surfaces can be generated from CT or MRI data. Most software packages allow landmark coordinates to be measured directly on these virtual surfaces or volumetric objects.

Cope's rule This "rule," which is probably better described as a trend, is attributed to Edward Cope (1840–97) and it suggests that lineages tend to increase in body size over the course of evolution. For example, all marine phyla, except molluscs, show a size increase between the

Cambrian and Permian (Novack-Goppottshall 2008). The *post hoc* explanation is that the trend can be explained by **directional selection** (e.g., larger body size buffers against changes in the paleoenvironment, lowers the risk of predation, etc.), but several factors that impose limits on the size (e.g., birds must be light enough to fly, changes in size may be accompanied by changes in ecological niche, and that a new niche may already be occupied) may oppose these pressures (Van Valkenburgh et al. 2004). Moreover, a complication with the "rule" is that it may be an artifact of the tendency for **adaptive radiations** to begin with small-bodied forms. Thus, if a clade begins with small-bodied ancestors, then as it diversifies to fill available niche-spaces, the evolution of both large- and small-bodied descendants may give the appearance of a trend towards increasing body mass simply because there was a small-bodied starting point. Some workers cite hominins as an example of Cope's rule insofar as the later members of the genus *Homo* are larger-bodied than the australopiths.

Coppens, Yves (1934–) Yves Coppens was born in Vannes, in the Brittany region of France, in 1934. He participated in local excavations during his school years and after graduating from the lycée in Vannes, Coppens entered the University of Rennes, where he completed a degree in the natural sciences. He pursued graduate studies in paleontology at the University of Paris (Sorbonne) where he studied the **Proboscidea** under the direction of Jean Piveteau. Coppens accepted an appointment at the **Centre National de la Recherche Scientifique** (National Centre for Scientific Research) in 1956 where he worked on vertebrate and human paleontology during the late **Tertiary** and **Quaternary** periods. In 1960 he undertook the first of four fieldwork seasons in Chad, Central Africa, and in 1961, while collecting fossils during this expedition, Coppens discovered a hominin cranium that he named *Tchadanthropus uxoris* (now considered *Homo sapiens*). He later took over from Camille **Arambourg** as the leader of the French team that, along with an American team lead by Clark **Howell** and a Kenyan team led by Richard **Leakey**, composed the **International Omo Research Expedition** exploring the deposits in the **Lower Omo Basin** in Ethiopia between 1967 and 1976. In 1974, Coppens participated in excavations with American paleoanthropologist

Donald **Johanson** and French geologist Maurice **Taieb** at **Hadar** that resulted in the discovery of *Australopithecus afarensis*. Besides these expeditions, Coppens has organized, led, or participated in field research in Algeria, Tunisia, Mauritania, Indonesia, and the Philippines. Coppens left the Centre National de la Recherche Scientifique in 1969 to accept a joint position in the Laboratory of Anthropology at the Muséum national d'histoire naturelle (National Museum of Natural History) and the **Musée de l'Homme** (Museum of Man). Beginning in 1981 Coppens became a prominent supporter of the idea, first proposed by the Dutch primatologist Adriaan Kortlandt, that the evolutionary separation of the **hominin** and **panin** clades was caused by environmental changes, namely the formation of the East African Rift System, which cut off forest living primates of the western side of the rift from primates that were forced to adapt to savannah conditions on the eastern side of the rift. This theory, popularly called the "east side story," argues that savannah conditions prompted our hominin ancestors to walk upright while forest-dwelling primates west of the rift valley faced no such selective pressure. However, the recent discoveries of *Australopithecus bahrelghazali* and *Sahelanthropus tchadensis* in Chad have posed a challenge to this hypothesis. Coppens was appointed to the chair of paleoanthropology and prehistory at the Collège de France in 1983 where he remained until his retirement in 2005.

coprolite (Gk *copros*=dung) The term for fossil feces or dung. Coprolites are an example of a **trace fossil**. *See also fossil*.

coprophagy (Gk *kopros*=dung, and *phagein*=to eat) The consumption of feces or dung. Coprophagy is a common strategy in animals with simple digestive systems that consume low-quality foods. Many primates use this dietary strategy, usually temporarily. Gorillas have been observed to eat their own feces and those of conspecifics, but in modern humans coprophagy is usually considered to be a sign of significant mental disorder or disease.

copy number variation (or CNV) Refers to a segment of DNA a thousand, or more, **base pairs** (or 1 kb) long that is devoid of high-copy repetitive sequences such as **long interspersed nuclear elements** (LINEs) and which is present

in variable copy number among individuals. CNVs may be inter- or intra-chromosomal, although the vast majority of CNVs are intra-chromosomal. Intra-chromosomal CNVs may be dispersed along a chromosome or they may be arranged in tandem. For molecular geneticists studying human and primate evolution, it has long been thought that the genomes of two modern human individuals are approximately 99.9% similar (Li and Sadler 1991, HapMap 2003, Hinds et al. 2005), while other research has indicated that the modern human and chimpanzee genomes are nearly 99% identical (Sibley and Ahlquist 1984, Ruvolo et al. 1994, Ebersberger et al. 2002, Shi et al. 2003, Watanabe et al. 2004). At both levels of comparison, this variation was thought to be primarily represented by single nucleotide differences. However, these basic assumptions have recently been reconsidered based on findings that copy number variants are more common than previously expected, both among modern humans (Iafate et al. 2004, Sebat et al. 2004, Tuzun et al. 2005) and between modern humans and chimpanzees (Newman et al. 2005, Wilson et al. 2006). In fact, in both cases, it appears that the total content of genomic variation (measured in base pairs) is greater for copy number variation than for single nucleotide-level variation (Cheng et al. 2005, Consortium 2005, Redon et al. 2006). The generation of such segments can involve both gains or losses of genomic material and an immediate consequence of a genomic copy number gain or loss may be a corresponding increase or decrease in gene expression (Ohno 1970). Thus, intra-specific CNVs may be involved in intra-specific phenotypic variation including individual differences in disease susceptibility. Inter-specific CNVs may likewise account for between-species differences in gene expression.

core (ME *core*=the hard, seed-containing central part of some fruits) Any piece of stone from which flakes have been deliberately removed. Cores are present at the earliest archeological sites such as those at Gona, Ethiopia, and they occur at most archeological sites where stone tool production has occurred (e.g., in Africa they are not restricted to one or other of the **Early**, or **Middle**, or **Later Stone Ages**).

coronal (L. *coronalis*=a crown) Refers to a plane at right angles to the **sagittal** plane or to the cranial **suture** that is aligned at right angles to the **sagittal**

suture. The coronal suture is where the front of a small crown, or a wreath, such as those worn by Roman notables, would cross the crown of the head. Coronal is a term applied to the bony skeleton and not to the dentition.

coronoid process See mandible.

corpus See mandible.

corpus callosum [L. *corpus*=body and *callosum*=callous (i.e., firm)] The largest bundle of **axons** in the brain of placental mammals. It runs across the midline of the brain and it physically and functionally links the **cerebral cortex** of the left and right **cerebral hemispheres**. The corpus callosum consists of both **myelinated** and unmyelinated axon fibers. In general, as brain size increases among primates, the axons that traverse the corpus callosum increase in diameter and develop a greater degree of myelination to minimize delay in the conduction of nerve impulses between the cerebral hemispheres, but there are no significant differences in axon diameters within the corpus callosum between modern humans and chimpanzees (Caminiti et al. 2009). This suggests that nerve impulses take longer to travel between the cerebral hemispheres in modern humans, which may relate to increased functional lateralization. In addition, several studies in modern humans have reported **sexual dimorphism** in the cross-sectional area of the corpus callosum relative to total brain size. These results have been disputed, and studies of corpus callosum size among common chimpanzees have not revealed a similar pattern of sexual dimorphism.

corpus striatum See striatum.

correlated-age methods See geochronology.

correlation (L. *cor*=together and *relatus*=relate) **Earth sciences** An attempt to relate **strata** that are exposed in two or more different locations within the same, or different, sites. Strata can be compared using the appearance of the fossils they contain or their chemical make-up. For example, **tuff** layers exposed in isolated sediment blocks within the **Koobi Fora** site have been correlated on the basis of their **lithology** and chemistry. This method for stratigraphic correlation is known as **tephrostratigraphy**. **Statistics** A measure of the

amount of association between two variables, such that when one variable changes the other also changes. If the changes are the same then the correlation is perfect, if they are similar the correlation is strong, but if the changes are only a little better than random the relationship is weak. The **correlation coefficient** (r) measures the strength of the relationship. The **coefficient of determination** (or r^2) is a measure of how much of the total variation in y can be explained, or determined, by variation in x . For example, in the case of two variables, if $r=0.8$ then $r^2=0.64$, so knowledge about one of the variables provides the researcher with information that explains approximately 64% of the variation in the value of the other. This is a useful measure, especially when combined with **regression**, for it describes the manner in which x changes in response to any with changes in y . *See also* **correlation coefficient**.

correlation coefficient The correlation coefficient (r) measures the strength of the relationship between two variables with $r=1$ or -1 for a perfectly positive or negative relationship, respectively, and $r=0$ for no relationship. The significance of r varies with the number of observations (N); generally the value of r needs to be high (approximately >0.8 or -0.8) if N is a small number. *See also* **correlation**.

correlation matrix An $n \times n$ square matrix corresponding to a data set with n variables. The value in each cell of the matrix corresponds to the **correlation** between the row and column variable for that cell. The values on the diagonal of the matrix are all correlations of variables with themselves and are thus all equal to one.

cortex [L. *cortex*=bark (i.e., outer covering)] The outer covering, or layer, of a structure or organ (e.g., the outer covering of gray matter of the **cerebral hemispheres**) or the outer layer of dense, or cortical, bone of a limb bone that lies immediately beneath the **periosteum**.

cortical *See* **cortex**.

Coryndon Museum *See* National Museums of Kenya.

cosmogenic nuclide dating Principle At least two versions of this dating method, $^{26}\text{Al}/^{10}\text{Be}$

and $^{10}\text{Be}/^9\text{Be}$, have been applied to dating hominin sites. The principle of the $^{26}\text{Al}/^{10}\text{Be}$ system is that the isotopes ^{26}Al and ^{10}Be are produced in **quartz** when neutrons, protons, and muons penetrate the upper few meters of the Earth, but if sediments are buried at depths greater than 5–10 m (this is why this version is called cosmogenic nuclide *burial* dating) the production of these isotopes ceases. Once the burial has halted the production of new ^{26}Al and ^{10}Be the different decay characteristics of the inherited ^{26}Al and ^{10}Be (the former has a shorter half-life than the latter) cause the ratio of these elements to change over time, thus providing an estimate of how long the quartz has been buried. The principle of the $^{10}\text{Be}/^9\text{Be}$ system is analogous to that of **radio-carbon dating**. Atmospheric ^{10}Be is adsorbed on aerosols then it gets transferred to the Earth's surface via precipitation where it is incorporated into sediments. It decays into ^{10}B with a half-life of $c.1.4$ Ma, and by using ^9Be as a “normalizing species” (Lebetard et al. 2008, p. 3228) the ratio of $^{10}\text{Be}/^9\text{Be}$ in silicate frustules can be used to provide an age for **diatomite** layers. Method ^{26}Al , ^{10}Be , and ^9Be are measured using **accelerator mass spectrometry** (or AMS). Suitable materials Quartz and diatomite. Time range This is determined by the half-lives of ^{26}Al ($c.0.7$ Ma) and ^{10}Be ($c.1.4$ Ma). After 5 Ma the amount of ^{26}Al is $<1\%$ of its original value, and this is too small to measure; thus the time range of the $^{26}\text{Al}/^{10}\text{Be}$ system is $c.1$ Ma to 4 or 5 Ma. The time range of the $^{10}\text{Be}/^9\text{Be}$ system is 0.2 to 14 Ma. Problems There are two sources of uncertainty: measurement uncertainty and uncertainty about the length of the half-lives of ^{26}Al and ^{10}Be . These two sources place a limit of $c.100$ ka on the precision of ages derived using cosmogenic nuclide dating. Examples *See* Partridge et al. 2003, Gibbon et al. 2009.

Cosquer Cave (Location $43^\circ 11' 57''\text{N}$, $5^\circ 27' 07''\text{E}$, France; etym. named after Henri Cosquer, the professional diver who found the site) History and general description Cosquer Cave is unique among **Upper Paleolithic** cave sites in that it is located underwater about 40 m off the French coast near Marseille. The large cave, discovered by divers in 1985, was recognized as an archeological site in 1991 and it has since been explored by a team led by Jean Clottes and Jean Courtin. The isolated environment has provided excellent preservation of a variety of cave art,

mostly painted hands and drawn and engraved animals, including horses, bison, and an assortment of birds. Temporal span and how dated? Conventional **radiocarbon dating** on charcoal from the sediments and from the paintings themselves have suggested two periods of inhabitation, one from 27.5 to 26.5 ka and the other from 19.5 to 18.5 ka. Hominins found at site None. Archeological evidence found at site The excellent cave paintings and engravings are the main feature of this site. Because of the difficulty accessing the cave, excavations have not been attempted. Key references: Geology, dating, and paleoenvironment Clottes et al. 1992, 1997, Clottes 1992; Hominins N/A; Archeology Clottes et al. 1992, 1997, Clottes 1992.

Cossack (Location 20°40'S, 117°11'E, Australia; etym. named after a local village) History and general description In 1972 a hominin partial skeleton was found eroding from a deflating coastal sand dune situated about 3 km/1.8 miles east of Cossack in Western Australia. Temporal span and how dated? The hominin skeletal remains were not suitable for direct dating but shell middens in the immediate area yielded radiocarbon ages of 2000–6500 years BP. Hominins found at site The Cossack individual was a c.40 year-old male *Homo sapiens* whose robusticity and cranial morphology (especially its low frontal and long overall skull length) is similar to the skulls from terminal Pleistocene sites (e.g., **Kow Swamp**, **Cohuna**, and **Coobool Crossing**) in eastern Australia. Archeological evidence found at site Surface scatters of stone artifacts, bone, and shell fragments. Key references: Geology and dating Freedman and Lofgren 1979; Hominins Freedman and Lofgren 1979; Archeology Freedman and Lofgren 1979.

COT Acronym for cost of transport. The cost of transport of an animal is the amount of oxygen it uses to transport a unit of its mass over a fixed distance. It is usually expressed as $\text{ml O}_2 \text{ kg}^{-1} \text{ m}^{-1}$.

Cova del Gegant (Location 41°13'17"N, 1°46'08"W, Catalonia, Spain; etym. Ca. Cave of the Giant) History and general description Cave site on the Mediterranean coast near the city of Sitges, about 40 km/25 miles south of Barcelona. First excavated in 1952 by the Agrupació Muntanyenca de Sitges, and excavations continued through the 1970s and 1980s, partially in an

attempt to save material threatened by the encroaching sea. Temporal span and how dated? **Biostratigraphy** suggests that the sequence in the cave spans between 128 and 40 ka. A recent study has shown that much of the archeological sequence dates between 49.3 ± 1.8 ka, the **uranium-series date** of the overlying flowstone, and 60.0 ± 3.9 ka, the optically stimulated **luminescence** date of the basal deposits. A uranium-thorium date of 52.3 ± 2.3 ka has been acquired on the Neanderthal mandible. Hominins found at site A hominin mandibular corpus was recovered during the first field season in 1952 but was not recognized as such until 2001. The morphology of the mandible, its chronology, and its **Mousterian** archeological context all point to the mandible belonging to *Homo neanderthalensis*. Archeological evidence found at site Around 60 Mousterian stone tools were recovered. Key references: Geology, dating, and paleoenvironment Viñas 1972, Daura et al. 2010; Hominins Daura et al. 2005; Archeology Martínez and Mora 1985.

Cova Negra (Location 38°59'N, 0°32'W, Spain; etym. Ca. Black Cave) History and general description Cave site located on the left bank of the Albaida River in the municipality of Xàtiva in the region of Valencia, Spain, approximately 17 m above the current water level. The initial excavations were carried out by G. Viñes from 1928 to 1933, the next phase by Fusté was from 1953 to 1958 and the third phase by V. Villaverde from 1981 to 1991. Cova Negra provides one of the most complete late Pleistocene stratigraphic sequences in Spain, and it has yielded numerous remains of *Homo neanderthalensis*, including abundant juvenile specimens. Archeological evidence from Cova Negra indicates sporadic, short-term hominin occupations of the site (Arsuaga et al. 2007) that has been interpreted as indicating a high degree of mobility among Neanderthals. Temporal span and how dated? **Thermoluminescence dating** produced remarkably old ages for the oldest layers, 235 ± 21 ka, but these ages are inconsistent with the **biostratigraphic** evidence, which suggests the most recent levels at the site are 50 ± 8 ka. Hominins found at site Twenty-four hominin fragments have been recovered from the three excavation phases, although many specimens lack precise stratigraphic information due to older imprecise excavation and recovery practices. The parietal bone originally described by Fusté (1953)

was attributed to *H. neanderthalensis*, and while some subsequent authors have judged it to be a “pre-Neanderthal”, the combined chronological, archeological, and morphological evidence is consistent with the initial judgment. Archeological evidence found at site The recovered artifacts are **Mousterian** in character and they are surprisingly uniform throughout the different levels; the majority of the artifacts are side **scrapers**. Key references: Geology, dating, and paleoenvironment Arsuaga et al. 2007; Hominins Fusté 1953, Arsuaga et al. 1989, 2007; Archeology Villaverde and Fumena 1990.

covariance A measure of association between two variables similar to **correlation** in which positive values indicate that an increase in one variable is associated with an increase in the other, and negative values indicate that an increase in one variable is associated with a decrease in the other, and the magnitude of the covariance indicates the strength of the association. Unlike correlation, covariance can take on any value and is not limited to the range -1 to 1. Correlation is actually a scaled version of covariance; the **correlation coefficient** for two variables is equal to their covariance divided by the standard deviation of the first variable and the standard deviation of the second variable. The covariance of a variable with itself is equal to the **variance** of that variable.

covariance matrix An $n \times n$ square matrix corresponding to a data set with n variables. The value in each cell of the matrix corresponds to the **covariance** between the row and column variable for that cell. The values on the diagonal of the matrix are all covariances of variables with themselves and are thus each equal to the **variance** or the corresponding variable.

covariation A concept similar to **variation**, covariation refers to how two variables change in response to each other. Covariation is typically measured as **covariance** or **correlation**.

coxa (L. *coxa*=hip, or hip bone, or hip-joint) An old-fashioned term that is best avoided. The proper name for the “hip bone” is the pelvic bone. *See also anatomical terminology.*

CPR Abbreviation for Ceprano. *See Ceprano 1.*

Cradle of Humankind World Heritage Site

Located in South Africa, this World Heritage Site includes important karstic early hominin sites (e.g., Cooper’s, Drimolen, Gladysvale, Gondolin, Kromdraai, Malapa, Sterkfontein, and Swartkrans), which are clustered to the southwest of Pretoria and to the northwest of Johannesburg in the province of Gauteng. This area was declared a World Heritage Site in 1999 thanks in large measure to the advocacy and persistence of Phillip Tobias and his South African colleagues. Subsequently, the sites of Makapansgat and Taung were added as components of the World Heritage Site. There is a fine interpretative center at Maropeng, near Sterkfontein.

crania (Gk *kranion*=brain case) Plural of **cranium**.

cranial (Gk *kranion*=brain case) Used informally for fossils of the bony skull and dentition. When used formally it refers to structures that are in the direction of the head; the opposite of **caudal**.

cranial base (Gk *kranion*=brain case and L. *basis*=base) This term is synonymous with the more formal term **basicranium** (*which see*).

cranial base angle (Gk *kranion*=brain case and L. *basis*=base) (or CBA) Quantifies the angular relationship between the two major (anterior and posterior) components of the **basicranium** in the sagittal plane. Various landmarks have been used to capture this relationship, but they are all variants on Huxley’s use of nasion–prospenion–basion (Huxley 1867). Some use a different anterior landmark (e.g., the anterior cribriform point; Scott 1958) and others a different middle landmark (e.g., the “pituitary point”; Cameron 1927), but the choice of basion as the posterior landmark is standard. Lieberman and McCarthy (1999, Table 1, p. 490) provide a summary of the various combinations of landmarks that have been used to measure the CBA. The anterior portion of the basicranium is derived from the prechordal (the part anterior to the end of the notochord) portion of the embryonic cranial base and the posterior cranial base is formed by the parachordal (the part alongside the notochord) part of the embryonic cranial base. The anterior component

comprises the ethmoid, the posterior part of the frontal, and the anterior part of the sphenoid body, and underlies the anterior cranial fossa. The posterior component comprises the posterior portion of the sphenoid body and the basioccipital, and underlies part of the posterior cranial fossa. The transverse “hinge” (i.e., the place where the anterior and posterior components of the basicranium meet) is the mid-sphenoidal synchondrosis, which is in the floor of the hypophysal fossa. The region beneath and between the two components of the basicranium is occupied, from posterior to anterior, by the oropharynx, nasopharynx, and part of the nasal cavity. Numerous factors influence the CBA, including the volume of the brain relative to the area of the cranial base, the length of the face, the size of the pharynx, and the relationships that must be maintained to ensure that the eyes point forwards during normal posture. Among the extant great apes and modern humans the average CBA is most acute in modern humans (mean \pm SD = $135 \pm 3.1^\circ$ in adult modern human crania) compared with adult chimpanzees ($157 \pm 4.9^\circ$) and adult bonobos (approximately 148°). The CBA changes during ontogeny; so, for example, in modern humans the CBA is 143° in neonates and then flexes (becomes more acute) during the first 2 years of postnatal life. This differs from the ontogenetic changes in non-human primates, in which the cranial base extends (becomes more acute) throughout ontogeny. Few fossil hominin crania are complete enough to be able to make a reliable estimate of the CBA, but what evidence there is suggests there is much variation in CBA among hominins depending on relative face size, brain size, and other factors. In pre-modern *Homo* taxa such as *Homo neanderthalensis* the CBA is approximately 15% more obtuse than in anatomically modern humans. Lieberman et al. (2000) provide a review of the comparative context and significance of the CBA in fossil hominins. See also **basicranium**; **chondrocranium**.

cranial base flexion See **cranial base angle**.

cranial fossa(e) See **basicranium**.

cranial vault (Gk *kranion*=brain case and L. *volvitus*=arched) The roof and side walls of the **cranium**. Formed from a pair of flat bones, the parietals, the flat or squamous parts of the two

temporal bones, and the squamous parts of the frontal and occipital bones. Vault bones have an inner and an outer layer of compact bone called the inner and outer tables and an intervening layer of spongy bone filled with red bone marrow, the **diploë**; this type of “layered” structure is said to minimize deformation and maintain a “low-strain” environment (Herring and Teng 2000). The **meningeal arteries** supply the vault bones and the diploic veins drain blood from the bones of the cranial vault to **dural venous sinuses** internally and also to veins on the external surface of the cranium. Veins that pass through the cranial vault and which thus connect the endocranial veins (i.e., the veins on the inside of the cranial vault) to the pericranial veins (i.e., the veins on the outside of the cranial vault) are called **emissary veins** and they run through **emissary foramina** (syn. **calvaria**).

cranial venous drainage (Gk *kranion*=brain case and L. *vena*=vein) Two venous systems drain the head. The intracranial system drains venous blood from the tissues that lie *inside* the bones of the **cranium** (e.g., the brain and the covering meninges) and from the cranial bones themselves. The extracranial system drains venous blood from the tissues that lie *outside* the bones of the cranium (e.g., the soft tissues of the scalp and face). The **intracranial venous system** is divided into two components: an internal and an external. The internal one consists of the deep cerebral veins that do not leave any trace on the bones of the cranium. The external component of the intracranial venous system consists of superficial cerebral veins that drain the surface of the brain, and these, in turn, drain into a system of venous channels called the **dural venous sinuses** that run between the fibrous and endosteal layers of the **dura mater**, the outer of the three meningeal layers. Importantly for paleoanthropology these dural venous sinuses do leave impressions on the inner, or **endocranial**, surface of the bones of the cranium. The venous sinuses that are of most concern to paleoanthropologists are the superior sagittal sinus that drains most of the blood from the superior surface of the brain and the dural venous sinuses within the posterior cranial fossa; namely the transverse, sigmoid, occipital, marginal, and petrosquamous sinuses. The transverse sinus runs from the midline laterally in the base of the tentorium cerebelli in a groove

on the internal surface of the **squamous** part of the **occipital**. In most modern humans and in the vast majority of chimpanzees and gorillas (Kimbel 1984) the venous blood draining the deep structures of the brain forms the deep cerebral veins that normally drain into the left transverse sinus and the superior sagittal sinus drains into the right transverse sinus. Each transverse sinus drains into a sigmoid sinus that runs inferiorly in a sigmoid-shaped groove from the lateral end of the transverse sinus to the superior jugular bulb, which marks the beginning of the internal jugular vein. This pattern of dural venous sinuses is known as the **transverse-sigmoid system** and individuals (e.g., **KGA 10-525**) with transverse and sigmoid venous sinuses on both sides are said to show transverse-sigmoid system dominance. In just a few percent of modern humans the venous blood from the brain takes a different route. Instead of draining into the transverse sinuses, the deep cerebral veins and the superior sagittal sinus drain into an enlarged midline occipital sinus, which runs down from the cruciate eminence towards the foramen magnum in a midline groove. The occipital sinus drains into uni-, or bilateral, marginal sinuses, which run(s) around the margin(s) of the posterior quadrants of the foramen magnum to drain into the superior jugular bulb and/or the **vertebral venous plexuses**. This is known as the **occipito-marginal system** of venous sinuses and individuals with a substantial occipital sinus and with marginal venous sinuses on both sides (e.g., **OH 5**) are said to show occipito-marginal system dominance. Some individuals (e.g., **A.L. 333-45** and **KNM-ER 23000**) have a transverse-sigmoid system of venous sinuses on one side and an occipito-marginal system of venous sinuses on the other, and a few individuals (e.g., **Taung I**) have been reported to show coexistence of the two systems on the same side (Tobias and Falk 1988). The petrosquamous sinus links the sigmoid sinus with the extracranial venous system (see below) and when present it occupies a groove that runs along the endocranial surface of the temporal bone at the junction of the squamous and **petrous** parts of the temporal bone. The extracranial venous system consists of four main external veins; from anterior to posterior they are the facial, superficial temporal, posterior auricular, and occipital veins. The facial drains into the internal jugular vein, the superficial temporal into both the internal and external jugular veins, the

posterior auricular mainly into the external jugular vein, and the occipital into both the internal jugular and the vertebral veins. None of the veins of the extracranial venous system leave any trace on the cranium. A system of **emissary veins** (plus some venous sinuses such as the petrosquamous sinus) connects the intra- and extracranial venous systems by passing through small foramina in the walls of the cranium. The first researcher to suggest that the pattern of intracranial venous drainage may have some taxonomic valency was Tobias (1967), who pointed out that **OH 5** showed clear evidence of occipito-marginal system dominance. Falk and Conroy (1983) followed this up with observations about the cranial venous drainage in *Australopithecus afarensis*, and subsequently Falk (1986, 1988b) suggested the incidence of occipito-marginal system dominance in *Paranthropus boisei* and *Au. afarensis* was 100%. Since then it has become clear that, while the incidence of occipito-marginal system dominance is distinctively higher in *P. boisei*, *Paranthropus robustus*, and *Au. afarensis* (Wood and Constantino 2007, Kimbel and Deleuzene 2009), cranial venous drainage is a **polymorphism** and the presence or absence of one system or the other cannot be used as a definitive taxonomic marker.

cranial venous sinuses See cranial venous drainage.

cranium (Gk *kranion*=brain case) The term used for a **skull** minus its **mandible**. In one scheme the **cranium** is divided into the **neurocranium** and the **viscerocranium**. The viscerocranium is the part of the cranium that covers the anterior aspect of the **brain** and it is equivalent to the **face** including the upper jaw. The viscerocranium develops from a combination of the frontonasal process and the first pharyngeal arch; all of its components derive from cells that come from the neural crest. The neurocranium consists of the bony elements that surround the brain and the special sense organs. It develops from the paraxial mesenchyme (i.e., the first five somites and the somite-like material rostral to the first somite) with a contribution from the neural crest. Another way to think of the cranium is that it consists of the **calvaria** (or cranial vault), the **face**, and the **basicranium**. See also **endocranial cavity**.

cribriform plate (L. *cribrum*=a sieve) Small, bilateral, perforated plates of bone that are part of the ethmoid bone. They are rectangular, with their long axis oriented anteroposteriorly, and are situated on either side of the midline *crista galli* in the depressed medial part of the floor of the anterior cranial fossa. The perforations transmit the nerves connecting the olfactory receptors in the nasal cavity with the olfactory bulbs that lie beneath the frontal lobes of the brain.

crista anterior The term used by Remane (1960) for an enamel crest on the crowns of the maxillary postcanine teeth that others call the *epicrista* (*which see*).

crista galli (L. *crista*=crest and *gallus*=a Gaul. Early anatomists thought the *crista galli* resembled the emblem on a Gallic soldier's helmet.) A midline crest on the **endocranial** surface of the ethmoid in the floor of the anterior cranial fossa. It marks the anterior attachment of the falx cerebri, a fold made up of the fibrous layer of the dura mater that lies between the parts of the cerebral hemisphere not joined by the **corpus callosum**.

crista nova The term used by Remane (1960) for a crest that others call the **mesial marginal ridge** (*which see*).

crista obliqua The term used by Remane (1960) for an enamel crest on the crowns of the maxillary postcanine teeth that others call the **distal trigon crest** (*which see*).

crista occipitomastoidea *See* occipitomas-toid crest.

crista paramastoidea (L. *crista*=crest, Gk *para*=beside, *mastos*=breast, and *oides*=shape. Literally "a crest beside the mastoid process") In some crania the **occipitomas-toid crest** is separate from another more lateral structure, which Franz **Weidenreich** (in his description of the Solo calvariae; Weidenreich 1951, p. 280) referred to as the *crista paramastoidea*. *See* **juxta-mastoid eminence**.

crista transversa The term introduced by Selenka (1898/1900) for an enamel crest on the crowns of the maxillary molar teeth that others call the **distal trigon crest** (*which see*).

crista transversa anterior The term used by Korenhof (1960) for an enamel crest on the crowns of the maxillary postcanine teeth that others call the *epicrista* (*which see*).

critical function This term was introduced by Rosenberger and Kinsey (1976) for the morphological counterpart of the ecological concept of **fallback foods**. It refers to morphology that enables an animal to process its fallback food(s) as opposed to its preferred foods. For example, it has been suggested that the distinctive **anterior pillars** of the face of *Australopithecus africanus* may be an adaptation to allow the premolars to be used for processing hard objects too large to be accommodated between the molars.

CRL Acronym for the **Cenozoic Research Laboratory** (*which see*).

Cro-Magnon (Location 44°56'N, 1°00'E, France; etym. local French name for the cliff and rock-shelter, originally written as "Cramagnon" on the public register of land boundaries) History and general description The site of Cro-Magnon was discovered in 1868 when a road crew was moving large blocks of limestone from the talus slope at the base of the steep cliffs lining the Vézère river just outside of the village of Les Eyzies. Édouard Lartet, a lawyer turned paleontologist and archeologist, excavated and described the 17 m-wide cave, which was shallow and low-ceilinged and only about 6 m from the mouth to the rear wall and 4 m from the base of the deposit to the stone ledge that made up the ceiling of the cave. Except for a small area at the back of the cave it was filled with sediment. Lartet recognized several archeological layers with animal bones, flint tools, and distinct hearths. The cave was excavated prior to the naming of the various tool technologies, so the layers were not linked with any particular stone tool industry. The modern human fossils found at the site were among the first in Europe, and thus gave rise to the term "Cro-Magnon Man." Temporal span and how dated? 25–30 ka based on correlation with **Abri Pataud**. Hominins found at site Several modern human skeletons were found at the back of the cave in the top-most archeological layer. The area contained the remains of five individuals. The most famous is the "Old man of Cro-Magnon" (**Cro-Magnon 1**), but within a 1.5 m-radius circle around this individual

they also found the remains of a female (Cro-Magnon 2), a perinatal infant (Cro-Magnon 5), and two more remains, likely males (Cro-Magnon 3 and 4). Lartet (1868) and subsequent researchers (e.g., Vallois and Billy 1965a) have interpreted the restricted area of the fossils as evidence of either a single burial or repeated use of a burial area. The skeletons were found on and just below the surface in the back of the cave, but the skulls were filled with calcrete and covered in a stalagmitic crust that continued towards the front of the cave and was covered by calcareous deposit that filled the front of the cave. Archeological evidence found at site Lartet (1868) mentions that scrapers make up the majority of the stone tools in the main archeological layers (which he labels F, G, and H) and that layer H contained several **bone tools**, including what he called punches and arrowheads (*pointçons* and *flèches*). Layer I, the layer in which the skeletons were found, was quite thin and contained no hearths, but it did yield a variety of stone tools, animal bones, bone tools, and amulets. Rivière (1897) excavated more of the site, and found what he determined were undisturbed **Magdalenian** layers, including several pieces of engraved bones. Pittard (1963) noted some tools that are typical of the Gravettian in a private collection of tools that were collected from the yard of the house next to the site. Key references: Geology and dating Movius 1969a; Hominins Broca 1868, Lartet 1868, Vallois and Billy 1965a, 1965b, Dastugue 1967, Vallois 1970; Archeology Lartet 1868.

Cro-Magnon 1 Site Cro-Magnon. Locality Layer I. Surface/in situ *In situ*. Date of discovery March 1868. Finder Édouard Lartet. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon None. Geological age *c.*25–30 ka. Developmental age *c.*50 years. Presumed sex Male. Brief anatomical description This specimen comprises a nearly complete skull that lacks all but the right M²; the rest of the dentition was lost post-mortem. Several postcranial elements, including robust femora and a tibia, were assigned to this individual, but the association between cranial and postcranial material from this site is much debated. Announcement Lartet 1868. Initial description Broca 1868. Photographs/line drawings and metrical data Vallois and Billy 1965a, 1965b. Detailed anatomical description Vallois and Billy 1965a, 1965b. Initial taxonomic

allocation *Homo sapiens*, “Cro-Magnon race” (Quatrefages and Hamy 1874). Taxonomic revisions None. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance This was among the first fossil evidence of *Homo sapiens* recovered in Europe. Location of original **Musée de l’Homme**, Paris, France.

Cro-Magnon 2 Site Cro-Magnon. Locality Layer I. Surface/in situ *In situ*. Date of discovery March 1868. Finder Édouard Lartet. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon None. Geological age *c.*25–30 ka. Developmental age *c.*20–30 years. Presumed sex Female. Brief anatomical description This fragmentary calvaria includes parts of the face and maxilla, including the right M¹ and M². A few postcranial elements have been assigned to this individual, but the exact association between the cranial and the postcranial material from this site is much debated. Announcement Lartet 1868. Initial description Broca 1868. Photographs/line drawings and metrical data Vallois and Billy 1965a, 1965b. Detailed anatomical description Vallois and Billy 1965a, 1965b. Initial taxonomic allocation *Homo sapiens*, “Cro-Magnon race” (Quatrefages and Hamy 1874). Taxonomic revisions None. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Much has been made of a minor scratch and fracture of the frontal bone, which Lartet and later Broca argued was made by a flint tool (Broca 1868, Lartet 1868), possibly due to violence or post-mortem defleshing. More recently researchers have suggested this was much more likely to be damage caused during excavation (Vallois and Billy 1965a, 1965b, Dastugue 1967, Vallois 1970). Location of original **Musée de l’Homme**, Paris France.

Cro-Magnon Man *See* Cro-Magnon.

Crocota (*L. crocuta* = literally the “saffron-colored one.” The term was said to have been used by Pliny the Elder to refer to a wild animal in northern Africa.) The **genus** name of the modern spotted hyena, *Crocota crocuta*, a member of the family **Hyaenidae**. These bone-crunching **carnivorans** are common and distinctive members

of the modern African fauna and extinct forms of hyena have been implicated in the bone **commi-nution** seen at some archeological and hominin paleontological sites. Thus hyenas may have been an important competitor for the earliest tool-making and tool-using hominins. *Crocuta* probably diverged from the true hyenas of the genus *Hyena* and first appears in the African fossil record in the late **Pliocene**.

Cromerian See glacial cycles.

cross-section Section normally taken at right angles to the long axis of a bone or a tooth. Cross-sections of teeth can also be in any plane that can be consistently located among observers.

cross-sectional data Data collected from many subjects at a single point in time. This type of “broad-swath” sampling aims to gather information from large numbers of individuals of similar or different ages and character states. It is used to acquire information about, and is considered representative of, the larger population from which the sample is drawn. **Longitudinal data** (derived from measurements taken from a series of observations on a single individual or group of individuals) are preferable to cross-sectional data for studies that wish to examine how individuals change over time, but for obvious reasons this type of data is more difficult to collect.

cross-sectional geometry (or CSG) A method for investigating the mechanical adaptations of bones, based on mechanical engineering formulae used for modeling the bending stress experienced in straight beams under static (non-moving) loads. A section of a bone is taken at a specified location (e.g., midshaft, 66% of the length from the proximal end, etc.) and in a plane perpendicular to the long axis of the bone. Sections can be obtained either by physically sectioning the bone or by medical imagery such as computed tomography scans or magnetic resonance imaging (in living people), or by tracing the external (periosteal) surface of the bone and approximating the thickness of the cortical walls and the approximate endosteal surface by means of two radiographs of the bone taken at a right angles to each other [generally anteroposterior (AP) and mediolateral (ML)]. Once the periosteal and endosteal contours of the section have been obtained, most

techniques model the space between the two contours as cortical bone of uniform mechanical properties. Using software such as SLICE (Nagurka and Hayes, 1980) or Sylvester et al.’s (2010) routine in R, a series of properties of the cross-section are then calculated including the centroid of mass [computed as the average (x, y) coordinate of each unit of area of cortical bone in the section], the total area (or TA) (i.e., the total area circumscribed by the periosteal contour), the medullary area (or MA) (i.e., the area circumscribed by the endosteal membrane), the cortical area (or CA) (i.e., the area occupied by cortical bone, calculated as TA–MA), the percentage of cortical bone in the section (%CA) [calculated as $100 \times (CA/TA)$], and a series of second moments of area. Each second moment of area captures the rigidity of the section and is partially proportional to that section’s ability to resist deformation under bending loads. Despite this imperfect proportionality with rigidity, second moments of area are often used in the literature as proxies for the strength of the bone. Second moments of areas are calculated around axes constrained to pass through the centroid of mass of the section; this is the case for straight beams but not necessarily the case for bones, which are rarely perfectly straight. Each second moment of area is calculated as the sum of each unit of area in the section occupied by cortical bone multiplied by that part of the area’s distance to bending axis squared. This gives the bone located farthest away from the bending axis exponentially more ability to resist bending than bone located close to the axis; bone located directly in the axis of bending has no ability to resist bending. Commonly used second moments of area include I_{xx} (the second moment of area around the x axis, generally set to equal AP bending), I_{yy} (the second moment of area around the y axis, generally set to equal ML bending), I_{max} (the maximum second moment of area of the section, whether it occurs along an AP, ML, or other direction), I_{min} (the minimum second moment of area of the section, which is always positioned 90° from I_{max}), and \mathcal{J} , the polar moment of area, which captures twisting around an axis perpendicular to the plane of the section and running through the centroid of mass (i.e., twisting about the long axis of the bone). \mathcal{J} is proportional to the sum of any two perpendicular second moments of area of the section (i.e., $\mathcal{J} = I_{xx} + I_{yy} = I_{max} + I_{min}$). Some additional properties are also occasionally calculated, including theta (Θ), the angle between the y axis and the direction of I_{max} , and additional

distance measures from the centroid of mass to the most distant point of bone in each of the bending axes to be considered. One must divide a second moment of area by that distance to compute the section modulus (Z) in the direction of bending; the section modulus, rather than the second moment of area, is the key aspect of the geometry of a section that determines its resistance to deformation under a bending moment. Once the cross-sectional properties have been calculated they have to be standardized for body size and shape to compare the strength relative to size of different individuals or populations. Several adjustments have been proposed to control for size; the best currently available divides areas (CA, TA, and MA) by body mass and second moments of area by the product of body mass times the bone's length (Ruff 2008). Ideally one should use section moduli rather than raw second moments of area, but this has rarely been done in the anthropological literature. One exception was Ruff's (1995) research on a sample of femora in which he found that the polar section modulus (Z_p) of a sample of femora could be approximated as $Z_p = (F)^{0.73}$; dividing Z_p by the product of body mass times bone length then provides a better approximation of the relative rigidity of the bone, albeit with the disadvantage of ignoring individual variation in the ratio of the length of the outermost piece of bone to the second moment of area. The drawbacks of CSG analysis stem from the fact that virtually all of its assumptions can be violated (e.g., the neutral axis may not pass through the centroid of mass or the bones do not bend in the direction one might expect based on their external form), thus rendering calculations based on that assumption inaccurate (Demes et al. 2001, Lieberman et al. 2004, Demes 2007). Also the various mechanical properties of bone may vary across a section, along the axis of a bone, and between individuals, thus leading to further inaccuracies (Currey 2002, Wang et al. 2010). With respect to inferences about recent activity patterns from bones there is reason to suspect that the plasticity of bones to given levels of activity varies across the life span and by location in the limb, thus adding additional levels of complexity to inferences about activity patterns based on CSG (see Lieberman et al. 2003, Pearson and Lieberman 2004, Ducher et al. 2009). Some researchers minimize the import of these complications (e.g., Ruff et al. 2006) but little empirical evidence has been offered to justify such a dismissal. Computer-aided studies of CSG, which became common in the mid-1980s, have produced insights into hominin functional anatomy. These

include evidence of a strong pattern of gracilization from archaic through modern *Homo* (Ruff et al. 1993, 1994, 1997); evidence of diachronic changes in bilateral asymmetry of the upper limb, with *Homo neanderthalensis* and early Upper Paleolithic humans having a stronger right than left upper limb (Trinkaus et al. 1994, Churchill and Formicola 1997); evidence that the marked sexual dimorphism in I_{xx} of the femur and tibia in many hunter-gatherer societies largely disappears in industrialized societies (Ruff 1987); evidence of a marked decline in mobility from late archaic *Homo* and early modern humans to recent times (Trinkaus and Ruff 1999a, 1999b, Holt 2003); and evidence that hip proportions, especially bi-acetabular breadth and femoral neck length, may account for some of the differences in morphology between *Homo erectus* and modern human femora and perhaps other otherwise unexplained anomalies such as the round femoral midshaft sections of Neanderthals and the Tyrolean Iceman (Ruff 1995, Ruff et al. 2006).

cross-striations (L. *stria*=furrow) **Short-period incremental lines** (i.e., **circadian**) in enamel running at approximate right angles across the long axis of **enamel prisms**, best seen under polarized light and with a typical spacing of 3–6 μm in hominoids (reviewed in Boyde 1989, Smith 2006). They reflect a 24-hour cycle of ameloblast secretory activity that can be used to determine the daily secretion rate of enamel. Cross-striations are equivalent to **von Ebner's lines** in dentine (Dean 1998b). *See also enamel development.*

cross-validation A form of **resampling** that is used to evaluate how well predictive models perform for known cases. In particular, cross-validation is useful for identifying when models are "overfit" with respect to a particular data set (i.e., when predictions are thought to be *more* accurate than they actually are because the efficacy of a model is highly dependent on the data set used to generate it). Cross-validation has been used heuristically in human evolutionary research, but typically it is not used for hypothesis testing. In predictive models such as **regression** or **discriminant function analysis**, portions of the data set are sequentially held back during the initial calculation and then predictions from the model are compared to the subset that was *not* included in the generation of the model. In this way the model is not influenced by the data

to be predicted and the **accuracy** and **precision** of predictions derived from the model can be assessed. A common application of cross-validation leaves each observation out in turn, predicts it from the resulting model, and calculates an overall measure of success; see Smith (2002) for other variants. For example, to investigate how well a regression predicts body mass from one or more variables, an investigator could calculate the regression using all but the first specimen, then calculate the difference between the predicted value and the actual value of the first specimen. This is repeated for the second, third, etc. specimen, enabling a metric of success to be calculated (for example, the standard deviation of differences, proportion of predictions within 20% of the actual value, the proportion of predictions that fall outside of a 95% prediction interval, etc.). Similarly, cross-validation can be used to evaluate the success of categorical predictions, for example as in the use of discriminant function analysis to predict habitat categories based on bovid skeletal metrics (DeGusta and Vrba 2003, Kovarovic and Andrews 2007). In general, cross-validation is not necessary in simple (bivariate) regression or for linear discriminant functions, but it becomes important to consider its use as more variables are added to multiple regression analyses or when quadratic discriminant function analysis is used. Because in these cases the models fit more tightly to the data, the possibility that the models are overfit with respect to the data becomes a concern. *See also* **discriminant function analysis**.

crossing over *See* recombination.

crown (L. *corona*=crown) The part of a tooth covered by enamel and which, after eruption, projects above the surrounding alveolar bone. It is made up of an outer enamel cap and an inner core of dentine. The rest of a tooth, made of dentine and embedded in the bony alveolus, is called the root. The boundary between the crown and the root on the surface of the tooth is called the cervix or the cemento-enamel junction (or CEJ), and the boundary between the crown and the dentine within the tooth is called the enamel-dentine junction (or EDJ).

crown area *See* crown base area.

crown base area A measure of the surface area of a **tooth** crown mainly used for **postcanine teeth**. It has most often been expressed as the

two-dimensional area of the base of the crown, rather than a three-dimensional estimate of the functional occlusal area. Crown base area has been either computed from the product of the maximum buccolingual breadth and the mesiodistal length of the crown, or measured using a device that can calculate the surface area of an area based on tracing its perimeter.

crown completion Developmental stage signified by the completion of the last-formed enamel covering the crown of a tooth so that extension of enamel formation towards the cervix and secretion of enamel matrix onto the crown surface are complete on all aspects of the tooth. It is identified radiographically when a spicule of root has formed beyond the cervix on the mesial or distal aspect of a tooth and histologically **enamel development** has completely ceased on the buccal or lingual aspects of a crown. In multicusped teeth this may be especially confusing as completion occurs in different cusps at different times and may even occur after the stage of root bifurcation in some hominid molars and premolars; the sectorial P₃ of great apes being an example (e.g., Beynon et al. 1998). It can also be assessed by scoring the distinctive developmental stages [A–H (Demirjian et al.) or 1–14 (Moorrees et al.)] from cuspal initiation through to crown completion (e.g., Moorrees et al. 1963, Figs 1 and 2; Demirjian et al. 1973).

crown formation time (or CFT) The time it takes to develop the whole of a tooth crown; i.e., from the onset of **amelogenesis** at the tip of the first (or only) **cuspal** to be formed to the end of amelogenesis at the cervix (the future **cemento-enamel junction**) of the last cusp to form. The same principle can be applied to the time it takes to form a single cusp of multi-cusped teeth but cusp-specific or total crown formation times should not be confused. Crown formation time is typically estimated through counts (Risnes 1986, Boyde 1990) of the **cross-striations** and **striae of Retzius** in the **cuspal enamel** (i.e., **appositional enamel**) and lateral enamel (i.e., **imbricational enamel**) (e.g., Beynon et al. 1991). *See also* **enamel development**.

crown group (Gk *koronos*=curved, refers to the round wreath on the very top of the head, hence the meaning of the “highest” taxon) A term introduced by Jefferies (1979) for the smallest subset of sister **taxa** within a **clade** or **monophyletic**

group that includes the living taxon, or taxa, within that clade. For example, the crown group of the **hominin** clade is the (*Homo sapiens*, *Homo neanderthalensis*) subclade.

crown module A compound variable used in dental metrical analysis. It is half the sum of the maximum mesiodistal length and the maximum buccolingual breadth of a tooth crown $(MD+BL/2)$. It was used by Middleton Shaw (1931) in his monograph on the **gnathic** morphology of the modern Bantu, by Robinson (1956) in his monograph on the dentition of the southern African hominins, and by Tobias (1967, 1991).

crude birth rate The number of births observed within in a year divided by the living population size at mid-year. Often written simply as *b*, the crude birth rate is expressed per unit time, usually a year, much as automobile speeds are given as distance traveled per time. But unlike automobile speeds (i.e., rates), *b* cannot be measured in terms of distance traveled, so instead it is measured in terms of the number of births per mid-year population size. In **paleodemography**, where the number of births within a year and mid-year population size cannot be directly observed, the crude birth rate is defined as the number of births per population size per year. This rate can be multiplied by 100 and given as a percentage, or by 1000 when the measure is per 1000. The use of “crude” is to distinguish this rate from the “age-specific fertility rate” as well to note that the rate is per population without specifying females. Consequently, the crude birth rate expresses the number of births per population, where much of the population is not at risk of giving birth (either because they are males or because they are pre- or post-reproductive females). Together with the **crude death rate**, the crude birth rate defines the intrinsic rate of increase of a population.

crude death rate The number of deaths observed within a year divided by the living population size at mid-year. The crude death rate, *d*, is expressed per unit time, usually a year, much as automobile speeds are given as distance traveled per time. But unlike automobile speeds (i.e., rates), *d* cannot be measured in terms of distance traveled, so instead it is measured in terms of number of deaths per mid-year population size. In

paleodemography, where the number of deaths within a year and mid-year population size cannot be directly observed, the crude death rate is defined as the proportion of a population that dies per year. This rate can be multiplied by 100 and given as a percentage, or by 1000 when the measure is per 1000. “Crude” is used to distinguish this rate from the “age-specific death rate.” Together with the **crude birth rate**, the crude death rate defines the **intrinsic rate of increase** of a population. *See also* **death rate, age-specific**.

crural index (*L. cruralis*=leg) The lower-limb equivalent of the brachial index; the ratio of the lengths of the tibia and femur, calculated as $100 \times (\text{tibia length} / \text{femur length})$, thus it measures the relative length of the leg. Among primates, the crural index varies by locomotor strategy and climate. The long-limbed terrestrial quadrupeds have disproportionately elongated **distal** elements (high crural indices). The distal elements are the narrowest and therefore the lowest-mass portions of the lower limbs, thus by elongating the distal part of the lower limb it minimizes the energetic costs of accelerating and decelerating the lower limbs during gait. Elongating the distal portion of the lower limb also increases the surface-area-to-volume ratio, which improves the ability to lose heat in hot, dry climates. Thus, short legs are more effective at retaining heat, and low crural indices are characteristic of taxa, including *Homo neanderthalensis*, that live in cold climates. *See also* **brachial index**.

crypt *See* **dental crypt**.

Crystal Tuff An **ignimbrite** eruption found over a large area in the **Ethiopian Rift System**. Dated at 3.56 ± 0.03 Ma (WoldeGabriel et al. 1992) it is a likely source for the **Kilaytoli Tuff** that is exposed in the **Woranso-Mille study area** and the **Lokochot Tuff** that is exposed in **Koobi Fora**. It is also the more general name for any fine-grained volcanic ash deposit containing a significant proportion of crystals from the parent magma.

CSF Abbreviation of **cerebrospinal fluid** (*which see*).

CSLM Acronym for **confocal scanning light microscope**. *See* **confocal microscopy**.

CT Acronym for **computed tomography** (*which see*).

CT-number scale overflow One of several technical problems involved in the data-acquisition stage of **computed tomography** (or CT). The CT-number scale ranges from -1000 to $+3095$ Hounsfield units: water has the value 0 and air -1000 . This means that the maximum X-ray attenuation coefficient is about four times that of water. When CT is used clinically this limit is reached by dense bone and enamel, but in fossils in which minerals of high atomic number have penetrated the bone during fossilization this can cause this limit to be surpassed. For example, the **Kabwe 1** cranium has been infiltrated with lead and zinc ore and the CT scans register 5000–6000 Hounsfield units, and the rock matrix in the **Gibraltar 1** cranium causes the CT scans to register between 2250 and 3150 Hounsfield units. When scanning small fossils such as single teeth there is a great risk of CT-number scale overflow as there is hardly any **beam-hardening** (i.e., most soft X-rays reach the detector, resulting in high attenuation coefficients). CT-number scale overflow manifests itself in different ways. In most cases CT-numbers over 3095 will be reconstructed as 3095 (the maximum value). This “white overflow” can lead to errors in distance measurements. In some CT scanners the CT scale is duplicated above 3095 (i.e., it reverts to -1000 and the sequence starts over again). This is called “black overflow” because it registers as black areas on the image.

Cueva de les Malladetes *See* Malladetes.

Cueva de Nerja (Location $36^{\circ}45'54''\text{N}$, $3^{\circ}50'30''\text{W}$, Spain; etym. Sp. *cueva*=cave and Nerja=the name of the nearby city) History and general description This extensive cave complex is located in the town of Maro, 3 km/1.8 miles from Nerja, in the province of Málaga, Spain. The caves lie on the slopes of the Sierra Almijara Mountains and since the cave was discovered by speleologists in 1959 the site has been under organized excavation and exploration but recent work has focused predominantly on the geological context. The cave is over 4 km/2.4 miles long but the only evidence of human habitation is near the opening where there is extensive evidence of anatomically modern human occupation including burials and artwork. Temporal span and how dated? The site preserves an intact sequence through the **Upper Paleolithic**

to the Chalcolithic. Conventional **radiocarbon dating** suggests the Upper Paleolithic is *c.*16,500 years BP and the Epipaleolithic is between 13,300 and 8770 years BP: an anatomically modern human skeleton from the Epipaleolithic level has been dated to 6800–7600 years BP. The Neolithic ranges from 7390 to 4950 years BP and the Chalcolithic ranges from 3750 to 2750 years BP. Hominins found at site Many fragmentary anatomically modern human remains were found in most levels. A well-preserved skeleton of a young woman was found in the Epipaleolithic levels (García Sánchez 1986). Several intact burials were found in the Solutrean level, but these fossils were badly damaged in a fire in the laboratory in which they were stored. Archeological evidence found at site The stone and bone tools and ceramics record evidence of occupation of the cave through the Upper Paleolithic (including **Aurignacian**, **Magdalenian**, and **Epipaleolithic** industries), **Neolithic**, and **Chalcolithic**. Key references: Geology, dating, and paleoenvironment Jordi Pardo 1986, Durán et al. 1993; Hominins García Sánchez and Jiménez Brobeil 1995; Archeology Jordi Pardo 1986, Sanchidrián Torti 1994.

Cueva Mayor-Cueva del Silo One of several sediment-filled cave systems in the Sierra de Atapuerca hills, 14 km/9 miles east of Burgos in Northern Spain. In this system there are several cave/fissure complexes including the Sima de los Huesos. *See also* **Atapuerca**; **Sima de los Huesos**.

Cueva Morín (Location $43^{\circ}22'\text{N}$, $3^{\circ}51'\text{W}$, Spain; etym. Sp. *cueva*=cave and meaning of *Morín* is unknown) History and general description This limestone cave is located in a ridge near the Cantabrian coast in the town of Villanueva de Villaescusa. Discovered in 1910, it was excavated between 1917 and 1920 first by the Reverend J. Carballo and then by the Conde de la Vega del Sella. Modern excavations by González-Echegaray and Freeman took place between 1966 and 1969. The recovered lithic material is significant because the site spans the transition between the **Middle Paleolithic** and **Upper Paleolithic** periods. Temporal span and how dated? Samples for **AMS (accelerator mass spectrometry) radiocarbon dating** taken in 2001 yielded ages of *c.*39 ka for the final **Mousterian** and *c.*36 ka for the archaic **Aurignacian** layers. Hominins found at site Two graves were discovered in the Aurignacian layer, both capped by red **ochre**.

The smaller grave, Morín II, contained no recognizable hominin remains, but the larger one, Morín I, contained well-preserved mold of an adult, created by the replacement of the organic material by fine sediment that was distinguishable from the surrounding matrix (Freeman and González-Echegaray 1970). In addition to the mold of the skeleton, there is also the mold of a small ungulate placed in the grave and molds of other, unidentified, organic grave goods. The Aurignacian date of these burials suggests they are *Homo sapiens*. Archeological evidence found at site The 22 archeological layers, which represent most technologies from the Mousterian to the Azilian, include evidence of a Mousterian bone industry, the first appearance of the **Châtelperronian** in Spain, and the presence of structural features (a hut foundation and post holes). Key references: Geology, dating, and paleoenvironment Maillo et al. 2001, Stukenrath 1978; Hominins Freeman and González-Echegaray 1970, González-Echegaray et al. 1971, 1973; Archeology Freeman and González-Echegaray 1970, González-Echegaray et al. 1971, 1973.

Cultural and Museum Centre, Karonga (or CMCK) An initiative of the Karonga community leaders and members of the **Hominid Corridor Research Project**, is a public/private partnership between the Government of Malawi represented by the Ministry of Wildlife, Tourism and Culture and the Uraha Foundation Malawi. Constructed with European Union funding it opened in December 2004 and it promotes the rich cultural and natural heritage of northern Malawi and provides facilities for research in that region. The main building in Karonga includes an exhibition area and a training and research facility; a separate paleoanthropological field station at **Malema** is also equipped with training and research facilities. Hominin fossil collections **HCRP UR 501** from **Uraha** and **HRCR RC 911** from Malema. Contact person Harrison Simfukwe (harrison.simfukwe@hotmail.com). Postal address Private Bag 16, Karonga, Malawi. Website www.palaeo.net/cmck. Tel/fax +265 1 362 574.

cultural transmission The process that gives rise to **culture**. In cultural transmission an individual learns information that is capable of affecting its behavior and/or other aspects of its phenotype from another individual (Boyd and Richerson 1985). In the past researchers debated whether the term should be restricted to cases in which

individuals learn from other individuals via **imitation**. Today, the consensus is that limiting the term in this way is not helpful, and most workers do not distinguish between different forms of **social learning** when discussing cultural transmission. In line with this, the terms cultural transmission, social learning, and cultural learning are now used interchangeably. Anthropologists often talk about culture as if it is unique to hominins. However, over the last few decades it has become clear that such is not the case. Work in the laboratory and field has pointed to the existence of cultural learning in a number of nonhominin animals, including chimpanzees, orangutans, killer whales, humpback whales, a variety of passerine bird species, and guppies (e.g. Whiten et al. 1999, Yurk et al. 2002, van Schaik et al. 2003, Laland and Galef 2009, Lycett et al. 2010). Some of these cases are still being debated, but others are not. For example, the notion that the songs of many passerine bird species are socially learned is no longer controversial. Similarly, there is general agreement that guppies engage in cultural learning (Laland and Janik 2006). The adaptive significance of cultural transmission appears obvious. The ability to learn new solutions to problems from other individuals would seem to be something that natural selection can be expected to always favor. So, why is cultural transmission not more widespread? Part of the answer seems to be that it is cognitively costly and its benefits outweigh its costs only in certain circumstances. Modeling work suggests that cultural learning is only favored when the rate of environmental change is moderate (Boyd and Richerson, 1985, Whitehead, 2007). When the rate of environmental change is slow, it is outcompeted by genetic adaptation, whereas when the rate of environmental change is fast, it is outcompeted by individual learning. In addition to investigating whether nonhominin animals have culture and trying to identify the conditions that favor the evolution of cultural learning, researchers have attempted to understand the operation of cultural transmission within human populations (e.g., Cavalli-Sforza and Feldman 1981, Boyd and Richerson 1985, Hewlett and Cavalli-Sforza 1986, Guglielmino et al. 1995, Shennan and Steele 1999, Collard et al. 2006, Tehrani and Collard 2009). This body of work has identified a number of modes of cultural transmission and several cultural learning strategies (Cavalli-Sforza and Feldman 1981, Boyd and Richerson 1985). The key modes of cultural

transmission are vertical transmission, oblique transmission, and horizontal transmission. In vertical transmission, a child learns from a parent. In oblique transmission, an individual in one generation learns from an individual in the previous generation who is not their parent. In horizontal transmission, an individual learns from another individual in the same generation. Of the cultural learning strategies that have been identified, the most notable are direct bias, indirect bias, and frequency-dependent bias. In direct bias, individuals evaluate alternative behaviors and choose among them. In indirect bias, individuals use some traits, such as those connoting health or prestige, to choose a cultural model, and then copy a range of the model's behaviors. In frequency-dependent bias, an individual copies a behavior on the basis of its frequency in the population; the most common form is thought to be conformist bias, which involves copying the behavior that is most widespread in the population.

culture (L. *cultura*=cultivation) Numerous definitions of culture have been put forward, but most are problematic for researchers interested in human evolution. The reason is that they automatically preclude the possibility that nonhominin animals have culture, which affects how the issue of the origins of culture is approached. There is substantial agreement among the other definitions. Crucially, they all hold that culture involves **social learning**. The issues on which these definitions differ are whether all forms of social learning give rise to culture, and whether social learning is the only process involved. Some researchers contend that a behavior exhibited by an individual is cultural if it was learned from another individual by any form of social learning (e.g., van Schaik et al. 2003, Laland 2008). Thus, according to these researchers, culture is simply socially learned behavior. Other researchers argue that culture should be restricted to behaviors that result from two particular forms of social learning: **teaching** and **imitation** (e.g., Galef 1992). Still other researchers suggest that the crucial feature of culture is that it is cumulative (e.g., Tomasello 1999, Boyd and Richerson 2005). According to these researchers, for a behavior to be considered cultural it not only has to be socially learned, but also has to show signs of elaboration through time and across generations. The latter two groups of researchers use the term “traditions” to refer to non-cultural socially learned behaviors, whereas proponents of

the first definition often use the terms culture and traditions interchangeably. Depending on which of the three definitions is employed culture may, or may not, be present in nonhominin animal species. If the first definition is employed, there is compelling evidence for the existence of culture in a number of nonhominin animal species, including chimpanzees (Whiten et al. 1999, Lycett et al. 2007), orangutans (van Schaik et al. 2003), and killer whales (Yurk et al. 2002). The term “culture” is also used in anthropology to refer to a complex of beliefs and behaviors, or to a suite of artifacts, that is diagnosably different from other such complexes or suites (e.g., American culture versus Japanese culture, or the **Aurignacian** versus the Gravettian) and which is associated with a group of individuals who interact socially. These uses of culture are problematic for several reasons. In the first place, in most cases we are ignorant about the mechanism(s) underlying a given belief, behavior, or artifact, and we do not know whether it is underpinned by social learning or by some other mechanism (e.g. individual learning). Second, the application of more effective dating methods has made it clear that many of the cultures that archaeologists have identified cannot be linked in any simple way to recognizable social groups. Thus, this fourth definition of culture is potentially inconsistent with the other three definitions of culture, which are all linked to social learning. Given these problems it may be more useful to refer to the complexes of beliefs, behaviors, and artifacts that we document ethnographically and archeologically as “ethnographic taxonomic units” and “archeological taxonomic units,” respectively (see Gamble et al. 2005). *See also* **social learning; teaching; imitation.**

Cunkong *See* **Bubing Basin.**

cursorial (L. *cursorius*=running) Animals, quadrupedal or **bipedal**, adapted for fast terrestrial travel (i.e., running). Cheetahs and gazelles are cursorially adapted and some researchers have suggested that the body size and shape of early *Homo* may have been adapted for endurance **running**. *See also* **endurance running hypothesis.**

Curve of Spee *See* **tooth wear.**

cusp (L. *cuspis*=point) A portion of a tooth crown demarcated by primary **fissures** and with

an independent apex. Cusps are divided into primary, or main, and accessory. The primary cusps on the mandibular molars are the **entoconid**, **hypoconid**, **hypoconulid**, **metaconid**, and **protoconid**. The latter two cusps are also the primary cusps on mandibular premolars. Examples of **accessory cusps** on mandibular molars are the **C6** and the **C7**. The primary cusps on the maxillary molars are the **hypocone**, **metacone**, **paracone**, and **protocone**. The latter two cusps are also the primary cusps on maxillary premolars. The **C5** is an example of an accessory cup on a maxillary molar. Enamel features that are not large and discrete enough to qualify as accessory cusps are called **conules** on maxillary teeth and **conulids** on mandibular teeth. The word “cusp” is a misnomer with respect to hominin teeth for their cusps are blunt rather than pointed. *See also* **accessory cusp**; **cuspid**; **cusp nomenclature**; **cuspile**.

cusp 6 *See* **C6**; **tuberculum sextum**.

cusp 7 *See* **C7**; **tuberculum intermedium**.

cusp morphology This term refers to the relative size and shape of the main and accessory cusps on the occlusal surface of a postcanine tooth crown. It refers to both metrical and non-metrical studies, with most of the latter addressing the incidence and prevalence of accessory cusps. Nearly all of the existing research in this area has focused on the taxonomic value of interspecific differences in cusp morphology; relatively few studies have looked at the functional significance of such differences. Research methods to quantify non-metric variation have often been adapted from standards used for contemporary humans (Dahlberg 1956). In modern human populations variability of expression of main and accessory cusps is usually described using the Arizona State University Dental Anthropology System (or ASUDAS; Turner et al. 1991, Scott and Turner 1997). This system, and its modifications, have also been employed to give an semiquantitative account of morphological details in fossil hominin dentition (e.g., Irish and Guatelli-Steinberg 2003, Bailey 2002, 2004, Martínón-Torres et al. 2008). Most, but not all, of the variation in cusp morphology observed in contemporary humans can be observed in fossil hominins (Bailey 2006, Irish and Guatelli-Steinberg 2003, Martínón-Torres 2007). Robinson (1956) drew attention to differences in

cusp morphology between *Paranthropus robustus* and *Australopithecus africanus*, but these differences were not quantified. The research methods used to capture metrical information about the relative size of the cusp areas of fossil hominin teeth were mostly adapted from similar comparative studies of extant modern human and higher primate populations (e.g., Hanihara 1981, Erdbrink 1965, 1967, Biggerstaff 1969, Corruccini 1977a, 1977b, 1978, Lavelle 1978). Corruccini and McHenry (1980) were the first researchers to focus on fossil teeth and this study was followed by a series of analyses of the East African early hominin fossil record (Wood and Abbott 1983, Wood et al. 1983, Wood and Uytterschaut 1987, Wood and Engleman 1988, Suwa et al. 1994, 1996). Bailey (2004, 2006) was the first to successfully apply and adapt these research methods to the fossil record of later hominins and many (e.g., Martínón-Torres et al. 2006, 2007) but not all (Moggi-Cecchi and Boccone 2007, Quam et al. 2009) of the more recent studies have addressed this later phase of hominin evolution. Relative variability in cusp morphology has also been studied in living apes (e.g., Uchida 1998a, 1998b, Pilbrow 2006, 2007). All of the above studies focused on cusp morphology at the outer enamel surface and they expressed cusp areas in two dimensions, but recently **micro-CT** imaging has been used to investigate cusp morphology in three dimensions and at the **enamel-dentine junction** as well as at the outer enamel surface (e.g., Skinner et al. 2008, 2009a).

cusp nomenclature (*L. cuspis*=point) The names of the cusps of the postcanine teeth of the upper and lower jaw were devised by Henry Fairfield Osborn (1888, 1892). They are consistent with what we now know is almost certainly an incorrect hypothesis (called the tritubercular theory) about the evolution of tooth crowns, but Osborn’s naming scheme has outlasted his theory. Osborn’s scheme begins with a reference **cusp**, which is on the **lingual** side of the crown in an upper postcanine tooth (the **protocone**) and on the **buccal** side of the crown in a lower postcanine tooth (the **protoconid**). He suggested that these cusps in mammals are **homologous** with the mesiodistally elongated main cusp in a reptile tooth hence the prefix “proto”. In the upper jaw he called the cusp on the mesiobuccal aspect of the reference cusp the **paracone** and the cusp situated distobuccally to it the **metacone**. The equivalent cusps in the lower postcanine teeth are

the mesiolingually situated **paraconid** (which has been lost in higher primates) and the distolingually situated **metaconid**. These triangular (or triconodont) units made up of three cusps are called the **trigon** in the upper teeth and the **trigonid** in the lower teeth. In higher primates each postcanine tooth may have a distal addition to the trigon or trigonid. This is called the **talon** in the upper teeth and the **talonid** in the lower teeth. In the upper postcanine teeth the talon is represented by the distolingual **hypocone**. In the lower teeth it is represented by the **entoconid** lingually, the **hypoconid** buccally, and the **hypoconulid** (if there is one) distally. Biggerstaff (1968) provides a succinct review of the history of the scheme: he refers to it as a nomenclature for molar cusps but it is used for all the postcanine teeth, especially the molarized premolars of *Paranthropus*.

cuspal enamel (L. *cuspis*=point) Term used for the first-formed enamel over the dentine horn that makes up the occlusal aspect of a tooth and which does not show long-period growth increments at the surface. In a completed unworn tooth no portion of the cuspal enamel is visible on the surface of a tooth crown, but the imbricational (or lateral) enamel does have increments visible on the tooth surface. In anterior teeth cuspal enamel forms a smaller percentage of the crown volume than in the posterior (or postcanine) teeth. Several methods have been applied to determine the cuspal enamel formation time, many of which involve assessment of the linear **enamel thickness** and the **daily secretion rate** or the total number of **cross-striations** (e.g., Dean 1998, Smith 2006).

cuspile An accessory cusp on a maxillary postcanine tooth crown. A small **C5** is an example of a cuspile. *See also* **accessory cusps**.

cuspid An accessory cusp on a mandibular postcanine tooth crown. A small **C7** is an example of a cuspid. *See also* **accessory cusps**.

cutmarks A hominin-induced modification inflicted on bone surfaces by stone **artifacts** or knives during carcass processing (e.g., the deflesh-

ing, disarticulation, or skinning of animal remains). Cutmarks have a deep, V-shaped cross-section, whereas the tooth marks of large carnivores tend to be shallower and U-shaped. Stone tool cutmarks frequently have fine, parallel lines within them called internal striations that are made by the undulating edge of an **artifact** as it is dragged across the bone and contextually stone tool cutmarks often appear in roughly parallel groups. When archeologists identify a cutmark on bone, they are demonstrating a temporal, spatial, and behavioral association between the hominins that formed an archeological site and the fauna. The percentages of bones showing cutmarks as opposed to those showing carnivore toothmarks have been used as a proxy for the intensity and scope of hominin activity involved in generating a given archeological assemblage and they have been used to make inferences about the relative timing of hominin access to animal remains. These indicators have been particularly relevant in the study of early archeological sites such as those at Bed I, **Olduvai Gorge**. Sharp-edged pieces of shell, bamboo, and bone may also produce cutmarks. Lyman (1994) and Dominguez-Rodrigo and Pickering (2003) provide useful introductions to cutmark identification and analysis. *See also* **Bouri**; **Dikika study area**; **taphonomy**.

cynodont (Gk *cyno*=dog and *dont*=teeth) Molar teeth that have short, dog-like, **pulp chambers** relative to the distance between the roof of the pulp chamber and the tip of the longest root (ant. **taurodont**).

cytoarchitecture (L. *cyto*=cell and *architectus*=builder) The cellular composition of any structure in the body, but in the **cerebral cortex** the term refers to the characteristic arrangement of **neurons** into layers according to their size, morphology, and spatial packing density. These variables allow researchers to distinguish the boundaries of **cortical areas** in the brain. For example, one of the most widely used maps of the **neocortex** by Brodmann is based on cytoarchitecture.

cytogenetic *See* karyotype.

D

D Prefix for fossils from **Dmanisi**, Georgia.

D211 (NB: this specimen was referred to as “Dmanisi 211” in the initial publication) Site **Dmanisi**. Locality Block 1. Surface/in situ *In situ*. Date of discovery September 24, 1991. Finder Antje Justus. Unit Stratum B1. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”), 1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A mandibular corpus that preserves all the tooth crowns and roots, but the base on both sides is damaged. Announcement Gabunia and Vekua 1995. Initial description Gabunia and Vekua 1995. Photographs/line drawings and metrical data Gabunia and Vekua 1995, Bräuer and Schultz 1996, Rosas and Bermúdez de Castro 1998b. Detailed anatomical description Bräuer and Schultz 1996. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Homo sp. indet.* (aff. *Homo ergaster*). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance The first hominin recovered from Dmanisi. The D211 mandible combined relatively small postcanine tooth crowns and a modern human-like molar size order with a corpus that was more robust than usually seen in modern humans and Neanderthals. The mandible is consistent in size with the cranium **D2282** and because they were found “close together” it has been suggested that they “probably represent one individual” (Rightmire et al. 2006b, p. 121). Location of original **Georgian National Museum**, Tbilisi, Georgia.

D2280 Site **Dmanisi**. Locality Block 1/Excavation Unit 50/62. Surface/in situ *In situ*. Date of discovery May 1, 1999. Finder Antje Justus. Unit Stratum B1. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A.

Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”), 1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description An almost complete calvaria, plus substantial parts of the basioccipital, left temporal, and sphenoid. Endocranial volume 775 cm³ (Rightmire et al. 2006b). Announcement Gabunia et al. 1999. Initial description Gabunia et al. 2000. Photographs/line drawings and metrical data Gabunia et al. 2000, Rightmire et al. 2006b. Detailed anatomical description Rightmire et al. 2006b, de Lumley et al. 2006. Initial taxonomic allocation *Homo* aff. *Homo ergaster*. Taxonomic revisions *Homo erectus* (Rightmire et al. 2006b), *Homo georgicus* (de Lumley et al. 2006). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance D2280 is one of the better-preserved hominin calvaria from Dmanisi. Location of original **Georgian National Museum**, Tbilisi, Georgia.

D2282 Site **Dmanisi**. Locality Block 1/Excavation Unit 52/62. Surface/in situ *In situ*. Date of discovery July 22, 1999. Finder Antje Justus. Unit Stratum B1. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”), 1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A cranium that has suffered substantial damage to the mid and lower face. In addition the cranial base and what remains of the face have been deformed. The roots and crowns of the right P⁴ and M¹ and the left M¹ and M² are preserved in the maxilla. Endocranial volume 650–660 cm³ (Rightmire et al. 2006b). Announcement Gabunia et al. 2000. Initial description Gabunia et al. 2000. Photographs/line drawings and metrical data Gabunia et al. 2000, Rightmire et al. 2006b, Martínón-Torres et al. 2008. Detailed anatomical

description Rightmire et al. 2006b, de Lumley et al. 2006. Initial taxonomic allocation *Homo* aff. *Homo ergaster*. Taxonomic revisions *Homo erectus* (Rightmire et al. 2006b), *Homo georgicus* (de Lumley et al. 2006). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance The D2282 cranium is consistent in size with the mandible D211 and because they were found “close together” they “probably represent one individual” (Rightmire et al. 2006b, p. 121). Location of original Georgian National Museum, Tbilisi, Georgia.

D2600 Site Dmanisi. Locality Block 2/Excavation Unit 64/59. Surface/in situ *In situ*. Date of discovery September 26, 2000 Finder Gocha Kiladze. Unit Stratum B1y. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”), 1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Aged adult. Presumed sex Unknown. Brief anatomical description A substantially complete aged adult mandibular corpus. Announcement Gabunia et al. 2002. Initial description Gabounia et al. 2002. Photographs/line drawings and metrical data Gabounia et al. 2002, Martínón-Torres et al. 2008, Rightmire et al. 2008. Detailed anatomical description N/A. Initial taxonomic allocation *Homo georgicus*. Taxonomic revisions *Homo sp. indet.* (aff. *Homo ergaster*). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance The D2600 mandible has a corpus that is larger and more robust than that the other Dmanisi mandibles (Skinner et al. 2006) and the preserved tooth root size and morphology, together with the molar size order (Martínón-Torres et al. 2008), have prompted these authors to suggest that D2600 may represent a second hominin taxon, or paleodeme, at Dmanisi. Location of original Georgian National Museum, Tbilisi, Georgia.

D2700/D2735/D2724/D3160, etc. Site Dmanisi. Locality Block 2/Excavation Units 65/60 and 66/60. Surface/in situ *In situ*. Dates of discovery August 11 and 30, 2001. Finder Gocha Kiladze. Unit B1x. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”),

1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Subadult. Presumed sex Unknown. Brief anatomical description A skull comprising a generally well-preserved adult cranium (D2700) and mandible (D2735) together with associated postcranial bones (D2724, etc.). Nearly all of the teeth are preserved. Endocranial volume 600 cm³, with a possible correction to 612 cm³ because of the immaturity of the specimen (Rightmire et al. 2006b). Announcement de Lumley and Lordkipanidze 2006. Initial description de Lumley and Lordkipanidze 2006, Rightmire et al. 2006b, de Lumley et al. 2006. Detailed anatomical description Rightmire et al. 2006b, de Lumley et al. 2006. Initial taxonomic allocation *Homo georgicus*. Taxonomic revisions *Homo erectus* (Rightmire et al. 2006b). Current conventional taxonomic allocation *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance The skull and postcranial skeletal elements are not necessarily from a single individual but several of the postcranial bones (clavicle, ribs, humeri) are juvenile and probably go with the D2700/D2735 skull. If so they would provide an important source of information about the relative size relationships of the main hominin taxon sampled at Dmanisi. Location of original Georgian National Museum, Tbilisi, Georgia.

D2724 *See* D2700/D2735/D2724/D3160, etc.

D2735 *See* D2700/D2735/D2724/D3160, etc.

D3444/D3900 Site Dmanisi. Locality Block 2/Excavation Units 64/61. Surface/in situ *In situ*. Date of discovery August 26, 2002, and thereafter. Finder Gocha Kiladze. Unit B1y. Horizon See previous. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon None. Nearest underlying dated horizon Stratum A1 (aka “VI”) 1.81 Ma. Geological age *c.*1.77 Ma. Developmental age Old adult. Presumed sex Unknown. Brief anatomical description A skull comprising an aged adult cranium (D3444) together with an associated mandible (D3900) and with the exception of the left upper canine, the individual was edentulous. The remains of an adult associated skeleton (see Lordkipanidze et al. 2007) are believed to belong to the same individual. Announcement Lordkipanidze et al. 2005. Initial description Lordkipanidze et al. 2005. Photographs Lordkipanidze et al. 2005. Detailed anatomical description N/A. Initial taxonomic allocation early *Homo*. Taxonomic revisions *Homo erectus*

(Rightmire et al. 2006b). Current conventional taxonomic allocation early *Homo sp. indet.* Informal taxonomic category Pre-modern *Homo*. Significance The extent of the resorption in the alveolar processes of the maxilla and mandible suggest that this individual lived for some time without the ability to chew effectively. The paper announcing the find suggested that this specimen “raises interesting questions regarding social structure, life history and subsistence strategies of early *Homo*” (Lordkipanidze et al. 2005, p. 718). Location of original **Georgian National Museum**, Tbilisi, Georgia.

D3900 See D3444/D3900.

D-loop Abbreviation of displacement loop. See mitochondrial DNA.

DABT Acronym for Daam Aatu Basaltic Tuff. See Aramis.

daily enamel increment See cross-striation; daily secretion rate; enamel development.

daily secretion rate The amount of enamel matrix measured in micrometers (μm) secreted by an **ameloblast** during each 24 hour period (i.e., the distance between adjacent **cross-striations** along an enamel prism). These linear (i.e., along the long axis of the prism) daily increments continue until the ameloblast ceases to secrete matrix and the end result is an elongated **enamel prism**. The average daily secretion rate in modern humans is close to 4 $\mu\text{m}/\text{day}$ but inner rates are close to the enamel dentine junction (or EDJ) of approximately 2.8 $\mu\text{m}/\text{day}$ and these rise as a gradient to approximately 5.5 $\mu\text{m}/\text{day}$ close to the enamel surface. The secretion rate in *Pan* (as well as other great apes) is a little higher at the EDJ (approximately 3.3 $\mu\text{m}/\text{day}$) but the main difference is that rates rise more quickly to approximately 5.5 $\mu\text{m}/\text{day}$ such that the cumulative trajectory of enamel thickness formed over time is greater than in *Homo sapiens*. This linear rate of matrix secretion may not reflect the volume of enamel matrix secreted in a day very accurately since prism diameter increases in some regions of a tooth crown (i.e., in the cusp) more than others. See also enamel development.

Daka Abbreviation of Dakanihyalo, the name of a locality in the Bouri region within the Middle

Awash study area in the Ethiopia section of the East African Rift Valley. See Dakanihyalo.

Daka calvaria See BOU-VP-2/66.

Dakanihyalo Locality in the Bouri region within the **Middle Awash study area** in the Ethiopia section of the East African Rift Valley. Dakanihyalo was discovered in 1981 by the **Rift Valley Research Mission in Ethiopia** (or RVRME) and an archeological assemblage from Dakanihyalo was briefly referred to by Clark et al. (1984). It is one of 29 localities within the Bouri region and it is now given the designation BOU-A1. It is widely referred to in the literature by the first four letters of the full name (i.e., as “Daka”, as in the “Daka calvaria”). See also **Bouri**; **Bouri Formation**.

Dali (大荔) (Location 34°51'57.49"N, 109°43'58.58"E, northwestern China; etym. named after the local county) History and general description An open-air site, discovered in 1978, located in the basal gravels of the third loess terrace of Luohe (Luo River) known as Tianshuigou, 1 km/0.6 miles south of Jiefang village, Dali County, Shaanxi Province. Temporal span and how dated? Initial thermoluminescence dating and geomagnetic dating methods assign Dali to Late **Middle Pleistocene**. Uranium-series dating of fossil mammals suggests an age range of 230–180 ka. Recent correlation between magnetic susceptibility records of the loess-paleosol sequences at Dali and those at Luochuan in the central part of Chinese Loess Plateau places the hominin-bearing layer between the loess L3/paleosol S3 boundary, which gives an age of *c.*270 ka. Hominins found at site A well-preserved, complete, and edentulous **cranium** with slight distortion on the left side of face and a cranial capacity of 1120 cm^3 . The specimen is presumed to be a young adult male. Archeological evidence found at site Thirteen stratigraphic horizons were identified at the site. Animal fossils and stone tools were recovered from layers 3–5 from bottom to top; the hominin fossil was recovered from layer 3. The lithic assemblage consists of 181 artifacts: seven small and irregular **cores** with no evidence of platform preparation, 152 small **flakes** (mostly **debitage**), and 22 simple, **retouched** tools (mostly **scrapers**). Raw materials consist of **quartzite**, vein quartz, and **flint**. Repository **Institute of Vertebrate Paleontology and**

Paleoanthropology. Key references: Geology and dating Wang et al. 1979, Chen et al. 1984, Xiao et al. 2002; Hominins Wang et al. 1979, Wu 1981, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Holloway 2000, Brown 2001; Archeology Wu and You 1979, Wu and Olsen 1985.

Damei *See* Bose Basin.

Danakil cranium *See* UA 31.

Danakil pubis *See* UA 466.

Dansgaard–Oeschger cycles Refers to *c.*1.5 ka cycles of cooling and warming that have been identified in the Greenland ice core and North Atlantic records during the last glacial. **Heinrich events** occur prior to periods of abrupt warming. *See also* **Greenland Ice Core Project**; **Heinrich events**.

Dar el ‘Aliya *See* Mugharet el ‘Aliya.

Dar es Soltane 5 Site Dar es Soltane II. Locality N/A. Surface/in situ *In situ*. Date of discovery 1975. Finders A Debénath and others. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 70–40 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description A robust partial skull preserving the upper face and the left side of the mandible. Announcement Debénath 1975. Initial description Ferembach 1976. Photographs/line drawings and metrical data Bräuer and Rimbach 1990. Detailed anatomical description Bräuer and Rimbach 1990, Schwartz and Tattersall 2003. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions None. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Modern human. Significance Similarity to the temporally earlier Jebel Irhoud (Irhoud 1 and Irhoud 2) crania may suggest local continuity in this region between pre-modern *Homo* and anatomically modern humans. Location of original Musée Archéologique, Rabat Chellah, Morocco.

Dar es Soltane II (Location 33°57′36″N, 6°35′59″W, Morocco; etym. Ar. sultan’s house) History and general description Several cave sites line the El Menzah range along the Atlantic coast of Morocco near Rabat. These were first explored by

A. Ruhlmann before WWII, but in 1969 a group led by André Debenath excavated another cave site roughly 200 m from the first Dar es Soltane deposit. They named the second site Dar es Soltane II. The cave is known for many hominin remains, but a relative lack of faunal and artifacts. Temporal span and how dated? The Aterian layers at nearby Dar es Soltane I have electron spin resonance spectroscopy dates of <110 ka, although other Aterian sites are mostly between 60 and 80 ka. Hominins found at site The remains of at least five individuals were recovered; **Dar es Soltane 5** is the most complete, consisting of a nearly complete cranium and mandible. Archeological evidence found at site Seven numbered layers were recovered with the second from the bottom containing Aterian technology. Key references: Geology, dating, and paleoenvironment Barton et al. 2009; Hominins Ferembach 1976, Bräuer and Rimbach 1990; Archeology Debenath 1976.

Dart, Raymond Arthur (1893–1988) Raymond Dart, who was born in Toowong, a suburb of Brisbane, Australia, entered the University of Queensland in 1911 to study for a Bachelor of Science degree and, despite being raised in a religiously fundamentalist family, he became interested in zoology and evolutionary theory. He graduated in 1913 and in 1914 he moved to the University of Sydney to study medicine. The British Association for the Advancement of Science held their annual meeting in Sydney that same year and the young Dart was able to meet the neuroanatomist and physical anthropologist Grafton Elliot Smith and the paleontologist and archeologist William Johnson Sollas. Between 1915 and 1917 Dart worked with James T. Wilson, head of the Anatomy Department at the University of Sydney, on anatomical studies of the human brain. After Dart completed his medical degree in 1917 he enlisted in the Australian Army Medical Corps and spent the last year of WWI in France. After his demobilization in 1919, Dart studied with Grafton Elliot Smith in the Anatomy Department at University College London. Dart was given funds by the **Rockefeller Foundation** to visit the USA and between the end of 1920 and late 1921 he worked with Robert J. Terry at Washington University in St. Louis and later he served as a demonstrator of anatomy in Cincinnati. By the time Dart returned to University College London he was interested in physical anthropology

and began examining the collection of brains kept at the **Royal College of Surgeons of England**. Dart's career changed course in 1922 when he accepted the Chair of Anatomy at the newly established University of the Witwatersrand in Johannesburg, South Africa. Soon after his arrival, Dart began to assemble a collection of primate fossils, including brain endocasts, unearthed in the many lime quarries located in the Transvaal. Early in 1924 Josephine Salmons, a medical student at the University of the Witwatersrand, brought Dart a fossil baboon skull that had been blasted out of the Northern Lime Company's quarries located near the town of **Taungs**. The find prompted Dart to arrange for any other interesting fossils to be sent to him and in November 1924 he received a crate of fossils from the quarry. He noticed two pieces of **breccia**, one containing a natural **endocranial cast** (the fossilized cast of a brain) and in the other was the anterior portion of a cranium. After 4 weeks of preparation Dart freed the face from the surrounding breccia, revealing the partial skull of a juvenile primate. Dart judged that many anatomical features of the skull and endocranial cast were modern human-like and from the position of the foramen magnum Dart concluded that the creature was bipedal. There were, however, also ape-like features to the skull, notably its small cranial capacity. Dart published a brief description of the fossil in *Nature* in February 1925, where he described its anatomy, the geological evidence for its antiquity and an interpretation of the fossil that suggested it represented a "man-like ape" that might be ancestral to modern humans. To reflect this interpretation Dart named the specimen *Australopithecus africanus*, meaning the "southern ape from Africa." Eugène Dubois' discovery of *Pithecanthropus erectus* in Java in the 1890s and the later discoveries of *Sinanthropus pekinensis* (both species are now classified as *Homo erectus*) in China during the 1920s and 1930s seemed to support Ernst Haeckel's idea that modern humans had evolved in Asia, thus few anthropologists were expecting fossil evidence of the early stages of human evolution in Africa. There were other reasons for scientists to be doubtful about Dart's interpretation of *Australopithecus*, for the small-brained but upright *Pithecanthropus* seemed to support the view that hominins had first become bipedal and that bipedalism then led to an increase in the size of the brain since the hands were free to use tools.

However, other researchers, such as Arthur **Keith** in England, believed that a large brain had evolved first and bipedalism later and the controversial discoveries at **Pitdown** of *Eoanthropus dawsonii* seemed to support this view. Most prominent physical anthropologists (e.g., Grafton Elliot Smith, Arthur Keith, and Arthur Smith Woodward) all expressed skepticism about Dart's claim that *Au. africanus* represented an intermediate form between the anthropoid apes and modern humans. However, Dart did gain one important supporter, the Scottish paleontologist Robert **Broom**, and shortly after the *Nature* article appeared Broom visited Dart and inspected the fossil. Broom immediately agreed the specimen represented a new species of primate that was intermediate between apes and modern humans. Dart's duties in the Anatomy Department and as Dean of the Medical School from 1925 to 1943 at the University of the Witwatersrand left little time for paleontological expeditions and Broom's considerable experience in searching for fossils resulted in Broom making most of the significant new hominin discoveries. In 1936 Robert Broom recovered evidence of an australopith from a quarry at Sterkfontein and in 1938 he obtained more evidence from **Kromdraai**. Dart worked and published on *Au. africanus* only sporadically during the 1920s and 1930s but WWII caused a serious interruption in research. Dart was thrust back into active research in 1947 when James Kitching of the **Bernard Price Institute for Palaeontological Research** found a portion of an *Australopithecus* cranium along with a large quantity of animal fossils at a limestone quarry at **Makapansgat** in the former central Transvaal, now Limpopo Province. The new fossil and the abundance of animal remains assumed a new significance when Kitching found fossil baboon skulls that had been fractured in a way that suggested they had been struck by a club. Dart concluded from the material recovered at Makapansgat that the australopiths had hunted big game animals thus explaining the vast quantities of **ungulate** bones, but more significantly Dart argued that there was evidence that some of those ungulate bones had been modified or used as tools. Dart suggested that the australopiths at Makapansgat had developed an osteodontokeratic (bone/tooth/horn) industry that preceded the use of stone tools. Between 1949 and the mid-1960s Dart studied and published extensively on the osteodontokeratic culture of the australopiths, but few other researchers accepted the idea and Dart's theory has subsequently been rejected in favor of interpretations

pioneered by C.K. (Bob) Brain. Dart retired from the University of the Witwatersrand in 1958, but continued to conduct research into the 1960s.

Dart collection See Raymond A. Dart Collection.

Darwin, Charles Robert (1809–82) Charles Darwin was born in Shrewsbury, England. Darwin's grandfather, Erasmus Darwin, had been a prominent physician and naturalist who had speculated upon the possibility that species might change over time. Darwin's father, Robert Darwin, was also a physician and it seemed that Charles was set to continue the family tradition when he was admitted to Edinburgh University in 1825 to study medicine. However, while there he studied with Robert Edmond Grant, a zoologist who taught the theories of Jean Baptiste de Lamarck who, in his *Philosophie zoologique (Zoological Philosophy)* published in 1809, had formulated a transmutationist theory of how biological species change over time. Darwin continued with his medical studies at Edinburgh University until 1827 after which he transferred to Cambridge University to study what is now called natural sciences, where he took botany classes with John Henslow and geology classes with Adam Sedgwick. This training would prove invaluable for after his graduation in 1831 Darwin was invited to join the HMS *Beagle*. The plan was to circumnavigate the globe, but a substantial proportion of the effort was to be devoted to surveying and mapping the coast of South America. During the 5 years of the voyage (1831–5) Darwin collected a vast quantity of geological, zoological, and botanical specimens. He also read widely and perhaps most importantly he read the *Principles of Geology* (1831–3) by Charles Lyell, who advocated the principle of **uniformitarianism**, which proposed that the geological processes operating today are the same as those that operated in the past. The detailed observations Darwin made while on the HMS *Beagle* were instrumental in the development of his seminal conclusion that species had changed over time. When Darwin returned to England he was already respected as a naturalist and he quickly became a member of Britain's scientific community. He married and eventually established a home, Down House, in Downe, Kent, where he set to work to explain how species could change and give rise to new species. By the late 1830s Darwin had formulated the idea of **natural selection** and in 1842 he wrote a brief

outline of the theory. Darwin wrote a long essay on his theory in 1844 and was working on a major treatise on his ideas when he received a letter in 1858 accompanied by a scientific paper written by the naturalist Alfred Russel Wallace. Wallace, when exploring the flora and fauna of the Malay Archipelago, had become convinced that species changed over time and in the paper he sent to Darwin he proposed a mechanism to explain how new species emerged that in many ways resembled Darwin's theory of evolution by natural selection. Darwin's and Wallace's accounts of their theories were presented at a meeting of the Linnaean Society in London in 1858 and thereafter Darwin lost no time in completing and publishing his *On the Origin of Species by Means of Natural Selection* (1859). Darwin largely avoided the question of human origins in *The Origin of Species* and the first substantial discussion of the implications of Darwin's evolution theory for human origins was Thomas Henry Huxley's *Evidence as to Man's Place in Nature* (1863). In that volume Huxley demonstrated the close anatomical affinities between modern humans and the African apes and he also discussed the then known examples of human fossil remains, including the fossils found in the **Kleine Feldhofer Grotte** in Germany in 1856. Darwin finally confronted the question of human evolution in *The Descent of Man and Selection in Relation to Sex* (1871) where Darwin examined the anatomical and physiological similarities shared between modern humans and the rest of the animal kingdom, discussed how these similarities could be explained by evolution, and addressed the more difficult problem of explaining how modern human mental faculties could have evolved by comparing the instincts, mental abilities, and social habits of modern humans and animals in order to trace continuities between the two. Darwin also addressed the issue of modern human racial variation and explained this from a biological perspective, while retaining the prevailing 19thC hierarchical arrangement of races, and he discussed the question of whether all modern humans share a common origin (monogenism) or whether the different races had separate origins and represent distinct species (polygenism). In *The Descent of Man*, Darwin explained how modern humans could have evolved from an ape-like ancestor and discussed the prehensile hands of monkeys and the origins of tool use by early human ancestors, arguing that bipedalism arose because of the increasing use of the hands for manipulating tools. He argued that the use of tools

led to the decrease in size of the canine teeth in modern humans and he claimed that this would have altered the morphology of the face in general. Darwin's view was that the evolution of **bipedalism** preceded the evolution of a larger brain and he argued that modern humans evolved from an Old World primate. Few fossil apes were known at this time except for the European *Pliopithecus* and *Dryopithecus* fossils discovered by French paleontologist Édouard Lartet earlier in the century, yet Darwin argued that modern humans had probably evolved in Africa. Darwin wrote *The Descent of Man* at a time when very few hominin fossil remains had been discovered and when many considered that the **Cro-Magnon** fossils from the Dordogne region in France, discovered by Louis Lartet in 1868, and the Neanderthal fossils discovered in 1856, were either ancient examples of modern humans and not truly ancestral forms, or they were frankly pathological. Darwin died in 1882, before the major hominin fossil discoveries of the late 19thC, and by the time a hominin fossil record began to be accumulated many anthropologists and biologists had turned away from Darwin's mechanism of natural selection and instead invoked non-Darwinian mechanisms to explain human evolution. Yet the description of human evolution presented by Darwin in *The Descent of Man* influenced generations of human origins researchers and he continued to examine the problem of the evolution of human behavior and mental faculties in *The Expression of the Emotions in Man and the Animals* (1872), showing that again there are continuities between modern humans and other animals even in relation to such an apparently unique human attribute as emotions. Darwin, who never held an academic position, was a prominent member of Britain's scientific establishment. He was elected a fellow of the Royal Society in 1839 and in 1864 he was awarded the Copley Medal, the Royal Society's highest scientific honor. In recognition of his scientific stature, after his death in 1882 Darwin was accorded the signal honor of being buried in Westminster Abbey in London.

Darwinian fitness *See* fitness.

data matrix Any data set that is organized into an $m \times n$ table, where m refers to the number of rows and n refers to the number of columns. Data matrices are typically used in a **multivariate analysis**. The number of rows and columns may be equal or different; when they are equal the matrix is referred to as a

square matrix. Some common examples of square matrices include **correlation matrix**, **covariance matrix**, and **distance matrix**.

date Used as a verb it refers to the act of dating, whereas as a noun it refers to a specific point in time (e.g., 1347 years BCE). Dates measured in years were abbreviated to "yrs," those in thousands of years were abbreviated to "ky," and those measured in millions of years were abbreviated to "myrs." Now it is conventional to refer to a specimen's age rather than its date and to use the abbreviation **ka** to refer to an age in thousands of years and the abbreviation **Ma** to refer to an age in millions of years before the present.

dating *See* absolute dating; relative dating; geochronology.

DAW Abbreviation of Dawaitoli. It is one of the three three-letter prefixes (the others are **BOD** and **HAR**) used for the paleontological evidence collected by the **Middle Awash Research Project**. Each fossil is identified by a three-letter prefix that refers to the geographical area where it was found, followed by VP (for Vertebrate Paleontology), the number of the collecting site within the area, then a final number that places the fossil in the sequence of fossils recovered from that collecting site. Thus DAW-VP-1/1 is the first fossil to be found in the first collecting site to be recognized in the Dawaitoli area of the **Middle Awash study area**. *See also* Dawaitoli.

Dawaitoli One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area** in Ethiopia. The area was first explored for its paleoanthropological potential in 1981 by a multidisciplinary team organized by the **Ethiopian Ministry of Culture and Sports Affairs** and led by Desmond Clark with more extensive excavations undertaken in 1990. The localities are in deposits that are part of the Bodo-Dawaitoli-Hargufia sedimentary sequence and several localities within Unit U of the Dawaitoli Formation have yielded archeological assemblages. Temporal span A tuff that is also exposed within Unit U of the Bodo-Dawaitoli-Hargufia sedimentary sequence suggests an age of 0.64 ± 0.03 Ma and biostratigraphic evidence suggests that all the localities are **Middle Pleistocene**. How dated?

Argon-argon dating and biostratigraphic correlation with **Olduvai Bed IV** and **Ologesailie**. Hominins found at site None. Archeological evidence found at site Localities DAW-A6 (Lower), DAW-A7, and DAW-A11 have yielded **Mode 1 Acheulean** artifacts. Localities DAW-A1, DAW-A2, DAW-A3, DAW-A4, DAW-A5, DAW-A6 (Upper), DAW-A8, and DAW-A9 have yielded **Mode 2 Acheulean** artifacts. Artifacts consistent with the **Middle Stone Age** have been recovered from locality DAW-A10. Key references: Geology and dating Clark et al. 1994, de Heinzelin et al. 2000; Hominins N/A; Archeology de Heinzelin et al. 2000.

"Dawn man" See *Pitdown*.

Day, Michael Herbert (1927–) Michael Day was born in London, UK. He served in the Royal Air Force from 1945 to 1948 and then entered the Royal Free Hospital School of Medicine where he earned his MB BS degree plus Membership of the Royal College of Surgeons (MRCS) and became Licentiate of the Royal College Physicians (LRCP) in 1954. In 1962 he was awarded his PhD for research on the anatomy and blood supply of the lumbosacral plexus. He spent his academic career within the University of London, first at the Royal Free Hospital School of Medicine (1957–62), then at the Middlesex Hospital Medical School (1962–72), and finally at St. Thomas's Hospital Medical School where he was the Head of the Anatomy Department (1972–89); he was appointed Reader in Physical Anthropology in 1969 and Professor of Anatomy in 1972. Although his PhD was in soft-tissue anatomy Day became involved, via **John Napier**, with the analysis of the hominin postcranial remains from **Olduvai Gorge** and this began a long collaboration with Louis and, more substantively, **Mary Leakey**. Initially together with Napier, but later on his own, he described and analyzed many of the key postcranial hominin fossils from Olduvai Gorge (**OH 8**, Day and Napier 1964; **OH 10**, Day and Napier 1966; **OH 20**, Day 1969; **OH 28**, Day 1971; **OH 34**, Day and Molleson 1976). He carried out the first multivariate analysis of a hominin postcranial fossil (**OH 10**, Day 1967), described and undertook the initial analysis of the hominin remains recovered from **Omo-Kibish** (Day 1969), and the hominin cranium from **Laetoli** (**LH 18**, Magori and Day 1983b) and contributed to the analysis of the postcranial fossils from **Swartkrans** and **Kromdraai** (Day and Napier 1964, Day and

Thornton 1986). Day was also one of the team of three anatomists who generated the initial descriptions of the hominin fossils recovered from **Koobi Fora**. His other important contribution to paleoanthropology was his authorship of the *Guide to Fossil Man*. This careful site-by-site treatment of the hominin fossil record was deservedly popular among researchers and students; the first edition was published in 1965 and the last, fourth, edition was published in 1986. Day also made notable contributions to professional organizations relevant to paleoanthropology, serving as President of the Royal Anthropological Institute (1979–83), and together with Peter Ucko he was instrumental in establishing the World Archeological Congress, being elected its Founding President in 1986.

day range The area exploited by an individual animal or group of animals during a day (i.e., a 24 hour period). Because it is a daily subset of movements within a home range, the day range is usually smaller than the home range. See also **home range**.

Daylight Cave See *Silberberg Grotto*.

dc Abbreviation for a deciduous canine. Upper, or maxillary, deciduous canines are identified by a line below the abbreviation (**d_c**) and lower, or mandibular, deciduous canines are identified by a line above the abbreviation (**d^c**).

de Heinzelin, Jean See *Heinzelin, Jean de (1920–98)*.

Deacon, Hilary John (1936–2010) Hilary Deacon was born in Cape Town, South Africa, and he completed his BSc in geology and archeology at the University of Cape Town in 1955. He worked as a geologist in East and West Africa before being appointed as an archeologist at the Albany Museum in Grahamstown in South Africa in 1963. In 1967, he spent a year at the University of London as a British Council Scholar and received his PhD from the University of Cape Town in 1974. Apart from the periods when he was a Visiting Professor at the University of California, Berkeley (1986), a Visiting Fellow at the Australian National University, Canberra (1984), and a Visiting Professor at the University of Chicago (1978), Hilary Deacon served as the head of the Archeology Department at

Stellenbosch University from 1971 until his retirement at the end of 1999. Deacon's special interest was the archeology of southern Africa and the origin of modern humans and arguably his most important contribution was the research he carried out at **Klasies River** from 1984 onwards. In addition, he contributed to paleoenvironmental studies and to a detailed study of the Fynbos Mediterranean System in the Cape. Deacon was a Past-President of the South African Archaeological Society, the Southern African Association of Archaeologists, and the South African Society for Quaternary Research, and was a member of the Board of Iziko Museums in Cape Town.

"Dear Boy" The nickname used by **Louis** and **Mary Leakey** for **OH 5**.

death rate, age-specific The instantaneous hazard of death at exact age t , and is often written as $\mu(t)$ or $h(t)$. The concept is closely related to the **age-specific probability of death**, the proportion of individuals who enter an age interval, but who die *within* that age interval. The age-specific death rate generalizes this by taking smaller and smaller age intervals, so that for example $\mu(50.29)$ is the death rate at exactly age 50.29 years. In the case where there is a constant hazard of death independent of age (also known as the exponential survival model) the hazard is the same as the instantaneous **crude death rate**. Organisms as diverse as yeasts, flies, worms, rodents, monkeys, and modern humans (Finch 2007) show age-specific death rates that do not follow an exponential survival model, but instead often follow a **Gompertz hazard model** for those who survive to adulthood.

débitage (Fr. *débiter*=to cut up) A French term used by English-speaking lithic technologists to refer to the flakes, flake fragments, and other debris that results from the process of stone tool manufacture. In French and some French translations the term is used to describe the action of intentional **knapping** as well as its byproducts.

deciduous dentition (L. *decidere*=to fall off and *dentes*=teeth) Refers to the teeth of the primary dentition (or milk teeth) shed during the normal course of dental development. In each jaw quadrant of all hominins and hominids it consists of two deciduous **incisors** (di1 and di2), a deciduous

canine (dc), and two deciduous **molars** (dm1 and dm2, or dp3 and dp4). Deciduous molars are occasionally found as fossils, but deciduous incisors and canines are rare; one of the exceptions is the southern African site of **Drimolen**. First lower deciduous molars, dm₁s, have been shown to be particularly useful for **alpha taxonomy**. For example, Robinson (1956) showed that the dm₁s of *Paranthropus robustus* and *Paranthropus boisei* have especially complex cusp morphology on their crowns.

declarative memory (L. *clarus*=to make clear) Memories come in two forms: those that can be explicitly recalled and those that cannot. Memories that can be articulated or consciously reckoned are referred to as declarative memories. Declarative memories stand in contrast to procedural memories, which are long-term memories for either skills or motor responses that are difficult to articulate or describe linguistically. Examples of this form of memory include most forms of motor learning such as tying one's shoes or riding a bicycle. Examples of declarative memory include **episodic memory**, having to do with the recollection of biographically relevant events, and **semantic memory**, having to do with knowledge of everyday facts or concepts that are disconnected from personal, autobiographical knowledge. Tulving (1983) has argued that while declarative semantic memory is likely to be phylogenetically ancient and shared among mammals and birds, declarative episodic memory is likely to be unique to modern humans, but researchers are unlikely to be able to determine whether this is the case.

decussation (L. *decussis*=the crossing of two structures after the roman numeral for 10, X, in which two lines intersect) A pattern formed by **enamel prisms** seen in hominin teeth, but it is most evident in rodent enamel. Enamel prisms do not typically run in a straight line from the **enamel dentine junction** to the surface of the tooth. Some researchers believe that over the dentine horn of a tooth cusp enamel prisms turn helically (like a snail shell) and intertwine as they move towards the tooth surface (e.g., Risnes 1986); this is known as gnarled enamel because of its complex appearance under a microscope. Others report a wave-like pattern in the **lateral enamel** (e.g., Osborn 1990, Macho et al. 2003). Typically prisms are said to twist in a sinusoidal manner two or three times before running straight to the surface in the outer one-third of the

enamel. When cut in cross-section, bands or tracts of prisms appear to intersect at an angle (thus the term enamel decussation) but actually they are just crossing over and past each other much as the component strands of a rope cross over one another. Christian Schreger and John Hunter both independently described the banding pattern visible on fractured or cut enamel surfaces that results from prisms moving in and out the plane of section; hence the eponymous term **Hunter–Schreger bands**, which are a manifestation of enamel decussation in enamel, bears both of their names. *See also* **diazone**; **enamel development**; **Hunter–Schreger bands**; **parazone**.

Dederiyeh (Location 36°24'N, 36°52'E, northern Syria; etym. “two entrances” in Kurdish) History and general description This cave site in the Afrin Valley, northern Syria, which is 400 km/250 miles north of Damascus and 60 km/40 miles northwest of Aleppo, was discovered in 1987 and was excavated for 5 years prior to the discovery of a child’s skeleton (**Dederiyeh 1**) in 1993. A second child’s skeleton (**Dederiyeh 2**) was identified in 1997 and as of 2000 the remains of at least 15 more individuals had been recovered. Fifteen recognizable layers are grouped into four major stratigraphic units with a combined thickness of 3 m. The artifacts from all four units correlate with those found at **Tabun** layer B, and are generally described as Levantine **Mousterian**. Each unit contains artifacts equivalent to the “Tabun-B Levantine Mousterian.” Temporal span and how dated? Synchronous with Tabun layer B from the archeological evidence. Hominins found at site **Dederiyeh 1** and 2, plus the remains of at least 15 other individuals. Archeological evidence found at site **Tabun-B** Levantine Mousterian. Key references: there is an excellent monograph on the context and morphology of the two **Dederiyeh** infant skeletons (Akazawa and Muhessen 2003) and several of the references below are from that publication; Geology and dating Akazawa et al. 2003; Hominins Akazawa et al. 1995, 2003; Archeology Akazawa et al. 2003.

Dederiyeh 1 Site **Dederiyeh**. Locality N/A. Surface/in situ *In situ*. Date of discovery August 1993. Finders Team led by Takeru Akazawa and Sultan Muhesen. Unit SU-III. Horizon Layer 11, but Akazawa et al. (1995) suggest it comes from Layer 8. Bed/member N/A. Formation N/A.

Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age No dates, but the artifacts are similar to those from **Tabun** layer B. Developmental age *c.*2 years. Presumed sex Unknown. Brief anatomical description This fragmentary, but remarkably complete, infant skeleton was found in more than 200 pieces. It includes much of the skull, axial skeleton, and parts of all four limbs, but because of its immaturity the hands and feet are relatively poorly represented. Announcement Akazawa et al. 1993. Initial description Akazawa et al. 1995. Photographs/line drawings and metrical data Akazawa et al. 1995, 2003. Detailed anatomical description Akazawa et al. 2003. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance A remarkably complete skeleton that provides important information about the ontogeny of *H. neanderthalensis*. Location of original Not known.

“**Deep Skull**” *See* **Niah** cave.

deep sea temperatures The temperature of the deep sea (defined as depths of >1 km/0.6 miles) is set by conditions in the regions of sinking water masses, which today are in the North Atlantic and around the coast of Antarctica. Deep sea temperatures are remarkably homogeneous and relatively stable through time within 2–4°C; however, subtle changes did occur between glacial and interglacial conditions. The **benthic** oxygen isotope record derived from calcitic **foraminifera** is used to reconstruct deep sea temperatures and **glacial ice volumes**. The cyclicity captured in these records and their uniformity across the world’s oceans provides a means of temporal correlation between ocean drilling sites. *See also* **astronomical time scale**.

definition A list of the features shared by all, or at least a large majority, of the members of a **taxon**. The features given in a definition of a taxon include all of its attributes, not just the ones that make it distinctive: the latter are the ones that are emphasized in the diagnosis of a taxon. (syn. **description**). *See also* **diagnosis**.

deflation The winnowing process whereby the surface of a body of sediment is partially eroded,

particularly by wind activity. This preferentially removes the finer-grained components of the sediment (sands, silts, and clay) and therefore concentrates the remaining larger/heavier clasts, including bones and stone tools. The sediments at sites in Chad (e.g., **Toros-Menalla**) are an example of deflation.

deflecting wrinkle In most lower molars the main ridge that runs from the metaconid cusp tip to the central fossa follows a straight path in a distobuccal direction. However, in some cases, the initial section of the ridge is orientated buccally and then it runs in a distal direction. This latter variant of the ridge running off the metaconid is described as a “deflecting wrinkle.” The feature is illustrated in Morris (1970) and Scott and Turner (1997).

degrees of freedom Functional morphology Refers to the number of independent axes at which movement can take place at a moveable (i.e., synovial) joint. A joint like the modern human elbow joint can only flex and extend, so it is uni-axial and thus it has *one* degree of freedom. The carpometacarpal joint of the thumb (between the first metacarpal and the trapezium) has two independent axes that are determined by the shape of the joint surfaces and thus it *two* degrees of freedom. Since there is a maximum of three axes about which independent rotations can occur, three is the maximum number of degrees of freedom there can be at a joint. Statistics In statistics, degrees of freedom refers to the number of values that are free to vary when calculating a particular statistic. For example, for a sample of n measurements with a given mean, $n-1$ of the measurements can take on any value. But if you know $n-1$ measurements then one can calculate the *exact value* of the n th measurement that will produce the given mean. Thus only $n-1$ of the n values are free to vary, for the n th value *must* equal whatever number will result in that particular mean value. This is why a one-sample t test that compares the mean of a set of measurements to a particular value has $n-1$ degrees of freedom. However, in **linear regression**, for a given slope and intercept, $n-2$ values can vary freely and knowing those $n-2$ measurements allows one to calculate what the $(n-1)$ th and n th values *must* be in order to produce the given slope and intercept. This is why there are $n-2$ degrees of freedom for linear regression.

But when linear regression is performed with the intercept constrained to zero (as is the case **phylogenetically independent contrasts**) the intercept is *not* a function of the data, thus given a particular slope only $n-1$ values can vary, so linear regressions with constrained slopes have $n-1$ degrees of freedom. In general, statistics tend to have as many degrees of freedom as the number of observations made (n) minus the number of **parameters** estimated in the calculation of that statistic (e.g., two parameters, the slope and the intercept, are estimated in the case of linear regression). With regard to the effect of degrees of freedom on statistical tests, as the number of values that can vary independently increases, so does the confidence in the accuracy of estimated parameters (e.g., mean, slope intercept, etc.). Thus, if all else is held constant, statistical significance increases as the number of degrees of freedom increases.

deinothere The informal name for the taxa within the family Deinotheriidae, which contains all of the proboscideans with downward-curving tusks. *See also* **Proboscidea**.

Deinotheriidae (Gk *deinos*=terrible plus *ther*=combining form, wild beast) A family of extinct Old World Proboscidea whose main distinguishing characteristics are downward-facing tusks in the lower jaw and, in later forms, strongly lophodont molars with extremely thick enamel; deinotheres have no upper tusks. Even when fragmentary, deinothere molars are easy to identify in fossil assemblages so their temporal and spatial distribution is well documented. The African species *Deinotherium bozasi* is known from the late Miocene and was the latest surviving form, with a last appearance date of approximately 1 Ma. It is found at many archeological and hominin paleontological sites. *Deinotherium* remains found with **Developed Oldowan** stone tools at FLKN II at Olduvai Gorge, Tanzania, have been cited as an early example of a single carcass butchery site.

Deinotherium *See* Deinotheriidae.

Deir El-Fakhuri *See* Esna.

DEJ Acronym for dentine-enamel junction. It is one of two conventional abbreviations (**EDJ** is the other) used for the interface between the

underlying dentine and the overlying enamel. *See* **enamel-dentine junction**.

Deko Weko One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin** of central Flores, eastern Indonesia.

deleterious mutation (*L. deleterius*=to harm and *mutare*=to change) A **mutation** that causes a reduction in the **fitness** of an individual (e.g., it may cause disease, reduce survival in other ways, or affect reproduction). Examples of deleterious mutations affecting modern humans are mutations in the *CFTR* gene (which encodes the cystic fibrosis transmembrane conductance regulator protein) that cause cystic fibrosis, deletions in the **DAZ** region of the **Y chromosome** that result in low sperm count and infertility, and mutations in the *HEXA* gene that cause Tay-Sachs disease.

deletion (*L. delere*=to abolish) A mutation in the **genome** where one or more **base pairs** (i.e., pairs of **nucleotides**) have been removed or deleted from a sequence of nucleotides. These deletions can be as small as one base pair or involve many thousands of base pairs. In a coding region any deletion that does not involve a multiple of three base pairs causes a **frameshift mutation**, which is typically deleterious. Large deletions that include genes, such as the **DAZ** region of the **Y chromosome**, or a substantial portion of a **chromosome** are usually detrimental whereas deletions in non-coding regions are usually neutral. **Insertions** and deletions are commonly referred to as **indels**.

δ Delta, or δ , is a standardized notation used in **stable-isotope biogeochemistry**. The δ notation is used to refer to the proportion of heavy to light **isotope** within a given substance relative to an international standard, where $\delta = [(R_{\text{sample}}/R_{\text{standard}}) - 1] * 1000$, and $R = {}^{13}\text{C}/{}^{12}\text{C}$, ${}^{15}\text{N}/{}^{14}\text{N}$, ${}^{18}\text{O}/{}^{16}\text{O}$, etc. Values are reported as parts per thousand (‰). It is important to note that δ values are relative. International standards differ for each element; thus δ values for each element are on different scales and are not directly comparable.

delta (*Gk delta*=fourth letter of the Greek alphabet, Δ , that is shaped like a triangle) *See* **carbon isotope analysis**; **deltaic**; **stable isotopes**; **hydrogen isotopes**.

deltaic (*Gk delta*=fourth letter of the Greek alphabet, Δ , that is shaped like a triangle) The name given to sediments formed in the sometimes triangular-shaped region at the mouth of a river. They are deposited when the flow in the river reduces prior to the river entering a lake or the sea. Because the water energy in a delta is very low the sediments tend to be dominated by fine-grained material (e.g., silts and clays).

deme (*Gk demos*=people) An informal category used for a geographically localized population of closely related individuals. When applied to the fossil record the concept is sometimes referred to as a "p-deme," paleodeme, or paleocommunity-deme, and the closeness of the relationship among individual fossils is determined from their morphology; the more similar they are, the closer the relationship is inferred to be (but *see* **homoplasy**). Clark **Howell** (1999) recommended that it might be less controversial to use p-demes rather than species for discussions about the taxonomy of the hominin fossil record. Presumably one or more p-demes may correspond to regional variants within a single species (i.e., equivalent to a subspecies) or they could correspond to the hypodigm of a species. The use of p-demes does not solve the problem of how many species to recognize in the fossil record, but this informal category may be a useful way to discuss the different parts of the fossil record prior to making decisions about its taxonomy.

demography Hinde (1998, p. 1) defines demography as "the study of population structure and change." This definition is not particularly useful within biological anthropology, as "population structure" is often used to refer to population genetic structure. A better definition of demography for the purposes of paleoanthropology is the study of age and sex structure and/or population size.

denature (*L. de*=cessation or separation and *hatura*=born or produced) The process whereby the DNA double helix is separated (or denatured) into two single strands. If you visualize DNA as a twisted ladder, denaturing breaks the hydrogen bonds that form the rungs of the ladder. Denaturation requires either heating or chemical treatment. *See also* **base pair**; **deoxyribonucleic acid**; **DNA hybridization**.

dendrite (Gk *dendrites*=of, or pertaining to, a tree) An extension of the cell body of a **neuron** that branches in a tree-like fashion (also known as a “dendritic arbor”) and that serves as the primary site for receiving and integrating information coming into that neuron from other neurons. Some dendrites have specialized outgrowths along their shaft called spines. These spines are the sites of excitatory synaptic inputs. Although some neurons lack dendrites (e.g., dorsal root ganglion cells), others have multiple dendritic trunks that arise from the neuronal cell body. For example, the **pyramidal cells** of the **cerebral cortex** have long slender sets of dendrites that emerge from the apex of the cell body, called *apical* dendrites, and other sets that emerge from the base of the cell, called *basal* dendrites. The basal dendrites of the **prefrontal cortex** in modern humans have been shown to have a much higher density of spines than in any other primate examined (Elston et al. 2006), but as yet comparable observations about ape prefrontal cortical neurons have not been made.

dendritic arbor (Gk *dendrites*=of, or pertaining to, a tree and L. *arbor*=tree) An extension of the cell body of a **neuron** that branches in a tree-like fashion and serves as the primary site for receiving and integrating information coming into that neuron from other neurons.

dendrochronology See radiocarbon dating.

Denisova Cave (Location 51°40'N, 84°68'E, Russia; etym. unknown, although Denisova is a common last name) History and general description This cave site in the Altai Republic of Siberia has been explored since 1977 and contains Middle and Upper Paleolithic assemblages. The **mitochondrial DNA (mtDNA)** from a hominin phalanx found in 2008 was found to be distinct from that of both *Homo neanderthalensis* and *Homo sapiens*, suggesting the late survival of another, yet-undefined, hominin lineage. Furthermore, analysis of the Denisova mtDNA established that it was more different from modern human mtDNA than it was from Neanderthal mtDNA. Temporal span and how dated? The lowest levels were dated to between 171 and 282 ka using **thermoluminescence dating**, but these dates are likely too old. **Biostratigraphy** suggests a maximum age of **Oxygen Isotope Stage 5e** (c.125 ka). The phalanx derives from a layer

with three **uncalibrated radiocarbon ages** of 48,650 ± 2380 years BP, an infinite age of more than 37,235 years BP, and 29,200 ± 360 years BP. Hominins found at site The proximal epiphysis of a juvenile manual phalanx from an unidentified hominin species was recovered. Archeological evidence found at site The site contains a sequence of Middle and Upper Paleolithic layers. The layer from which the fossil was recovered contains elements of both industries, including both bone tools and Levallois points. The authors argue that this is not evidence of post-depositional stratigraphic mixing, since other Early Upper Paleolithic sites in the area have similar assemblages. Key references: Geology, dating, and paleoenvironment Derevianko 1998, Krause et al. 2010; Hominins Krause et al. 2010; Archeology Derevianko 1998, Krause et al. 2010.

dense bone See bone.

dental crypt (L. *dens*=tooth and *crypta*=hidden) The space within the **alveolar process** of the maxilla or mandible within which a tooth germ develops. Bone is resorbed to make space for the developing **tooth germ**, and this space may be detected radiographically before hard-tissue formation begins.

dental development A broad term that encompasses the initiation, morphogenesis, mineralization, and eruption of the teeth and even the establishment of occlusion. Modern human dental development is a process of c.20 years, stretching from embryo to young adult; the same process takes c.12 years in chimpanzees (Nanci 2007, Kuykendall 2009). Because teeth are highly mineralized, they are conserved as fossils more often than other tissues, and because they are not remodeled their macrostructure and microstructure preserve a record of history, of their formation, and of interruptions to their growth. Some of dental development have a lower coefficient of variation than comparable measures of skeletal development (Lewis and Garn 1960) and a lower component of environmental variance (Tanner 1955). Mammalian dental development is both revealing and amenable to study because individuals mature through a series of distinctive stages to a fixed final size with many clues to developmental stage and age. Each tooth of each tooth type is a variable and within each tooth each component of the crown and root is another variable; dental

development is the antithesis of a simple continuous increase in size. Recognizable dental stages are often used to define traditional life stages of infant, juvenile, and adult in both human biology and primatology (Schultz 1960, Bogin 1999b). In modern humans initial dental development is observed in the late stage embryo, with the differentiation of precursor tissues. Tooth buds form as an organic matrix that is subsequently mineralized: in modern humans mineralization of deciduous teeth begins in the second trimester and for earliest permanent teeth just before birth (see Kraus and Jordan 1965). Cell activity responds to circadian rhythms, leaving lines and bands in enamel and dentine that reflect both the passing days and also longer-period physiological rhythms (see Aiello and Dean 1990). Stressors can interrupt growth, leading to more pronounced lines; the best known of these is the neonatal line, a virtual “birth certificate” preserved in teeth that were mineralizing at birth. Eruption of teeth through the alveolar bone and gingival tissue occurs after tooth crowns are complete and roots are actively forming; roots close after eruption. At this point the enamel cap may be worn or decayed, but cannot grow, although dentine-producing cells on the interior of the tooth can respond to stimuli in maturity by gradually filling in the pulp chamber. Most chronologies of dental development are chronologies of mineralization or emergence, although chronologies based on dissection or histology and microscopy are far more sensitive to the early stages of dental development than are radiographic studies (Beynon et al. 1998). Although most primates are born with some teeth already erupted, modern humans and great apes are born with toothless gums (Smith et al. 1994). At birth, in both modern humans and chimpanzees mineralization of the crowns of deciduous teeth is well under way and first permanent molars are mineralized at the cusp tips, although the chimpanzee neonate has more advanced deciduous crowns. In slow-growing mammals like anthropoid primates, the deciduous dentition may function alone for a prolonged period before the first permanent molar emerges. Molars emerge distal to the deciduous dentition, apparently developing in time with the growing face and jaws. The small deciduous teeth, partly or wholly formed *in utero* in placental mammals, are eventually shed and succeeded by more densely mineralized “replacing” permanent incisors, canine, and premolars, emerging in limited and characteristic sequences (Schultz 1935, Smith 2000). Dental development has been both the subject

and a tool of human evolutionary research. As actual data on timing became available on a variety of primates, the age of emergence of M_1 was shown to be highly correlated with onset or duration of other events in life history, from gestation length to reproductive maturation and life span, brain size and, to a lesser degree, body size (Smith 1989). Some events in dental development are related to events in life history (e.g., weaning and emergence of first permanent molars; sexual maturity and canine emergence). On finer scales, tooth surfaces preserve evidence of growth disturbances that reveal the timing of stress episodes that characterize populations and particular ages of death (Armstrong et al. 2009). In the fossil record, tooth histology can be used to count or estimate (depending on the scale of inquiry) the time elapsed between birth and death for individual juvenile fossils. The key to opening the hominin fossil record to such inquiry has been the introduction of methods that avoid destruction of specimens, either by using surface manifestations of incremental features (Bromage and Dean 1985) or, more recently, through high-energy imaging of hidden increments (Smith and Tafforeau 2008). As work progresses, each fossil juvenile with an associated age of death builds towards a chronology of growth and development of its own species. To date, dental histologists have established that *Australopithecus* and *Paranthropus* matured on a time scale closer to apes than to modern humans (Beynon and Dean 1988); dental development within the genus *Homo* is under investigation (Smith et al. 2007, Dean and Smith 2009). In recent years, experimental studies (often with mice) manipulate dental development to discover how it is regulated on a genetic or cellular level and how a change in developmental program can alter tooth shape, size, and proportion (Jernvall and Thesleff 2000). This renewed interest in ontogeny and phylogeny (as “evo-devo”) is yielding new perspectives on the historical record of dental evolution. *See also* enamel development; dentine development; hypoplasia; long-period incremental lines; perikymata; secondary dentine; short-period incremental lines; synchrotron radiation micro-computed tomography.

dental follicle (L. *dens*=tooth and *folliculus*=a little bag, diminutive of *follis*=a bag) The fibrous sac that surrounds the developing tooth germ in the bony crypt. The dental follicle begins as a cellular condensation of mesenchymal origin and when fully formed it encloses the developing

tooth germ, both enamel organ and dental papilla (the future pulp). The follicle is maintained in constant relationship to the mucous membrane that lines the mouth, or oral cavity, through its attachment to the gubernacular cord that runs in the **gubernacular canal**. The dental follicle is involved in the formation of alveolar bone and **cementum** as well as with tooth eruption.

dental formula (L. *dens*=tooth) The numbers of teeth in each of the four quadrants of the jaws. The formula is written beginning mesially with the number of incisors (I or di), the number of canines (C or dc), the number of premolars (P), and ending with the number of molars (M or dm/dp). In all higher primates, including fossil hominins, the dental formula for the normal **deciduous dentition** is “2. 1. 2,” and for the normal **permanent dentition** it is “2. 1. 2. 3.”

dental macrowear (L. *dens*=tooth and Gk *macros*=large) Tooth wear you can see with the naked eye. *See* **tooth wear**.

dental mesowear (L. *dens*=tooth and *mesos*=middle) Tooth wear you can see with the naked eye. *See also* **tooth wear**.

dental microwear Occlusal tooth wear that needs a microscope in order to see it. Dental microwear focuses on the size, number and orientation of microscopic scratches, pits, etc. on the enamel, or on the overall complexity and the degree of **isotropy** of the enamel surface. Whereas dental macrowear is a measure of the abrasiveness of the diet in the long term, dental microwear signals on fossil teeth indicate whether the food ingested in the days or weeks before death contained hard or abrasive material. Such abrasive material can be either intrinsic to the ingested foods (e.g., **phytoliths**) or extrinsic to the foods (e.g., adherent sand grains). Dental microwear can also detect evidence for softer or tougher foods (e.g., polished or finely pitted surfaces). If any striations or scratches have a predominant orientation, this can be used to reconstruct the direction of the jaw movement(s) that generated the microwear. Dental microwear studies were revolutionized when precision-molding materials were introduced, enabling positive molds of whole teeth to be examined with a scanning electron microscope (Walker et al. 1978). Fred Grine, Peter Ungar, and Mark Teaford have been in the van of applying dental

microwear analysis to fossil hominins (e.g., Ungar et al. 2006) and in the process they have helped develop new analytical methods (e.g., dental microwear textural analysis; see Scott et al. 2005).

dental microwear textural analysis *See* **dental microwear**.

dental reduction Decrease in the metric proportions of teeth between successive taxa or populations. For example the reduction in crown size from the large postcanine teeth of *Australopithecus* to the smaller postcanine teeth of early *Homo* and the further reduction in crown size from pre-modern *Homo* to *Homo sapiens*. The term may also refer to a **metameric** trend of decreasing size along the tooth row in a tooth type (e.g., the pattern of decreasing crown dimensions from M1 to M3 seen in later fossil hominins and in modern humans).

dental wear *See* **tooth wear**.

dentine (L. *dens*=a tooth and *inus*=“of” or “relating to,” hence “pertaining to a tooth”) The term coined by Richard Owen for the hard tissue that forms the bulk of a tooth crown and tooth root. Dentine is one of the three dental hard tissues (the others are **enamel** and **cementum**). Dentine (or ivory, which is the same thing), unlike bone, contains no blood vessels or included cell bodies. However, fluid-filled dentine tubules containing some nerves and odontoblast processes make dentine a vital (i.e., living) and exquisitely sensitive tissue. Like enamel, dentine is biphasic [i.e., it consists of both a mineral inorganic **hydroxyapatite** phase (70%) and an organic phase made up of collagen, lipids, and noncollagenous proteins]. The dentine core of a tooth is continuous between the crown and root. Coronal dentine underlies the enamel cap and root dentine, which is covered by cementum, supports the crown and anchors the tooth within its bony **alveolus** or socket. Primary dentine forms the first-formed inner part of the coronal dentine and the root dentine. Secondary dentine is slowly and continuously laid down after primary crown and root formation are complete around the periphery of the pulp chamber, thus reducing the size of the pulp chamber with age. Tertiary dentine, a reactionary tissue that is secreted quickly and irregularly in response to exposure of dentine through

attrition, abrasion, caries, or trauma, blocks off open tubules from the pulp (Nanci 2003). Dentine is not as hard or dense as enamel, but it is harder and denser than compact bone. Unlike enamel, dentine has no “grain” or planes of cleavage and it is a relatively elastic material (hence ivory was originally the material of choice for billiard or pool balls). Several classes of **incremental features** are found in dentine, including long-period **Andresen lines** and short-period **von Ebner’s lines**. They correspond to long- and short-period increments in enamel (Dean et al. 1993).

dentine development Odontoblasts derived from the mesenchymal cells of the dental papilla (the precursor of the dental pulp) secrete a collagenous matrix called predentine which undergoes **mineralization** to form primary **dentine**. Dentine formation begins at the **dentine horn** that underlies the future cusp tip and progresses inward through secretion, thus slowly defining and reducing the size of the central pulp chamber as tooth formation proceeds. Extension of the odontoblast sheet finally reaches the apex of the **root**. The extension rate of the dentine is the rate at which new terminally differentiated odontoblasts appear along the length of the future **enamel-dentine junction**, or cemento-dentine junction. Like enamel formation the secretion of dentine has short-period (*c.* 24 hour) and long-period (>24 hour) rhythms; these result in dentine increments that are preserved in the fully formed tissue as **von Ebner’s lines** and **Andresen lines**, respectively. The secretory process of a single odontoblast remains behind in a canal called a **dentine tubule**, which runs from the enamel-dentine junction to the pulp. Dentine formation and **enamel formation** proceed in tandem, but with dentine formation slightly in advance of enamel formation (Witzel et al. 2008).

dentine horn The tallest point of the **dentine** underlying one of the cusps or features that make up the **enamel** cap of a tooth. The tip of the dentine horn is usually slightly posterior to the corresponding enamel cusp tip but projections of dentine that may be “horn-like” or pointed exist at the **enamel-dentine junction** (or EDJ) with little or no overlying enamel relief related to them. A signaling center, the enamel knot, which controls cell proliferation, appears initially over the tip of each of the future dentine horns. There

is reciprocal induction between the epithelial and mesenchymal components of the inner enamel epithelium so that signals exchanged between the future enamel- and dentine-secreting cells initially trigger the deposition of dentine and then subsequently enamel. Dentine matrix secretion proceeds from the EDJ inwards towards the pulp and then enamel matrix secretion follows in the opposite direction from the EDJ outwards towards what will eventually be the surface of the crown.

dentine tubule Small rounded tunnels approximately 2–3 μm in diameter running through the dentine from the pulp chamber towards the **enamel-dentine junction** or the cemento-dentine junction at the root surface. In life each tubule is fluid-filled and for a variable distance it is occupied by the elongated process of an **odontoblast** and a proportion of dentine tubules also contain nerve fibers. Changes in either osmotic pressure (e.g., sugar on exposed dentine) or temperature cause intertubular fluid to rush inwards or outwards and trigger dentine sensitivity. This is a major mechanism for protective feedback against tooth damage. Dentine tubules are similar in function to the canaliculi in bone that connect osteocytes and which signal changes in stresses or strains via fluid-filled tubules. See Nanci (2003) for an illustration. *See also* **dentine development**.

dentinogenesis (L. *dens*=a tooth and *inus*=“of” or “relating,” and Gk *gena*=to give birth to) The cellular activity involved in the development of **dentine**. *See also* **dentine development**.

dentition (L. *dentes*=teeth) A collective term for all of the teeth in an individual. In the context of the hominin fossil record it is used to refer to the teeth preserved in a particular specimen (e.g., “the dentition of KNM-ER 3734 comprises the roots and crowns of the left C, P₃, P₄, M₁, M₂, and the root and part of the M₃ crown”). Otherwise it refers to the type of dentition [i.e., **deciduous dentition** (primary) or **permanent dentition** (secondary)].

dento-gnathic (L. *dens*=tooth and Gk *gnathos*=jaw) Shorthand for “teeth and jaws.”

deoxyribonucleic acid (or DNA) A nucleic acid the components of which are **bases** (the four standard versions of bases are adenine, guanine,

cytosine, and thymine), and a backbone made of a phosphate and a sugar. In DNA the sugar is 2-deoxyribose and it alternates with a phosphate to form the backbone. These three components (i.e., a base+phosphate+a sugar) make up a **nucleotide**, and nucleotides linked by phosphodiester bonds make up a single strand of DNA. The phosphodiester bond joining adjacent nucleotides is formed from the phosphate group of one nucleotide and the hydroxyl group of the other. The two ends of a single strand of DNA are distinctive. The 5' (or five prime) end is called that because the fifth carbon of the deoxyribose sugar has a terminal phosphate group attached to it. The other end, the 3' (or three prime) end, is called that because the third carbon has a hydroxyl group attached. The significance of the directionality of a DNA strand is that the processes of **replication** and **transcription** only occur in the 5' to 3' direction. Typically, DNA is present as a double strand arranged in a double helix with the two strands being held together by hydrogen bonds that link a base in one of the DNA strands with a complementary base in the other strand (i.e., adenine always pairs with thymine and guanine always pairs with cytosine). In double-stranded DNA the two DNA molecules are antiparallel (i.e., one of the strands is in the 3' to 5' orientation, while the other is in the 5' to 3' orientation). The structure of DNA was solved in 1953 by Francis Crick and James Watson with the help of X-ray diffraction data from Rosalind Franklin. Some DNA (the minority) contains genetic information in the form of **genes** and is called coding sequence, while the vast majority of the DNA is called structural or non-coding DNA (e.g., the DNA in the centromeres of **chromosomes**). Coding DNA is transcribed (*see* transcription) into **ribonucleic acid** (or RNA). The RNA is then either translated (*see* translation) into **protein** or it forms one of many kinds of functional RNA molecule [e.g., transfer RNA (tRNA), ribosomal RNA (rRNA), or small interfering RNA (siRNA)].

dependency ratio A ratio of those individuals "too young" or "too old" to be self-sufficient against those individuals who are between these two age thresholds, and are consequently at an age where they can be self-sufficient. In the **demography** of recent modern human populations these ages are often taken as the age at which one reaches maturity (generally taken as 15 years) and the age of retirement (generally 65 years), so

that the dependency ratio is the sum of those individuals less than 15 years old and those individuals greater than 65 years old, divided by the number of individuals between 15 and 65 years old. This is therefore the number of individuals who are "dependent" per the number who are "self-sufficient." Note that this ratio, or the related proportion of individuals who are "self-sufficient," must be calculated using the number of individuals alive in an age interval. Consequently, a **life table** or hazard model approach must be used in **paleodemography** to calculate the dependency ratio from an estimate of the **living age distribution**. Also note that the age thresholds used in the demography of recent modern human populations may be completely inappropriate for prehistoric modern humans and for other hominin taxa.

derived (L. *derivare*=to draw off) A version or state of a **character** that is not its primitive **character state**. For example, if the character is the root system of the first mandibular premolar tooth, the primitive condition for the hominin clade is most likely two roots, a plate-like distal root, and a mesiobuccal accessory root, or in shorthand 2R: MB+D. In this example there are two derived trends within the hominin clade. One is toward root reduction and simplification; that is, a single root (1R) via one root divided for part of its length (1/2R: Tomes' root). The other is toward a more complex molar-like system of two plate-like roots (2R: M+D). *See also* **apomorphy**.

derived character A version or state of a **character** that is not its primitive **character state**. *See also* **derived**; **apomorphy**.

dermal bones (Gk *derma*=skin) Bones of the cranium the shape of which resembles that of the flat cells that make up the epidermis of the skin. The dermal bones form from connective tissue by a process called intramembranous **ossification** and they make up the **desmocranium**. *See also* **ossification**.

dermocranium *See* **desmocranium**.

description A list of features shared by all or at least a large majority of the members of a taxon. It is sometimes referred to as the **definition** of a taxon.

desmocranium (Gk *desmos*=to connect and *kranion*=brain case) The part of the **cranium**

formed from connective tissue by the process called intramembranous **ossification**. The desmocranium consists of most of the **calvaria**, a very small part of the **basicranium**, and much of the **face** and **mandible**. The calvarial elements are the flat, or squamous, components of two unpaired bones (the frontal and the occipital), the two parietal bones, and the squamous part of the paired temporal bones. The frontal and temporal components form from neural crest cells, the parietals from mesoderm, and the occipital component has a mixed neural crest/mesodermal origin. The parts of the basicranium that form via intramembranous ossification are the tympanic component of the temporal bone and the medial pterygoid plate. The bones of the face that form via intramembranous ossification include the paired lacrimal, **maxilla**, **palatine**, and **zygomatic** bones, the unpaired **vomer**, and the mandible. *See also ossification.* (syn. dermocranium).

deuterium A stable isotope of hydrogen with two neutrons, also called ^2H . *See also $^2\text{H}/^1\text{H}$: hydrogen.*

Developed Oldowan An African stone tool tradition defined by Mary Leakey. It was based on **artifact assemblages** excavated from Beds II to IV, **Olduvai Gorge**, Tanzania, that were judged to be advanced relative to the **Oldowan** and which largely overlapped the **Acheulean** industry in time. The Developed Oldowan, which was seen by Leakey as emerging directly from the Oldowan, was suggested to have three time successive phases. The oldest phase, Developed Oldowan A (*c.*1.7–1.4 Ma), was known from lower and middle Bed II and differed from the **chopper-** and **flake-**dominated Oldowan *sensu stricto* primarily in having a higher frequency of subangular to round artifacts termed “subspheroids and spheroids,” as well as a higher frequency of crude **handaxe-**like artifacts termed “protobifaces.” Developed Oldowan B was viewed as a continuation of Developed Oldowan A, with the addition of “poorly made,” generally small, bifaces as well as a higher frequency of light duty (small flake) tools. It is known from middle and upper Bed II and possibly Bed III at Olduvai Gorge. Developed Oldowan C was described as having a higher proportion of light duty tools as well as a higher frequency of pitted **anvils** and **hammerstones** relative to the Developed Oldowan B and was best known from Bed IV. In reality, there is not much distinguishing

the Developed Oldowan B and C and some would subsume the former into the latter and if that is done they are **coeval** with the Acheulean at Olduvai Gorge for approximately a million years (*c.*1.5–0.5 Ma). Leakey argued that the Developed Oldowan and Acheulean likely represented two distinct cultural traditions, perhaps made by *Homo habilis* and *Homo erectus*, respectively. This interpretation has been called into question on several grounds. First, the protobifaces seen in the Developed Oldowan A may be bifacial cores that fortuitously attained a biface-like shape through heavy reduction rather than through a conscious attempt to make a handaxe. There is thus little distinguishing the Developed Oldowan A and the Oldowan *sensu stricto* and the former could reasonably be collapsed within the latter. Second, differences in biface form between the Developed Oldowan B and the Acheulean likely reflect differences in blank shape (cobble vs flake) and raw material, rather than “cultural” differences. Finally, the presence in the Developed Oldowan B and C of low frequencies of bifaces made on large flakes in a manner indistinguishable from the Acheulean suggests a connection between these traditions. Rather than being transitional between the Oldowan *sensu stricto* and the Acheulean, or a separate tradition from the Acheulean, the Developed Oldowan may be best regarded as a biface-poor **facies**, or variant, of the Acheulean.

development Indicating an increase in functional ability, sometimes used interchangeably with maturity. The end point of development is often considered the age at which successful procreation is functionally possible. This involves biological as well as behavioral maturity, and is complete in the late teens in modern humans. The relationship between growth and size and progress in maturation is not a linear or straightforward one, especially in modern humans. The conflation of chronological age, overall size, and degree of development is one that obscures the meaningful way in which these systems can vary among individuals or populations. The most commonly used markers of development include secondary sexual development, skeletal maturity, and dental maturity (which also mature according to dissimilar schedules). This dissociation between processes of development, as seen in KNM-WT 15000, creates problems for researchers wishing to estimate age of extinct species based on developmental criteria drawn from extant populations: both the intra- and

interpopulational variation provide challenges, as do the inconsistent agreement between chronological and developmental age assessed by examination of multiple systems. *See also* KNM-WT 15000.

developmental stability Developmental stability refers to the tendency for **development** to produce the same **phenotype** under the same environmental conditions. One measure of developmental stability is the **variance** that remains once both genetic and environmental factors are accounted for. The closest approximation of this is the random variation that occurs across planes of symmetry in symmetrical organisms, or fluctuating asymmetry. The variance of genetically identical individuals under identical environmental conditions is also a theoretically possible measure. Variation in developmental stability has been linked to stress, sexual selection, phenotypic extremeness, and **heterozygosity** although all of these correlations are weak, difficult to detect, and controversial.

Devil's Lair (Location 34°19'S, 115°9'E, Australia; etym. a cave in which bones of an extinct Tasmanian Devil were found) History and general description Devil's Lair, a cave near Augusta in southwestern Australia, documents a long human cultural occupation during the late Pleistocene that includes hearths, artifacts, rock art, and items of personal adornment. A hominin tooth and an ilium have been recovered from the site. Temporal span and how dated? The cave was periodically occupied, presumably by modern humans, from *c.*48 to 13 ka with the modern human skeletal remains likely dating to the end of the occupation. The earliest date of occupation in the cave was corroborated by four independent dating techniques thus supporting an early occupation of the Australian continent. Hominin found at site The Devil's Lair ilium is that of an aged modern human adult male. Archeological evidence found at site Hearths, tools, rock art, and personal adornment including a pendant and beads. Key references: Geology, dating, and paleoenvironment Turney et al. 2001; Hominins Davies 1968; Archeology Dortch 1979.

Devil's Tower *See* Gibraltar.

dexterity (L. *dexter*=on the right side, or skillful) Having precision and/or skill when performing a function using the fingers/hands (e.g., the manufacture of an **Aurignacian** fine bone

needle requires more dexterity than the manufacture of an **Oldowan** chopper). As the etymology implies it refers to most people's preference for their right hand when performing such functions.

dextra (L. *dexter*=skillfull) Refers to the D- or right-handed form of a complex molecule. *See also* **epimerization**.

DFA *See* **discriminant function analysis**.

DFT Abbreviation for **Duinefontein** (*which see*).

DHA Abbreviation of docosaheaxanoic acid. *See* **essential fatty acids**.

di Abbreviation for a deciduous incisor. Upper, or maxillary, deciduous incisors are identified by a superscript number (di¹ and di²) and lower, or mandibular, deciduous incisors by a subscript number (di₁ and di₂).

diachronic (Gk *dia*=through and *kronos*=time) Any change or process that occurs through time (e.g., evolution, radioactive decay).

diagenesis (Gk *dia*=through, across and *genesis*=birth, coming into being) The complex physical, chemical, and biological changes that occur when sediments are converted into rocks and mineralized tissues (bones and teeth) turn into fossils. During the process organic and inorganic components of the biogenic material can be altered and replaced by chemicals from the surrounding burial environment. An understanding of the processes involved, their effect, and the degree of alteration of biogenic signals is critical for the meaningful interpretation of data obtained from archeological/fossil bone and teeth for the reconstruction of diet, habitat, migration, or climate. Post-mortem diagenesis of mineralized tissues affects both the organic and mineral phases through processes of either degradation and/or exchange of single elements and molecules. Investigations of the mechanisms and effects of diagenesis include the measurement of changes in crystallinity and phase of the mineral, rare earth element uptake and distribution in the specimen, the assessment of collagen preservation, microbial degradation, and stable isotope analyses of various compounds such as oxygen from mineral derived phosphate and carbonate, and compound specific

stable isotope analyses of the organic phase. See reviews by Collins et al. (2002), Hedges (2002), and Lee-Thorp (2008).

diagenetic See *diagenesis*.

diagnosis (Gk *diagnosis*=to distinguish). When a new hominin species or genus is announced one of the requirements is that the authors provide a diagnosis. This is a list of the features or characteristics shared by all (or a large majority) of the members of a taxon that enable its members to be distinguished from the those of other taxa. There is considerable confusion about the proper use of the terms diagnosis and **definition**. Diagnosis is what a medical doctor does when she/he uses their skills and experience to discriminate between the likely causes of an illness. Thus, in taxonomic terms a diagnosis is how you tell taxa apart. A definition, on the other hand, concentrates on the morphology the members of a taxon have in common. Thus, a definition is a list of the features that binds members of a taxon together, whereas a diagnosis lists the ways a taxon differs from other taxa.

diaphysis (Gk *dia*=apart and *physis*=growth) The part of a long bone, usually equivalent to the shaft, that is formed from the primary center of ossification. See also *ossification*.

diatomite (Gk *diatomos*=to cut in half) A sedimentary rock composed primarily of the siliceous skeletons (frustules) of diatoms (i.e., algae with cell walls made of two interlocking silica “valves” that belong to the class Bacillariophyceae). Diatomite is characteristically powdery and has a low density. Diatomite often contains accessory biotic components such as sponge spicules, molluscs, and ostracods. Diatoms occur in both marine and non-marine settings and because some types of diatoms have limited ecological ranges they can be used for **paleoenvironmental reconstruction**. For example, localities with significant diatomite sequences, such as those at **Ologesailie** (Owen et al. 2008) can be used to reconstruct the paleoecology of that part of the landscape.

diazone (Gk *dia*=apart and *zone*=girdle) The region of a **Hunter-Schreger band** that when cut longitudinally shows **enamel prisms** running transversely (cross-cut or end on). Diazone, like parazone and perikymata, were terms first invented

to describe structural features in ungulate enamel by Gustav Preiswerk (1895), but see also later descriptions by Pickerill (1913) and Osborn (1990) (ant. **parazone**). See also *decussation*.

DID Abbreviation for Digiba Dora and the prefix for fossils recovered from Digiba Dora, Western Margin, **Middle Awash study area**, Ethiopia. See **Digiba Dora**.

Die Kelders (Location 34°32'S, 19°22'E, Western Cape Province, South Africa; etym. Afrikaans for “the cellars;” and also known as Klippgat, which means “cliff cave”). History and general description A network of caves on the shore of the Indian Ocean, roughly 120 km/74 miles southeast of Cape Town. The caves are formed in the contact between the Table Mountain Sandstone Group (Paleozoic quartzites) and the overlying Bredasdorp group (Cenozoic sediments). The caves were initially excavated in 1969–73 by archeologists from the **South African Museum** under Franz Schweitzer. Schweitzer’s excavation revealed 17 layers, the topmost of which was a shell **midden** from the **Later Stone Age**. **Middle Stone Age** (or MSA) deposits begin under a roof fall in layer 4 and continue through layer 15. The MSA occupation levels consist of dense concentrations in sand of bone and lithics that alternate with layers containing only sporadic fauna and lithics. Further excavations conducted in 1992–5 by a team led by Graham Avery, Frederick Grine, Curtis Marean, and Richard Klein substantially expanded the horizontal exposure of MSA sediments. Temporal span and how dated? Optically stimulated **luminescence** dates from the MSA sand layers date point to an age of c.60–70 ka and **electron spin resonance spectroscopic** dates on teeth spanning the MSA sequence are very similar (i.e., 70±4 ka assuming early uptake of uranium) and suggest the whole MSA sequence accumulated in less than 10 ka. Hominins found at site The MSA layers contained 27 hominin specimens including 24 isolated teeth, an edentulous mandibular fragment, and two manual middle phalanges. These remains may derive from a minimum of 10 individuals some of which are likely juvenile. The teeth are morphologically similar to, but tend to be larger than, than those of living Africans. Archeological evidence found at site The new studies of the stratigraphy confirmed Schweitzer’s basic outline, but demonstrated that MSA sediments were more complex than originally envisioned. Some bone

fragments found in layers 10–13 **refit** and there is evidence of downward movement of bones and perhaps artifacts in these levels. Of the more than 150,000 identifiable faunal remains recovered from the MSA levels, the most common are dune mole rats. Fauna accumulated by hominins include tortoises, small to medium-sized **bovids**, Cape fur seals, and sporadic remains of many other taxa. There is no evidence of artifacts characteristic of the Howieson's Poort industry. The great majority of the artifacts are fashioned of locally available fine-grained gray **quartzite** and generally resemble the artifacts in the later MSA levels at **Klasies River**. The artifacts from the lower MSA levels contain a higher frequency of **silcrete** and other non-local raw materials. The vertebrate faunal remains largely mirror patterns observed at Klasies River and other MSA sites in southern Africa and have helped fuel debates about the hunting abilities of MSA people as well as the impact of hominin population density on the accumulation of the faunal assemblage. Key references: Geology, dating, and paleoenvironment Tankard and Schweitzer 1976, Schweitzer 1979, Schwarcz and Rink 2000, Feathers and Bush 2000, Goldberg 2000; Hominins Grine et al. 1991, Grine 2000; Archeology Schweitzer 1979, Klein and Cruz-Uribe 2000, Grine et al. 1991, Avery et al. 1997, Klein et al. 1999b, Marean 2000, Marean et al. 2000, Thackeray 2000a.

diencephalon *See* forebrain.

diet (L. *diaeta*=way of life from the Gk *diaita*=to live one's life) The food and drink consumed by an animal. The diets of the extant higher primates have proved to be surprisingly complex, in that they vary according to the abundance and availability of a wide range of possible food items. It is heuristically useful to think of possible foods in two categories, preferred foods and **fallback foods**. The former are the food items animals prefer to eat in times of plenty; the latter are the food items animals eat when their preferred foods are scarce or unavailable. Diets can be broadly characterized as either ecologically specialized (i.e., **stenotopy**), or ecologically generalized (i.e., **eurytopy**). Reconstructing the diet of extinct hominins has proved to be a challenging task for in some cases the various lines of evidence result in conflicting evidence about the nature of the food items. *See also* **diet reconstruction**; **fallback foods**.

diet breadth Refers to the total number of resources incorporated in the diet of an individual or of a taxon. An obvious measure of diet breadth is the number of taxa recovered in an archeological bone assemblage. Diet breadth has long been examined within an **optimal foraging theory** framework in an effort to explain changes in modern human and fossil hominin subsistence behavior in response to social and/or environmental changes. For example, according to the broad-spectrum revolution hypothesis the emergence of the Neolithic in western Asia was preceded by an expansion of diet breadth in response to environmental and demographic stress at the end of the Paleolithic.

diet reconstruction (L. *diaeta*=way of life, from Gk *diaita*=to live one's life) This entry briefly reviews the lines of evidence that can be used to reconstruct the types of foods eaten by extinct organisms. It should be emphasized that the effectiveness of many of these lines of evidence is sensitive to the scale of the reconstruction being attempted. For example, just because tooth morphology is effective at coarse-grained levels of taxonomic and functional dietary discrimination (e.g., the carnassials of a **carnivore** vs the hypsodont molars of a **herbivore**) it does not mean tooth morphology will be as effective at discriminating at much finer-grained levels (e.g., among omnivorous extinct hominins). It is also important to consider that diet embraces possible **fallback foods** as well as preferred foods. The former may only be eaten on the relatively rare occasions when preferred foods are in short supply, but the ability to access them may determine the fate of individuals and thus potentially the fate of species. The more general, species-level, lines of evidence for reconstructing diet include information about archeology, **dexterity**, **locomotion**, masticatory morphology, **paleoenvironment**, and **paleohabitat**. If archeological evidence can be securely associated with a particular extinct hominin, the form of the **artifacts** (stone, bone, antler, wood, etc.) and evidence such as **use-wear** and **residue analysis** can be used to infer what foods were being accessed by the hominins that manufactured and used the tools. The presence of **cutmarks** is direct evidence that artifacts are being used to process carcasses. More proximate, but still species-level, lines of evidence include masticatory morphology. Do the species' parameters for the

absolute and relative sizes and shapes of the jaws and teeth and the thickness and microstructure of the enamel either point towards, or preclude, particular feeding strategies? In other groups of large mammals observations about the food preferences of morphologically analogous extant taxa have proved to be useful sources of evidence for reconstructing the diets of extinct taxa. However, some extinct hominin taxa (e.g., *Paranthropus*) have no obvious extant primate analogue, so some researchers have started with observations about the masticatory morphology of hominins such as *Paranthropus* and then used information from materials science and the principles of **optimization** (e.g., Rudwick 1964) to make predictions about the physical attributes of the foods (e.g., particle size, hardness, toughness, etc.) that the observed derived morphology is best adapted to process. The paleoenvironment and the paleohabitat determine the types of foods available (e.g., lake-shore habitats vs habitats far from aquatic resources) and other lines of evidence (e.g., dexterity and locomotor mode) constrain an animal's ability to access those resources. Observations at the level of the individual (which can be combined to generate species' parameters) are both physical and chemical. The physical methods include the detection of distinctive **phytoliths** and **starch grains** from ingested plant foods embedded in the hardened dental plaque (called calculus or tartar) that accumulates around the base of tooth crowns. **Tooth wear** can be investigated at the gross and microscopic levels. Observations about gross dental wear, also called dental macro-wear or dental mesowear, focus on the development of wear facets, including measurements of their size and orientation. Dental microwear focuses on the size, number, and orientation of microscopic scratches, pits, etc. on the enamel. Dental macrowear is a measure of the abrasiveness of the diet in the long term, whereas dental microwear indicates whether the food ingested in the days or weeks before death contained hard or abrasive material. Such abrasive material can be either intrinsic to the ingested foods (e.g., phytoliths) or extrinsic to the foods (e.g., adherent sand grains). Chemical methods of dietary reconstruction applied to the individual may be based on the isotopic ($^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, $^{18}\text{O}/^{16}\text{O}$) or trace-element composition (Sr/Ca, Ba/Ca) of hard tissues. The $^{13}\text{C}/^{12}\text{C}$ system is based on photosynthesis. Plants such as shrubs, trees, and

non-grass herbs that use the Calvin Benson cycle (in which CO_2 is initially fixed in molecules that have *three* carbons; thus they are referred to as C_3 plants) for photosynthesis have less ^{13}C relative to plants that use a photosynthetic system that initially fixes CO_2 in molecules that contain *four* carbons (C_4 plants). Plants that use a third photosynthetic system based in crassulacean acid (CAM plants) have an intermediate proportion of ^{13}C . These carbon ratios are passed on to the animals that consume the various plant types. The $^{15}\text{N}/^{14}\text{N}$ system is based on the finding that levels of the heavier nitrogen isotope, ^{15}N , generally increase through the food chain, so **carnivores** tend to have significantly higher levels of ^{15}N than **herbivores**. As for the $^{18}\text{O}/^{16}\text{O}$ system, leaves are relatively enriched in ^{18}O compared to the water animals drink from streams, freshwater lakes (except for lakes with extensive evaporation), and water holes (this is referred to as meteoric water) so $^{18}\text{O}/^{16}\text{O}$ ratios can be used to discriminate between animals that get much of their water needs from browsing on leaves compared to those that drink mostly meteoric water. The Sr/Ca chemical system is based on the observation that herbivores discriminate against dietary strontium, so their bones and late-forming tooth enamel have lower Sr/Ca ratios than the plants they consume. The carnivores that consume those herbivores also discriminate against dietary strontium, so their bones and tooth enamel have even lower Sr/Ca ratios than the herbivores they consume. Among herbivores, grazers tend to have a higher Sr/Ca than browsers and animals that consume insects and underground storage organs are also generally richer in strontium, but grazers and insectivores are also rich in barium (Ba), so relatively high **Ba/Ca ratios** may enable researchers to discriminate between high Sr/Ca ratios due to grazing or insectivory from high Sr/Ca ratios due to the consumption of, say, **underground storage organs**. All of the relative differences referred to are within a single trophic system; wide geographic variation in soil concentrations of both Sr and Ba prevent other types of comparison. Reconstructing the diet of extinct hominins has proved to be a challenging task for in some cases the various lines of evidence result in conflicting evidence about the nature of the food items. For further reading see Ungar (2007). *See also* $^{13}\text{C}/^{12}\text{C}$; **dental macro-wear**; **dental microwear**; **diet**; **fallback foods**; $^{15}\text{N}/^{14}\text{N}$; $^{18}\text{O}/^{16}\text{O}$; Sr/Ca; **structure–function relationship**.

differential preservation The bones and teeth that make up the hominin fossil record are made up of a mixture of organic matrix and inorganic material. The dense cortical bone that forms much of the cranium and mandible and the outer cortical bone of the long bones of the limbs is comprised approximately 70% by volume of mineral, or inorganic, material, and 20% by volume of organic material. The balance (approximately 10% by volume) is made up of water. **Dentine** forms the core of mammalian teeth and when mineralized it has a composition similar to that of bone. **Enamel** is the hard, white, outer covering of teeth. It consists of approximately 95% by weight (approximately 98% by volume) inorganic material, and less than 1% by volume organic material. Enamel is the hardest tissue in the body. Thus, for the reasons set out above, teeth are denser than bones and bones that have a higher proportion of cortical bone are denser than bones with more cancellous bone. Because of these regional differences the components of the skeleton are not equally dense (Lam and Pearson 2005) and therefore not equally durable, nor do they behave in the same way if they are transported by water. Whereas the light, less dense, bones such as vertebrae are carried along by high-energy streams of water and only fall to the bottom when the water is flowing more slowly, teeth and the dense bones fall to the beds of streams and will be incorporated into the rocks that form from stream and river beds. Thus, the lighter, less dense, bones float out into the lakes where they are incorporated into the sediments that accumulate in the bed of the lake. These lake-bed (called **lacustrine**) sediments are usually ignored by researchers looking for fossils. The honeycomb construction that makes bones like vertebrae lighter also makes them more vulnerable to damage prior to burial and this together with their relative buoyancy are probably the main reasons why bones like vertebrae are so scarce in the hominin fossil record. Other factors, such as the predilection of carnivores for the hands and feet of primates (Brain 1981), explain why some parts of the skeleton are relatively rare in the hominin fossil record. The hands and feet of most early hominins were gnawed and devoured before they had a chance to become part of the fossil record. *See also* **bone**; **taphonomy**.

differentiation (L. *differentia*=diversity, difference) At the cellular level, this refers to the process whereby naive cells become differentiated into specific cell types (e.g., skin, muscle, neurons,

blood cells). During this process, several properties of the cell (e.g., size, shape, and responsiveness) alter. Although it had been previously believed that genetic material was lost during this process of specialization, it is now known that each differentiated cell remains capable of giving rise to a new animal with the genetic information contained therein (e.g., Dolly, the cloned sheep) and that the process of differentiation is guided by gene expression. Totipotent cells (such as the zygote) are able to differentiate into all cell types; pluripotent cells (such as embryonic stem cells) are able to differentiate into any cell type seen in an adult. In some organisms that possess regenerative capabilities, differentiated cells are able to undergo a process of “dedifferentiation” in which they revert back to a less-specialized form.

digging stick A tool used for excavating soil, acquiring **belowground food resources**, and/or planting seeds. Digging sticks may be made of wood, bark, other plant materials, or bone, and may also have stone components. The simplest digging sticks known are unmodified tree branches, sticks, and pieces of bark used by chimpanzees to aid in the excavation of the **underground storage organs** of edible plants (Hernandez-Aguilar et al. 2007), termites, ants, and sweat bees (Boesch et al. 2009). Digging sticks are widely used by modern humans in traditional hunter-gatherer and agricultural societies. **Hunter-gatherers** such as the **Hadza** of Tanzania, the Bushmen/San of southern Africa, Australian Aborigines, and various South American Indian groups currently use, or are known to have used in the past, sharpened digging sticks in the excavation of belowground resources (including plants and animals) or other activities such as digging post holes or planting. Digging sticks may be regularly re-sharpened depending upon how often they are used and the nature of the soil being excavated. Digging sticks are sometimes further modified by fire-hardening though this is not a universal feature of the tool type (Marlowe 2005). The most complex variation of the digging stick involves weighting the tool with a bored stone to increase the force with which the stick strikes/penetrates the ground. This type of digging stick is more commonly associated with agricultural applications such as planting. Stone digging-stick weights often survive in the archaeological record while the sticks themselves more often than not decompose. A notable exception to the absence of digging tools in **Paleolithic**

archeological assemblages is the discovery of probable digging sticks in Members 1–3 at **Swartkrans**, **Sterkfontein** Member 5, and **Drimolen** in South Africa. These putative digging tools are made from medium-large mammal long bones, and recent analyses indicate that anthropogenic modification by grinding sharpened at least some of these artifacts. Further research suggests that these tools may have been employed variously in excavating underground storage organs, digging into termite mounds, and processing fruits (d’Errico and Backwell 2003, 2009). The 1.7–1.0 Ma putative digging sticks associated with *Paranthropus robustus* and *Homo ergaster*, taken in combination with the use of digging tools by extant chimpanzees, raise intriguing questions about the possibility of tool use by hominins prior to the advent of the flake and core-based **Oldowan** stone tool culture, with implications for our understanding of early human technological evolution, innovation, cognition, social organization, learning strategies (imitation vs emulation) and mechanisms of cultural transmission.

digit (L. *digitus*=finger) The term applies to either fingers (i.e., manual digits) or toes (i.e., pedal digits). In clinical anatomy manual digits are normally named and pedal digits are numbered. *See also ray*.

digit ratios *See hand, relative length of the digits.*

DIK Abbreviation of Dikika and prefix for fossils recovered from Dikika, Ethiopia after 2000. *See Dikika study area.*

DIK-1-1 Site Dikika. Locality DIK-1. Surface/in situ *In situ*. Date of discovery 2000 with further excavations and screening in 2002, 2003, and 2005. Finders Team led by Zeresenay Alemseged. Unit N/A. Horizon N/A. Bed/member Sidi Hakoma. Formation **Hadar Formation**. Group N/A. Nearest overlying dated horizon TT-4 tuff (3.24 Ma). Nearest underlying dated horizon SHT tuff (3.42 Ma). Geological age *c.*3.37 and 3.34 Ma. Developmental age *c.*3 years. Presumed sex Female. Brief anatomical description The skeleton includes much of the cranium, a natural endocast, a well-preserved mandible, all the deciduous teeth except the crowns of the left lower incisors, the hyoid, both scapulae and clavicles,

much of the vertebral column, sternum, many ribs, a fragment of the right humerus, a manual ray, both knee joints, both patellae, and the distal end of the left lower limb including the left foot. Announcement Alemseged et al. 2006. Initial description Alemseged et al. 2006. Photographs/line drawings and metrical data Alemseged et al. 2006. Detailed anatomical description N/A. Initial taxonomic allocation *Australopithecus afarensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Au. afarensis*. Informal taxonomic category Archaic hominin. Significance A remarkably complete skeleton that provides exquisite detail about the morphology and life history of *Au. afarensis*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

Dikika Research Project (or DRP) Intensive paleoanthropological research in the **Dikika study area** began in 1999 when Zeresenay Alemseged led an Ethiopian expedition to explore the deposits between the **Hadar** and **Gona** areas to the north and the Middle Awash region to the south. Alemseged and Denis Geraads studied a diverse **Middle Pleistocene** fauna and reported **Acheulean** and **Middle Stone Age** tools from the Asbole area. During initial surveys the team identified extensive fossil deposits in the central Dikika area and in 2000 they recovered the first evidence of **DIK-1-1**, the most complete early hominin infant skeleton known and **DIK-2-1**, the earliest hominin from the **Hadar Formation**. New scientists expanded the scope of the DRP in 2002 and 2005, including two vertebrate paleontologists, René Bobe and Denné Reed, a geologist, Jonathan Wynn, and an archeologist, Shannon McPherron. Wynn mapped the geology of the site in detail, particularly the volcanic tuffs and marker beds that provide a chronostratigraphic framework for the regional stratigraphy that spans >3.8 to <0.16 Ma. McPherron et al. (2010) announced the recovery in 2009 of two faunal bones (DIK-55-2 and DIK-55-3) from deposits that date to approximately 3.39 Ma that they claim bear stone tool cut and percussion marks made prior to fossilization.

Dikika study area (Location 11°05’N, 40°35’E, Ethiopia; etym. Dikika is the local Afar name for a hill in the central part of the Dikika study area) History Portions of the Dikika study area adjacent to **Hadar** were explored by the

International Afar Research Expedition during expeditions from 1973 to 1977 and the **Rift Valley Research Mission in Ethiopia** (or RVRME) during expeditions from 1975 to 1978. Following a long hiatus, surveys were undertaken by the **Dikika Research Project** (or DRP) and have continued since 1999. General description Area located south of the Awash River and south and east of the **Hadar** and **Gona** paleoanthropological study areas in Ethiopia's **Afar Rift System** section of the East Africa Rift System. Temporal span and how dated? Tephrostratigraphic correlation with argon-argon dated units of the **Hadar Formation** and **Busidima Formation** suggest deposits in the area contain the complete sequences of the Hadar Formation $c.>3.8$ – 2.9 Ma and the Busidima Formation $c.2.7$ – <0.16 Ma. Hominins found at site The first hominin specimen recovered was A.L. 277-1, a left mandible fragment with C–M₂ found in 1974. Specimens recovered from 1976 to 1977 are A.L. 400-1, a complete mandible and associated right upper canine, and A.L. 411-1, a right mandible fragment with broken M₁–M₃. **DIK-1-1**, a nearly complete juvenile skeleton, was recovered in the field seasons of 2000, 2002, and 2003 by members of the DRP. **DIK-2-1**, a left mandibular fragment and associated dentition, was found at locality **DIK-2** in 2000. All the hominin specimens recovered from the area are attributed to *Australopithecus afarensis*. Archeological evidence found at site Oldowan, Acheulean, and Middle Stone Age technologies are found in the area but they are not associated with the reported cutmarked bones (see below). McPherron et al. (2010) announced the recovery in 2009 of two faunal bones (**DIK-55-2** and **DIK-55-3**) found in deposits dated to approximately 3.39 Ma that they claim bear stone tool cut and percussion marks made prior to fossilization. dimension A property of a variable that describes how many of the three dimensions of space the variable occupies. **Size** variables may have a dimension equal to one (linear), two (area), or three (volume) dimensions. Measures of mass are typically treated as three-dimensional because mass is a property of objects in three-dimensional

space and an object's mass is generally proportional to its volume. **Shape** variables are typically dimensionless (dimension equals zero). Dimension is important in a **scaling** analysis because the isometric slope is determined by the ratio of the dimensions of the two variables. *See also* **scaling**.

Dingmo *See* **Bubing Basin**.

dip In structural geology this term describes the orientation, in 3D space, of a 2D geological feature such as a stratum or bed. Dip has two main components, the first being the maximum angle between the feature and the horizontal, and the second being the direction, which is recorded as a compass bearing from north in the direction of the maximum angle (this is sometimes referred to as true dip as opposed to apparent dip). These data are reported either directly as the dip direction and bearing relative to north (i.e., 45° to 270°), or as a dip and **strike** (where strike refers to a bearing at 90° to the dip direction). Dip and strike are usually measured in the field using a compass clinometer. A consideration of both the angle of dip and its direction is important during paleontological fieldwork, as knowing these allows surveying teams to identify the directions in which the strata will be relatively older or younger. In archeology, it is important to consider whether beds dip when excavating for tectonic processes, such as **faulting** or **folding**, may have altered their orientation from the horizontal plane in which they were originally lain down.

diploë (Gk *diploë*=doubling from the feminine of *diplous*=twofold or double) The cancellous or spongy bone between the dense inner and outer tables of the bones of the cranial vault. It contains endothelial-lined spaces containing venous blood. *See also* **cranial vault**.

diploid (Gk *diplous*=double and *eidōs*=shape or form) The term used for organisms (e.g., all primates, including modern humans and the great apes) or cells that have two **homologous** copies of each **chromosome**. The term also refers to possessing two complete sets of chromosomes. Thus, the genetic complement of modern humans is 22 pairs of diploid chromosomes (also called autosomes) and one pair of sex chromosomes. The diploid number of chromosomes for modern humans is 46.

directional selection Natural selection that favors (i.e., increases the **fitness** of) a particular

phenotype so that **allele** frequency shifts in a direction that results in an increase of that particular phenotype (and a decrease of all other phenotypes) in the population. An example of an advantageous trait subject to positive natural selection in modern humans is the null allele of the *FY* gene, which is protective against *Plasmodium vivax* malaria; the frequency of this allele is almost fixed in sub-Saharan Africa. Other examples of alleles likely to have been selected for during human evolution include those involved in the morphology needed to be an efficient biped, to increase brain size, etc. (Sabeti et al. 2006) (syn. positive selection).

disconformity *See* unconformity.

discrete morphological variants *See* non-metrical traits.

discrete traits *See* non-metrical traits.

discriminant function analysis A form of multivariate analysis similar to **principal components analysis** (or PCA), discriminant function analysis finds linear transformations of the variables in a data set that maximize the variation between user-identified groups as opposed to the maximizing the variation across all observations in a data set. Like PCA, the resulting new variables (discriminant functions) are independent of each other; that is, they have **correlations** of zero with each other. However, whereas PCA produces as many principal components as there are original variables, discriminant function analysis produces a number of discriminant functions equal to the lesser of the number of original variables and the number of groups minus one. For example, a researcher may collect a set of 10 measurements from a sample of chimpanzee, gorilla, and modern human skulls where groups correspond to species. A PCA would produce 10 principal components while a discriminant function analysis would produce two discriminant functions. Each specimen would have a score for both discriminant functions, and a bivariate plot of discriminant function scores for each specimen would show whether the discriminant function does a good job of identifying differences between groups: if each group of skulls plots in their own portion of the graph with no overlap between groups, the discriminant functions provide good separation between groups,

whereas if there is substantial overlap between skulls belonging to different groups, then the discriminant functions do not provide information that separates groups well. Typically researchers use discriminant function analysis to generate functions which separate specimens for known groups, then calculate discriminant function scores for specimens of unknown group membership (e.g., use skeletal metrics from extant bovids living in known habitat categories to generate functions which can be applied to extinct bovids of unknown habitat). The group **centroid** that is closest to the unknown specimen is identified as the group to which the specimen has the highest probability of belonging. Note that each unknown specimen will be classified as belonging to some group regardless of whether or not it is actually a member of any of the user-specified groups in the analysis, and it can only be classified into one of the groups identified by the user. If the discriminant functions do not separate the known groups well, it is likely that unknown specimens will be misclassified. To get a sense of how likely this is to happen, it is common to calculate prediction accuracy by predicting the group membership of every known specimen and calculating the percentage of specimens that are correctly classified into the group to which they actually belong. In any case, if an unknown specimen belongs to a group not represented by the known sample, it is impossible for the unknown specimen to be correctly classified. Some versions of discriminant function analysis also weight results by the number of specimens in each original group (i.e., unknown specimens are more likely to be classified into groups represented by many specimens in the known sample than into groups with relatively few known specimens); end users of computer programs that perform discriminant function analysis should be aware of whether this is case for their particular analysis. It is worth noting that discriminant function analysis and **multivariate analysis of variance** (MANOVA) are both based on the same **matrix** derived from the original data (which is functionally equivalent to a ratio of between-group and within-group covariances); thus a significant result from a MANOVA indicates that a discriminant function analysis should provide functions that separate groups well; conversely a non-significant result suggests that one should not waste any time conducting a discriminant function analysis.

dispersal (L. *dis*=apart and *spargere*=to scatter) A change in the location of a population of organisms brought about by the physical movement of the entire population or a subset. Three types of dispersal can be recognized. **Range expansion** occurs when the area in which a population is found increases but the increased range still includes the original, ancestral area. For example, toward the end of the **Pliocene** increasing aridity led to an expansion of grasslands in Africa and many grazing mammalian species experienced range expansion during this time period. **Range shift** occurs when the area in which a population is found changes location. For example, during aridification trends in the southern hemisphere, mesic vegetational zones shift their location in the direction of the equator (*see* **habitat theory hypothesis**). This should lead mammals adapted to mesic conditions to experience a northward range shift. **Jump dispersal** occurs when a sub-population of a larger population of organisms crosses an existing barrier to dispersal. Stochastic processes may play an important role in generating jump dispersals, or novel adaptations may enable individuals to traverse regions that had previously been impassable. A particularly dramatic example of jump dispersal is the colonization of South America by African **anthropoids** during the early **Miocene**, in which the founding populations of **platyrrhines** may have crossed the Atlantic Ocean on raft-like mats of floating vegetation. Jump dispersal may be a prelude to **allopatry**. The peopling of **Oceania** is one of a number of examples of jump dispersal during human evolution.

disposable soma hypothesis (Gk *soma*=body) One of several theories put forward to explain the evolution of **senescence**. The disposable soma hypothesis (Kirkwood 1977) suggests that the deterioration of the body with age is an inevitable consequence of an imbalance between the resources devoted to reproduction and those devoted to maintenance. Since the resources available to an organism are finite, if a greater proportion of that finite resource is directed to reproduction then inevitably the proportion of the total resource devoted to repair reduces such that bodily functions decline with age. *See also* **life history**.

dissociation (L. *dissociare*=to disunite) One of the major evolutionary mechanisms by which

variation in development is generated. Specifically, **modules** or processes that were previously linked become unlinked, or dissociated. Relative timing of developmental events can also become dissociated, leading to morphologies shaped by heterochronic processes (e.g., **acceleration**, **neoteny**) in the descendants that differ from those in the ancestors. Furthermore, dissociations can occur between size change and shape change during ontogeny; these kinds of dissociations can result in adult shape differences that are allometrically scaled. Dissociations between modules and processes often take place early in ontogeny, and patterns of dissociation often differ between regions of the body (e.g., dissociations among early growing tissues, such as the brain, commonly occur). For example, comparisons of bonobo and common chimpanzee ontogeny suggest that shape differences between these taxa have been produced by localized dissociations of size and shape.

distal (L. *distare*=to stand apart) In the limbs distal refers to structures that are in the direction of the extremity of that limb (i.e., towards the tips of the fingers or toes), and with respect to the teeth, or their components, distal refers to teeth or structures within teeth that are in the direction of the back of the jaw. Thus, the elbow joint is distal to the shoulder joint, the hallucial-metatarsophalangeal joint is distal to the ankle joint, the right M₂ is distal to the right P₄ of the same dentition, and the **hypoconulid** of an M₁ crown is distal to the **protoconid** on the crown of the same tooth.

distal accessory ridge An enamel crest that is sometimes present on the lingual face of maxillary or mandibular canines. It is located between the **median ridge** and the **distal marginal ridge** and it is variably expressed.

distal accessory tubercle An accessory cusp on the **distal marginal ridge** of a postcanine tooth crown. In the case of maxillary molars it has a number of synonyms (e.g., C5, distoconule, distoconulus, hypostyle, metaconule, and postentoconule).

distal fovea (maxillary) *See* **fovea posterior (maxillary)**.

distal marginal ridge A crest of enamel that delineates the distal border of the lingual face

of a canine or incisor anterior tooth or the occlusal surface of a postcanine tooth crown. In a maxillary postcanine tooth crown it is an enamel crest running between the **hypocone** and the **metacone** and in a mandibular postcanine tooth crown it is an enamel crest running between the **entoconid** and the **hypoconulid** (syn. **distal margocrista (-id)**, **distocrista (-id)**, **postcristid**, **distal rim**, **posterior margin**, **posterior wall**).

distal margocrista (-id) Term used by Schwartz and Tattersall (2002) for an **enamel crest** more commonly referred to as the **distal marginal ridge** (*which see*).

distal pit The term used by Kraus et al. (1969) for a tooth crown feature that others call the **fovea posterior**. *See also* **fovea posterior (maxillary)**; **fovea posterior (mandibular)**.

distal rim *See* **distal marginal ridge**.

distal trigon crest One of the three **enamel crests** on the **trigon** of maxillary molar teeth; the others are the **mesial marginal ridge** and the **epicrista**. It runs between the **metacone** and the **protocone** and it forms the distal boundary of the trigon. The lingual/metacone end of the ridge is sometimes called the **postprotocrista** and the buccal/protocone end is called the **premetaconule crista** (syn. *crista obliqua*, *crista transversa*, *metaloph*, *plagiocrista*, *postprotocrista*, *transverse ridge*, *trigon crest*, *oblique crest*, *oblique ridge*).

distal trigonid crest An **enamel crest** on the crown of a mandibular molar that runs between the **protoconid** and the **metaconid**, distal to the **mesial marginal ridge**. An additional crest, the **mid-trigonid crest**, can also be present, in some cases, between the **mesial marginal ridge** and the **distal trigonid crest** (syn. **protolophid**, **protocristid**, **posterior or distal trigonid ridge**, **trigonid crest**, **transverse ridge**).

distance matrix An $n \times n$ square **matrix** corresponding either to a data set with n observations/specimens or to a single observation/specimen with n spatial landmarks. In the first case, values in each cell correspond to the distance (morphological or otherwise) between the row and column observations/specimens. For example, it may refer to the

morphological distance between two skulls, or the geographical distance between two fossil sites. This type of distance matrix is often referred to as a pairwise distance matrix. In the second case, the value in each cell corresponds to the spatial distance between two landmarks in a single specimen; for example, the distance between prosthion and inion in a single cranium. This type of distance matrix is used in **Euclidean distance matrix analysis**. In either case, the values on the diagonal of the matrix are distances of observations or landmarks from themselves and are thus all equal to zero.

distobuccal cusp A term sometimes used for the **primary cusp** on a maxillary molar called the **metacone**, and for the primary cusp on a mandibular molar called the **hypoconid**. *See also* **hypoconid**; **metacone**.

distocone A term introduced by Vanderbroek (1961, 1967) for what most cusp nomenclature schemes refer to as the **metacone** (*which see*).

distoconid A term sometimes used for the enamel feature on mandibular molars that is more commonly referred to as the **protostyloid** (*which see*).

distoconule *See* **distal accessory tubercle**.

distoconulid A small accessory cuspid on the **distal marginal ridge** of a mandibular postcanine tooth crown (syn. **distoconulus**).

distoconulus *See* **distal accessory tubercle**.

distolingual cusp Cusp on the distolingual part of the maxillary or mandibular molar tooth crown. The distolingual cusp on a maxillary molar is the **hypocone** and on a mandibular molar it would be the **entoconid**. *See also* **entoconid**; **hypocone**.

distosagittal ridge A rare non-metric trait on the maxillary first premolar crown occurring mostly in American Indian populations. It is described by Scott and Turner (1997) as an “exaggerated distobuccal rotation of the paracone in combination with the presence of a fossa at the intersection of the distal occlusal ridge and distal marginal ridge.” *See also* **Uto-Aztec premolar**.

distostyle A term introduced by Vanderbroek (1961, 1967) and used by Grine (1984) for a small enamel feature on the **distal marginal ridge** close to the tip of the **metacone** on the occlusal surface of a maxillary molar (syn. hypoconule, metastyle, tuberculum accessorium posterium externum). *See also* **metastyle**.

distostylid A term introduced by Vanderbroek (1961, 1967) for what most cusp nomenclature schemes refer to as the **hypoconulid** (*which see*).

Ditsong National Museum of Natural History On May 28, 2010, the Transvaal Museum was renamed the Ditsong National Museum of Natural History. *See also* **Transvaal Museum**.

diurnal (L. diurnus = daily) Referring to animals that are active in the day (i.e., between dawn and dusk). For most **platyrrhines** and for all **catarrhines** it is the predominant activity pattern. Dependence on daylight may have been a crucial factor in limiting most nonhuman primate ranges to the tropics. Primates spend their days undertaking four main activities: feeding, resting, traveling, and socializing. Since the cohesion of complex primate groups relies on social interactions such as grooming, time is a major constraint in the lives of primates, especially **anthropoids** (Dunbar 1988). In temperate (i.e., high) latitudes, daylight is highly seasonal and in winter there may be insufficient time for primates to maintain social bonds and fulfill their need to feed, travel, and rest. This latitudinal effect may therefore impose limits on the geographic ranges of most primates. When hominins expanded into higher latitudes behavioral and cultural developments may have freed them from such constraints. For example, technology may have made it easier and more efficient for hominins to procure food in temperate regions where resources are generally more seasonal and less abundant. The evolution of language, hypothesized by Dunbar (1996) to be a form of grooming that is essential for group bonding, may have reduced the time needed for the maintenance of social relationships and the control of fire may have increased the time available for social interactions. These innovations may have helped diurnal hominins prosper in higher latitudes with variable day lengths.

divergence time (L. *dis* = apart and *vergere* = to bend) The time since two **lineages** separated. So, for

example, the divergence time of the lineages leading to modern humans and to *Homo neanderthalensis* has been estimated to be *c.* 350–700 ka using data from the genome (e.g., Krings et al. 1997, Noonan et al. 2006). It is important to stress that the genetic **coalescence**, population separation, and phenotypic differentiation of two taxa represent chronologically distinct successive events. However the genetic **coalescent time** of two taxa cannot be more recent than their divergence time.

dizygotic twins When two offspring produced in the same pregnancy are derived from two separately fertilized eggs. Dizygotic twins are also known as fraternal or non-identical twins. Both dizygotic and monozygotic twins have been important in studies of **heritability** in modern humans because they can help identify the balance between the genetic and environmental influences on a phenotypic trait.

Djebel Irhoud *See* **Jebel Irhoud**.

Djebel Qafzeh *See* **Qafzeh**.

Djurab Desert *See* **Chad Basin**.

DK Acronym for the Douglas (Leakey) Korongo, one of the archeological localities at **Olduvai Gorge**. Excavations beginning in 1962 resulted in many artifacts and faunal evidence. *See also* **Olduvai Gorge**.

DLNs Acronym for dimensionless numbers. *See* **Charnov's "dimensionless numbers"**.

dm Acronym for deciduous molar. Individual upper, or maxillary, deciduous molars are identified by a superscript number (dm^1 and dm^2) and lower, or mandibular, deciduous molars by a subscript number (dm_1 and dm_2). John **Robinson** (1956) showed that lower deciduous molars, especially the dm_1 s, are a useful taxonomic tool for discriminating among early hominin taxa. (e.g., the dm_1 s of *Paranthropus robustus* and *Paranthropus boisei* have especially complex crowns). These teeth are sometimes referred to as deciduous premolars (or dps) because the permanent premolars develop under the deciduous molars.

Dmanisi (Location 41°20'10"N, 44°20'38"E, Georgia; etym. after the medieval city of Dmanisi, a major center on the Silk Road occupied until the 18thC) History and general description This open-air site is located on a basalt and bedrock

promontory formed at the confluences of the easterly flowing Masavera and northerly flowing Pina-sauri rivers. Bronze Age and medieval archeological deposits including substantial masonry architectural remains cover the promontory and these deposits overlie and sometimes intrude into the underlying Plio-Pleistocene sediments. Excavations of the medieval ruins at Dmanisi, 55 km/34 miles southwest of Tbilisi, began in the 1930s. Between 1983 and 1987 excavations in Medieval Room XI resulted in the recovery of Plio-Pleistocene fossils and this attracted paleontologists from the Georgian Academy of Sciences and the discovery that artifacts were buried in the same deposits led to the 1989 archeological excavations in Block 1 by the Archaeological Center of the Georgian Academy of Sciences. In 1991, archeologists from the Römisch-Germanisches Zentral-Museum joined the field team, and on September 24, 1991 the first hominin fossil (the D211 mandible) was recovered. The joint Georgian/German team continued excavations from 1991 to 1999. The excavations involved expanding Block 1 (only within Strata B2–B3 deposits), five shallow test trenches (M1–M5) peripheral to Block 1, and the opening of Blocks 2 and 3, east and southeast of Block 1, respectively. In 1999 the deep part of Block 1 was reopened and the D2280 and D2282 crania were discovered. Since 2000, the Dmanisi investigations have been the responsibility of the **Georgian National Museum**, under the direction of David Lordkipanidze. Fieldwork between 2000 and 2008 included (a) expansion of Block 2 to the north, with recovery of numerous hominin fossils and associated faunal remains and artifacts, (b) excavations in Block M6, 30 m northwest of Block 1, and (c) deep testing in Unit M5 (75 m west of Block 2). Stratigraphic and paleomagnetic studies in Block 1 and Room XI by Ferring and Swisher resulted in stratigraphic revision of the 1980s VI–I scheme (Gabunia et al. 2000). The Plio-Pleistocene sediments are dominated by primary and locally reworked ashfall and they are divided into two major units: Stratum A (with subunits A1–A4), which conformably overlies the Masavera Basalt, and Stratum B (with subunits B1–B5), which is separated from Stratum A by a minor erosional disconformity (Lordkipanidze et al. 2007). Subsequent stratigraphic and paleomagnetic studies in Block 2 by Ferring and Ohms (Lordkipanidze et al. 2007) contradict the reports of the recovery of hominin remains and artifacts

from “Layers VI–IV” (de Lumley et al. 2005, de Lumley and Lordkipanidze 2006). All the hominin remains and the associated fauna and artifacts recovered from Blocks 1 and 2 are from firmly defined Stratum B contexts. Temporal span and how dated? Argon-argon ages for the Masavera Basalt average 1.848 ± 0.005 Ma (Gabunia et al. 2000) and 1.81 ± 0.05 Ma on Stratum A1 ashes (de Lumley et al. 2002). The Orozmani Basalt, which covers the Dmanisi deposits west of the locality, has been dated by $^{40}\text{Ar}/^{39}\text{Ar}$ to 1.759 ± 0.005 Ma (Gabunia et al. 2000). The Masavera Basalt and all Stratum A deposits exhibit normal geomagnetic polarity, suggesting correlation with the **Olduvai subchron**. The Strata A/B contact corresponds with the 1.77 Ma Olduvai–Matuyama boundary, and all Stratum B deposits exhibit reversed polarity and are correlated with the **Matuyama** chron (Lordkipanidze et al. 2007). The fauna shows paleozoogeographical similarities with the Late **Villafranchian** of Western Europe (Lordkipanidze et al. 2007). Evidence from sedimentology, soils, and bone **taphonomy** suggests that the temporal span of the deposits to be “less than 10,000 years” (Lorkipanidze et al. 2007) and the best estimate of their age is 1.77 Ma. Hominins found at site A rich collection of skulls (e.g., D2700/D2735/D2724/D3160, etc., D2282, D211, D3444/D3900), crania and calvaria (e.g., D2280), mandibles (e.g., D2600), and adult and subadult associated skeletons (e.g., D2724, 4166); all the components of the associated skeletons have been given different specimen numbers (see Lordkipanidze et al. 2007). There is an ongoing debate about how primitive the Dmanisi remains are, with some arguing they are more primitive than *Homo erectus sensu stricto* (e.g., Gómez-Robles et al. 2008), and others arguing that they are best interpreted as being relatively small-bodied examples of that taxon. An initial review of the dental remains suggests the dentition displays a mix of presumed primitive features seen in archaic hominins and more derived features seen in pre-modern *Homo* (Martinón-Torres et al. 2008). Archeological evidence found at site The stone artifacts are all classic **Mode 1** type. The Dmanisi industry is dominated by **debitage**, **cores**, **choppers**, and **manuports**; **retouched** pieces are rare. Key references: Geology, dating, and paleoenvironment Gabunia et al. 2000, Lordkipanidze et al. 2007; Hominins Gabunia and Vekua 1995, Gabunia et al. 2000, Vekua et al. 2002, Lordkipanidze et al. 2005, 2007,

Rightmire et al. 2006b, 2008, Martín-Torres et al. 2008, Pontzer 2010; Archeology Gabunia et al. 2000, de Lumley et al. 2005.

Dmanisi 211 *See* D211.

Dmanissi The spelling used in Gabunia et al. (2001, 2002) and de Lumley et al. (2006) for the site now referred to as **Dmanisi** (*which see*).

DNA *See* deoxyribonucleic acid.

DNA chip *See* DNA microarray.

DNA hybridization (*L. hybrida*=something made of at least two different components) A method for comparing DNA fragments or whole genomes. It can also be used to assess genetic distance (as DNA–DNA hybridization) or, when very stringent conditions are applied, to identify specific DNA sequences. The method involves separating the double-stranded nuclear DNA from two samples into single strands by heating them and then cooling them to allow them to anneal (i.e., to come together again). When used to identify DNA fragments, the conditions are set such that only a sample with an identical sequence will anneal to the control sequence (often referred to as a **probe**). This is what is involved in methods such as **Southern blotting** and denaturing high-performance liquid chromatography (or DHPLC). When whole genomes are being compared, the heat that needs to be injected into the system to separate the annealed single strands is used as a **proxy** for the number of bonds joining the strands. Because DNA strands from the same individual would be linked by the maximum number of bonds this is taken as the standard: the more distant the relationship the fewer the bonds linking the annealed strands, so less heat is required to separate them. Whole-genome DNA hybridization has been superseded by **DNA sequencing**. Sibley and Ahlquist (1984) used DNA–DNA hybridization to investigate the phylogeny of the great apes and they confirmed the hypothesis that chimpanzees, bonobos, and modern humans were more closely related to each other than to gorillas.

DNA methylation (*Gk methu*=wine and *hule*=wood, from “wood alcohol” the common name for methyl alcohol) Usually the modification

of the cytosine in a DNA sequence by the addition of a methyl group to form 5-methylcytosine. Methylation is associated with **gene expression** being silenced and it typically occurs in CpG dinucleotides or “CpG islands” (i.e., clusters of CpG dinucleotides) that are common in the regulatory regions of genes.

DNA microarray A technology used to (a) distinguish particular **alleles** of a DNA sequence (such as the detection of **single nucleotide polymorphisms**), (b) sequence a specific region of DNA (*see* **DNA sequencing**), (c) investigate patterns of **gene expression**, or (d) identify **deletions** or **insertions** (such as **copy number variations**). It is a glass, plastic, or silicon chip onto which fragments of DNA have been spotted. Fluorescent **probes** are then used to distinguish a specific **base pair**, allele, or gene expression pattern. These arrays are the basis of the rapid high-throughput analysis that allows researchers to sequence DNA more rapidly than in the past.

DNA sequencing (*L. sequi*=to follow) Several methods can be used to determine the sequence of **bases** present in a DNA molecule. The most common is the Sanger or chain-termination method. This method uses dideoxynucleotide triphosphates (or ddNTPs) which lack the 3'-OH group necessary for the formation of a phosphodiester bond as “chain terminators.” Specifically, the DNA is **denatured** and a mixture comprising a DNA primer, polymerase, deoxynucleotide triphosphates (or dNTPs), and ddNTPs is added. The standard dNTPs (dATP, dGTP, dCTP, and dTTP) and the ddNTPs are used by the polymerase to copy the single-stranded DNA. However, whenever a ddNTP is added by the polymerase the copying stops. The newly synthesized DNA is then denatured and the DNA is separated by its size (i.e., its molecular weight) using **electrophoresis**, which can distinguish DNA strands that differ in size by as little as one **base pair** (1 bp). In order to **read** the sequence the ddNTPs are labeled either radioactively or with different fluorescent dyes.

DNH Abbreviation for Drimolen hominids and the prefix for hominins recovered from **Drimolen** (*which see*).

DNH 7 Site Drimolen. Locality N/A. Surface/ in situ *In situ*. Date of discovery October 21, 1994.

Finders R. Smith and André Keyser. Unit N/A. Horizon N/A. Bed/member N/A. Formation Monte Christo Formation. Group Chunniesport. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age *c.*2.0–1.5 Ma. Developmental age Adult. Presumed sex Female. Brief anatomical description An almost complete adult skull extensively restored over a period of 5 years by Ron Clarke. The face lacks only the left zygomatic arch, parts of the left orbital margin, and the nasal bones, and the base lacks substantial parts of the sphenoid and the anterior margin of the foramen magnum. The walls of the orbits, the ethmoid, and the pterygoid plates are badly damaged, but damage to the mandible is confined to the base. Other than distortion caused by bilateral compression, the skull overall is in remarkably good condition. Announcement Keyser 2000. Initial description Keyser 2000. Photographs/line drawings and metrical data Keyser 2000. Detailed anatomical description N/A. Initial taxonomic allocation *Paranthropus robustus*. Taxonomic revisions None. Current conventional taxonomic allocation *P. robustus*. Informal taxonomic category Megadont archaic hominin. Significance An exceptionally well-preserved specimen of a *P. robustus* skull that confirms the claimed distinctions between *Paranthropus boisei* and *P. robustus*. It also provides support for the hypothesis that specimens such as KNM-ER 407 and KNM-ER 732 represent females of *P. boisei*. Location of original School of Anatomical Sciences, University of the Witwatersrand, South Africa.

Dolní Věstonice I (Location 48°53'N, 16°40'E, Czech Republic; etym. name of nearby village) History and general description One of three (Dolní Věstonice I, II, and III) open-air loess sites along the northern slopes of the Pavlovské Hills above the Dyje River floodplain. Dolní Věstonice I (or DV I) is closely associated with the nearby Pavlov sites (Pavlov I and II) that have yielded *Homo sapiens* remains and **Upper Paleolithic** industries. Excavation (both systematic and salvage) and survey have been conducted at DV I since 1924 and intermittently until 1993. DV I is a large, complex settlement site and has yielded Upper Paleolithic (**Gravettian**) archeological and hominin skeletal remains, including burials (DV 3 and possibly DV 4), as well as scattered individual modern human skeletal remains (DV 1, 2, 5–10, 23–32, 35, 37, 38). Temporal span and

how dated? Conventional and **accelerator mass spectrometer** radiocarbon dates on charcoal suggest that settlement of the site probably spans from *c.*29 to 27 ka uncalibrated radiocarbon years BP for the lowermost layers to *c.*26–25 ka uncalibrated radiocarbon years BP for the uppermost layers. A direct date on an anatomically modern human femur has yielded a late age of 22,840 radiocarbon years BP, but this has been disputed. Hominins found at site An associated skeleton (DV 3), two calvarae (DV 1 and 2), cranial fragments (DV 4–6, 23–25, 28, 30), teeth (DV 7–10, 26, 27, 29, 31, 32, 37, 38), and a femoral shaft (DV 35). Archeological evidence found at site Upper Paleolithic (Gravettian) figurines, dwelling structures. Key references: Geology and dating N/A; Hominins Jelinek 1969, Trinkaus and Svoboda 2006; Archeology Klima 1954, 1959.

dolomite The name, which derives from the French mineralogist Deodat de Dolomieu, is used for a magnesium-rich carbonate mineral [calcium magnesium carbonate or $\text{CaMg}(\text{CO}_3)_2$] and for limestone rocks which are predominantly composed of this mineral. Dolomite is often formed in warm tropical ocean environments; however, it can also be formed by the diagenetic alteration of pre-existing limestones. The early hominin cave sites in southern Africa are breccia-filled solution cavities formed within the Precambrian dolomite that makes up much of the high veld.

domain In molecular biology, a domain is part of a **protein** that has a specific structure and function. Specific domains may be found in many different protein families. For example, the alpha helix, a right-handed spiral, is one of the most common protein domains, and it is found in such proteins as hemoglobin, rhodopsins, and G-protein-coupled receptors. Specific domains may also be characteristic of a particular family of proteins. For example, *HOX* genes encode a protein domain known as the homeodomain, which is a highly conserved helix–turn–helix structure of 61 amino acids that can bind to enhancers of other genes and turn them on or off.

dome In structural geology this term has more than one meaning. Dome can refer to an anticlinal fold, which is closed (by folding) in all directions; in other words, having a dome or upside-down bowl-like shape. In its simplest symmetrical form

such a feature when eroded, would give a circular bull's-eye-like **outcrop** pattern with the oldest rocks in the core of the structure. The term dome can also refer to the accumulation of magma and solid rock around and above a volcanic vent; this is sometimes referred to as a lava dome. *See* **Sangiran dome**.

dominance *See* **allele**; **dominant allele**.

dominant allele In an organism that has two **homologous** copies of each **chromosome**, the dominant allele is the one that determines the **phenotype** no matter whether two copies of that allele (i.e., as in a **homozygote**) are present or just one copy (i.e., as in a **heterozygote**) is present. An example of a dominant allele in modern humans would be the normal or wild-type allele for the *CFTR* gene that encodes the cystic fibrosis transmembrane conductance regulator (or CFTR) protein. Homozygotes and heterozygotes for this allele are both phenotypically normal, whereas those who are **homozygous** for the recessive (mutated) allele have the disease cystic fibrosis.

dosage compensation For genes that are present on the part of the **X chromosome** not found in males, the amount (or dosage) of protein produced is regulated so that it is the same in males (XY) and females (XX). To do this, in placental mammals in every female cell one X chromosome is randomly inactivated. It is this inactivated X chromosome that forms the **Barr body**.

double stance phase *See* **walking cycle**.

downstream Downstream is in the direction (as indicated by the numbered carbon molecules of the sugars in the DNA backbone) toward the 3' (three prime) end of a DNA strand. The 3' end is so called because the *third* carbon has the hydroxyl group attached. The other end of a single strand of DNA is called the 5' (five prime) end because the *fifth* carbon of the deoxyribose sugar has a terminal phosphate group attached to it. The significance of the directionality of a DNA sequence is that the processes of **replication** and **transcription** only occur in the 5' to 3', or downstream, direction.

Dozu Dhalu One of the Early and Middle Pleistocene sites in the exposures of the **Ola Bula Formation** within the **Soa Basin** of central Flores, eastern Indonesia.

dp *See* **dm**.

draft sequence A **genome** sequence that has either not been completed and/or checked for errors. For example, the first modern human genome sequence to be published (International Human Genome Sequencing Consortium 2001) was a draft sequence because it covered only 94% of the genome and only 25% of that sequence was "finished" (i.e., sequenced with at least fourfold coverage and with a quality score of 99% accuracy). The first chimpanzee sequence to be published (The Chimpanzee Sequencing and Analysis Consortium 2005) was also a draft sequence.

drift Geology Term used to describe surficial sediments deposited by glaciers or associated processes. In practice it is commonly used to describe a wide variety of quaternary sediments in areas that have been glaciated. Genetics *See* **genetic drift**.

Drimolen (Location 25°58'08"S, 27°45'21"E, Gauteng Province, South Africa; etym. named after van Drimolen, the owner of the farm at the time the site was discovered) History and general description Discovered by André Keyser in 1992, Drimolen is a complex of **breccia**-filled caves in Precambrian **dolomite** 5.5 km/3.4 miles northwest of **Sterkfontein**. Temporal span 2.0–1.5 Ma. How dated? Biostratigraphy. Hominins found at site Most of the many well-preserved hominins recovered from Drimolen (including DNH 7, a complete skull, and DNH 8, a mandible with an almost complete dentition) have been referred to *Paranthropus robustus* and after **Swartkrans** its sample (>80 specimens) is the next largest contributor to the *P. robustus* **hypodigm**. The Drimolen contribution to the *P. robustus* dental hypodigm is smaller in overall size than the contributions from Swartkrans and **Kromdraai**, but the range of variation is greater, and Lockwood et al. (2007) have suggested this may be due to taphonomic differences between the sites, with males dominating in the Swartkrans sample of *P. robustus*. The Drimolen contribution to the *P. robustus* hypodigm is interpreted as intermediate in non-metrical morphology between the Swartkrans and the Kromdraai samples of *P. robustus*. A minority of the hominins, mainly teeth (e.g., DNH 35), have been assigned to *Homo* sp., and Curnoe and Tobias (2006) have referred DNH 45 and 70 to *Homo* aff. *H. habilis* and *Homo*

habilis, respectively. Curnoe (2010) includes DNH 70 in the hypodigm of *Homo gautengensis*. Archeological evidence found at site Bone tools. Key references: Geology, dating, and paleoenvironment Keyser et al. 2000; Hominins Keyser 2000, Curnoe and Tobias 2006, Moggi-Cecchi et al. 2010; Archeology d'Errico and Backwell 2003.

DRP Acronym for the **Dikika Research Project** (*which see*).

DSR Acronym for **daily secretion rate** (*which see*).

dual-unit foraging model A model for Oldowan site formation based on an analogy with social carnivores. It argues that site formation resulted from the intersection of two independent strategies used by hominins to reduce predation risk. In the first, males unencumbered by offspring transport carcass parts away from high-risk, highly competitive, death sites, and in the second hominins are attracted to relatively secure areas where altricial offspring and caregivers can forage safely (Oliver 1994). The fitness benefits of provisioning mothers, infants, and caregivers with this high-quality food may then have introduced and established the principle of goal-directed transport of food for sharing, thus providing the selective milieu for the further evolution of cognition and for the eventual emergence of modern human language.

Dubois Collection *See* Rijksmuseum van Natuurlijke Historie.

Dubois, Marie Eugène François Thomas (1858–1940) Eugène Dubois was born in Eijsden, The Netherlands, and in 1877 he entered the University of Amsterdam to study medicine. There he came under the influence of Max Fürbringer who instilled in Dubois the idea that comparative anatomy and embryology should be used to reconstruct phylogeny. Dubois completed his medical degree in 1884 and in 1886 he accepted a post as a lecturer of anatomy at the University of Amsterdam where he became interested in human evolution. Influenced by Ernst Haeckel and by the discovery of primate fossils in the Siwalik Hills of India by Pilgrim in 1878, Dubois resigned from his university post in 1887 and enlisted as a medical officer in the Royal Dutch East Indies Army so he could search in

Southeast Asia for the evolutionary link between apes and modern humans. Dubois managed to obtain financial assistance from the colonial government as well as practical assistance in the form of convict laborers to help in his search. Dubois arrived on Sumatra in 1887 and soon found animal fossils, but news of the discovery in 1888 of a human skull near the village of **Wadjak** on the island of Java prompted Dubois to request a transfer to Java in 1889. In November 1890 he found a mandibular fragment at Kedung Brubus and in 1891 he began excavating along the banks of the Solo River near the village of **Trinil**. In September of that year a molar was discovered and in October Dubois' excavators found a calotte. At first he thought it belonged to an extinct ape, but with features that were more modern human-like than those seen in any previously discovered anthropoid ape. In August 1892 a nearly complete modern human-like femur was found in the same strata and this led Dubois to reassess the affinities of the calotte. In a preliminary report prepared in 1892 but presented and published in 1893, Dubois assigned the specimen to *Anthropopithecus erectus*, but when a fuller description of the fossils appeared in 1894 the genus name of the taxon was changed to *Pithecanthropus erectus*. In 1895 Dubois returned to The Netherlands and exhibited his fossils at the Third International Congress of Zoology held in Leiden. Dubois' interpretation that the skullcap belonged to an intermediate form that linked apes and modern humans attracted the support of Ernst Haeckel, Gustav Schwalbe, and the American paleontologist Othniel Marsh but few others accepted his interpretations. This position was not improved by the discovery of the fossils from **Piltdown**, England between 1908 and 1915, since they supported the view that the large brain of modern humans had evolved before bipedalism. It was only when Piltdown Man was exposed as a fraud that paleoanthropologists began to reconsider the importance of *Pithecanthropus*. Soon after his return to The Netherlands Dubois was granted an honorary doctorate and accepted a position at the University of Amsterdam in 1898 to teach geology and paleontology. He also became curator of the Teylers Museum in Haarlem in 1897, a position he held until his death. Dubois continued to present his specimen at scientific meetings during the late 1890s and even prepared a life-size reconstruction of *Pithecanthropus erectus* for the World Exhibition held in Paris in 1900.

He became increasingly disappointed and discouraged with the lack of acceptance for his theories, so much so that after 1900 he stopped presenting the fossils, and eventually would not allow anyone to see them. He published little on *Pithecanthropus* between 1900 and 1912 except for a few papers on the fossil fauna of Trinil that supported his interpretation of the age of *Pithecanthropus*. However, Dubois did not abandon research and he began to work on the problem of brain evolution in vertebrates. Specifically, he investigated the mathematical relationship between the size of the brain and the size of the body and was one of the first researchers to systematically investigate the relationship between brain and body size (Dubois, 1898, 1914). In 1920 Dubois returned to human origins research by publishing papers on *Pithecanthropus* and the Wadjak skulls, but made no significant new contributions to paleoanthropology before retiring from his position at the University of Amsterdam in 1929. *See also allometry.*

Duinefontein (Location 33°43'S, 18°27'E; South Africa; etym. in Dutch it means “dune spring.” Colonial farms were always sited near springs and many farms, including this one, were named after that local spring) History and general description The Duinefontein sites occur within the Koeberg Nature Reserve, adjacent to the Koeberg Nuclear Power Station, about 35 km/21 miles north of Cape Town on the Atlantic Coast of South Africa. Power station construction revealed numerous buried fossil and archeological sites, of which two – Duinefontein 1 (or DFT 1) and Duinefontein 2 (or DFT 2) – have been extensively investigated. DFT 1 is a fossil hyena den excavated in 1973. DFT 2 is a multilayered archeological site, excavated in 1973, 1975, and 1997–2002. Artifacts and bones at DFT 2 occur on paleosurfaces within a thick sequence of aeolian sands. Excavation exposed two paleosurfaces known as Horizons 2 and 3. Wind-polished bones and artifacts on the present surface are assumed to come from a now-deflated paleosurface designated “Horizon 1.” The sediments at DFT 2 broadly resemble those at **Elandsfontein**. Temporal span and how dated? Optically stimulated **luminescence** has provided an age of 270 ka for the sands surrounding Horizon 2 and 290 ka for sands between Horizons 2 and 3. **Uranium-series dating** has provided an age of 160 ka for a capping **calcrete** and **biostratigraphy** suggests an age of 400–200 ka. Hominins found at

site None. Archeological evidence found at site Lithic artifacts from Horizon 2 have been attributed to the Late **Acheulean** Industrial Complex. Sediments and fauna (e.g., buffalo, wildebeest, and kudu) suggest an environment with locally abundant water, grass, and broad-leaved brush, substantially different from the fynbos (or “fine-leaved shrub”) that characterizes the area today. Although numerous large mammal bones occur at the site, many more were damaged by hyena teeth than by stone tools, suggesting perhaps limited Acheulean hominin hunting or scavenging. Key references: Geology and dating Klein et al. 1999a, Feathers 2002, Cruz-Uribe et al. 2003; Hominins N/A; Archeology Cruz-Uribe et al. 2003.

duplication A region of DNA that is present in more than one copy. For example, nonhomologous **recombination** or retrotransposition can result in the duplication of a region of the **genome** involving one or more genes. **Copy number variants**, **microsatellites**, and segmental duplications of chromosomes are examples of duplications. *See also gene duplication.*

dura mater (L. *dura*=hard and *mater*=mother) The outer of the three meningeal layers. The dura mater is made up of an outer endosteal layer, which adheres to the endocranial surface of the cranial vault and is effectively the endocranium and an inner meningeal, or fibrous, layer that forms the folds of dura mater (e.g., the **falx cerebri** and the **tentorium cerebelli**) that incompletely subdivide the endocranial cavity. The **dural venous sinuses** are endothelium-lined spaces between the endosteal and the fibrous layers of the dura mater. *See also meninges.*

dural venous sinuses (L. *dura*=hard) Venous channels lying between the inner, or fibrous, and the outer, or endosteal, layers of the **dura mater**, the outer layer of the three meningeal layers. They transmit blood from the veins draining the cerebral hemispheres and from the veins draining the **diploë** of the bones that form the walls of the cranial cavity. Dural venous sinuses usually leave a groove on the **endocranial** surface of the cranium, so their presence can be inferred from fossils that preserve that part of the endocranial surface, but because they do not *always* leave a groove, the lack of a groove is not unambiguous evidence of an absent dural venous sinus. Small **emissary veins**

provide a communication between the cerebral venous system and the veins of the scalp. The dominant pattern of venous drainage in modern humans is superior sagittal sinus→right transverse sinus→right sigmoid sinus→right jugular bulb→right internal jugular vein. However, in approximately 3% of modern human crania the main venous drainage route is superior sagittal sinus→occipital sinus→marginal sinuses→jugular bulbs→internal jugular veins. This is also the dominant pattern in *Paranthropus boisei* (Wood and Constantino 2007) and *Australopithecus afarensis* (Kimbel et al. 2004).

durophagy (ME *dure*, from L. *dura*=hard, plus Gk *phagein*=to eat) Durophagy, which refers to hard-object feeding, was first described in aquatic animals and fish that consume objects such as shelled invertebrates (Pregill 1984). Most major vertebrate groups feature at least one durophagous lineage [e.g., fish (Grubich 2003), sharks (Huber 2005), rays (Summers 2000), snakes (Jackson and Fritts 2004), lizards (Metzger and Herrel 2005), bats (Nogueira et al. 2005), cats (Biknevicius 1996), bears (Sacco and van Valkenburgh 2004), red pandas (Pradhan et al. 2001), and primates (Lambert et al. 2004)]. The diets of some early hominin taxa have been interpreted as being durophagous on the basis of morphological features that are considered adaptations to hard-object feeding (e.g., thick tooth enamel, chewing teeth with low, blunt cusps, and anteriorly positioned jaw musculature; Rak 1983) and more recently it has been suggested that tooth chipping in some hominin taxa is also indicative of hard-object feeding (Constantino et al. 2010). However, there is considerable debate about the relative importance of durophagy in hominins, with some researchers supporting the hypothesis that hard foods were not a dietary staple, but were primarily consumed during periods of resource scarcity (i.e., as **fallback foods**) (Ungar et al. 2008).

Duynfontein See Duinefontein.

DV Acronym for Dolní Věstonice and the prefix for hominin fossils from Dolní Věstonice. See Dolní Věstonice I.

DV I See Dolní Věstonice I.

dynamic mutation (Gk *dunamikos*=powerful and L. *mutare*=to change) An unstable region of a DNA sequence, such as a **microsatellite** or

short tandem repeat, where the probability of **mutation** increases as the size of the region increases. Dynamic mutations at trinucleotide (e.g., CAG, CTG, etc.) repeats are responsible for pathologies that cause diseases such as Huntington's disease (CAG repeat), myotonic dystrophy (CTG repeat), and fragile X syndrome (CGG repeat). Such repeats are a special class of **duplication**.

dynamic modeling Most simulations of locomotion are performed using dynamic modeling, which is concerned with predicting force from motion (or vice versa) in a multibody system of given mass distribution. Inverse dynamic modeling predicts force from known motion. It is less computationally demanding than the reverse approach, forward dynamic modeling (e.g., Yamazaki et al. 1996) and hence was applied earlier to the reconstruction of hominin gait mechanics (e.g., Crompton et al. 1998, Kramer and Eck 2000) to compare the mechanical costs of locomotion of *Australopithecus afarensis* in different gaits and by Wang and Crompton (2004) to compare the mechanical costs of load transport in *Au. afarensis* and *Homo ergaster*. However, since it assumes known joint motion, inverse dynamics do not allow the identification of mechanically optimal motion for a given morphology. Thus, more recent studies have increasingly adopted forward dynamic modeling, which calculates motion from force. In practice, forces are not required to be known as they can be established on the basis of simulated muscles activated by a neuromuscular model (Ogihara and Yamazaki 2001) or another pattern generator (e.g., Sellers et al. 2003) plus a muscle model (e.g., Umberger et al. 2003). This system also allows researchers to predict metabolic, rather than mechanical, energy costs (e.g., for the gaits of *Au. afarensis* by Sellers et al. 2004 and Nagano et al. 2005). Such models are far more computationally demanding than inverse dynamics approaches in that they require extensive repetition to search for optimal solutions using optimization algorithms such as those from evolutionary robotics (Sellers et al. 2003, 2005). On the other hand, the derivation of optimal gaits for a given morphology means that they can be used together with other data to assess a much wider range of phenomena (e.g., the speed of the Laetoli trail-maker from stride lengths and predicted energetically optimal speed; Sellers et al. 2005). In the

future inverse dynamic modeling is likely to be restricted to analyses where motion is experimentally determined (e.g., predicting the internal mechanics of the foot from surface-marker motion).

Dzeravá Skála (Location 48°29'N, 17°19'E, Slovakia; etym. the site is also known as Deravá Skála. Slovak *derav*=sieve, *skála*=rock) History and general description This cave site near the town of Plaveck Mikuláš in western Slovakia is important for understanding the **Szeletian** transitional lithic industry. A hominin tooth recovered from a layer with Szeletian lithics was recently classified as *Homo sapiens*, suggesting the Szeletian was not created by *Homo neanderthalensis* as previously thought. However, questions remain about the exact stratigraphic association of this tooth since it may also be

associated with **Aurignacian** tools. Three main layers were found at the site, with the Szeletian overlain by an Aurignacian layer and then a **Gravettian** layer. Temporal span and how dated? Radiocarbon dating was performed on all three layers, providing dates of 35–30 ka for the Szeletian, 36–30 ka for the Aurignacian, and *c.*25 for the Gravettian layer. Optically stimulated **luminescence dating** provided slightly earlier dates for the Szeletian layer (*c.*57 ka), but similar dates for the Aurignacian layer (36–30 ka). Hominins found at site An M₂ germ attributed to *H. sapiens* was found either in the Szeletian or Aurignacian layer. Archeological evidence found at site Stone tools attributed to the Szeletian, Aurignacian, and Gravettian. Key references: Geology, dating, and paleoenvironment Kaminská et al. 2004; Archeology Kaminská et al. 2005; Hominins Churchill and Smith 2000, Bailey et al. 2009.

E

E686 The British Natural History Museum, London (or BMNH) accession number for the Kabwe 1 cranium. *See* **Kabwe 1**.

E691 The British Natural History Museum, London (or BMNH) accession for the Kabwe 2 tibia recovered from the site of **Kabwe** the same day that the **Kabwe 1** cranium was discovered. *See* **Kabwe 2**.

EAGRU Acronym for East African Geological Research Unit. *See* **Bishop, Walter William**.

ear *See* **external ear**; **middle ear**; **inner ear**.

early African *Homo erectus* An informal term used by some authors for a subset of *Homo erectus sensu lato* that others refer to as *Homo ergaster* Groves and Mazák, 1975. *See* *Homo ergaster*.

Early Stone Age (or ESA) The oldest period in the tripartite division of the African archeological lithic record formalized by A.J.H. Goodwin and C. van Riet Lowe (1929) in *The Stone Age Cultures of South Africa*. Although it was developed for sequences in southern Africa, the terminology has subsequently been applied to sites across sub-Saharan Africa. There have been numerous calls to abandon the tripartite division (e.g., Clark et al. 1966b, Barham and Mitchell 2008) but the terminology persists because of its utility for describing broad stages in the general trend towards a more sophisticated lithic record (i.e., a trend towards aspects of the manufacture of stone tools that are conceptually and technically more elaborate). As used today, the ESA incorporates lithic evidence from **Oldowan** and **Acheulean** sites. The evidence at Oldowan sites consists largely of stone flakes and cores made using direct freehand percussion, whereas at Acheulean sites **handaxes** and **cleavers** are added to the mix. At some Acheulean sites there is evidence that the artifacts may have been shaped by hammers or billets made of organic (e.g., wood, bone, or antler) materi-

als. Recognizing that first and last appearance dates vary locally and are subject to change as new sites are found, existing dating methods are improved, new methods are introduced, etc., the present evidence suggests the ESA began *c.* 2.6 Ma and ended *c.* 200 ka.

East Africa and Uganda Natural History Society *See* **National Museums of Kenya**.

East African Rift System (or EARS) A continental-scale tectonic feature that dominates the East African landscape and which has influenced climate, vegetation, and faunal distribution throughout the **Neogene**. The East African Rift System comprises two major branches, eastern and western. In the north, the eastern branch begins in the **Afar Depression**, a triple junction where the East African Rift System meets the Red Sea and Gulf of Aden oceanic rifts. The Afar trends into the **Main Ethiopian Rift System**, and continues southwards into the Gregory Rift that bisects Kenya. The eastern branch splays out and terminates in northern Tanzania. Throughout its extent, the eastern branch is characterized by abundant volcanism (Oligocene to recent) both within and flanking the rift valley and it is partly occupied by numerous shallow lakes commonly saline and alkaline in nature (e.g., Lakes Baringo and Turkana). The eastern branch is renowned for the rich fossiliferous sedimentary deposits of its **basins**, along with an archeological record from the earliest sites (2.6 Ma in the Afar) to recent accumulations. The western branch curves from Lake Albert through large mainly freshwater lakes (e.g., Lakes Tanganyika and Malawi) to the coast in Mozambique. Deep lakes and more localized volcanism characterize this branch and although fossiliferous and archeological sites occur along its length they are generally associated with thinner and more localized sedimentary accumulations. Although its most prominent feature is the East African Rift System the entire region has seen significant uplift, effectively blocking penetration of Atlantic-derived moisture

from the Congo Basin and leaving the region in a rain shadow subject to monsoonal influence from the Indian Ocean (see Sepulchre et al. 2006). Most of the fossil hominin sites in East Africa occur either in, or close to, the eastern branch of the East African Rift System. The eastern branch consists of a series of river valleys and basins that includes in the north the **Afar Rift System**, the **Ethiopian Rift System**, and the **Omo rift zone**. *See also* paleoclimate; tectonism.

East Lake Turkana *See* Koobi Fora.

East Rudolf The name previously used for the site now known as either Koobi Fora or East Turkana. It was given this name because the lake now known as Lake Turkana was originally named Lake Rudolf and the site lay to the east of the lake. *See also* Koobi Fora.

East Rudolf Research Project Paleoanthropological research along Lake Turkana (formerly Lake Rudolf) began in 1968 when Richard Leakey led a **National Museums of Kenya** expedition, comprising Margaret Leakey, Paul Abell, Kamoya Kimeu, and two graduate students, John Harris and Bernard Wood, to explore the deposits along the eastern shore of Lake Rudolf. During this initial survey the group identified extensive fossil deposits and recovered several fragmentary hominin fossils. As a result a base camp was established in the following year on a spit along the lakeshore called Koobi Fora. New scientists joined the project in 1969, including Kay Behrensmeyer, a geologist, Meave Epps (now Meave Leakey), a zoologist, and the paleoanthropologist Glynn Isaac. Behrensmeyer began the task of mapping the geology of the site, particularly the volcanic tuffs that allowed the radiometric dating of the deposits. **Oldowan** tools were soon discovered and before the end of the field season two crania belonging to *Paranthropus boisei* were found (KNM-ER 406 and KNM-ER 407). In 1970 the East Rudolf Research Project was established under the co-leadership of Richard Leakey and Glynn Isaac to pursue expanded excavations at Lake Rudolf with an even larger company of scientists participating. Specialists studied the various species of fossil mammals present, including hominins, while geological mapping also continued. A mandible (KNM-ER 992) was discovered in 1971 that later became the type specimen of *Homo ergaster* and in 1972 Bernard Ngeneo discovered a hominin cranium (KNM-ER 1470) that was to become the

lectotype of *Homo rudolfensis*. Arguments over the dating of the **KBS Tuff** became a major issue during the 1970s since it had implications for the age of the KNM-ER 1470 cranium and other remains from below the KBS Tuff, and the controversy was not resolved until the early 1980s. Two additional crania discovered in 1973, the first (KNM-ER 1805) by Paul Abell and the second (KNM-ER 1813) by Kamoya Kimeu, were subsequently assigned to *Homo habilis*. In 1975 the Kenyan government renamed Lake Rudolf Lake Turkana and this prompted the East Rudolf Research Project to be renamed as well, so in the same year it became the **Koobi Fora Research Project**. *See also* Koobi Fora Research Project.

"east side story" *See* Coppens, Yves.

East Turkana *See* Koobi Fora.

eccentricity (L. *eccentricus*=not having the same center) One of the three rhythms, or cycles, affecting the Earth's orbital geometry (i.e., the manner in which the Earth orbits the sun). The *c.*100 ka-long eccentricity cycle affects the shape of the Earth's orbit and especially affects **insolation** at high latitudes. It has been the dominant cyclical signal affecting global climate for close to a million years. *See also* astronomical theory; astronomical time scale.

eclectic feeder One of the several terms (others include ecological generalist, **eurytope**, and omnivore) used for animals that include a diverse array of foodstuffs in the diet. Eclectic feeders might include an exceptionally wide range of plant foods into their diets (flowers, fruits, young leaves, seeds) or they might mix plant and animal foods (for example, supplementing a largely fruit-based diet with insects, small vertebrates, or eggs). Within primates, baboons are the classic eclectic feeders, ingesting a wide range of foods from cultivated crops to flamingos and juvenile antelopes. Much of the foraging for supplementary items may be done opportunistically. Eclectic feeding may have enabled Old World monkeys to inhabit a wide range of habitats, respond quickly to environmental changes (either climatic or anthropogenic), and exploit a wide geographic area (O'Regan et al. 2008). However, primates that feed eclectically do not necessarily incorporate a wide range of foods in the short term, but adjust their subsistence strategies seasonally, cycling between different foodstuffs as they become available (Chapman and Chapman

1990). The ability to feed eclectically is seen as one of the hallmarks of ecological generalists or eurytopes. Hominins were most likely eclectic feeders.

ecofact (Gk *oikos*=house and L. *facere*=to do) In the context of archeology an ecofact is a naturally occurring object that has not been handled or altered by modern humans or hominins. Examples include seeds, shells, or bones, which can become incorporated into archeological deposits through natural processes. Although ecofacts are not directly relevant to understanding hominin behavior, they can provide important information concerning the environmental context of an archeological site. For example, the identification of plant seeds in an archeological deposit could provide insight into the past vegetation cover at the time of deposition.

ecological intelligence The ability to adapt to an ecological niche by having an understanding of organisms and their ecosystems. By saying an organism has ecological intelligence, it is inferred that the organism has the capacity to learn from experience and deal effectively with the environment. This term was first introduced as “natural intelligence” by Howard Gardner, a psychologist at Harvard University, but Daniel Goleman (2009) adapted this term to ecological intelligence and applied it to how modern humans adapt to their changing environment in the face of industrialism. *See also* **cognition**.

ecology (Gk *oikos*=house and *logia*=study) First used by Haeckel (1866), this term refers to all the interactions between an organism and its environment. These can include the relationships between the organism and its physical, or **abiotic**, environment, as well as between it and its organic, or **biotic**, environment (i.e., the other organisms it comes into contact with). Three subdisciplines of ecology particularly relevant to hominin evolution are **paleoecology**, **behavioral ecology**, and **human ecology**.

economic utility index Measures the combination of the meat, marrow, fat, grease, or other energetic returns associated with a skeletal element. In zooarcheology these indices are used to evaluate skeletal part frequencies in terms of **carcass transport strategies**. The first economic utility index was developed for caribou (*Rangifer*) by Lewis Binford in 1978 and has since been developed for a number of

mammalian taxa, including buffalo (*Bison*), horse (*Equus*), and Phocid seals, among others. Binford proposed a family of hypothetical utility curves, representing a bivariate scatterplot comparison of skeletal part frequencies against economic utility to illustrate three hypothetical carcass transport strategies: (a) the bulk strategy, whereby all but the lowest-utility elements are transported, (b) the gourmet strategy, in which only the highest-utility elements are transported, and (c) the unbiased strategy, in which skeletal elements are transported in direct proportion to their economic utility. Economic utility indices are also referred to as food utility indices. *See also* **carcass transport strategy**.

economy *See* efficiency.

ecosystem The biotic community and its abiotic environment functioning as a system. It consists of dynamic interactions between plants, animals, and micro-organisms and their environment working together as a functional unit. An ecosystem can be as large as the Sahara Desert, or as small as a puddle or vernal pool. Ecosystems are typically comprised of several **habitats**.

ecotone [etym. *eco*(logy) plus *tone*, from Gk *tonos*=tension; i.e., an ecology in tension] In ecology, an ecotone is the transitional zone between two adjacent plant communities (e.g., open grassland and forest). The ecotone may represent a sharp boundary between adjacent habitats or a gradual blending of habitats across a broader area. Plant and animal species found in the adjacent communities are often found in the ecotone, in addition to organisms largely restricted to the ecotone. For example, the African impala (*Aepyceros melampus*) is often regarded as an ecotone species because it favors the ecotone between open grassland and savanna woodland; early hominins may well have occupied the same ecotone.

ectocranial morphology (Gk *ectos*=outside and *kranion*=brain case) Morphological features on the outside of the cranium. They can take the form of lines, crests, or grooves and mark where **connective tissue** (either the covering of a muscle, the epimysium, or the septa within a muscle, the perimysium) attaches to the external surface of the cranium. *See also* **nuchal crest**; **parasagittal crests**; **sagittal crest**; **striae parietales**.

ECV Acronym for **endocranial volume** (*which see*).

edaphic (Gk *edaphos*=ground or soil) Refers to anything related to **soil** (*which see*).

EDJ Acronym for the **enamel-dentine junction**, the three-dimensional boundary between the dentine core and the enamel cap of a tooth. *See* **enamel-dentine junction** (syn. **dento-enamel junction**).

EDMA Acronym for **Euclidean distance matrix analysis** (*which see*).

effect hypothesis One of several hypotheses proposed by Elisabeth Vrba (the others are the **habitat theory hypothesis** and the **turnover-pulse hypothesis**) that seek to explain how environmental change influences macroevolutionary patterns in the fossil record. The effect hypothesis provides a mechanism to explain the evolution of morphological trends in the fossil record that does not involve **directional selection**. Vrba (1980) noted the evolutionary histories of species that are ecological generalists (also called **eurytopes**) are expected to differ from those of species that are ecological specialists (also called **stenotopes**). Eurytopic, or generalist, species are able to survive under a wide variety of environmental conditions, whereas stenotopic, or specialist, species can only survive under a narrow set of environmental conditions. Thus, as environmental conditions change, stenotopic species are expected to experience higher rates of speciation and extinction than eurytopic species because the former are less well equipped to tolerate the new environment. In contrast, eurytopic species are more likely to be able to cope with, or adapt to, the new environment, so they are expected to be less likely to speciate or to go extinct. As a result, within a clade that contains both stenotopes and eurytopes, there are expected to be more species of the former than the latter. This gives the appearance that natural selection has favored the evolution of specialized morphological characteristics when in fact the observed species pattern (i.e., more stenotopes than eurytopes) is the result of a **macroevolutionary** “effect” and not the result of selection at the microevolutionary level. *See also* **eurytope**; **habitat theory hypothesis**; **macroevolution**; **stenotope**; **turnover-pulse hypothesis**.

effective population size In an idealized population (with random mating and no selection) it is the number of breeding individuals who contribute genes to the next generation. Introduced by the population geneticist Sewall Wright, effective population size (or N_e) influences the amount of **genetic drift** experienced by a population. Specifically, genetic drift is weaker in large populations and stronger in small ones. Usually the **census size** of a population is at least three times larger than the effective population size because it includes individuals who are too young, or too old, to produce offspring as well as those who are of reproductive age, but who do not reproduce. Effective population size can be affected by age structure, overlapping generations, unequal numbers of males and females, skewed family size distributions, fluctuations in population size, and the geographical dispersion of populations, but all of these issues can be corrected for statistically. Fluctuations in population size results in effective population size being the harmonic mean of the actual population size. Since the harmonic mean is typically dominated by the smaller population sizes, one or more periods of small population sizes (often called **population bottlenecks**) have a significant effect. In modern humans, N_e has been estimated at approximately 10,000 despite our current estimated population size of over 6 million people. This value is due to the fact that modern human effective population size still reflects much smaller population sizes in the past.

efficiency The ratio of work done to energy expended. Thus a large car can be more efficient than a small car even if it requires more energy to travel a given distance, as long as the amount of energy per unit of work done is less. It is useful to make a distinction between efficiency and economy. Economy refers to the thrifty use of resources; economy cars can be less efficient than larger automobiles, but they are more economical if they travel further on less fuel. In general, larger animal species are less economical than smaller species in that they use more energy to power their larger bodies. However, they are generally more efficient because they use less energy per gram of their body mass.

efficiency hypothesis This hypothesis is one of several purporting to explain the origin of upright posture and bipedal locomotion within the **hominin clade**. The hypothesis was proposed by Peter Rodman and Henry McHenry (1980) and is based

on what were then ground-breaking experimental data on the energetics of locomotion in two juvenile chimpanzees (Taylor and Rowntree 1973). When the locomotor energetics in two juvenile chimpanzees was compared with those of adult modern humans, Taylor and Rowntree (1973) showed that modern human bipedalism is more energetically efficient than chimpanzee quadrupedalism. However, the key aspect of Rodman and McHenry's efficiency hypothesis is the observation that chimpanzee quadrupedalism is approximately as energetically efficient as chimpanzee bipedalism (Taylor and Rowntree 1973). Rodman and McHenry (1980) interpreted this to mean that the transition from quadrupedalism to bipedalism would not have involved passing through an energetically inefficient mode of locomotion against which natural selection would have acted. Thus, as the earliest hominins were adapting to shrinking forests and increased fragmentation of forest patches at the end of the **Miocene**, neither terrestrial quadrupedalism nor bipedalism would have initially been favored on energetic grounds. However, over time, natural selection would act to improve the efficiency of the locomotor system and Rodman and McHenry (1980) suggest that bipedalism would have been favored over quadrupedalism because it would have allowed the earliest hominins to more effectively compete for arboreal resources by more efficient travel between forest patches. The major assumption that the energetic pattern for chimpanzee adults would be equivalent to Taylor and Rowntree's (1973) results collected on 3 year-old juveniles was confirmed by data from Sockol et al. (2007) on five adult chimpanzees. They showed that the energetic cost of chimpanzee knuckle-walking and bipedality were similar (and above average for comparably sized mammals) and modern human bipedality was about 75% less costly (and well below average for comparably sized mammals). Perhaps most importantly, in most chimpanzee individuals Sockol et al. (2007) found significant differences in efficiency between knuckle-walking and bipedal walking and they showed that this could be explained by biomechanical differences in gait. Some individuals, using more extended hip and knee postures (that more closely resemble the gait of moderns) walked more efficiently with a bipedal gait than during knuckle-walking. Sockol et al. (2007) suggest that intraspecific variation in the last common ancestor of modern humans and chimpanzees/bonobos meant that some individuals would have been able to better extend their hindlimbs and thus have longer contact

times, resulting in a bipedal gait that was more efficient than knuckle-walking; thereafter small increases in hindlimb extension or length would accentuate the energetic savings of bipedal gait in the earliest bipeds. Sockol and colleagues' version of the efficiency hypothesis posits that bipedality in the earliest ape-like hominins could have been less energetically costly than knuckle-walking and could have been a driving factor in the origin of hominin bipedality (Sockol et al. 2007). *See also bipedal locomotion.*

Ehringsdorf (Location 50°58'0"N, 11°21'0"E, Germany; etym. named after Ehringsdorf, a suburb of Weimar) History and general description The Ehringsdorf fossils were discovered as a result of blasting in the Fischer and Kämpfe quarries; all come from the 15 mm-thick Lower Travertine. Most attribute the Ehringsdorf remains to *Homo neanderthalensis*, but some researchers have drawn attention to the presence of more modern human-like morphology. Temporal span and how dated? *c.*230 ka based on uranium-series dating of the travertine, electron spin resonance spectroscopy dates on tooth enamel, and biostratigraphy of the microfauna. Hominins found at site At least nine individuals are represented by 35 hominin fragments that include cranial fragments, two mandibles, and post-cranial evidence. Archeological evidence found at site A variant of the **Mousterian** that includes worked **scrapers** and **points**. Several hearths have been identified in the lower and middle parts of the Lower Travertine. Key references: Geology, dating, and paleoenvironment Blackwell and Schwarcz 1986, Grün et al. 1988, Schüler 1994; Hominins Virchow 1920, Weidenreich et al. 1928, Smith 1984, Vlcek 1993; Archeology McBurney 1950, Behm-Blanke 1960, Feustel 1983.

Ein Gev (Location 32°46'N, 35°39'E, Israel; etym. He. *Ein Gev*="cistern spring," named after the nearby Ein Gev Kibbutz) History and general description Ein Gev refers to a complex of four sites on the eastern shore of the Sea of Galilee, just outside of the Golan Heights. Temporal span and how dated? 15.7 ka based on radiocarbon dating of associated burnt faunal remains. Hominins found at site A fairly complete female skeleton (though lacking a mandible) was recovered by Ofer **Bar-Yosef** and M. Stekelis from site I during the 1964 season. The remains are consistent with other female inhabitants of the **Natufian**. Archeological evidence found at site The sites of Ein Gev are characterized by a primarily

Kebaran assemblage. Key references: Geology, dating, and paleoenvironment Vogel and Waterbolk 1972; Hominins Arensburg and Bar-Yosef 1973; Archeology Arensburg and Bar-Yosef 1973.

El Harhoura (Location 33°57'17"N, 6°55'27"W, Morocco; etym. named after the nearby town) History and general description These two cave sites (El Harhoura 1, also known as Zouhrah Cave, and El Harhoura 2) near Témara, Morocco, were excavated in the late 1970s by André Debenath and F. Sbihi-Alaoui. They lie on the coast roughly halfway between Dar es Soltane and Smuggler's Cave, and contain predominantly Upper Paleolithic deposits. Temporal span and how dated? Upper Paleolithic based on stone tool technology. Hominins found at site Roughly 15 individuals were found in the Epipaleolithic layer of El Harhoura 1, and one canine, similar to that found at Dar es Soltane, was found in the lower layers. Two individuals were found in the Neolithic layer at El Harhoura 2. Archeological evidence found at site El Harhoura 1 had an epipaleolithic layer directly overlying two layers containing a mixed assemblage with both primitive-looking stone tools, like choppers, as well as relatively advanced Aterian points. The faunal profile and abundance of coprolites suggests that the site was primarily a carnivore den with only ephemeral human habitation. El Harhoura 2 contained Neolithic, Epipaleolithic, and Aterian layers. Key references: Geology, dating, and paleoenvironment Débénath and Sbihi-Alaoui 1979; Hominins Débénath and Sbihi-Alaoui 1979; Archeology Débénath and Sbihi-Alaoui 1979, Monchot and Auraghe 2009.

El Kherba (Location 36°25'12"N, 5°49'12"E, near Sétif, Algeria) History and general description El Kherba is an **Oldowan** archeological site sometimes considered a sublocality of the nearby **Ain Hanech** site, which was discovered in 1947 by French paleontologist Camille Arambourg. El Kherba itself was discovered and first excavated by Sahnouni and de Heinzelin in 1992–3. El Kherba preserves the earliest stratigraphically contextualized evidence of hominins living in North Africa. Temporal span and how dated? Based on paleomagnetic dating (the site has normal polarity) and biostratigraphy, Sahnouni and de Heinzelin (1998) proposed that the site falls with the Olduvai subchron and is thus within the 1.95–1.78 Ma range. Other researchers such as

Raynal et al. (2001) dispute this and claim a date closer to 1.2 Ma. Even if the younger date is the correct one, this site is still holds the earliest primary-context evidence for hominin occupation in North Africa. Hominins found at site None. Archeological evidence found at site El Kherba has yielded a **Mode 1** tool assemblage with a low degree of standardization. As of 2002 some 952 artifacts had been recovered by Sahnouni et al. and of these around 72% were less than 2 cm in length and were classified as debitage. The primary raw materials for the tools are limestone and flint, both locally available from eroding Plio-Pleistocene conglomerates. Three artifacts consisting of two whole flakes and one denticulate fragment display use wear consistent with their use for cutting animal soft tissue and bone. Key references: Geology, dating, and paleoenvironment Sahnouni and de Heinzelin 1998, Raynal et al. 2001; Hominins N/A; Archeology Sahnouni and de Heinzelin 1998, Sahnouni et al. 2002, Lahr 2010.

El Niño Anomalously warm waters in the eastern equatorial Pacific that contrast with cool waters in normal years and the even cooler water temperatures in the opposite (cold) phase called La Niña. This phenomenon is part of the **El Niño Southern Oscillation** (or ENSO). More recent observations have uncovered and distinguished two distinct warm patterns of El Niño: the central Pacific or Modoki El Niño and the canonical eastern Pacific El Niño (Yeh et al. 2009).

El Niño Southern Oscillation (or ENSO) A quasi-periodic (2–7 year) pattern of natural climate variability in the tropical Pacific with far-reaching consequences around the globe. ENSO is preferred over the terms **El Niño** (ENSO positive or warm phase) and **La Niña** (ENSO negative or cold phase) because ENSO includes reference to both the ocean surface temperatures and the changes in atmospheric pressures (**Southern Oscillation Index**) that describe the full extent to which this ocean/atmosphere oscillation can alter climate around the globe. ENSO has been identified as the dominant mode of modern inter-annual climate variability. Paleoclimate reconstructions show that the modern sea surface temperature gradient in the Pacific Ocean between a warm western **tropical** Pacific and a cool eastern tropical Pacific was established *c.* 2 Ma; prior to that warm temperatures across the tropical Pacific indicate a “super-El Niño” state that may not have

included the periodic ENSO cyclicality and if this is correct the pattern of global climate and inter-annual variability would have been quite different. In Africa ENSO influences the amount and seasonality of precipitation with regional characteristics. ENSO events and related changes in the Indian Ocean most strongly influence East and southern Africa with strengthened upper westerly winds that lead to decreased rainfall in southern Africa (December–March) and increased rainfall in East Africa (October–December) (Hastenrath et al. 1993). North and West Africa are partially influenced by ENSO variability. In the Sahel, El Niño events tend to correlate with dry conditions (July–September). Sustained El Niño- or La Niña-like conditions may also explain global climate patterns during paleoclimate events such as the warm, wet mid-Pliocene (Ravelo et al. 2006) or be a possible trigger mechanism for abrupt climate events such as the Younger Dryas (Clement et al. 2001).

El Sidrón (Location 43°23'01"N, 5°19'44"W, Spain; etym. uncertain, but local pseudo-mythological humans are called “sidrones”) History and general description This site, located in the Asturias region of Spain, was first explored in the 1970s by a team led by T. Pinto, but it was not until 1994 that the first hominin fossils were accidentally unearthed: systematic excavations have been ongoing since 2000. The fossils were found in the Osario Gallery, one of several galleries that run at right angles to the long axis of the cave system and were recovered from the exposed surface of “stratum III.” Many of the modest collection of artifacts can be refitted. Temporal span and how dated? The age of the hominin fossils is c.39–49 ka and probably closer to the latter age. The ages come from calibration of the raw AMS radiocarbon dates obtained from two teeth and a bone fragment coming from excavations. Amino acid racemization dating of gastropods, electron spin resonance spectroscopy dating and optically stimulated luminescence dating have also been performed. Hominins found at site Hominins dominate the fauna at the site, and more than 1900 hominin specimens have been recovered from the El Sidrón cave. Of these 140 were unearthed by amateurs (designated with the prefix SDR) with the remainder being recovered during formal excavations (designated with the prefix DR). All parts of the skeleton are preserved. The crania are mostly fragmentary with a bias towards young individuals. There is evidence of at least 11 individuals and of these one is an infant, one a juvenile,

two are adolescents, and four are young adults. There is no evidence that the collection samples more than one hominin taxon and there is ample morphological evidence (e.g., supraorbital torus, suprainiac fossa, small mastoid, shovel-shaped, labially convex incisor crowns with strong lingual tubercles, distinctive pre-molar occlusal morphology, taurodont molars, large joint surfaces, etc.) that the collection samples *Homo neanderthalensis*; the El Sidrón Neanderthals have broader and shorter faces than more northerly samples. Mitochondrial and nuclear ancient DNA has been recovered from several specimens (two specimens that could belong to the same individual) and the extracted DNA provides evidence that evolutionary changes in the *FOXP2* gene seen in modern humans are also seen in Neanderthals. There is copious evidence of hominin-induced bone modification. Archeological evidence found at site A total of 333 stone artifacts have been recovered, including side scrapers, denticulates, a handaxe, and several Levallois points. The raw material, which is dominated by chert with some quartzite, was available locally. Key references: Geology, dating, and paleoenvironment Rosas et al. 2006, Fortea et al. 2008, de Torres et al. 2010. El-Wad (Location 32°40'N, 35°05'E, Israel; etym. Ar. *Mugharet el-Wad*=Cave of the Valley) History and general description El Wad is one of the “classic” Mount Carmel sites excavated by Dorothy Garrod from 1928 to 1934. It is by far the largest of the caves and is situated near the entrance to the Wadi-el-Mughara (Valley of the Caves). Temporal span and how dated? The early Natufian layers have been dated using radiocarbon dating from c.12.9 to 11.7 ka; the ages of the lower layers are unknown. Hominins found at site A number of burials ornamented with shells are known from the epipaleolithic Natufian layers, but no hominin remains were found in the lower Mousterian layers. Archeological evidence found at site There is a dense lithic sequence that spans the Middle Paleolithic to the Epipaleolithic, including artifacts from what Garrod called the Levallois-Mousterian, Aurignacian, and Natufian industries. Key references: Geology, dating, and paleoenvironment Garrod and Bate 1937, Weinstein-Evron 1991; Hominins Garrod and Bate 1937, Mastin 1964, Oakley et al. 1975; Archeology Garrod 1932, Garrod and Bate 1937.

Elandsfontein [Location 33°05'S and 18°15'E, South Africa; etym. named after the Elandsfontein (Afrikaans for “eland’s spring”) farm. The alternative names are taken from the nearby towns of **Hopefield** and **Saldanha** (the latter named after the Portuguese explorer António de Saldanha)] History and general description After the initial surface collection by G. Smit, excavations were undertaken between 1951–4 and 1965–6 by Ronald Singer, J. Wymer, and M. Drennan. Elandsfontein is a former dune field near South Africa’s Atlantic coast where wind **deflation** exposed Pleistocene–Holocene artifacts and fossils in numerous interdunal “bays.” The mammalian fauna and artifacts date mainly from the Middle Pleistocene, but later Pleistocene and Holocene artifacts and fauna, including **Middle Stone Age** lithics and Khoekhoe pottery, have also been found. The large mammalian fauna, **Acheulean bifaces**, and flaking debris are associated with a calcareous duricrust formed on quartzose and shell-rich **aeolian** sands that promoted bone preservation. Most of the 13,000 faunal elements and numerous handaxes and other tools were collected unsystematically in deflation bays, but some were found in the excavation known as Cutting 10. Temporal span and how dated? Assuming the same pattern of faunal turnover observed in eastern Africa, the co-occurrence of the extinct long-horned buffalo *Pelorovis antiquus* and the ancestral hartebeest *Rabaticerus arambourgi* implies an age of between 1.0 and 0.6 Ma. The meticulously made handaxes suggest an age near the younger end of this range. Hominins found at site In 1953 K. Jolly and Ronald Singer found the **Saldanha 1** calvaria, and a mandibular fragment that may belong to the calvaria was reported separately in 1955. Archeological evidence found at site Most of the Acheulen artifacts associated with the duricrust likely accumulated independently of the animal bones, for stone-tool marks or other traces of hominin activity occur on less than 1% of the studied sample of 2184 **bovid** limb elements. Cutting 10 provided the only *in situ* artifact sample, comprising 37 **handaxes**, two **cleavers**, and several **flakes** related to their manufacture and resharpening, as well as other **cores**, flakes, and **retouched** pieces made of **silcrete** and quartz ($n=260$). Hippopotamus (*Hippopotamus amphibius*), reedbuck (*Redunca arundinum*), and other taxa suggest the environs were much moister than they were historically, but the most striking element of the Elandsfontein fauna is its diversity and lack of a modern or historic analogue. Occasional Middle

Stone Age artifacts, including **Still Bay points**, and Later Stone Age artifacts, including sherds of Khoekhoe pottery, occur in deposits that overlie the Acheulean duricrust. Key references: Geology, dating, and paleoenvironment Klein et al. 2007, Butzer 2004; Hominins Singer 1954, Drennan and Singer 1955, Bräuer 1984, 2008, Rightmire 2008; Archaeology Singer and Wymer 1968, Volman 1984, Klein et al. 2007.

Elandsfontein 1 See **Saldanha 1**.

elastic modulus A material property defined as the ratio of **stress** to **strain** within a material being subjected to tensile forces applied along an axis, as the material is being deformed elastically (meaning that the material returns to its original shape after the applied force is removed). The modulus can be thought as a uniaxial measure of the stiffness of a material and can be visualized as the slope of the elastic portion of the stress/strain curve, which is linear. Strain is a dimensionless value, so the elastic modulus, denoted by E and also known as Young’s modulus, is measured in Pascals (Newtons per square meter), which is the unit that describes stress. Typically, the elastic modulus of cortical bone is measured in terms of gigapascals (i.e., GPa, or billions of Pascals). Cortical bone is often said to have an elastic modulus of 15–18 GPa, although this is an oversimplification, as the elastic modulus varies by direction (anisotropy) in many regions. Values of 15–18 GPa or greater are usually found in the direction of greatest stiffness in the cortical plane, whereas values of approximately 5–12 GPa can often be found in one or two directions orthogonal to the direction of greatest stiffness in bone.

electromyography (or **EMG**) A technique that measures electric activity within a muscle and then uses that as a proxy for the work performed by that muscle. EMG research is most commonly conducted using superficial EMG sensors applied to the skin that detect electrical activity of muscles deep to the skin, but more precision can be obtained with implanted electrodes inserted directly into the muscle tissue. By back-stimulation (i.e., using a weak electrical current to stimulate the muscle of interest to become active) researchers can verify the electrode lies in the targeted muscle. Then, when the subjects recruit their muscles during natural activities, telemetry systems

send the electrical signal wirelessly to a detector, allowing researchers to study anatomical movements while the subjects are unencumbered. Stern and Susman (1981) provide an example of successful EMG research. They collected EMG data on the activity of gluteus medius, gluteus superficialis (the equivalent of gluteus maximus in modern humans), and tensor fascia femoris in gibbons, chimpanzees, and an orangutan during climbing and bipedal and quadrupedal locomotion. They found that, contrary to previous suggestions, the gluteus medius in apes acts primarily to medially rotate, not extend, the thigh while in its typically flexed position. They conclude that the role of gluteus medius during bipedality is the same in apes as in modern humans, namely to provide side-to-side balance of the trunk at the hip. This in turn suggests that the evolution of the hominin lateral balance mechanism during bipedal gait was primarily osteological, thus allowing the same muscle to function in the same way, but with the thigh extended (i.e., in modern humans) instead of flexed (i.e., chimpanzees, etc.).

electron spin resonance spectroscopy dating (or ESR) A radiation-based dating method involving the measurement of the trapped electrons resulting from “molecular-level” radiation damage caused by the uptake of uranium and other radioactive elements into crystalline materials such as in *calcite* (e.g., shells and coral) or *apatite* (e.g., bones and teeth), often at the time of their burial. The same provisos as those for **luminescence dating** methods apply to ESR dating (i.e., the resetting of the “electron clock” must be unambiguously linked with hominin activity, radiation dose rate must be established, etc.). One suitable crystalline material whose formation can be linked with hominin intervention is the enamel of the teeth of animals used by the hominins for food or as a source of raw materials. The technique can provide dates over a time range of a few thousand years to more than *c.*1 Ma. The ESR technique is not without its problems and an important unknown is the timing of the uranium uptake by the sample. The “early uptake model” assumes that uranium reaches its present levels soon after burial, whereas the “linear model” assumes that the rate of uranium accumulation is linear, but neither model may accurately account for the complex history of uranium accumulation or loss in particular specimens. An example of an appropriate application of

the ESR technique is the dating of **Hexian** (Grun et al. 1998).

electrophoresis [L. *electricus*=literally “like amber” (electricity is produced when amber is rubbed) and Gk *phoresis*=to bear] A method that separates biological molecules (e.g., **DNA**, **RNA**, or **proteins**) according to their mobility in a gel (commonly made of agarose, starch, or polyacrylamide) under the influence of an electric field. The size of the pores in the gel affects the speed that molecules can move through it and the distance the molecules move depends on their electric charge (which is determined by their chemical make-up) and on their mass (i.e., their molecular weight). Electrophoresis is commonly used in genetics laboratories for such things as identifying protein variants, checking **polymerase chain reactions** to make sure that they worked, identifying size variants in **restriction fragment length polymorphisms** or insertion/deletion polymorphisms, and for **DNA sequencing**.

Elephantidae The formal name of the only extant family of **proboscideans**. It includes *Loxodonta*, the African elephant, and *Elephas*, the Asian elephant. *See also* **Proboscidea**.

Eliye Springs *See* KNM-ES 11693.

Eliye Springs cranium *See* KNM-ES 11693.

ELM Acronym for eastern lake margin, the term used for the eastern margin of the paleo-lake in the **Olduvai Basin** called Lake Olduvai. *See also* **Lake Olduvai**; **Olduvai Gorge**.

EMG Abbreviation of **electromyography** (*which see*).

Emireh points *See* Boker Tachtit.

emissary foramina (L. *emissarium*=a drain and *foro*=to pierce, the root of *foramen*=a hole, or opening) The holes in the cranium (e.g., the hypoglossal, mastoid, occipital, parietal, and posterior condylar foramina) that transmit **emissary veins** which provide a communication between the **intracranial cerebral venous system** and the extracranial venous system (e.g., the veins of the scalp or the vertebral venous plexus).

emissary veins (L. *emissarium*=a drain and *vena*=a water course, or blood vessel) Small thin-walled veins (e.g., hypoglossal, mastoid, occipital, parietal, posterior condyloid) that provide a communication between the **intracranial cerebral venous system** and the extracranial venous system. With the exception of the parietal emissary vein, which connects the superior sagittal sinus with the veins of the scalp via the parietal foramen, the remaining emissary veins transmit venous blood through foramina in the **cranial base**. From posterior to anterior, the major emissary veins of the cranial base are the occipital (occipital foramen), mastoid (mastoid foramen), condylar (condylar canal), hypoglossal (jugular foramen), and sphenoidal (emissary sphenoidal foramen). Falk (1986) suggested that in some early hominin taxa (e.g., *Paranthropus boisei* and *Australopithecus afarensis*) the emissary veins around the base of the cranium, along with the **occipito-marginal system** of intracranial venous sinuses, provided a route for significant amounts of venous blood to drain from the superficial and deep cerebral veins into the vertebral venous system.

enamel (OF *esmail*=a vitreous coating, often white, baked on metal, glass, etc.) The hard, white, outer coating of the **crown** of a tooth. One of three dental hard tissues (along with **dentine** and **cementum**), enamel is the hardest of the biological tissues and this accounts for the relative abundance of teeth in fossil assemblages. Mature enamel consists of two components or phases, inorganic and organic. Most mature enamel (approximately 96% by weight) is an inorganic mineral called hydroxyapatite, sometimes abbreviated to just **apatite**. The smallest structural unit of enamel, the enamel crystallite, is only a few nanometers wide in cross-section but it can grow to be a millimeter or more long. The cells responsible for the manufacture of what eventually becomes mature enamel, the **ameloblasts**, secrete a matrix of proteins, water, and mineral ions. The organic phase of mature enamel (approximately 4% by weight) consists of proteins that function as a “glue” to bind the crystallites together. Some of the proteins (e.g., amelogenins) provide a framework or scaffold along which crystallite growth is guided in its long axis (or C-axis). In mature aprismatic, or prismless, enamel the crystallites are bound together by remnants of the organic matrix. Most reptiles have aprismatic enamel, but although it occurs in primate teeth occasionally, especially close to the crown

surface, almost all mammalian enamel is prismatic. In the same way that minute glass fiber threads can be bound together to form flexible glass fiber optic bundles, so too can enamel crystallites become associated into bundles called **enamel prisms**, or enamel rods. Prism boundaries are no more than places where crystallites meet each other at different angles and where remnants of the organic matrix get squeezed during enamel maturation. In cross-section, prisms may be rounded pencil-like structures or alternatively more complex and keyhole-like in outline. They may pack together in bundles, as flat-sided pencils would, in a “close-packed” hexagonal manner with one at the center surrounded by six prisms, or in layers that alternate one above the other like bricks in a wall. The appearance of enamel prisms viewed end-on has been classified into pattern 1, pattern 2, and pattern 3 depending on their outline, area, and packing arrangement. **Hominids** mostly have the keyhole-shaped hexagonally packed pattern 3 enamel, but with areas of round hexagonally packed pattern 1 enamel; pattern 2 enamel arranged into alternate layers of rounded prisms predominates in Old World Monkeys. Enamel is known to show several classes of **incremental features**. **Short-period incremental lines** form either daily or even occasionally every approximately 8–12 hours. These daily **cross-striations** and so-called intradian lines look like fine dark lines in transmitted light microscopy and run across the prisms in line with the face of the secretory end of the ameloblast (or Tomes’ process) that formed them. Laminations, another incremental phenomenon, look like (and may actually be) daily increments in regions of aprismatic and prismatic enamel and their layered appearance suggests that many cross-striations formed at the same time may have merged. Long-period markings called **striae of Retzius** are aligned along previous positions of the whole ameloblast cell sheet. These **long-period incremental lines** have a modal value of 7 days apart in australopiths and 8 days in fossil *Homo* (Lacruz et al. 2008). All these structures in primate enamel are described, illustrated, and reviewed in Boyde (1989, 1990), Aiello and Dean (1990), and Smith (2006). The presence of incremental lines in enamel allows researchers to determine the **crown formation time** and rate, and in some cases the **mean age at death**; these applications are reviewed in Aiello and Dean (1990), Dean (2000, 2006), and Smith et al. (2006). *See also enamel development; enamel microstructure.*

enamel chipping The loss of volume that affects the dentition is mostly a gradual process (see **tooth wear**), but tooth volume is also lost suddenly in the form of substantial (i.e., millimeter-sized) edge chips of surface enamel. Enamel chipping has been documented in numerous mammalian species and more than 50 years ago John **Robinson** compared the frequency of chips on the teeth of *Australopithecus africanus* and *Paranthropus robustus* from southern Africa (Robinson 1954). He concluded that the latter featured more chips and he suggested that this may have been because *P. robustus* was eating **underground storage organs** covered in exogenous grit. Phillip **Tobias** also looked at enamel chipping in his 1967 monograph of **OH 5** (Tobias 1967a), the type specimen of *Paranthropus boisei*, but he did not find any difference in the incidence of chipping in the southern African hominins and Wallace (1973) reached a similar conclusion. Tobias suggested that the large size of the chips precluded them from being caused by small hard particles like grit and instead proposed that they might have been the result of chewing on bones. Enamel chipping has since been documented in a number of other East African taxa including *Australopithecus afarensis* (Johanson and Taieb 1976), *Australopithecus anamensis* (Ward et al. 2001), and early *Homo* (Constantino et al. 2010). Constantino et al. (submitted) showed how a simple fracture equation could be used to estimate peak bite forces from the sizes of enamel edge chips. A preliminary analysis revealed that bite forces calculated from chips on the posterior teeth of fossil hominins frequently exceed 1000 N and can approach 2000 N, thus supporting the idea of consumption of large hard foods like seeds; this latter hypothesis is given some support from the high frequency of similar chips seen in extant seed crushers (e.g., orangutans and peccaries). The semi-permanence of enamel chips means that hard-object consumption can be detected even if the hard foods are eaten rarely, as is the case with **fallback foods**.

enamel decussation See **decussation**; **enamel development**.

enamel-dentine junction (or **EDJ**) The interface or boundary between the outer surface of the **dentine** core of a tooth crown and the inner surface of the enamel cap that covers it. Although the EDJ looks smooth at the gross level, at the microscopic scale the microtopography of the dentine

surface is sometimes scalloped to help key enamel into the dentine. Its overall shape defines the shape of the crown and the shape of the EDJ is determined by the contours of the **inner enamel epithelium** and the underlying mesenchymal cells that make up the dental papilla in developing tooth germs (see illustrations in Aiello and Dean 1990 and Nanci 2003). The shape of the EDJ is generally replicated at the outer enamel surface, except where differential rates of enamel formation modify the EDJ template (e.g., Skinner et al. 2009b). Smith et al. (2006b) have shown that within a single species (modern humans) both EDJ shape and **enamel thickness** differ among molar types, between the sexes and among regional populations; syn. **dento-enamel junction**.

enamel development Enamel is formed by **ameloblasts** that are derived from the **inner enamel epithelium**, the invaginated **ectodermal** layer of a developing **tooth germ**. In the early stages of the development of the tooth germ, cell division begins where the tips of the future **dentine horn** will be. At the apex of each developing horn the inner enamel epithelium differentiates into ameloblasts with secretory poles facing inwards towards the future **enamel-dentine junction** (or EDJ). The underlying mesenchymal cells of the dental papilla differentiate into **odontoblasts** whose secretory poles face outwards towards the EDJ: the interface between the two layers of cells is what will become the EDJ. Secretory odontoblasts differentiate first at the tips of the dentine horns and the wave of secretory activation moves down the sides of the tooth germ along the EDJ to the cervical margin or **cervix**. Enamel formation always lags slightly behind dentine formation. The rate at which fully differentiated ameloblasts become active secretory cells is known as the **enamel extension rate** (Shellis 1984). As each ameloblast moves outwards away from the EDJ in its wake it secretes an increasing thickness of matrix consisting of proteins, water, and mineral ions. Once the full thickness of enamel matrix is secreted, these secretory ameloblasts switch roles and become maturational ameloblasts. They alternate between pumping mineral (mostly Ca^{2+} and PO_4^{3-} ions) into the matrix and drawing water and degraded proteins out of the matrix thus enabling the crystallites (see **enamel**) to expand in diameter and pack increasingly tightly together. Enamel maturation can take years but by the time of its eruption the enamel of a tooth is hard and mostly mature. Rhythmic slowings of enamel matrix secretion

are preserved in the form of **short- and long-period incremental lines**. The short-period enamel incremental features are called **cross-striations** and the longer-period enamel incremental features are called **striae of Retzius**. See the references in Humphrey et al. (2008) for more information about enamel mineralization. *See also* **extension rate; mineralization**.

enamel extension rate *See* extension rate.

enamel formation *See* enamel development.

enamel microstructure The microstructural features of enamel reflect the cellular activity of the ameloblasts that secrete a protein-rich matrix during **enamel development**. Enamel is comprised of **enamel prisms** that are marked by various types of incremental line (e.g., **striae of Retzius**, **cross-striations**, laminations, and **intradial lines**). Enamel prisms weave across each other and create a regular banding pattern known as **decussation** and its manifestation is **Hunter–Schreger bands**. Counts and measurements of the incremental microstructure of enamel can be used to estimate **daily secretion rates** and/or **crown formation time**. *See also* **enamel development; incremental features**.

enamel prism Enamel prisms consist of bundles of hydroxyapatite crystallites formed into long rods. They are approximately 5 μm in diameter and run from the **enamel-dentine junction** to the surface of the **enamel**. The shape of the secretory tip of an **ameloblast** (the Tomes' processes) determines the cross-sectional shape of a prism and the prism path is determined by the direction of movement of the secretory ameloblast. Enamel prisms preserve microscopic **incremental features** such as daily **cross-striations** and the longer-period **striae of Retzius** (syn. enamel rod).

enamel thickness Enamel thickness is typically quantified by linear (e.g., Gantt 1977), areal (i.e., two-dimensional; e.g., Martin 1983, Smith et al. 2006a) or volumetric (i.e., three-dimensional; e.g., Kono 2004, Olejniczak et al. 2008a) measures of the enamel cap. Martin (1983) proposed that measurements of average and relative enamel thickness be made from two-dimensional controlled section of the tooth crown. Average enamel thickness represents the average linear thickness across the

tooth crown (i.e., the enamel cap area divided by the enamel-dentine junction length), while relative enamel thickness represents a measure of average enamel thickness divided by coronal dentine area. The latter approach facilitates comparisons across taxa (as enamel thickness is scaled using a proxy for body mass – the square root of the area of the dentine cap – that scales isometrically with body mass across primates; Shellis et al. 1998). Non-destructive **micro-CT** has been used by several researchers to calculate these indices of relative enamel thickness in three dimensions (e.g., Kono 2004, Olejniczak et al. 2008a), thus providing a more accurate representation of whole-crown enamel thickness. Linear measurements of enamel thickness have been used to support taxonomic distinctions among hominin taxa (e.g., Beynon and Wood 1986), generate functional models of tooth structure (e.g., Schwartz 2000), as well as to estimate cuspal or whole-crown formation times (e.g., Risnes 1986, Dean et al. 2001). Average enamel thickness in modern human molars has been shown to be greater in upper than in lower molars (Smith et al. 2006a) and it also increases along the tooth row from incisors through molars (Smith et al. 2008). Enamel thickness in hominins is known to vary from the very thick enamel of *Paranthropus boisei* to the thick enamel of *Australopithecus* and *Homo* (e.g., Beynon and Wood 1986, Grine and Martin 1988, but see Olejniczak et al. 2008b) to the reportedly thin enamel seen in *Ardipithecus kadabba* (Suwa et al. 2009a), but the use of different measurement techniques presently precludes meaningful direct comparisons. *See also* **enamel thickness, relative**.

enamel thickness, relative A method of quantifying **enamel thickness** proposed by Martin (1983, 1985) that involves measuring the area of the **enamel cap**, the length of the **enamel-dentine junction**, and the area of the coronal **dentine** from a controlled (two-dimensional) buccolingual plane of section (i.e., across the tips of the dentine horns of the mesial or distal molar cusps). The measure, relative enamel thickness (or RET), is intended to facilitate comparisons across taxa (as it is scaled by a proxy for tooth size). Recent studies using **micro-CT** have quantified the three-dimensional relative enamel thickness using volumes and surface areas rather than areas and linear distances (e.g., Kono 2004, Olejniczak 2006) and Kono (2004) and Smith et al. (2006b) review the published two-dimensional

enamel thickness data for extant hominoid molars. See also **enamel thickness**.

encephalization (L. *cephalon*=brain from the Gk *enkephalos*=literally “marrow in the head”) A relative measure of a species’ **brain size** that tries to capture the degree to which it is larger or smaller than expected for a typical animal of the same **body size**. Formulae for calculating encephalization differ according to the choice of **line-fitting technique** and what taxa are included in the reference sample. In primates, increased encephalization has been linked to a number of factors including **intelligence**, **diet**, innovation rate, the degree to which the animals use binocular vision, and the total amount of visual input to the brain. See also **encephalization quotient**.

encephalization quotient (L. *cephalon*=brain from the Gk *enkephalos*=literally “marrow in the head” and L. *quotiens*=how many times) (or EQ) Introduced by Harry Jerison in his 1973 book *Evolution of the Brain and Intelligence*, but the idea originated with Eugène **Dubois**’ (1897) initial proposal for an equation to quantify **encephalization**. It was devised to account for the interspecific **allometric** effects of body size on brain size so that the degree of encephalization can be meaningfully compared across a range of different species. A number of studies (e.g., Bauchot and Stephan 1969, Gould 1975, Jerison 1973, Martin 1981) have shown that brain size scales with **negative allometry** with respect to body size. The exact scaling exponent depends on the species included in the reference sample and the statistical method of line fitting employed. In practice, the EQ of a particular species is determined by calculating the ratio of its observed brain size over its “expected” brain size. The expected brain size is calculated from a prediction equation based on a scaling relationship, either theoretical (i.e., Jerison 1973) or empirically determined (i.e., Martin 1981, Holloway and Post 1982). Thus, a species with an EQ that is greater than 1.0 has a brain that is larger than expected for its body size and an EQ that is less than 1.0 indicates that the species has a brain that is smaller than expected. Although the exact EQ depends on the composition of the reference sample used in the analysis, without exception modern humans have been found to have the highest EQ in comparative studies of mammals and primates.

Attempts to link variation in EQ to general cognitive capacities across diverse mammalian taxa have met with mixed results.

encounter-contingent prey-choice model
See **prey-choice model**.

endemism (Gk *endmia*, *en*=in, *demos*=people) Belonging, or native to, a particular place, group, field, area, or environment. In an ecological context, endemism refers to the state of being unique to a particular geographic location. Typically, endemic types or species are more likely to develop on actual, or what are effectively, islands due to the geographic isolation of these populations. For example, all lemur species (Lemuriformes) are endemic to the island country of Madagascar and 50% of the primate species of Indonesia are endemic to its islands. In contrast, only 30% of the species in Brazil are endemic, and even fewer primate species in Africa are endemic to individual countries (about 11%). By default larger tropical countries may have more endemic species simply because they may have more species and greater habitat diversity (e.g., Brazil has more endemic species than Madagascar, but it covers an area around 15 times as large). Among fossil hominin taxa the obvious and best candidate for being an endemic species is *Homo floresiensis*.

endocasts (Gk *endo*=within and ME *casten*=to form an object from a mold) Applies to a cast made of any cavity in the body, but it is usually used as an abbreviation for an endocranial cast. See also **endocranial cast**; **endocranial cavity**.

endochondral ossification (Gk *endo*=within and *chondros*=cartilage) Bone formation within a framework of cartilage. Endochondral ossification is a two-staged process. First, cells called chondroblasts form a hyaline cartilage model of the future bone. Cells in the middle of the cartilage model first divide and grow by interstitial growth (as distinct from appositional growth). This enables rapid formation of the cartilage model. Chondrocytes then swell (hypertrophy) and die, leaving only a mineralized shell of cartilage matrix. This mineralized cartilage is then resorbed by osteoclasts (strictly speaking they should be called chondroclasts) and at the same time cells called osteoblasts start forming osteoid matrix on the walls of the spaces once occupied by chondro-

blasts. This happens first at the primary center of ossification, and that center is soon surrounded by a sleeve of subperiosteal bone that forms beneath the **periosteum**. In long bones the bone formed from the primary center of ossification is called the **diaphysis**. Primary centers usually appear between 7 weeks and 4 months of intrauterine life. Some bones (e.g., **auditory ossicles**, zygomatic, carpals, and tarsals) usually form from a single primary center but others, called complex bones (e.g., sphenoid, temporal), form from multiple primary centers. Secondary centers of ossification, or **epiphyses**, form in complex bones (e.g., vertebrae), at the ends of long bones and at the sites of bony processes (e.g., trochanters of the femur and the tubercles of the humerus). Long bones continue to grow in length because new cartilage is laid down in epiphyseal plates between the primary center in the shaft of the bone and the epiphyses at either end. *See also* **ossification**.

endocrone A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **hypocone** (*which see*).

endoconid A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **entoconid** (*which see*).

endocranial (Gk *endo*=within and *kranion*=brain case) **Noun** The cavity formed by the walls, roof, and floor of the cranium. **Adjective** Refers to any structure within the cranial cavity (e.g., the dural venous sinuses are sometimes referred to as the endocranial venous sinuses).

endocranial capacity *See* **endocranial volume**.

endocranial cast A natural or prepared cast that uses the walls, roof, and floor of the cranial cavity as a mold. The best known natural hominin endocasts are those recovered from the southern African cave sites (e.g., **Taung**). Ralph **Holloway** developed the method that is widely used to make artificial endocranial casts. This involves stopping up the foramina and fissures then pouring just enough liquid latex into the **foramen magnum** to form a thin coating over the endocranial surface of the cranial cavity. Once the latex has cured, it is peeled off

the endocranial surface (hence it is referred to as a “peel”), extracted via the foramen magnum, and used to make the mold from which solid latex or plaster casts can be made. It is also possible to use the data collected from a computed tomography (or CT) scan to make a virtual endocranial cast that can then be used to manufacture a solid rendering of the virtual cast. Only rarely are fossil crania well enough preserved to enable a really accurate endocranial cast to be made and in most cases some guesswork is involved when reconstructing the parts of an endocast that are missing. The problem is that the volume of inaccurate endocranial casts can be measured as precisely as the volumes of accurate endocranial casts. Thus most estimates of the endocranial volume of fossil hominin taxa contain a mixture of reliable and less reliable measures of endocranial volume depending on the degree to which the walls of the endocranial cavity have been reconstructed.

endocranial cavity Refers to the cavity formed by the walls, roof, and floor of the cranium.

endocranial fossae The endocranial surface of the cranial base is conventionally divided into three endocranial fossae. The two anterior endocranial fossae house the **frontal lobes** of the **cerebral hemispheres**, the two middle endocranial fossae house the **temporal lobes** of the cerebral hemispheres, and the two posterior endocranial fossae house the cerebellar hemispheres. *See also* **endocranial cavity**.

endocranial morphology Endocranial morphology comprises whatever features of the external surface of the dura mater have been preserved in the form of negative impressions on the endocranial surface of the bones of the cranial vault. These preserved features include negative impressions of **sulci**, **gyri**, and the branches of the **meningeal vessels**.

endocranial volume The sum of **brain volume**, plus the volumes of the **meninges**, the extra-cerebral cerebrospinal fluid (or CSF) (i.e., the CSF outside the ventricles), the intracranial (but extra-cerebral) vessels, and the cranial nerves within the endocranial cavity. All of the latter (i.e., the meninges, etc.) generally amount to approximately 15% of the endocranial volume. Count (1947) suggested that endocranial volume=brain

mass $\times 1.14$. The volume of the endocranial cavity is usually measured by stopping up the foramina and fissures with cotton wool, inverting the **cranium**, pouring bird seed or another type of granule into the **foramen magnum**, and then decanting the seed or granules into a measure. Endocranial volume can also be measured by dipping a plaster or latex **endocranial cast** into water and measuring the volume of water displaced, or by using specialized software to convert data obtained from computed tomography (or CT) scans into a measure of endocranial volume (syn. endocranial capacity).

endolymph (Gk *endon*=within and L. *lymph*=water) Watery fluid contained within the **membranous labyrinth** of the **inner ear**. Chemically it resembles intracellular fluid.

endosteum The osteogenic layer lining the internal surface of the bones that make up the walls of the **endocranial cavity**. It is equivalent to the periosteum that covers the external surface of the skull and limb bones. *See also* **periosteum**.

endurance running hypothesis Posits that modern humans perform unusually well compared to other mammals at sustained running and that selection for this capacity shaped the evolution of modern human anatomy and physiology. The endurance running (ER) hypothesis was first articulated in detail by Carrier (1984), who attributed conversations with Dennis Bramble (see below) and S.C. Carrier as the motivation for his article. Acclimatized modern humans can run down prey (e.g., duicker, gemsbock, wildebeest, zebra, deer, antelope, kangaroo) by persistent pursuit until the animal collapses from exhaustion. Carrier (1984) pointed out the "energetic paradox" that modern humans have a very high energetic cost (ml O₂/kg \times km) of transport (i.e. movement over distance), and yet modern humans are able to sustain their running over much longer distances than mammals of the same body size. Energetic inefficiency and ER would seem incompatible, but the ER hypothesis argues that modern humans can sustain long-distance running because they have evolved physiological mechanisms to (a) dissipate metabolic heat and (b) store and use large reserves of energy. The former include sweat glands that secrete enough moisture for evaporative cooling (horses and camels are other exemplars), but at substantial costs to water and salt reserves, and diminished body hair that

facilitates evaporative cooling. These factors support the argument that modern humans are derived in their abilities to dissipate heat, and evidence suggests that heat generated from activity is the limiting factor. Carrier hypothesized that adaptations for ER may have shaped the anatomy of *Australopithecus*, noting for example that its bipedal posture for locomotion would have decoupled breathing and running for, unlike panting, sweating is decoupled from breathing while running (Carrier 1984). However, the relative energetic inefficiency of modern human running means that ER (e.g., for predation or scavenging) would require unusually high energy stores to outlast prey. Twenty years later, Bramble and Lieberman (2004) published an influential article that built on Carrier's ER hypothesis, presenting data that had accrued since 1984, and more explicitly linked modern human musculoskeletal anatomy (e.g., long Achilles tendon compared with that in great apes) with the potential advantages of ER. Bramble and Lieberman's version of the ER hypothesis argues that selection for ER was the main driver of the musculoskeletal changes seen in the transition from *Australopithecus* to *Homo*, notably **early African *Homo erectus***. Other circumstantial evidence that modern humans are adapted for sustained running over long distances (ER) includes the observation that modern humans frequently experience an endocannabinoid "runner's high;" a similar response is seen in mammalian cursors but it is lacking in non-cursors (Raichlen et al. 2010). What remains to be established is whether ER is the only possible explanation for the adaptations seen in modern humans presently linked with ER, or whether long-distance walking or sprinting might be equally good adaptive explanations, and at what stage in human evolution ER (or walking, or sprinting) became an important selective force.

energetic returns *See* **optimal foraging theory**.

Engihoul *See* Schmerling, Philippe-Charles (1790 or 1791–1836).

Engis (Location 50°34'N, 5°25'E, Belgium; etym. named for the town of Engis) History and general description This cave site (also called Awirs) has been destroyed by mining. The **hominin** fossils come from stratified cave deposits that were excavated by P.C. Schmerling in 1829 (Engis 1–3) and by

E. Dupong in 1872 (Engis 4). Although it was not recognized as such until 1936, Engis 2 was one of the first, if not the first, specimen of *Homo neanderthalensis* to be discovered. Engis 1 is recognized as a modern human buried in **Mousterian** deposits. Temporal span and how dated? Any date is based on the associated **Mousterian** and **Aurignacian** archeological evidence. Hominins found at site Nearly complete adult **neurocranium** of *Homo sapiens* (Engis 1), partial child's cranium with separate maxilla of *H. neanderthalensis* (Engis 2), cranial and postcranial fragments (Engis 3; NB: this specimen has been lost), and a taxonomically undiagnostic ulna fragment (Engis 4). Archeological evidence found at site Mousterian (Engis 2) and **Upper Paleolithic** (Engis 1). Russell and Le Mort (1986) suggested there is evidence of cutmarks on the Engis 2 cranium. White and Toth (1989) agreed that the marks were anthropogenic but claimed they are not cutmarks, but "sandpaper striae formed during restoration of the vault, moulding striae formed when mold part lines were incised into the fossil and profiling striae formed when craniograms were made with sharp steel instrument tips" (*ibid*, p. 361). Key references: Geology, dating, and paleoenvironment Fraipont 1936; Hominins Fraipont 1936, Fenart and Empereur-Buisson 1970; Archeology Fraipont 1936, Russell and Mort 1986, White and Toth 1989. Location of the hominin fossils found at site Service de Paléontologie Animale et Humaine, Université de Liège.

enhancement The presence of another individual may enhance or inhibit specific behaviors in the observing individual. These socially driven effects are considered to be basic (low-level) motivational and affective states that compel individuals to act and the mechanisms are believed to be phylogenetically ancient and shared among all mammals. But enhancement is also found in many bird species, particularly the passerines including the corvids (crows); it is not known whether reptiles show evidence of enhancement. As such it is likely that the enhancement seen in birds and mammals are the result of **convergent evolution**. In the animal behavior and comparative literature several motivational (enhancement) states are associated with **social learning**. These include **social enhancement**, **stimulus enhancement**, and **local enhancement**. These different "primitive" enhancement effects serve to orient attention and motivation learning mechanisms and they are

often contrasted with **imitation**, considered by many to be a derived cognitive trait in primates (see Subiaul 2007 for a review). *See also social learning*.

enhancer A regulatory sequence of **DNA** that positively influences **gene expression**, often from a distance (i.e., the enhancer sequence may be a long way away – in terms of the number of intervening nucleotides – from the gene whose expression it influences). Enhancers do not themselves bind to the **promoter** region of a gene where **transcription** is initiated. Rather, they are chemically bound by activator and repressor proteins that interact with **transcription factors** and RNA polymerase II, which then transcribe the gene.

Enkapune ya Muto (Location 0°50'S, 36°09'E, Kenya; etym. unknown, but the site is also known as Twilight Cave) History and general description Stanley Ambrose directed excavation of this rockshelter located west of Lake Naivasha in the Kenyan section of the **East African Rift System**. An area of 14 m² was excavated from 1982 to 1987 and bedrock was reached at a maximum depth of 5.54 m below the surface and the excavations yielded **Iron Age**, **Later Stone Age**, and **Middle Stone Age** artifacts. Sediments include windblown silts and sands and at least three layers of **tephra**, gravels, and anthropogenic deposits such as **hearths** and wood ash. Temporal span and how dated? **Radiocarbon dating** estimates on charcoal, charcoal-impregnated sediment, and ostrich eggshell document presumably modern human occupation of the rockshelter from 41.4±0.7 to 0.5±0.15 ka (the former age is uncalibrated). Age estimates using **obsidian hydration dating** on artifacts from the Later and Middle Stone Age strata, corrected for Pleistocene temperatures –5°C from present, range from 32.46±1.25 to 46.41±2.76 ka. Average sedimentation rates are used to argue for an age for the earliest Later Stone Age of more than 55 ka. Hominins found at site None. Archeological evidence found at site Enkapune ya Muto is an important site for dating Iron Age and **Neolithic** sites in East Africa and these upper strata include a rich faunal assemblage. The Later Stone Age artifact assemblages are divided into the Sakutiek and older Nasampolai industries. The Sakutiek industry includes stone implements typical of the Later Stone Age (e.g., thumbnail **scrapers** and backed **microliths**) and the Middle Stone Age (e.g., discoidal **cores** and faceted platform **flakes**), as well as a range of ostrich eggshell bead

fragments demonstrating on-site manufacture, directly dated to 39.9 ± 1.60 ka. The Nasampolai industry is characterized by geometric microliths and large backed blades, many of the latter retaining traces of red ochre, suggesting hafting parallel to the long axis of the blade. The flake-based Middle Stone Age Endingi Industry also includes flakes with traces of ochre on them, as well as an ochre-stained lower grindstone. Obsidian is the dominant raw material type throughout the sequence. Faunal evidence is rare in the Later and Middle Stone Age strata. Key references: Geology, dating, and paleoenvironment Ambrose 1998; Archeology Ambrose 1998, 2001.

enrichment The isotope enrichment value (ϵ) provides the exact isotopic difference between two substances and is not limited by the isotopic scale (e.g., the Pee Dee Belemnite for carbon and Standard Mean Ocean Water for oxygen) on which it is calculated. The ϵ and Δ (see **fractionation**) values are nearly identical when isotopic differences among tissues are approximately 1–2‰, but the difference between the two values increases as the isotopic differences among tissues increases. When tissues are approximately 10‰ different, Δ and ϵ values can differ by as much as 0.5‰ (Cerling and Harris 1999). To calculate ϵ , one first must calculate α , the fractionation factor (see **fractionation factor**): $\alpha_{a-b} = (\delta^H X_a + 1000) / (\delta^H X_b + 1000)$ and $\epsilon_{a-b} = (\alpha_{a-b} - 1) \times 1000$. Note that the sign of enrichment is dependent on which substance is in the numerator and which in the denominator.

ENSO Acronym for the El Niño Southern Oscillation (*which see*).

entoconid (Gk *ento*=within; *konos*=pine cone) One of the terms proposed by Osborn (1888) for the main cups of mammalian molar teeth. It is the more distal (hence the prefix meaning “within”) of the two main lingual cusps of a mandibular (lower) (hence the suffix “-id”) molar tooth crown. It forms part of the **talonid** component of a mandibular postcanine tooth crown. (syn. **endoconid**, **dis-tolingual cusp**, **tuberculum posterium internum**)

entoconulid A term sometimes used for an accessory cusp situated mesial to the **entoconid** on the occlusal surface of a mandibular molar. The term entoconulid is used by Scott and Turner

(1997) as a synonym for **tuberculum sextum**, but the latter is normally distal and not mesial to the entoconid. *See also* **tuberculum sextum**.

entostylid A term sometimes used for an enamel feature on the occlusal surface of a mandibular molar more commonly referred to as a **tuberculum intermedium**. *See* **tuberculum intermedium**.

environment (OFr. *environer*=to encircle and L. *mentum*=verb-to-noun suffix) The sum of the biotic and abiotic conditions with which an organism interacts. The term environment is used to refer to processes at different geographical scales (e.g., local, regional, and global). Biotic and abiotic conditions often interact [e.g., local vegetation (biotic) is affected by the amount of groundwater, precipitation, and soil conditions (abiotic)] so the concept of environment is necessarily a complex one.

enzyme (Gk *en*=in and *zume*=leaven; i.e., the factor that causes bread to rise) A protein whose function is to change the rate (i.e., act as a catalyst for) a biochemical reaction. Enzymes are often named after the substrate they act upon or the chemical reaction that they catalyze with an addition of the ending “-ase”. For example, lactase is the enzyme that breaks down the sugar lactose and it is the enzyme that is lacking in individuals who cannot digest lactose into glucose and galactose as adults. Thus, individuals with lactose intolerance cannot consume most milk products without discomfort.

Eoanthropus dawsoni Dawson and Woodward, 1913 (Gk *eos*=dawn and *anthropos*=human, and *dawsoni*=to acknowledge the role played by Charles Dawson in the recovery of the remains of Piltown I) On December 18, 1912, Charles Dawson and Sir Arthur Smith Woodward read a communication to The Geological Society entitled *On the discovery of a Paleolithic Human Skull and Mandible* and a paper with the same title and with the same authorship appeared in the *Quarterly Journal of the Geological Society* in 1913 (Dawson and Woodward 1913). In that paper the authors proposed “that the Piltown specimen be regarded as the type of a new genus of the family Hominidæ to be named *Eoanthropus* and defined by its ape-like mandibular symphysis, parallel molar-premolar series, and narrow lower molars which do not decrease in size backwards; to which diagnostic characters may probably be added the

steep frontal eminence and slight development of the brow ridges” and they went on to suggest “The species of which the skull and mandible have now been described in detail may be named *Eoanthropus dawsoni*, in honour of its discoverer.” See also **Pitdown**.

Eocene (Gk *eos*=dawn and *kainos*=new) The Eocene epoch is the second epoch of the Paleogene period within the Cenozoic era, spanning the interval of time from 55.8 to 33.9 Ma. Rocks of the Eocene series are the global record of Earth history through that interval of time. The Eocene was a “hothouse world” and saw significant diversification of early mammalian orders.

eocone A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **paracone** (*which see*).

eoconid A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **protoconid** (*which see*).

colith (Gk *eos*=dawn and *lithos*=stone, thus “dawn stone”) A term used in the late 19thC and early 20thC to describe minimally modified stones considered to be evidence for hominin tool use in pre-Quaternary sediments. Although most coliths were subsequently shown to be naturally modified rocks, their study initiated a series of experimental approaches aimed at distinguishing hominin-modified stones from those made by other means (e.g., stream abrasion) that is the basis for contemporary **lithic analysis** (Grayson 1986). See also **Pitdown**.

EP Acronym for Eyasi Plateau Paleontological Project and the prefix for fossil hominins recovered from Laetoli, Tanzania by the **Eyasi Plateau Paleontological Project**. See also **Laetoli**.

epi- (Gk *epi*=upon, around or “outside of,” “close to,” or “at the same time”) Prefix used for structures that lie on top of, or around, other structures, or for events or effects that occur around the same time (e.g., the epidural space is the space immediately outside/around the dura mater and an epidemic refers to an illness that affects many people more or less simultaneously).

epicone A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **protocone** (*which see*).

epiconid A term introduced by Vanderbroek (1961, 1967) for what more commonly used cusp nomenclature schemes refer to as the **metaconid** (*which see*).

epiconule A term introduced by Vanderbroek (1967) for a small enamel feature on the occlusal surface of a maxillary postcanine tooth crown at the lingual end of the **mesial marginal ridge** close to the tip of the **protocone** (syn. **paraconule**, **protoconule**, **protoconulus**, **tuberculum accessorium anteriorium internum**, **mesial accessory tubercle**).

epicrista One of the three enamel crests on the **trigon** of maxillary molar teeth; the other crests are the **distal trigon crest** and the **mesial marginal ridge**. The term was introduced by Vanderbroek (1961) for the crest-like structure that runs between the **paracone** and either the **protocone** or the **epicristid**. It is also a term introduced by Hershkovitz (1971) for an enamel structure that others call the middle trigonid crest. See also **middle trigonid crest**.

epicristid A term introduced by Hershkovitz (1971) for a structure on the crowns of the mandibular postcanine teeth that others call the **middle trigonid crest** (*which see*).

epicristoconule A term introduced by Grine (1984) for a small cuspule on the occlusal surface of maxillary molars that may be on, or take the place of, an **epicrista**. When present it is either between the **paracone** and the **mesial marginal ridge** or between the former and the **protocone**.

epigenesis (Gk *epi*=around and *genesis*=birth or origin; literally the “influences around development”) The generation of form through a series of causal interactions between **genes** and extragenetic epigenetic factors. Epigenetic effects include heritable information (e.g., patterns of gene expression) that is not encoded in the organism’s DNA. See also **epigenetics**.

epigenetic See **epigenetics**.

epigenetic landscape A visual metaphor used by Conrad H. Waddington (1957) to illustrate his concepts of **canalization** and **epigenetics**. In the metaphor, the development of an individual organism is likened to a ball rolling down a grooved landscape. At one level the landscape represents the developmental system, at another it represents the probability of different phenotypic outcomes. Genes are likened to guy-wires that underpin the landscape and shape its valleys and ridges. According to this metaphor mutations can shift both the mean (the locations of valleys) and also the variance (the steepness of the sides of the valleys) of the phenotypic outcomes produced by a particular **genotype** or developmental configuration.

epigenetic traits *See non-metrical traits.*

epigenetics (Gk *epi*=around and *genesis*=birth or origin; literally the "influences around development") This term is used in two quite distinct ways in the literature. The original Conrad H. Waddington definition of epigenetics is that it subsumes all that is involved in the process of converting the **genotype** into the **phenotype**. Thus, it would include *all* of the factors, intrinsic or external/environmental, acting on and influencing the genetic program for the **development** of an organism. Under this definition intrinsic influences include gene–gene interactions and hormones; external influences include diet and temperature. In modern genetics, the term has acquired a different meaning. In this context, it refers to the influence of various forms of chromatin modification on gene expression. This is a growing field that has relevance to both evolution and human disease and for this reason this latter and more specific meaning of the term has become dominant in the literature. Another way of expressing this contemporary and more exclusive definition of epigenetics is that it is the "study of heritable changes in gene function that *cannot* [our italics] be explained by changes in the DNA sequence" (Russo et al. 1996). Thus, under this more exclusive definition epigenetics embraces information (e.g., patterns of gene expression) that is heritable, but which is not encoded in the DNA of the organism. Thus, as Bird (2007) stresses, without epigenetic mechanisms "hard-won changes in genetic programming could be dissipated and lost" (*ibid*, p. 398). Practical examples of epigenesis

include the propensity of offspring to inherit levels of energy extraction from food in the gut. If a previous generation was relatively short of food, their gut is programmed to extract more energy. If this propensity is passed on to a successive generation that has access to potentially excessive amounts of processed, calorie-rich food, and if they continue to extract the maximum amount of energy from the food they ingest, then this can result in high levels of obesity. For a review of this and other similar hypotheses see Gluckman and Hanson (2006). Both meanings of epigenetics are broadly consistent with Waddington's original intent since they both refer to mechanisms that act either directly on genes (or regulatory sequences) or are acting above the level of genes, but the parallel use of the word in these two contexts is a potential source of confusion. *See also epigenetic landscape.*

epimerization (Gk *epi*=upon and *meristos*=divided) Epimerization is when there is a change from one of two possible forms of a complex molecule to the other, usually from the L, left-handed, or levo form to the D, right-handed, or dextra form. For example in **ostrich egg shell dating** the change is from L-isoleucine to D-alloisoleucine. That reaction is temperature-dependent, but if average temperature can be estimated independently of sample age, the method can provide dates for material that is difficult to date using other methods.

epiphyseal plate (Gk *epi*=upon and *physis*=growth) The radiotranslucent cartilaginous plate between the **diaphysis** (formed from a primary ossification center) of a long bone and the epiphyses that are formed from the secondary ossification centers. *See also endochondral ossification; growth plate; ossification.*

epiphysis (Gk *epi*=upon and *physis*=growth) The part of a bone that develops from a secondary ossification center. *See also ossification.*

episodic memory According to the multiple memory systems model (Tulving 1983) episodic memory, also known as auto-noetic or autobiographical memory, is a declarative form of memory that can be explicitly described and articulated. It is also independent of other forms of memory such as the procedural and **semantic memory** systems. Episodic memories encode and structure multiple forms of

semantic knowledge or information for a given event, including: *what* (i.e., categorization), *where* (i.e., location), *who* (i.e., individual/s involved), and *when* (i.e., the time when a given event occurred or duration). This information is bound to a context and charged with emotion. These features of episodic memory are what allow us to re-visit the past as well as re-live past events. Tulving has referred to this feature of episodic memory as mental time travel. But just as one can travel to the past, one can also travel to the future by using past episodic experiences to imagine a possible, future world (Tulving 2002). Tulving has long argued that while procedural and semantic memories are phylogenetically ancient memory systems present in all mammals and birds, episodic memory is unique to modern humans. However, there is evidence that birds and apes encode information in an “episodic-like” fashion (Clayton and Dickinson 1998, Schwartz et al. 2002) and that they are capable of encoding *what*, *where*, *when*, and even *who*. *See also* **memory**.

epistasis (Gk *epistanai*=to place upon, from *epi*=upon and *histanai*=to place) The name given to the interactions among **genes** that influence a **complex trait**. The action of a gene can be affected by one or more modifier genes. For example, the *ABO* locus on chromosome 9 encodes the blood-group antigens that determine blood type. In individuals with the *ABO* secretor allele, these antigens are also expressed in most cells of the body that produce bodily fluids interacting with the environment (e.g., saliva). This allele is encoded by the *FUT2* (fucosyltransferase 2) locus on chromosome 19. However, the antigens are not expressed in individuals called nonsecretors who are homozygous for the nonsecretor *FUT2* allele. Epistasis is also applied to the phenomenon whereby the effect of a **mutation** on the **phenotype** depends on its context (i.e., where in the **genome** it occurs). In classical Mendelian genetics, epistasis referred to non-allelic dominance relationships. Epistasis increases the complexity of adaptive, or fitness, landscapes and thus may have been involved in the evolution of complex morphological and behavioral traits during the course of human evolution.

epistemology (Gk *episte*=to understand and *logos*=to learn) The study of the nature, validity, and scope of knowledge. Discussions of what types of knowledge can, and cannot, be deduced from

the hominin fossil record are epistemological discussions. Colloquially, how we know what we know or what we think we know.

epoch (Gk *epokhe*=a point in time) Epoch is used in at least two senses that are relevant to paleoanthropology; both are units of time. As a geochronologic unit an epoch is a subdivision of a **period**, and it is itself subdivided into ages. For example, the **Pliocene**, **Pleistocene**, and **Holocene** are all epochs within the **Tertiary** period. The corresponding **chronostratigraphic unit** equivalent of an epoch is a **series**. In the second sense it is a prolonged period in the past when either a normal or a reversed magnetic field predominated. Superseded by the term “polarity chronozone” which is usually shortened to the word **chron**. *See also* **magnetostratigraphy**.

equid The informal name for the perissodactyl family comprising the horses and their allies. *See* **Perissodactyla**.

Equidae One of the perissodactyl families comprising the horses and their allies, whose members are found at some hominin sites. *See* **Perissodactyla**.

equifinality (L. *aequi*=equal and *finis*=end) The principle that different processes can produce similar, if not identical, patterns or results. The term was coined in 1949 by Ludwig von Bertalanffy in the context of general systems theory. The concept became widely applied in the zooarcheological and taphonomic literature in the 1980s, often in reference to cases where it is unclear which taphonomic process created the patterns observed in a fossil assemblage. A classic case of equifinality is observed in the archeological bone assemblages from **Olduvai Gorge**. The bone assemblages from **FLK-Zinjanthropus** and **FLKN** levels 1–2 are characterized by an abundance of limb elements and relatively low frequencies of pelvis, vertebrae, and ribs. This pattern was originally interpreted as evidence that hominins preferentially transported limbs to the site, while discarding the axial elements at the point of carcass acquisition (*see* **schlepp effect**). This was consistent with the view that early archeological sites were “home bases” or “central-place foraging sites” to which hominins supposedly transported and shared a variety of foods, including meat hunted from large game. Subsequent tapho-

nomics research, however, demonstrated that carnivores preferentially consume and destroy vertebrae, ribs, and pelvis (*see* **low-survival elements**; **carnivore ravaging**), calling into question the argument that hominins preferentially transported appendicular elements to these sites. Thus, the dominance of limb elements at FLK-*Zinjanthropus* and FLKN levels 1–2, which could be the result of hominin activities or carnivore ravaging, represents a case of equifinality.

Equus Cave (Location approximately 27°37'S, 24°38'E, northern Cape Province, South Africa; etym. after Latin for horse, named after the abundant equid fossils recovered) History and general description A cave in the western face of the Oxland tufa fan on the Gaap escarpment at Bruxton, northern Cape Province. It was initially located as part of a geological study of the long series of tufa deposits, but Peter Beaumont and Myra Shackley were the first to excavate the site in 1978 and Beaumont returned in 1982. The site contains abundant vertebrate fossils in four stratigraphic units designated 1A, 1B, 2A, and 2B. 1A contains **Later Stone Age** artifacts; the others contain **Middle Stone Age** (or MSA) tools. Eight isolated teeth were recovered from units 1B–2B and C.K. **Brain** found a mandibular fragment in 1971 in a scree slope that was the result of a road cutting. Temporal span and how dated? **Late Pleistocene** to **Holocene**. Unit 1A dates to 2.39–7.48 ka by radiocarbon and correlations with nearby tufa deposits suggest that the MSA-containing units 1B–2B likely date to between *c.*33 and 94 ka. Hominins found at site Eight isolated teeth from the MSA levels and a left mandibular corpus with M₂–M₃ that may derive from the same MSA levels. Archeological evidence found at site *See above*. Key references: Geology, dating, and paleoenvironment Butzer et al. 1978, Grine and Klein 1985; Hominins Grine and Klein 1985; Archeology: Beaumont et al. 1984, Grine and Klein 1985.

ER Acronym for East Rudolf and the prefix for fossils recovered from East Rudolf (now called **Koobi Fora** or East Turkana), Kenya.

era (L. *æra*=counters used for calculations) A unit of geological time (i.e., a **geochronologic unit**). It is next in order of magnitude below an eon (e.g., the Phanerozoic eon is divided into three eras, the Paleozoic, Mesozoic, and **Cenozoic**, each

marked by major faunal turnovers). Eras, which usually span hundreds of millions of years, are subdivided into **periods**. The **chronostratigraphic unit** equivalent of an era is an **erathem**.

erathem The **chronostratigraphic unit** equivalent of an era; erathems are subdivided into **systems**.

error *See* **Type I error**; **Type II error**.

eruption (L. *erumpere*=to break up) The process of tooth movement through the alveolar bone, past the gumline (gingival emergence) and into functional position. The assessment of the stage of eruption is typically based on either hard or soft tissue evidence. The hard tissue evidence measures the position of a tooth from a relatively stable landmark (e.g., the bony alveolar margin) usually from radiographs. One key stage in this process is alveolar emergence, when the tip of the tooth passes the level of the margin of the tooth crypt opening in the bony alveolus. Gingival emergence, when the tip of the tooth first pierces the gingival soft-tissues, can only be observed in living subjects. The extrinsic stain on the teeth of many wild collected primates that forms when they erupt into the oral cavity is a way to judge how much of a tooth was subgingival and how much was beyond gingival emergence. Eventually, the tooth reaches the occlusal plane, where it comes into functional occlusion with the teeth in the other jaw and thus begins to play a functional role in **mastication**. Studies of modern humans show there is only *c.*10–12 months between alveolar and gingival eruption of a lower first molar and that the gingival eruption of molar teeth is very close in time to their coming into functional occlusion. It is self-evident that the progress of tooth eruption in the hominin fossil record has to be based on evidence from the hard tissues. Evidence for the age of gingival eruption (notably the first permanent **molar**) has been used to compare the age at death in developing hominin dentitions with those in modern humans and great apes at the same developmental stage and so to predict **life history** schedules in fossil great apes and hominins (e.g., Smith 1986, 1991a, Kelley and Smith 2003). The sequence of tooth eruption has also been reported to distinguish **hominin** taxa from each other and among fossil hominins, great apes, and modern humans (e.g., Dean 1985). Data on tooth eruption ages and sequences in modern humans (and other primates)

are given in Smith (1991b), Smith et al. (1994), Godfrey et al. (2001), and Swindler (2002).

ESA Acronym for the **Early Stone Age** (*which see*).

ESC Acronym for the **evolutionary species concept** (*which see*).

Esna Site Deir El-Fakhuri E71K1 (Location 25°22'30"N, 32°28'50"E, Egypt). Locality Site 5 Locality A. Surface/in situ Subsurface. Date of discovery 1964–5. History and general description The Late Paleolithic occupation at Deir El-Fakhuri is represented by six sites spread in a rough semicircle slightly to the south of an abandoned Coptic monastery after which the site is named. The monastery is located 11 km/6.8 miles northwest of Esna. On the western slope of the E71K1 site, heavily weathered and partially disarticulated modern human remains were found eroding out on the surface. Finder Martin A. Baumhoff. Unit N/A. Horizon N/A. Bed/member N/A. Formation Dibeira-Jer silts. Group N/A. Nearest dated horizon Samples of *Unio* shell collected from the artifact-bearing levels at E71K1 gave a date of 16,070 ± 330 years. Archeological evidence found at site The assemblage has many microliths as well as denticulates, retouched pieces, end scrapers, double-backed perforators, and bladelets with Ouchtata retouch. The presence of both chipping debris and faunal remains indicates that the site was used both as a workshop and a living site. The assemblage is considered to be part of the Fakhurian industry. Temporal span and how dated? Radiocarbon dating of the related artifact-bearing level suggests that the site is between *c.*24 ka and *c.*12 ka but the deposition of the Dibeira-Jer silts began before *c.*24 ka and ended shortly after *c.*18 ka. Developmental age The cranial and upper limb material belong to a young adult (about 18 years old) and the pelvis and lower limb bones belong to a more mature individual. Presumed sex The more mature individual is probably male. Brief anatomical description The skeletal material from site E71K1 represents the remains of a minimum of two individuals. The skeletal material recovered is quite fragmentary. The cranial fragments appear to be morphologically similar to the juveniles of a similar age from the Sahaba series. Initial taxonomic allocation *Homo sapiens*. Announcement Butler 1974. Initial description Butler 1974. Photographs/line drawings and metrical data Butler 1974. Geology, archeology, and dating

Buckley and Willis 1969 (I-3416), Lubel 1974. Detailed anatomical description Butler 1974. Location of original Department of Ancient Egypt and Sudan, British Museum, London, England.

ESR Abbreviation for **electron spin resonance spectroscopy dating** (*which see*).

essential crest A term employed to indicate the most prominent enamel ridge running down from the incisal edge of the incisors or from the cusp tip of a canine or from a cusp on a post-canine tooth crown. (syn. essential ridge).

essential ridge *See* essential crest.

estrogens (New L. *estrus*=period of fertility plus *gen*=to generate) A class of steroids with 18 carbon atoms ("C18 steroids") that includes estrone, estriol, and estradiol. Estrogens are all produced from androgen precursors through enzymic action and this conversion primarily takes place in the ovaries and peripheral tissues. Estradiol is the main estrogen during premenopausal life in women and estrone, a weaker estrogen, is more plentiful in postmenopausal women. Critical for female reproductive function and key in the development of female secondary sexual characteristics, estrogens are also believed to exert a protective effect on neural and other tissues. However, excessively high levels of estrogens and so-called "environmental estrogens" have been linked to unusually high incidences of cancer.

Ethiopian rift system The Ethiopian section of the East African Rift valley comprises three main components, the **Afar Rift System** (also known as the Afar Depression) in the northeast, the **Main Ethiopian Rift System** in the middle, and what some call the **Omo rift zone** and others refer to a "300-km-wide rifted zone" (Renne et al. 1999, p. 869) in the southwest of the country. The Ethiopian rift system contains many productive hominin sites, including those in the **Dikika**, **Gona**, **Hadar**, and **Middle Awash study areas** in the Afar Rift, **Chorora**, **Gadeb**, **Gademotta**, **Kesem-Kebena**, **Konso-Gardula**, and **Melka Kunturé** in the Main Ethiopian rift, and **Fejej**, **Omo-Shungura**, and **Usno Formation** in the Omo Rift Zone.

ethology (Gk *ethos*=character and *logia*=study) The scientific study of animal behavior. This discipline is important to paleoanthropology.

gists because primate ethology generates information about the behavior of living primates (and sometimes other mammals) and thus provides the context for developing hypotheses about the behavior of early hominins and the evolution of modern human behavior.

euchromatin *See* chromosome.

Euclidean distance A multivariate measure of distance that can be applied to the distance between objects in space or the morphological distance between objects or groups. Euclidean distance is equal to the square root of the sum of squared differences in all variables. For example, the spatial distance between two specimens is equal to the square root of $(X_1 - X_2)^2 + (Y_1 - Y_2)^2 + (Z_1 - Z_2)^2$. The morphological distance between two specimens with measurements in four variables A , B , C , and D is equal to the square root of $(A_1 - A_2)^2 + (B_1 - B_2)^2 + (C_1 - C_2)^2 + (D_1 - D_2)^2$. However, morphological distance is more typically measured using distances that take into account the standard deviation of variables and their correlation with each other (e.g., **Mahalanobis distance**). *See also* **Mahalanobis distance**.

Euclidean distance matrix analysis (or EDMA) A technique for comparing the two- or three-dimensional **shape** and **form** of objects such as crania, mandibles, and postcranial elements (Lele and Richtsmeier 1991). In EDMA a series of **landmarks** is identified for an object and the form of that object is represented by a square **matrix** of pairwise Euclidean distances between landmarks. The rows and columns of the matrix are the landmarks and the value for each cell in the matrix corresponds to the physical distance in two- or three-dimensional space between that pair of landmarks. For example, consider an analysis consisting solely of two landmarks: **prosthion** and **inion**. The upper-left-most cell (row 1, column 1) will contain the Euclidean distance between prosthion and itself (i.e., zero). Both the next cell to the right (row 1, column 2) and the cell directly below (row 2, column 1) will contain the distance between prosthion and inion. The final cell (row 2, column 2) will contain the distance between inion and itself (again, zero). Thus the matrix for any object will contain only zeros along its diagonal, and all of the values below the diagonal will be duplicated above the diagonal. As a consequence, EDMA typically

only considers those cells either below or above the diagonal (i.e., a triangular matrix). The resulting matrix is typically referred to as a **form matrix**. Form matrices for multiple objects can be analyzed in a variety of ways. Often, the form or shape is compared between two groups of objects [e.g., between male and female articular surfaces (Lague and Jungers 1999) or between crania of two taxa (Krovitz 2003)]. An estimated form matrix is calculated for each group, which can be thought of as an average of the form matrices for each individual object within a group. Form difference matrices are calculated as the ratio of the value in each cell for the estimated form matrices in each group (e.g., in the cell corresponding to prosthion–inion distance, the form difference matrix will contain the ratio of the average prosthion–inion distance from the first group to the average prosthion–inion distance from the second group). Shape matrices can also be calculated by dividing a form matrix by a scaling factor [i.e., a measure of overall size of the object(s) represented in the matrix]. This scaling factor is typically the **geometric mean** of all pairwise distances in the matrix. Shape difference matrices are calculated as the difference between two shape matrices. Continuing the example above in the cell corresponding to prosthion–inion distance the shape difference matrix will contain the scaled average prosthion–inion distance from the first group minus the scaled average distance from the second group. A variety of statistical comparisons of shape and form (e.g., testing whether the form of one group is a scaled-up version of the form of another group, identifying influential landmarks that distinguish two shapes, etc.) are available using these matrices. Hypothesis tests in EDMA typically rely on **bootstrap** procedures to generate confidence intervals for scaling ratios, difference values, etc. It should be noted that there is a debate in the literature between proponents of EDMA and **Procrustes analysis** regarding the validity and/or appropriateness of these various procedures, focusing in particular on (a) the power and Type I error rates of the methods, (b) the consistency within a method for estimating mean form and/or shape, and (c) any bias in shape estimation (e.g., Rohlf 2000, 2003, Lele and Richtsmeier 2001).

eukaryote (Gk *eu*=good or true, *karyote*=the inside, or kernel, of a nut) A single-cell or multi-

cellular organism where each cell contains at least one membrane-bound nucleus usually containing multiple different chromosomes and other membrane-bound organelles such as **mitochondria** and Golgi bodies. Eukaryotic organisms include animals, plants, fungi, and protists.

Euler–Lotka equation The problem of how to relate the proportional growth rate of a population to the characteristic functions that define life history was originally solved by Euler (1760) and rediscovered in the context of modern population genetics by Lotka (1907). This equation, considered to be the central equation relating to life history evolution and demography, specifies the relationships of age at maturity (α), age at last reproduction (ω), probability of survival to a given age class (l_x), and number of offspring expected in a given age class (m_x), to the intrinsic rate of increase (r), which measures the potential for growth rate in a population. The Euler–Lotka equation is one way to estimate r ; using life tables based on the Euler–Lotka equation is another. The Euler–Lotka equation is especially useful because it provides a way to weight contributions of different age classes to overall fitness, although one of the assumptions for solving the equation is that there is a stable age distribution within a population.

European hypothesis See *Homo heidelbergensis* Schoetensack, 1908.

European mammal neogene A system that uses **biozones** for dating **Miocene** and **Pliocene** sites within the age range of 24 to more than 2 Ma. The original system focused on sites in the **Neogene** (Mein 1975), but it has since been updated (Mein 1990) and is constantly being refined (e.g., Agusti 1999). The zones of the European mammal neogene (or MN) system run from MN1, the oldest, at the beginning of the Miocene, to MN17 in the **Plio-Pleistocene**. Some of the MN zones span several millions of years (e.g., MN5 between *c.*17 and *c.*14 Ma), whereas others span less than a million years (e.g., MN15 between 4 and 3.5 Ma). Each zone has one or more sample localities containing the taxa characteristic for that zone (see Steininger et al. 1989, 1996). The MN system is replacing the classical system of European mammalian biozonations (e.g., **Vallesian**, **Turolian**, **Ruscinian**, **Villafranchian**, **Cromerian**, etc.). See also **biostratigraphy**.

eurytope (Gk *eurus*=broad or wide and *typos* = place) A **species** adapted to a broad range of environmental conditions or to a broad ecological **niche** (e.g., bush pig), or having **morphology** that is interpreted as being part of a eurytopic adaptation (e.g., the molars of a bush pig). The term was introduced to paleoanthropology by Elisabeth Vrba (e.g., Vrba 1980, 1985a, 1985b, 1988, 1992) in a series of hypotheses that sought to explain how environmental change influences **macroevolutionary** patterns in the fossil record. Several recent studies (Teaford and Ungar 2000, Wood and Strait 2004, Scott et al. 2005, Sponheimer et al. 2005) have concluded that most early hominin species were ecological generalists rather than specialists, particularly with respect to diet. See also **effect hypothesis**; **turnover-pulse hypothesis**; **habitat theory hypothesis** (syn. **generalist**).

eurytopic See eurytope.

eurytopy See eurytope.

Eustachian tube The endodermally derived first pharyngeal pouch that connects the middle ear to the nasopharynx. See also **auditory tube**.

event (L. *evenire*=to happen) A short period of the opposite field direction during a prolonged period when either a normal or a reversed magnetic field predominated (e.g., the **Olduvai event** is a normal event within the Matuyama reversed chron, previously referred to as an **epoch**). Superseded by the term **subchron**.

eversion Foot movement around an anteroposterior axis in which the sole of the foot turns outward away from the midline of the body. Often incorrectly used interchangeably with pronation (see **foot movements**), eversion refers only to rotation about the long (anteroposterior) axis of the foot. Eversion occurs primarily at the subtalar joint but movement at the talocrural (ankle) joint can be incorporated in extreme eversion. Eversion is limited by the deltoid ligament, which is robust in modern humans. See also **foot movements**.

Evidence as to Man's Place in Nature This book by Thomas Henry Huxley, first published in London in 1863, is arguably the first scientific

book about human origins. It consists of three essays: *On the Natural History of the Man-like Apes*, *On the Relations of Man to the Lower Animals*, and *On Some Fossil Remains of Man*. The first essay considers and evaluates reports of sightings of what we now refer to as chimpanzees and bonobos, gorillas, orangutans, and gibbons, and in that section Huxley pays a fulsome tribute to Richard Owen's 1835 memoir *On the Osteology of the Chimpanzee and Orang*. The second essay addresses what Huxley refers to as "The question of questions for mankind—the problem which underlies all others, and is more deeply interesting than any other—is the ascertainment of the place which Man occupies in nature and of his relations to the universe of things" (p. 57) and in this essay Huxley writes that he "set(s) forth... the chief facts upon which all conclusions respecting the nature and the extent of the bonds which connect man with the brute world must be based" (p. 59). He reviews the evidence that existed at the time, including observations about limb proportions and the teeth which he describes as "organs which have a peculiar classificatory value, and whose resemblances and differences of number form and succession, taken as a whole, are usually regarded as more trustworthy indicators of affinity than any others" (p. 81). As for the brain, he writes of "the impossibility of erecting any cerebral barrier between man and the apes" (p. 96). The best-known quotations that reflect Huxley's assessment of the morphological evidence are "Whatever part of the animal fabric—whatever series of muscles, whatever viscera might be selected for comparison—the result would be the same—the lower apes and the Gorilla would differ more than the Gorilla and Man" (p. 84), and "Thus, whatever system of organs be studied, the comparison of their modifications in the ape series leads to one and the same result—that the structural differences which separate Man from the Gorilla and the Chimpanzee are not so great as those which separate the Gorilla from the lower apes" (p. 103). It is as a postlude to this second essay that Huxley rounds on Richard Owen for claiming that the "posterior horn of the lateral ventricle" and the "hippocampus minor" are peculiar to the genus *Homo*. The third essay discusses the child's cranium from **Engis** and the adult cranium from the **Kleine Feldhofer Grotte**, which Huxley refers to as "the Neanderthal cavern." Huxley's analysis of the two fossil crania is perceptive and prescient. He suggests that even though the Neanderthal remains are "the most pithecoïd of known human

skulls" he goes on to write that "in no sense... can the Neanderthal bones be regarded as the remains of a human being intermediate between Man and Apes" and he notes that if we want to seek "the fossilized bones of an Ape more anthropoid, or a Man more pithecoïd" than the Neanderthal cranium, then researchers need to look "in still older strata" (Huxley, 1863, p. 159). Huxley is also the first writer to propose objective criteria for comparing crania, and he writes that "I have arrived at the conviction that no comparison of crania is worth very much, that is not founded upon the establishment of a relatively fixed base line, to which measurements, in all cases, must be referred. Nor do I think it is a very difficult matter to decide what that base line should be. The parts of the skull, like those of the rest of the animal framework, are developed in succession: the base of the skull is formed before its sides and roof; it is converted into cartilage earlier and more completely than the sides and roof: and the cartilaginous base ossifies, and becomes soldered into one piece long before the roof. I conceive then that the base of the skull may be demonstrated developmentally to be its relatively fixed part, the roof and sides being relatively moveable" (*ibid*, p. 148). Moreover, the "cranio-facial" angle he refers to (*ibid*, p. 150) and illustrates (*ibid*, p. 151) is effectively the same as the **cranial base angle** that is still in use today. *See also basi-cranium*.

evo-devo Abbreviation of **evolutionary developmental biology** (*which see*).

evolutionary developmental biology

Often abbreviated to "evo-devo," this term was first used by Brian Hall (1992), but interest in the relationship between development and evolution has a long history. Within evolutionary biology, interest in development as the missing element of the modern synthesis reached a turning point in the 1970s and 1980s with works by Gould, Raff and Kaufman, Hall, and others (e.g., Hall 1975, Gould 1977, Raff and Kaufman 1983). To some, the modern discipline of evolutionary developmental biology is mainly concerned with the ways in which development relates to evolutionary explanation (Hendrikse et al. 2007), while others regard it more inclusively as being about the evolution of developmental mechanisms. Either way, the field of evo-devo represents a novel synthesis of evolutionary and developmental

biology that has had tremendous influence on both fields and it has the potential to illuminate the molecular basis of the important morphological changes that have made the hominin clade distinctive.

evolutionary scenario (L. *scaena*=scene) A complex hypothesis that attempts to explain why a phylogeny looks the way it does. It provides explanations for speciation and extinction events and for patterns of morphological evolution (e.g., the **endurance running hypothesis**).

evolutionary species concept (or ESC) An attempt by Simpson (1961) to add a temporal dimension to the **biological species concept**. Simpson suggested that under the evolutionary species concept a species is “an ancestral-descendant sequence of populations evolving separately from others and with its own evolutionary role and tendencies”. *See also* **species**.

evolutionary taxonomy A major approach to **classification**. Like the rest of biology, the discipline of **taxonomy** was transformed by the work of Charles Darwin. During the first half of the 19thC, most naturalists held that the evidently hierarchical organization of **taxa** revealed the plan of a divine creator. In *On the Origin of Species* Darwin argued that this view was unsatisfactory because it added nothing to knowledge and he offered an alternative interpretation of the fact that **species** could be grouped into **genera** and genera into higher-level taxa on the basis of phenotypic similarities and differences. He suggested that the so-called “natural order” that previous generations of naturalists had uncovered was exactly what would be expected if species had evolved by descent with modification. Evolutionary taxonomy is one of the approaches that taxonomists have developed in response to Darwin’s insight. The other is **phylogenetic systematics**. Both approaches hold that classifications should reflect descent. However, they differ over the validity of **paraphyletic** taxa and the importance of incorporating information about adaptation into classifications. Phylogenetic systematics insists that taxonomic groups include all the descendants of the most recent common ancestor of that group and therefore rejects paraphyletic taxa. In addition, information about **adaptation** plays no part in the creation of taxa in phylogenetic systematics. In contrast, evolu-

tionary taxonomy recognizes that one or more of the descendants of a given ancestor may be so adaptively different (i.e., they are in a different **grade**) from the ancestor or the other descendants that they warrant allocation to a distinct group. Thus, unlike phylogenetic systematics, evolutionary taxonomy accepts both **monophyletic** and paraphyletic taxa.

evolvability (Ge. *Evolutionsfähigkeit*=the “ability to evolve”) This term, coined by Wagner (1986), refers to the degree to which a species or structure responds to natural selection with evolutionary change. Key determinants of evolvability are the extent to which genetic variation is expressed at the phenotypic level, the rate of **mutation**, and the extent to which variation in the trait under selection is correlated with variation in other traits. Evolvability is a key concept in quantitative genetic theory. It is also key to **evolutionary developmental biology** because the determinants of evolvability themselves have a basis in development. *See also* **canalization**; **integration**; **modularity**.

exact randomization A form of **randomization** that computes exactly the right number of data combinations to test a hypothesis. *See* **randomization**; **resampling**.

exact test *See* **exact randomization**.

exaptation A useful feature or **trait** that did not originate as a direct consequence of **natural selection** acting on its current function. Rather, the trait may have been co-opted to perform its current functional role *after* having been initially nonfunctional or adapted (through natural selection) to perform a different role (e.g., feathers most likely evolved in the ancestors of birds as an **adaptation** related to thermoregulation, but, once present, feathers were co-opted for flight and display and thus can be thought of as exaptations for those two functions). A complication, of course, is that once the exaptation has been co-opted, natural selection may act upon it to modify its form and function. Thus, modern birds have experienced considerable evolution in feather and, more broadly, wing form related to locomotion, and these changes can legitimately be thought of as adaptations. Thus, the presence of feathers is an exaptation to flight, but the modifications to feathers associated with different types of flight (e.g.,

long distance “cruising” and agile maneuvering through a dense forest canopy) are adaptations. In some cases, therefore, adaptation and exaptation can be hierarchically nested concepts. An example of an exaptation in modern humans and later hominins is the opposable thumb. A mobile, grasping thumb evolved in our earliest primate ancestors as an adaptation for grasping branches, and that basic design, plus subtle but important modifications, was co-opted for tool use by later members of the hominin clade. Exaptation explains the related term **preadaptation**, which describes the phenomenon in which a trait appears to be well designed for a functional role it does not currently perform. The term exaptation was introduced to the lexicon of evolutionary biology by Stephen J. Gould and Elisabeth Vrba (Gould and Vrba 1982). In historical context, this contribution can be seen as part of a broader critique of what Gould and Lewontin (1979) called the “adaptationist programme,” namely the tendency for evolutionary biologists to ascribe to natural selection a nearly limitless ability to explain the evolution of form.

exon (L. *ex*=to move out) The portion of a **gene** that undergoes **transcription** and eventually forms part of a functional messenger **RNA** molecule (as opposed to the **intron** part of a gene, which is excised from the RNA). The mature RNA may then move into the cytoplasm and be translated into a **protein**. Portions of this mature RNA include the 5' and 3' untranslated regions, which help guide and/or regulate the process of **translation**. Other exonic sequences may be directly transcribed into one of the many different varieties of structural and/or functional RNAs (e.g., tRNA, rRNA, siRNA, miRNA, and snRNA).

expensive tissue hypothesis (or **ETH**) Proposed by Leslie Aiello and Peter Wheeler in 1995 to suggest that the metabolic requirements of relatively large brains are offset by a corresponding reduction of the gut. Because gut size is highly correlated with diet, relatively small guts imply high-quality, easy-to-digest food. This led to the conclusion that brain-size increase in hominin evolution could not have been achieved without incorporating increasing amounts of high-quality animal-based foods in the diet, irrespective of the selective factors resulting in large hominin brains.

Dietary change was proposed to have occurred with the appearance of *Homo ergaster* approximately 1.7 Ma. This is based on the claimed increase in brain size, the smaller teeth and jaws, and the emergence of more modern human-like body proportions implying a smaller gut and the increased evidence for scavenging and/or hunting in the archeological record. The basic premise of an energetic trade-off with brain size has stood the test of time. However, new research suggests that it might involve features other than, or in addition to, diet and gut size, such as muscle mass or locomotor efficiency. The expensive brain hypothesis allowed Isler and van Schaik (2009) to provide a unifying explanatory framework, arguing that the costs of a relatively large brain in mammals in general must be met by any combination of increased total energy turnover or reduced energy allocation to another expensive function such as digestion, locomotion, or production (growth and reproduction). Application to the fossil record has also been complicated by evidence for animal-based foods in the diet predating significant brain expansion, the suggestion that cooked food played an important role in hominin brain evolution, and new interpretations of the body proportions of early *Homo*. However, these factors do not diminish the importance of the ETH in focusing research on energetic trade-offs in hominin evolution.

exploratory analysis The process of using multiple statistical techniques to identify patterns in a data set, as distinct from **hypothesis testing** in which a specific relationship which has been identified *a priori* is tested.

exponential population growth A model of population growth in which a population increases (or decreases) in size by a constant factor per unit time. The simplest equation for this model is $N_{t+1} = N_t \exp(r)$. If $r=0$, then it is a **stationary population** (i.e., neither increasing nor decreasing in size) because $\exp(0)=1.0$. If $r>0$, then the population is increasing in size whereas if $r<0$ then the population is decreasing in size.

exposure (L. *exponere*=to set forth) A place where cross-sections of **strata** have been exposed by erosion or by faulting and thus these are places where the fossils contained in those strata are also partly or fully exposed to view (syn. **outcrop**).

expressivity When different levels of expression of a **gene** are reflected in differences in the **phenotype** and specifically when individuals with the same **genotype** vary in their phenotype. For example, two individuals who have the same genotype for a gene influencing weight may differ in their weight (i.e., their phenotypes differ) because the expression of the gene could be affected by factors such as age, diet, illness (i.e., epigenetic factors), sex, or other genes.

extant (L. *ex*=out and *stare*=stand) Means literally “still standing” and refers to taxa that are alive today (syn. living, surviving).

extant species One of the many terms used to describe a contemporary **species** that is defined on the basis of criteria that can be observed, such as evidence of interbreeding, or the lack of any evidence of interbreeding between individuals belonging to that species and individuals belonging to any other species. *See also* **species** (syn. **neontological species**, **biological species**).

extension *See* polymerase chain reaction.

extension rate The rate at which fully differentiated **ameloblasts** or **odontoblasts** become active secretory cells (Shellis 1984). Extension rates are usually measured along the **enamel-dentine junction** (or EDJ) in longitudinal sections of teeth. Initial extension rates close to the cusp tip are fast (approximately 20–30 $\mu\text{m}/\text{day}$) in all tooth types, but the rate falls to approximately 3–6 $\mu\text{m}/\text{day}$ in the cervical two-thirds of the crown. Extension rates in the longitudinal plane of section of a tooth relate directly to the time taken to form a tooth from dentine horn to enamel cervix or onwards through root extension rates to apex completion of the root tip. However, circumferential expansion (or reduction) in tooth crown or root diameter also occurs. The initial spread or extension of ameloblasts over the occlusal surface of a tooth as cusps form and coalesce is very fast. Newly differentiated ameloblasts in the crown must, therefore, also feed into circumferential extension (or out of it and into tooth length extension). The rate of extension is inferred from the angle between the **long-period incremental lines** or **accentuated lines** in the enamel and the dentine and the enamel-dentine junction; low angles are taken to infer a rapid extension rate

and high angles a relatively slow extension rate (Boyde 1964, Shellis 1984, Beynon and Wood 1986) or it may be calculated directly by inspection. *See also* **dentine development**; **enamel development**.

external auditory canal *See* external ear.

external auditory meatus (L. *ex*=outer, *audire*=to hear, and *meatus*=passage) The passage between the ear lobe (auricle or pinna) laterally and the tympanic membrane medially. The lateral one-third is made of a U-shaped fibrocartilaginous tube that is continuous laterally with the elastic cartilage of the pinna. The medial two-thirds is the bony part of the external auditory meatus. Two components of the temporal bone contribute to the margin of the lateral end of the bony external auditory meatus. The superior part of the meatal margin is formed from the squamous part of the temporal bone and the inferior part from the tympanic plate of the temporal bone. Some researchers have suggested that the size and shape of lateral end of the osseous part of the external auditory meatus are useful for discriminating among early hominin taxa (e.g., *Australopithecus anamensis* or *Kenyanthropus platyops*, Leakey *et. al.* 1998).

external ear (L. *ex*=outer) The external ear is made up of the earlobe (auricle or pinna) and the **external auditory meatus**. The skeleton of the lateral one-third of the external auditory meatus is fibrocartilage and the pinna is made up of elastic cartilage; neither of these structures fossilizes. The medial two-thirds of the external auditory canal is bony and is made up of contributions from the squamous and tympanic plate components of the temporal bone. The lateral end of the bony part of the external auditory meatus is called the osseous auditory meatus.

extinct (L. *ex*=out and *stinguere*=to put out, or quench) The term means literally “to extinguish” and it refers to all taxa (e.g., *Australopithecus afarensis*) that are no longer alive.

extractive foraging The name for the sequence of behaviors that enables organisms to extract embedded foodstuffs (e.g., fruits enclosed in hard shells, underground storage organs buried in the soil, marrow within the trabecular cavities of

bones, or the soft tissues within the exoskeleton of insects) to remove the edible or palatable parts (King 1986). In **hominin** evolution tool use is seen as being key to this behavior (Gibson 1986) although extractive foraging can take place in nonhominins without using **tools** (e.g., the aye-aye). The importance of extractive foraging has been discussed widely in the primate **cognition** literature (e.g., Gibson 1986, King 1986) as it has been argued that it takes greater mental ability to remove or process embedded foods than foods that are not embedded. Thus, extractive foraging might act as a selective pressure for the evolution of the brain and cognition in primates and hominins (see references in Elton et al. 2001). Of the nonhuman primates, **chimpanzees**, capuchins, and the aye-aye all use extractive foraging and they are also relatively highly encephalized (Sterling and Povinelli 1999). However, there are a number of limitations to the extractive foraging model of primate, and perhaps hominin, intelligence. One of the most important of these is the disjunction between observations of extractive foraging and measured intelligence in a range of animals and birds (King 1986, Russon, 2004). Nonetheless, the hypothesis that extractive foraging was central to hominin food procurement and allowed hominins access to a wider range of foods, enabling competition with other members of their ecological communities, is an attractive one.

extrastriate cortex (L. *striatus*=furrowed, striped, ridged and *cortex*=husk, shell) Refers to parts of the cortex of the occipital and parietal lobes of the cerebral hemispheres other than the primary visual cortex (also known as the **striate cortex** in primates). These regions correspond to areas 18 and 19 in the nomenclature of **Brodmann's areas**. In modern parcellation schemes based on **cytoarchitecture** and physiology, the extrastriate cortex of primates includes a large number of distinct areas that contain both complete and partial representations of the retina, which each process different features of visual stimuli (e.g., movement, color, contour). One of the main signs of brain reorganization in hominin evolution involves the relative size of the striate and extrastriate cortex. The **lunate sulcus** forms the anterior boundary of the striate cortex (or primary visual cortex) and it has been proposed that the more posterior displacement of the lunate sulcus in some hominins compared to its location

in chimpanzees and other great apes indicates a reduction in the proportion of striate cortex (or primary visual cortex) relative to the extrastriate cortex and the **posterior parietal cortex**.

Eyasi (Location 3°32'26"S, 35°16'05"E, Tanzania; etym. after Lake Eyasi, which borders the site) History and general description Eyasi comprises at least two fossiliferous localities on the shore of Lake Eyasi. **Kohl-Larsen** collected at the locality in the 1930s, recovering fossil evidence of three partial hominin crania. Subsequently, it has been revisited several times by researchers trying to clarify the stratigraphy. Some of these studies have uncovered additional fragmentary hominin cranial fragments to make a total of seven hominins. **Eyasi 1** to **Eyasi 3** were recovered by Kohl-Larsen, **Eyasi 4–5** (two undescribed mandibles) by C.A. Keilland and J. Ikeda, **Eyasi 6** by A. Mabulla, and **Eyasi 7** by Domínguez-Rodrigo and colleagues. Temporal span and how dated? Late **Middle** or early **Upper Pleistocene**. Domínguez-Rodrigo et al. (2008) obtained **electron spin resonance spectroscopy** (104 ± 13 – 207 ± 26 ka) and **uranium-series** ($^{230}\text{Th}/^{234}\text{U}$) (92.4 ± 4.1 – 138.3 ± 0.7 ka) ages for a wildebeest tooth found 5 m from the hominin frontal. Hominins found at site **Eyasi 1**, a fragmentary cranium, **Eyasi 2**, a fragmentary occipital, **Eyasi 3**, cranial fragments and teeth, **Eyasi 4** and **5**, two mandibles, **Eyasi 6** (NB: **Eyasi IV** of Bräuer and Mabulla 1996), an occipital fragment, and **Eyasi 7**, a frontal. All of the hominins have been assigned to archaic *Homo sapiens*. Archeological evidence found at site An early **Sangoan** or **Njarasan** late **Acheulean** industry as well as an overlying **Middle Stone Age** industry. Key references: Geology, dating, and paleoenvironment Kohl-Larsen and Reck 1936, Mehlman 1987, Manega 1993, Domínguez-Rodrigo et al. 2007b, 2008; Hominins Leakey 1936a, Weinert 1939, Kohl-Larsen 1943, Bräuer 1984, Bräuer and Mabulla 1996, Domínguez-Rodrigo et al. 2008; Archeology Kohl-Larsen 1943, Mehlman 1984, 1987, 1989, Domínguez-Rodrigo et al. 2007b.

Eyasi 1 Site **Eyasi**. Locality N/A. Surface/ in situ Surface. Date of discovery November 29, 1935. Finder N/A. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age c.100 ka. Developmental age Adult. Presumed sex Female. Brief anatomical

description Most of the occipital and much of the left parietal (but many fragments are not contiguous), some of the left temporal, and parts of the frontal including the right supraorbital margin. Announcement Kohl-Larsen and Reck 1936. Initial description Leakey 1936. Photographs/line drawings and metrical data Kohl-Larsen and Reck 1936, Weinert 1939, Schwartz and Tattersall 2003. Detailed anatomical description Weinert 1939. Initial taxonomic allocation *Palaeoanthropus njarasensis*. Taxonomic revisions “*Pithecanthropus*” (Leakey 1936), *Africanthropus njarasensis* (Weinert 1939). Current conventional taxonomic allocation *Homo* sp. Informal taxonomic category Pre-modern *Homo*. Significance The holotype of *Pa. njarasensis* and *Afri. njarasensis*. Location of original Eberhard-Karls-Universität Tübingen, Institut für Ur- und Frühgeschichte, Tübingen, Germany.

Eyasi Plateau Paleontological Project A multidisciplinary field project investigating the geology and paleontology of the fossil hominin site at Laetoli and at other paleontological localities on the Eyasi Plateau to the north of Lake Eyasi.

The project, which was initiated in 1998, is directed by Terry Harrison and organized in collaboration with the **National Museum of Tanzania**. The major aims of the project are to recover additional fossil hominins and to obtain more detailed information on their paleoecological and geological context. In addition to new specimens of *Australopithecus afarensis* from the Upper Laetoli Beds, the project has recovered the first fossil hominins from the Upper Ndolanya Beds attributed to *Paranthropus aethiopicus*. Study of the fossil hominins has been accompanied by research on the fossil vertebrates, invertebrates, and plants (more than 22,000 specimens have been collected since 1998), as well as on the geology, geochronology, **palynology**, **stable isotopes**, **taphonomy**, and modern ecology, by a team of more than 50 specialists. Further investigations of the fossil footprints at Laetoli, initially discovered and excavated by Mary **Leakey**, have not been a primary focus of this project, but an independent team of researchers, led by Charles Musiba, has continued this effort.

F

F. One of the prefixes used by the US contingent of the **International Omo Research Expedition** for localities in the **Omo Shungura Formation** (e.g., F. 511). The prefix is also used for fossils found within that locality (e.g., F. 511-16).

F statistics *F* statistics (also known as fixation indices) were developed by the population geneticist Sewall Wright to measure the effects of various types of population subdivision. *F* statistics describe the level of **heterozygosity** in a population and they can be used as a measure of **genetic distance**. The *F* statistics are derived from *F*, called the inbreeding coefficient. The three types of *F* statistic are F_{ST} (which compares the heterozygosity of the subpopulation to that of the total population), F_{IS} (which compares the heterozygosity of an individual to that of the subpopulation), and F_{IT} (which compares the heterozygosity of an individual to that of the total population). The three types of *F* statistic are related to one another through the equation $1 - F_{IT} = (1 - F_{IS})(1 - F_{ST})$. A high F_{ST} means that (a) homozygosity in the subpopulation is high relative to the total population, (b) heterozygosity within the subpopulation is low, (c) inbreeding within the subpopulation is high, (d) there is high genetic differentiation (or structure) between subpopulations, (e) genetic drift is high, and (f) genetic distance is large. In modern humans, F_{ST} is typically approximately 9–15%, which is a relatively low value compared with other animal species.

F test A statistical test applied to a ratio of two measures of variability to identify whether they differ from each other. *F* tests have two different degrees of freedom that are associated with the numerator and the denominator. The most common application of an *F* test is in testing for the significance of linear models such as **regression** or **analysis of variance**. The *F* test is used to identify whether the **variance** of observed values for the dependent variable around their estimated

values is significantly less than the variance of the observed values about their mean; that is, does the addition of the independent variables (be they continuous, categorical, or both) significantly improve the ability to predict particular observations relative to predictions that are simply the mean of the dependent variable? In a similar way, *F* tests can be used to determine whether the addition of one or more variables to a regression model significantly improves the fit of the model by analyzing the difference in the residual error produced by the regression with and without the extra variable(s). An *F* test can also be used to test whether two variances are equal (e.g., comparing variance in femoral head size in gorillas and a sample of fossil hominins), but such comparisons are highly sensitive to non-normality in the distribution of the data. Instead, alternative tests for the equality of variance such as the **Levene test** should be applied.

face (L. *facies* = face) One of the three main components of the **cranium**; the others are the **vault**, or **calotte**, and the **basicranium**. The unpaired bones making up the face are the anterior part of the frontal (the flat, or squamous, part of the frontal belongs to the vault), the **ethmoid**, and the **vomer**; the paired bones are the **nasal**, **maxillary**, **palatine**, and **zygomatic**. Rak (1983) lamented the lack of an authoritative definition of the face, and suggests that a good working definition is that it is the part of the cranium that extends from the alveolar plane of the upper jaw superiorly and posteriorly to the point of minimum frontal breadth. Thus, in this definition, the face includes the supraorbital region of the frontal bone.

faceted platform A platform on a flake that has multiple facets resulting from previous flake removals undertaken to shape or modify the **striking platform**. Many (but not all) **Levallois** flakes have faceted platforms.

facial mask The term used by Yoel Rak (1983) for the parts of the facial skeleton that are visible when the cranium is seen in a *norma frontalis* (i.e., when the cranium is viewed from the front or anteriorly).

facial visor The term used by Yoel Rak (1983) for the mostly relief-free, antero-superiorly facing, plate-like infraorbital surface of the face in *Paranthropus boisei* (*ibid.* Fig. 18B, p. 137). This relief-free morphology contrasts with the morphology of the same part of the face of *Paranthropus robustus*, which displays, from anterior to posterior, an **anterior pillar**, a **maxillary trigon**, and a **zygomaticomaxillary step**.

facies (L. *facies* = face) Earth science A lateral, different-looking, subdivision of the same stratigraphic unit that formed under different conditions. For example, at lake margins, sedimentary strata often grade from sandy clays near the lake margin to coarser sands further inland. Archeology The lateral variability implied by facies as used in geology has also been applied to archeological assemblages, notably by François Bordes (e.g., Bordes and de Sonneville-Bordes, 1970), who used the term to describe variation within the **Mousterian** that he attributed to contemporaneous but distinct cultural groups.

factorial A mathematical operation such that the factorial of an integer is equal to the product of all positive integers equal to or less than the original value. It is denoted by an exclamation point after an integer. For example, factorial 4, or 4!, is equal to $4 \times 3 \times 2 \times 1$.

facultative biped *See* bipedal.

FAD Acronym for **first appearance datum** (*which see*).

failure Mechanical failure is the inability of a system to perform its intended mechanical function. In an organism the failure of a tissue such as bone or enamel could mean excessive elastic deflection without yielding (the bone or enamel is too compliant to perform its intended function), yielding, or full fracture.

fallback foods [etym. The origin of the term is lost in the “mists of time,” but the concept has been used in agriculture for a long time because the *Oxford English Dictionary* cites its use in a contribution to the *Journal of the Royal Agricul-*

tural Society (1851, 12, p. 402) suggesting that if you keep sheep then “it is . . . advisable . . . to provide a ‘fall-back’, or adjacent stubble field into which the flock may retire at pleasure” (*ibid.*, p. 402)]. With respect to an animal’s diet, fallback foods are not the foods an animal prefers, but the foods an animal turns to when its preferred foods are not available. Marshall and Wrangham (2007) suggest that fallback foods are food items that are abundant, available year round, and are of low nutritional quality and they suggest that their consumption is negatively correlated with the availability of preferred foods. **Optimal foraging theory** suggests that animals forage in such a way that they favor foods that are (a) abundant, (b) energy-rich, (c) easily accessed, and (d) easily processed, so that, all things being equal, an individual gets the greatest yield per unit of energy expended on feeding. But when these preferred foods are unavailable for either predictable (e.g., seasonality) or unpredictable (e.g., drought, volcanic eruption) reasons, animals have to turn to foods that are either less energy-rich or that cost more energy to procure and process. Hladik (1973) was among the first to point to an example of fallback foods among primates, namely that chimpanzees increase their consumption of leaves and stems when their preferred food item, fruit, is scarce. Altmann (1998) provided an operational definition of fallback foods as those foods consumed in negative correlation with the availability of preferred resources and suggested that grass corms are a fallback food of **baboons**. Lambert et al. (2004) suggested that hard foods such as bark and seeds are fallback foods of the grey-cheeked mangabey. Although Rosenberger and Kinzey (1976) proposed that specific aspects of morphology may be linked to the need to deal with mechanically demanding foods, Lambert et al. (2004) was the first to suggest that the critical ability to process fallback foods may have shaped the evolution of the masticatory system (especially enamel thickness) in at least some primates. Laden and Wrangham (2005) followed up on the observations of Hatley and Kappelman (1980) to suggest that the need to be able to process **underground storage organs**, a possible early hominin fallback food, may have been an important factor in the emergence of the derived masticatory morphology of megadont early hominins. Since then Grine et al. (2006) and Ungar et al. (2008) have suggested that fallback foods may explain mismatches between two lines of evidence about diet, dental microwear, and gross morphology.

Paleoanthropologists and morphologists are increasingly interested in examining the role of fallback foods in shaping hominin craniodental morphology and in developing hypotheses about the adaptive niches of early hominins. Marshall and Wrangham (2007) review their possible role in shaping evolution and a whole issue of *Journal of Human Evolution* [140 (4)], edited by Paul Constantino and Barth Wright, was devoted to fallback foods.

falx cerebelli (L. *falx*=sickle and *cerebelli*=diminutive of *cerebrum*=brain, so the “little brain”) A small, usually insignificant, sickle-shaped fold of the meningeal, or fibrous, layer of the **dura mater** that partially separates the cerebellar hemispheres. If an **occipital sinus** is present it will run between the meningeal and the endosteal layers of the dura mater within the base of the falx cerebelli. *See also cranial venous sinuses.*

falx cerebri (L. *falx*=sickle and *cerebrum*=brain) A sickle-shaped fold of the meningeal, or fibrous, layer of the **dura mater** superior to the **corpus callosum** that partially separates the **cerebral hemispheres**. It runs from the **crista galli** anteriorly to merge with the **tentorium cerebelli** posteriorly. The superior and inferior sagittal venous sinuses run between the meningeal and the endosteal layers of the dura mater within its base and free border, respectively. In modern humans the superior sagittal venous sinus usually drains into the right **transverse sinus**, thence to the **sigmoid sinus** and **jugular bulb** of the same side. *See also cranial venous sinuses.*

Fate *See Caverna delle Fate.*

fault In structural geology this is a planar fracture through the Earth’s crust such that the rocks above and below the fracture move relative to each other. If the hanging wall (i.e., the rocks above the fault plane) is displaced downwards (i.e., down the **dip**) relative to the rocks of the footwall (i.e., the rocks below the fault plane) this type of fault is referred to as having an extensional geometry and it is called a **normal fault**. However, if the hanging wall is displaced upwards (i.e., up the dip) relative to the rocks of the footwall this type of fault is referred to as having a compressional geometry, and it is called a **reverse fault**.

fauna (L. *fauna*=in Roman mythology the sister of the Faunus, the god of nature and *faunus*=

a mythological creature that has the head of a man and the body of a goat) Meaning literally “animals,” this term can be used to refer to the complete animal component of an **ecosystem** or, combined with a taxonomic modifier (e.g., mammal/ian, vertebrate, avian) a particular component of the animal life. The most common ways the term fauna is used in paleoanthropology is (a) to refer to all animal remains from a particular site (e.g., **Swartkrans** fauna) or (b) to refer animals known from a defined time period (e.g., **Pliocene** fauna), or from a region (e.g., British fauna). Usually at a paleoanthropological site the fauna is first described by a faunal or taxon list which enumerates, in rank taxonomic order and to the minimum determinable level, all the species to which faunal remains recovered from the site have been assigned. In the absence of other more precise and reliable dating methods, a **faunal list** can be used as an indication of the age and paleoenvironment of the fossil site.

faunal assemblage (L. *fauna*=in Roman mythology the sister of the Faunus, the god of nature and L. *faunus*=a mythological creature that has the head of a man and the body of a goat) A group of associated animal bones or fossils, generally found in a specific spatial and temporal context, which can be treated as a unit for analysis (e.g., the accumulated fauna from all of the localities in Bed I of **Olduvai Gorge** would be regarded as a “faunal assemblage”). *See also assemblage.*

faunal break A discontinuity that results in an apparently abrupt faunal change. Within Bed II at Olduvai Gorge there is an abrupt change in the fauna just above the Lemuta Member, which is referred to as the “faunal break.” *See also Olduvai Gorge.*

Fauresmith A southern African stone artifact industry characterized by the variable presence of diminutive **handaxes** (Humphreys 1970 suggested that their size may reflect the material properties of the local stone raw material), elongated **flakes**, or **blades**, **points**, and **Levallois** technology. The Fauresmith has traditionally been considered a regional variant of the later or terminal **Acheulean** or intermediate between the Acheulean and the industries of the **Middle Stone Age**. Evidence from **Wonderwerk Cave** and elsewhere suggests a **Middle Pleistocene** age (i.e., >c.285 ka) (Porat et al. 2010).

favored place hypothesis This model for **Early Stone Age** site formation was proposed by Schick (1987; see also Schick and Toth 1993) and it suggests that archeological site formation was a byproduct of hominin transport and discard behavior. The anticipated need for stone tools led to the habitual transport of **lithic artifacts**. Over time, the occasional discard of artifacts at “favored places” (i.e., frequently visited foraging areas where hominins would find and consume foods, rest, carry out social activities, sleep, etc.) would lead to the passive accumulation of a local store of raw material. This would reduce the need for artifact transport while foraging in the immediate area and, over time, stone and debris from multiple butchery events could form dense archeological concentrations.

FEA Acronym for **finite element analysis** (*which see*).

feature Archeology Any non-portable object made, modified, or used by hominins. Houses and **hearths** are examples of features. Morphology Used in studies of dental morphology to refer to cusps, crests, ridges, and pits on the outer surface of the **enamel**.

fecundity (L. *fecundus*=fruitful) Typically a measurement of the potential reproductive capacity of an organism. Fecundity can be gauged generally by an organisms’ age in relationship to the average reproductive life span for that taxon, or more precisely by the number of gametes (eggs or sperm) possessed by an individual at a given time during their life span. This more specific measure of fecundity is used to calculate **fitness** in demographic studies. In addition to gamete number, other factors such as gamete quality, nutritional status, stress, and environmental conditions can affect fecundity. In modern human females, fecundity reaches a peak in the early 20s and declines thereafter (until menopause, when it reaches zero), whereas modern human males do not show such clear age-related patterns of diminishing reproductive capacity.

feeding Feeding is an inclusive term for the ingestion and intra-oral processing (including chewing) of food items. Feeding occurs in sequences of gape cycles, in which the lower jaws are cyclically depressed and elevated relative to the upper jaws and the tongue is moved to position the food item (s) for chewing and swallowing. A feeding sequence

begins with an ingestion cycle, often followed by a variable number of cycles in which the food is manipulated, investigated, and transported to the molar tooth row for chewing. A feeding sequence ends with a swallow. *See* **chewing**.

Fejej (Location 4°07’N, 36°04’E; Ethiopia; etym. from the name of a nearby police post) History and general description Site in the northeast of the **Turkana Basin** in southern Ethiopia. An extensive reconnaissance survey during the 1970s by the Canadian Geological Survey provided broad-scale geologic mapping of the region and established the area contained fossiliferous sedimentary rocks ranging in age from the Oligocene through the **Miocene** and into the early **Pliocene**. The **Paleoanthropological Inventory of Ethiopia** conducted a reconnaissance of the Fejej area in 1989 to evaluate its potential for paleoanthropological research and this led to a collaboration between the National Museum of Ethiopia and Stony Brook University. A French archeological team directed by Henry de Lumley has also worked at the site. Temporal span *c.*34.2–*c.*1.88 Ma, but the radiogenic ages of the basalts capping the FJ-4 locality plus the geomagnetic dating evidence suggest a minimum age for the FJ-4 locality of 4.0–4.18 Ma (Kappelman et al. 1996). How dated? **Argon-argon dating**, **potassium-argon dating**, and **biostratigraphy**. Hominins found at site Two specimens have been recovered from locality FJ-4: FJ-4-SB-1, a collection of six heavily worn mandibular teeth and tooth fragments, and FJ-4-SB-2, an unworn right P₄, have been attributed to *Australopithecus afarensis*. However, the FJ-4 dentition is in the size range of *Australopithecus anamensis* and some (e.g., White 2002) assign them to that taxon. Archeological evidence found at site Artifact assemblages attributed to the **Oldowan Industry** were found at locality FJ-1. Geology, dating, and paleoenvironment Asfaw et al. 1991, 1993, Kappelman et al. 1996; Hominins Fleagle et al. 1991; Archeology Asfaw et al. 1991, de Lumley and Beyene 2004.

Feldhofer Grotte *See* **Kleine Feldhofer Grotte**.

feldspar The most abundant group of minerals in the Earth’s crust, having a basic composition of $x\text{AlSi}_3\text{O}_8$, where x is usually K, Na, or Ca. Feldspars are generally of igneous or metamorphic origin, but may form authigenically (i.e., formed in place) within sediments. The alkali (i.e., rich in sodium and

potassium) feldspars are good targets for **isotopic dating**, as radioactive potassium decays to argon gas which, if it is trapped and accumulates within the crystal lattice, functions as a geochronometer. *See also* **argon-argon dating**; **potassium-argon dating**.

felid The informal name for the **Felidae** (the cat family), one of the feliform families whose members are found at some hominin sites. *See also* **Carnivora**.

Felidae The Felidae are carnivores and it is one of the **feliform** families whose members are found at some hominin sites. The Felidae include two sub-families: the Felinae (cheetahs and other small-medium size cats) and the Pantherinae (lions, leopards, and tigers). Felids first appear in the fossil record in the Oligocene. *See also* **Carnivora**.

feliform Informal term for taxa within the sub-order **Feliformia**, one of the two suborders in the order **Carnivora**.

Feliformia One of the two suborders in the order **Carnivora**. Common feliform families at hominin sites are the **Felidae** (cats), **Hyenidae** (hyenas), **Viverridae** (civets and their relatives), and **Herpestidae** (mongooses and relatives).

FEM Acronym for finite element models. *See* **finite element analysis**.

Fengshudao *See* **Bose Basin**.

fertility Although this term is used loosely in a number of different ways in the paleoanthropological literature, in demography it is generally synonymous with the **total fertility rate**. As such, fertility as a population-level measurement is the number of births divided by the number of childbearing lives. On a per-individual basis, fertility is the number of births that a woman can be expected to have over her entire reproductive career. The measure does not include any aspects of mortality, so for an individual woman who has not yet reached menopause the assumption is that she will survive until the end of her reproductive career. The measure also does not consider the survival of her offspring, and only requires that they be live births.

fertility rate, age-specific The age-specific fertility rate (or ASFR) in its simplest form is the

number of births in a year to women age x years old divided by the number of women at age x alive at the midpoint of the year. For example, f_{20} would be the number of births in 1 year to women who were 20 years old (from 20 years old to 20 years and 364 days old) on the date of birth, divided by the number of women 20 years old (again, 20–20.9973 years old) at the midpoint of the year. As in an **abridged life table**, it is more common to see the ASFR given for broader age intervals. For example, the ASFR for women ages 20–25 (24.9973) years old could be written as ${}_5f_{20}$, and would be the number of births in a year to women ages 20–24.9973 years old divided by the midyear number of women in the age bracket.

fibrocartilage *See* **cartilage**; **joint(s)**.

field theory Model of dental morphogenesis proposed by Percy Butler (1939) that posited the existence of developmental fields within which regional (**incisor**, **canine**, **molar**) morphogenetic cues influence the development of specific tooth types. Butler suggested that the position of the germ and the concentrations of the specific morphogens led to the different tooth types seen in mammals, including hominins and the other higher primates. *See* Butler (1982) and Kieser (1990) for critical reviews of this theory.

finger *See* **digit**.

finished sequence A genome that has been sequenced (usually multiple times) and checked for errors. For example, when first completed only 25% of the modern human genome had a “finished” sequence and in that example there was at least fourfold coverage and with a quality score of 99% accuracy.

finite element analysis (or FEA) An advanced computational technique used by engineers to predict the response of physical systems subjected to known loading conditions. The most common anthropological application of FEA is to biomechanical problems concerning the **stress** and **strain** experienced by bones when exposed to various types of forces. In FEA, an object of complex geometry (e.g., a bone) is typically modeled as a mesh of tetrahedra or hexahedra (these are the “elements” referred to in the name of the method) joined at nodes (e.g., the vertexes of

the tetrahedra). The elements are assigned the material properties (e.g., stiffness) of a given substance (e.g., cortical bone), forces are applied to nodes, certain nodes are constrained from moving and displacements are found at each node. The displacement field within each element is interpolated from the calculated using known polynomial functions. Strains and stresses throughout each element are then obtained by differentiating the element displacement field using the known or estimated material property for that element. The result is a characterization of stress and strain patterns across the object as a whole. In general, the generated stress and strain patterns are approximations to the theoretically exact stress and strain patterns. The accuracy of the solution can be improved by "refining the mesh" (i.e., by modeling the system with more nodes and elements) and by improving the modeling of geometry, material properties, loads, and boundary conditions (e.g., constraints). Recent advances in computer power and software have made feasible the relatively rapid construction of geometrically precise finite element models. Although geometry is the most visible component of a model, the importance of incorporating realistic forces, material properties, and constraints is sometimes unappreciated. Poor assumptions with respect to any of these variables may potentially render a model unrealistic even if it accurately reflects bony architecture. For this reason, it is critical that all finite element models be subjected to a validation study in which results from the FEA are compared to experimentally derived strain data. If there is good correspondence between the experimental and the FEA data, then the model can be interpreted and used to test biological hypotheses. FEA has been widely employed in orthopedics to understand bone growth and adaptation, and it is becoming increasingly important in anthropology as a tool for testing hypotheses about functional morphology (see Richmond et al. 2005 for a review). For example, Strait et al. (2009) used FEA to test hypotheses of facial biomechanics in early hominins.

finite element method *See* finite element analysis.

finite element modeling *See* finite element analysis.

fire *See* pyrotechnology.

first appearance datum (or FAD) Refers to the date of a taxon's earliest appearance in the fossil record and in paleoanthropology it is usually used in connection with a species (e.g., *Paranthropus boisei*) or a genus (e.g., *Homo*). For various reasons the FAD of a taxon is almost certainly later than when the taxon actually originated in, or migrated into, that region. Just how much earlier the origination or migration occurred is determined by two factors. The first is any error in the date, the second is the nature of the relevant fossil record prior to the FAD. The problem is the old adage that "absence of evidence is not evidence of absence." Hominins are such a rare component of the mammalian faunal record that researchers need to find a substantial number of nonhominin mammalian fossils (at least several hundred) without finding *any* evidence of a particular hominin taxon before it can be reasonably assumed that hominin taxon was not part of the faunal assemblage being sampled. In such cases (e.g., *Homo* at Omo-Shungura in Bobe and Leakey 2009, pp. 178–9) the FAD has an acceptably low 95% confidence interval, but if, as is the case at Koobi Fora, there is a major unconformity spanning several hundred thousand years prior to the FAD of *Homo* (i.e., there is no fossil record during that time), then the FAD of *Homo* at that location has an unacceptably high 95% confidence interval (c.0.7 Ma).

F₁₅ *See* F statistics.

FISH Acronym for fluorescence *in situ* hybridization (*which see*).

fish Despite being less dense than bones of terrestrial animals, fish bones are surprisingly common in early hominin sites (e.g., Lothagam, Kanapoi, Kanjera, Koobi Fora, Middle Awash, Olduvai Gorge, and Toros-Menalla). Most, but not all, of these bones were deposited post-mortem through natural water transport, which promotes rapid burial and preservation. Fish bones can provide information on hominin predation and other aspects of hominin behavior, as well as biogeographic and environmental information relevant for the reconstruction of hominin paleoecology. For example, the ecology of the fish taxa helped to reconstruct the paleoenvironment of the late Miocene Lothagam site as being close to a large and slow-moving river with non-brackish, well-vegetated back bays and swamps (Stewart 2003). This

reconstruction indicates the availability to hominins of potable water and sources of river margin foods (e.g., **sedges** and **catfish**). A further example lies in the similarities between certain fish groups at Lothagam and Wadi Natrun (Egypt), which suggest there must have been a fluvial connection between the two regions with biogeographic implications for hominins. Evidence for fish as prey is rare in early hominin sites, due to either taphonomic processes and/or consumption of the whole fish that would leave few traces. Nevertheless fish bones with tooth and/or cutmarks have been reported from Koobi Fora (Pobiner 2007, Braun et al. 2010) and Olduvai Gorge (Stewart 1994). Fish bone scatters occur at other archeological sites in the **Turkana Basin** (Braun et al. 2010, Stewart 2010). The dominant fish taxon in these and other Pleistocene archeological sites is the large catfish *Clarias*, a common food today in Africa, which is readily caught in shallow or receding waters. Other inshore fish, including cichlids, are also easily caught when stranded in receding waters. While most **Pleistocene** hominins could only catch the most accessible fish; improved technology, especially boats, in the latest Pleistocene and **Holocene** resulted in much increased numbers and diversity of fish in later archeological sites. Such sites include the late Pleistocene site of **Cueva de Nerja** (coastal Spain) which is one of the first with a diversity of marine fish, and the early Holocene site of Esh Shaheinab, Sudan, which has large numbers of both shallow and deep freshwater fish.

Fish Hoek [Location 34°07'S, 18°24'E, Western Cape Province, South Africa; etym. *Fish Hoek*, from Afrikaans *Vishoek* = “fish corner,” derived from the High Dutch meaning “Fish Bay” and the name of a nearby town. Also known as Skildergat, from the Afrikaans meaning either “Schilder’s (a local farm hand’s) cave” or “cave with paintings” and Peers Cave, after the original excavators] History and general description A.J.H. Goodwin excavated a trench from the front to the back of the cave in 1925 and encouraged the local father-and-son pair of naturalists and amateur archeologists, Victor and Bertie Peers, to continue exploration of the site, which they did between 1927 and 1929. Goodwin wrote an unpublished report on those excavations in 1929, and Sir Arthur **Keith** published a summary of the site in 1931. The Peers found a recent, culturally sterile level in the first 15 cm, followed by up to 1.5 m of **Later Stone Age** (or **LSA**) shell **midden** that contained six skeletons. The **Middle Stone Age**

(or **MSA**) (**Stillbay**) deposits began below the midden and contained two poorly preserved skeletons, both apparently intrusive from the **LSA**. A ninth skeleton (**Fish Hoek 1**) was recovered from the Howieson’s Poort layers beneath the Stillbay and a tenth skeleton that was too poorly preserved to be recovered was discovered in what may have been **MSA** layers below the Howieson’s Poort. The Peers’ excavation in the cave stopped at 3 m below the top of the deposit. They also excavated a trench in the talus, encountering at a depth estimated as 6 m below surface late **Acheulean** (Stellenbosch Culture) artifacts. Keith Jolly conducted more excavations at the site in 1946–7; Jolly thought there was no post-Howieson’s Poort **MSA** below the **LSA** midden. Barbara Anthony conducted a third excavation in 1963, the results of which are contained in an unpublished report to the National Monuments Council. Temporal span and how dated? Charcoal samples from Anthony’s excavation of the upper **MSA** yielded uncalibrated **conventional radiocarbon** ages of >35 ka and 36±2.4 ka; Protsch later obtained a date of 35 ka from an equid bone from the level of Fish Hoek 1 but all his dates are suspect and are most likely fabricated. The **MSA** layers are apparently beyond the range of radiocarbon dating and optically stimulated **luminescence** dates at other sites suggest the Stillbay dates to *c.*70 ka and the Howieson’s Poort to *c.*65–60 ka (Jacobs et al. 2008). Hominins found at site They include Fish Hoek 1, a well preserved cranium, mandible, and postcranial skeleton. Archeological evidence found at site A stratified sequence of deposits containing, from top to bottom, **LSA**, Stillbay (post-Howieson’s Poort **MSA**), Howieson’s Poort, Stillbay (**MSA**), and possibly **Acheulean** artifacts in the talus of the cave. Key references: Geology, dating, and paleoenvironment Jacobs et al. 2008; Hominins Keith 1931, Schwartz and Tattersall 2003; Archeology Keith 1931, Deacon and Wilson 1992, d’Errico and Henshilwood 2007.

Fish Hoek 1 Site **Fish Hoek**. Locality Peers Cave. Surface/in situ *In situ*. Date of discovery 1927–9. Finders V.S. and B. Peers. Unit Excavated from the Howieson’s Poort levels, although it was recognized that the burial may be intrusive. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Strata are **Late Pleistocene** through to the **Holocene** (see below). Developmental age Adult. Presumed

sex Male, based on size. Brief anatomical description A well-preserved cranium and mandible that are larger in size than most Holocene Khoesan analogues, but it is otherwise reminiscent of them in morphology. Announcement Keith 1931. Initial description Keith 1931. Photographs/line drawings and metrical data Keith 1931, Schwartz and Tattersall 2003. Detailed anatomical description Keith 1931, Schwartz and Tattersall 2003. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance Fish Hoek was long considered to possibly derive from the Howieson's Poort layers and thus be a representative of Middle Stone Age hominins in southern Africa. However, recent direct, calibrated AMS radiocarbon dates obtained by Stynder et al. (2009) indicate the cranium only dates to 7457–7145 cal. years BP, thus it is mid-Holocene in age and much too young to be from the Howieson's Poort levels. Location of original The cranium and mandible are in the **South African Museum (Iziko Museums of Cape Town)**; the postcranial skeleton is missing.

fission track dating (L. *fissus*=to split) Principle A radiogenic dating method that exploits the tendency of an ubiquitous isotope of uranium ^{238}U to undergo spontaneous disintegration, or fission. Method The fragments produced by the fission pass through the rock crystal leaving a trail, or “track,” of damage in the crystal. Thin sections of the rock are etched with chemicals to visualize the tracks. First, the “natural” tracks – those that have accumulated since the formation of the crystal – are counted. Then the specimen is subjected to a dose of neutrons large enough to drive all the remaining ^{238}U to undergo fission, at which time the “induced” tracks are counted. The ratio of the two track counts and the neutron dose are sufficient to calculate the age of the crystal. Suitable material To be suitable for fission-track dating, rocks have to be rich in uranium. This effectively confines its use to natural glasses, zircon, sphene, and apatite. Time range Certainly older than 100 ka and preferably older than 300 ka. Problems Generally reliable, but only used on tephra if for some reason they are unsuitable for argon-argon dating. Example The Soa Basin of Flores, Indonesia (O'Sullivan et al. 2001).

fissures (L. *fissura*=cleft) Morphology: central nervous system In adult brains the outer layer or

cortex of the cerebral and cerebellar hemispheres is thrown into folds. The blunt crests of the folds are called **gyri** and the fissures between the gyri are called **sulci**. The major gyri and sulci are named (e.g., temporal gyrus and the **lunate sulcus**). Morphology: teeth The enamel that covers the crowns of postcanine teeth is shaped into folds called fissures where developing enamel fronts meet one another. The primary fissures are between the main cusps and the secondary fissures mark the surfaces of the main cups and delineate accessory cusps.

F_{IT} See *F* statistics.

fitness The capability of an individual to reproduce so that its **genes** are represented in the next generation. Fitness is measured as the proportion of genes contributed to the next generation by an individual relative to the contributions of others. It is equal to the relative probability of survival and reproduction for a **genotype**. Since fitness is a relative term, the genotype with the best fitness is usually assigned a value of 1 and other genotypes have values less than 1. The concept is also known as genetic fitness or Darwinian fitness.

fitness-generating function A numerical function that describes the genetic **fitness** of a particular combination of **traits** by taking into account all the fitness trade-offs related to that **phenotype** (Rosenzweig et al. 1987). Rosenzweig et al. (1987) suggest that **grades** or **genera** share a similar fitness-generating function (or **G-function**) and that when a new adaptive type emerges it shares a new G-function, which has better fitness trade-offs than the G-function of the group of taxa it replaced. For example, the ability to consistently and efficiently manufacture small sharp stone flakes that can be used to cut the hide of a large mammal would allow the user access to important food resources that would be denied hominins that had to wait until nonhuman predators had penetrated the carcass. This ability would be an example of a new G-function.

fitness landscapes A metaphor introduced by Sewall Wright for the three-dimensional landscape in which the peaks are regions of higher genotypic **fitness** and the valleys are regions of lower fitness. He and others make the point that these landscapes are complex and that complexity is in part due to interactions among genes, and in part due to phenomena such as **epistasis**, which is

when the effect of a **mutation** on the **phenotype** depends on its context (i.e., whereabouts in the genome it occurs). Many of the possible pathways across the fitness landscape are inaccessible for one reason or another and these restrictions result in evolutionary **constraints** (e.g., additional cusps on mandibular postcanine teeth tend to occur in the **talonid**, the distal part of the crown, and not in the more mesial **trigonid**). George Gaylord Simpson later applied a similar principle to population-level dynamics in the form of adaptive landscapes.

fixation In a population where more than one form of a gene (an allele) exists, fixation occurs when, through any number of processes (including random **genetic drift**, **natural selection**, or as a consequence of small breeding populations), variation in allelic distribution declines to the point where only one allele remains. Once this happens, mutation or the immigration of new alleles are the only ways for the population to move out of fixation for this allele.

fixation indices These are better known as *F* statistics. *See F statistics; fixation.*

FJ Abbreviation of Fejej and the prefix for fossils from Fejej, Ethiopia. *See Fejej.*

flake An inclusive term for any fragment removed from a **core** made of stone (or much less commonly) bone. Some types of flake (e.g., **blades**) are morphologically distinctive. The term can be applied to complete flakes, as well as to the various flake-like fragments (which go under a variety of terms including debris and **débitage**) that are produced during the process of fracturing stone to make flakes (also called **knapping**). Flakes may also be produced in the absence of hominin activity as a result of post-depositional processes, but these flakes do not normally show the distinctive morphology associated with **conchoidal fracture**.

flake-blade This term is encountered in descriptions of southern African **Middle Stone Age** sites such as **Klasies River**. Unlike the term **blade** that refers to artifacts that are at least twice as long as they are wide, a flake-blade is an elongated **flake** with dorsal scars that suggest several parallel (or subparallel or convergent) flakes have been previously removed.

flake types A typology used to describe stone flakes produced during knapping based on the occurrence of cortex (original exterior surface of the raw material) on the surface of the flake. The distribution of types in an assemblage provides information about the knapping methods employed and the representation of different stages within a **reduction sequence**. The widely used system is that of Toth (1985), which includes seven types defined in terms of the partial or total absence of cortex from (a) the dorsal (exterior) surface of the flake and (b) the “striking platform” (surface surrounding the point of percussion). These are Flake Type I, a cortical platform and dorsal surface; Flake Type II, a cortical platform and partially cortical dorsal surface; Flake Type III, a cortical platform and noncortical dorsal surface; Flake Type IV, a noncortical platform and cortical dorsal surface; Flake Type V, a noncortical platform and partially cortical dorsal surface; Flake Type VI, a noncortical platform and noncortical dorsal surface; and Flake Type VII, indeterminate. Experimental replication generates expectations for the distribution of flake types that would be associated with early or late reduction stages, and with assemblages that include all stages of reduction versus those in which only part of the reduction sequence is represented or from which certain types have been preferentially removed (for example due to utility as tools). With respect to knapping methods, cortical platforms are associated with “unifacial” reduction, in which percussion is consistently addressed against the original raw material surface, whereas noncortical platforms are associated with “bifacial” or “polyfacial” methods in which the “scars” left by previous flake removals are used as the platforms for subsequent flake removals.

flint *See chert.*

FLK Acronym for the Frida Leakey Korongo, one of the localities at **Olduvai Gorge**. Discovered and excavated in 1931, it was the first site where artifacts were found *in situ* in Bed I. In 1959 the **OH 5** cranium was recovered “within a few yards of the 1931 excavation,” **OH 6** was recovered there in 1960, and **OH 16** in 1963. Two other localities, **FLKN** and **FLKNN**, are nearby. *See also Korongo; Olduvai Gorge.*

FLK-Zinjanthropus *See FLK.*

FLKN Acronym for Frida Leakey Korongo North, one of the localities at **Olduvai Gorge**. Excavations in 1961–2 resulted in many artifacts and faunal evidence and **OH 10** was recovered there in 1961. *See also* **Korongo**; **Olduvai Gorge**.

FLKNN Acronym for Frida Leakey Korongo North North, one of the localities at **Olduvai Gorge**. The locality is some 365 m north of **FLK**. Hominin remains (**OH 7** and **OH 8**) were discovered here in 1960–1. *See also* **Korongo**; **Olduvai Gorge**.

flora (L. *flora*=Roman goddess of flowers) A collective term for the plant life that occurs in a specific area or at a particular time. The fossil records of plants at paleoanthropological sites tend to be sparser and less well known than the **faunal** records. Nonetheless, the flora at several **hominin** sites have been studied by investigating fossilized pollen (e.g., Bonnefille et al. 2004), fossilized leaves, vines, woods, and fruits (e.g., Bonnefille and Letouzey 1976, Goren-Inbar et al. 2002). The floral record can also be studied through **phytoliths** (i.e., the silica components of plants) (e.g., Alexandre et al. 1997, Bamford et al. 2006), **paleosols** (i.e., fossilised soils) (e.g., Levin et al. 2004), and plant leaf wax biomarkers (e.g., Huang et al. 1999a, Schefuß et al. 2005, Feakins et al. 2007). *See also* **palynology**; **trace fossil**.

Florisbad (Location 28°45'S, 26°00'E, Orange Free State, South Africa; etym. Afrikaans “Floris’ bath,” after a spa operated on the site by Floris Venter) History and general description Vertebrate fossils were discovered in an old spring eye 40 km/24 miles northnorthwest of Bloemfontein, in what was the Orange Free State (now Free State Province), by Floris Venter in 1912. Robert **Broom** described some of the fossils, but it was the subsequent excavations by T.F. Dreyer that resulted in the **Florisbad 1** cranium. A variety of more recent excavations have attempted to clarify the stratigraphy and obtain absolute dates and additional fossils. Temporal span and how dated? The Peat I (see below) levels are beyond the range of **radiocarbon dating**. **Biostratigraphy** of the associated fauna suggests a Late **Middle** to **Upper Pleistocene** age. **Electron spin resonance spectroscopy dating** applied to teeth (both faunal and the hominin M³) produced an age of 259±35 ka, and optically stimulated **luminescence dating** suggests an age of 300–100 ka. Hominins found

at the site **Florisbad 1**, a fragmentary cranium, was made the holotype of *Homo (Africanthropus) helmei* Dreyer, 1935. Archeological evidence found at site Three levels (Peats I–III) of old land surfaces containing **Middle Stone Age** artifacts. The provenance of the cranium is uncertain, but its taphonomic state best matches the fauna from Peat I. Key references: Geology, dating, and paleoenvironment Van Zinderen Bakker 1957, Oakley 1957, Cooke 1963, Vogel 1970, Protsch 1975, Clarke 1985a, Grün et al. 1996; Hominins Dreyer 1935, Clarke 1985a, Day 1986, Curnoe and Brink 2010; Archeology Dreyer 1935, Clarke 1985a, Brink and Henderson 2001.

Florisbad 1 Site **Florisbad**. Locality N/A. Surface/in situ *In situ*, but from an old spring eye choked with debris and fossils. Date of discovery 1932. Finders G. Venter and T.F. Dreyer. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Late **Middle** or **Upper Pleistocene**. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A fragmentary cranium comprising the frontal, both parietals, both nasals, the right zygomatic and maxilla, part of the left maxilla, and the right M³. Endocranial volume Uncertain, but probably approximately 1200–1400 cm³ based on vault dimensions. Announcement Dreyer 1935. Initial description Dreyer 1935. Photographs/line drawings and metrical data Dreyer 1935, Drennan 1937, Galloway 1937, Rightmire 1978, 1984, Bräuer 1984, Day 1986, Schwartz and Tattersall 2003. Detailed anatomical description Dreyer 1935, Rightmire 1978, 1984, Bräuer 1984, Tappen, 1987, Schwartz and Tattersall, 2003. Initial taxonomic allocation *Homo helmei*. Taxonomic revisions *Homo florisbadensis* (Drennan 1935), *Homo sapiens* (Rightmire 1978). Current conventional taxonomic allocation Some favor placing it in its own species, *H. helmei* (Lahr and Foley 1994, McBrearty and Brooks 2000), others advocate placing it in late archaic *H. sapiens* (Bräuer 1984), and yet others view it as an early form of modern humans, *H. sapiens* (Galloway 1937, Rightmire 1984b, 2008, Bräuer 1984, 2008). Informal taxonomic category Pre-modern *Homo* or anatomically modern human. Significance The supraorbital torus is large, yet smaller than in **Kabwe** or **Saldanha** and, according to some, shows incipient separation of its medial and lateral segments. The forehead rises more steeply than in the latter specimens, the face is broad but vertically

short and bears a canine fossa. The cranial vault is wide. The thick vault bone bears two circular tooth marks, suggesting the individual was killed or scavenged by a large carnivore. The Florisbad cranium appears to be intermediate, and probably transitional, in morphology between *Homo heidelbergensis* and *Homo sapiens* in its vertical facial dimensions, brow ridge size, and inclination of the frontal bone. It retains primitive features such a large brow ridge, receding frontal, and broad vault that distinguish it from anatomically modern humans. If *H. helmei* can be satisfactorily diagnosed, which is debatable, Florisbad would serve the holotype of the taxon. Location of original National Museum, Bloemfontein, Free State Province, South Africa.

flowstone *See* calcium carbonate; speleothem.

fluorescence in situ hybridization (or FISH) A cytogenetic method in which fluorescently labeled probes are used to detect specific DNA sequences. The method can also be applied to entire chromosomes, in which case the method is called chromosome painting. FISH can be very useful for identifying the physical location of genes, or of other loci, on chromosomes and for identifying duplicated, deleted, or rearranged DNA sequences.

fluorine analysis *See* fluorine dating.

fluorine dating (*L. fluor*=the name of a group of minerals used to make fluxes) No longer used to date fossil hominins (see Goodrum and Olson 2009 for an excellent history of fluorine dating), it played an important role early in the history of paleoanthropology and its contribution to uncovering the Piltdown fraud was a crucial one. In the middle of the 19thC James Middleton suggested that fossil bone absorbs fluorine from the surrounding groundwater and he hinted that the process could be used to track time. However, it was a French scientist, Adolphe Carnot, who exploited the potential of the system. On the principle that bones buried at the same time in the same deposit should have taken up equal amounts of fluorine, Carnot showed that a human tibia found at the site of Billancourt, outside of Paris, was much younger in age than the many animal bones recovered from the site. Carnot's method was applied to Eugène Dubois' discoveries at Trinil, and the results were consistent with the proposed antiquity of those fossils because they had levels of fluorine comparable to those

of Pliocene fossils from Europe. The method was little used in the early decades of the 20thC, until it attracted the attention of Kenneth Oakley who spoke about its potential at the First Pan-African Congress on Prehistory in Nairobi in 1947. Although fluorine dating failed to resolve the controversy over the age of the **Kanjera** (the volcanic sediments contained so much fluorine that it saturated *all* of the bones from the site) and **Kanam** hominin fossils, it did show that the anatomically modern human **Galley Hill** skeleton, one of the critical pieces of evidence in favor of the **pre-sapiens hypothesis**, was an intrusive burial and not **Pleistocene** in age (Oakley and Montagu 1949) and it confirmed the antiquity of the hominin fossils recovered from **Swanscombe** (Oakley 1949). However, fluorine dating is probably best known for the role it played in helping to expose the Piltdown fraud. The animal fossils at the Piltdown site were found to have fluorine levels that varied between 3 and 1.6%, whereas the levels in the alleged hominin fossils claimed to be from Piltdown were only approximately 0.2% (Oakley and Hoskins 1950). These levels were similar to those found in contemporary bones, and the authors' suggestion that the result "requires some explanation" (*ibid*, p. 381) was undoubtedly an important element in spurring Joseph Weiner and Wilfrid Le Gros Clark to re-examine the fossil hominin evidence from Piltdown. They collaborated with Oakley to apply a more sensitive form of fluorine analysis to the allegedly ancient hominin fossils. These analyses showed that the fluorine levels in the cranial bones and the mandible were 0.1 and 0.03%, respectively (Weiner et al. 1953). These fluorine levels implied two things. First, the cranial bones and the mandible of **Piltdown I** were not the same age, and second, the mandible was almost certainly modern. These results, along with other lines of evidence showing the cranial bones and the mandible had been stained and that the cusps of the teeth in the mandible had been filed down, were sufficient for Weiner, Oakley, and Le Gros Clark to say with confidence that the Piltdown hominin fossils were modern and not ancient and that their association with the Piltdown site was the result of an elaborate hoax. *See also* Kenneth Oakley; Piltdown.

fluvial (*L. fluvius*=river) Pertaining to a river or stream, so a fluvial paleoenvironment is one involving a river or stream, and in geology fluvial is the name applied to sediments laid down by rivers or streams.

fluvialite *See* fluvial.

fMRI Acronym for **functional magnetic resonance imaging** (*which see*).

foliate point (*L. foliates*=leafy) A pointed stone artifact whose shape resembles that of a leaf. It is presumed that, depending on their size, foliate points were hafted onto a wooden shaft for use either as a spear (larger points) or as arrows (smaller points). *See also point*.

folivory (*L. folium*=leaf and *vorous*, from the stem of *vorare*=to devour) Literally, leaf eating; animals that eat leaves are folivores. Leaves are less energy-rich than fruits or insects. This is because the complex cellulose of leaves requires specialized digestive processing and bacterial colonies in the fore- or hindgut to break it down. Folivorous primates tend to have shearing crests on their teeth that mechanically process leaves much as scissors slice through paper. Soft-tissue digestive adaptations to folivory in primates include adaptations to the foregut in the form of a large, complex, multi-chambered stomach (as found in **colobine** monkeys) and adaptations to the hindgut as either an enlarged caecum (found in some strepsirrhines) or a long colon (found, for example, in howler monkeys and gorillas). Folivory is most common among larger primates, which require relatively less dietary energy per unit of body mass than smaller animals. Large animals can eat leaves because they have a long digestive tract that enables them to successfully process low-quality food. Nonetheless, some small primates are folivorous (e.g., *Lepilemur*) and they solve the problem of energy extraction by eating feces that contain high proportions of undigested plant materials. Folivory only features prominently in the diets of one extant great ape, the gorilla, and it has not been seriously proposed as a dietary specialization of extinct hominins. *See also coprophagy; Jarman/Bell principle*.

follicle *See dental follicle*.

Fond-de-Forêt *See Schmerling, Philippe-Charles (1790 or 1791–1836)*.

Fontana Ranuccio (Location 41°45'35"N, 13°16'03"E, Italy; etym. *It. fontana*=fountain and *Ranuccio*=a family name, possibly of the local landowner) History and general description This open-air site 60 km/40 miles southeast of Rome in the Sacco-

Liri valley was exposed during mining and has been explored since the late 1960s by the Istituto Italiano di Paleontologia Umana. An ancient volcano produced pyroclastic flows, which allowed for fairly specific **potassium-argon dating** on many of the levels in the sequence. The level in which the artifacts and hominin remains were found is also made of pyroclastic sand, allowing direct dating of this level. Temporal span The archeological levels were dated to *c.*458 ka. How dated? Potassium-argon dating. Hominins found at site Three hominin teeth were recovered: a lower left I₁, and a left and right lower M₂. They have been compared with the teeth of *Homo erectus*, but no formal taxonomic assignment has been made. Archeological evidence found at site The few artifacts that have been recovered include elephant bone implements and small flint handaxes and scrapers and are likely **Acheulean**. The **Levallois** technique does not appear to have been used. Key references: Geology, dating, and paleoenvironment Biddittu 1979, Segre and Ascenzi 1984, Muttoni et al. 2009; Hominins Segre and Ascenzi 1984, Ascenzi and Segre 1996; Archeology Segre and Ascenzi 1984, Ascenzi and Segre 1996, Segre-Naldini et al. 2009.

fontanelle (*L. fontanelle*=small fountain or spring) Fontanelles are places on the newborn **cranium** where the bone of the cranial vault is not yet completely ossified. The largest of the fontanelles are the rhomboid-shaped anterior fontanelle at **bregma**, where the frontal (**metopic**), **coronal**, and **sagittal** sutures meet and the triangular posterior fontanelle at **lambda**, between the sagittal and the lambdoid sutures. They were called fontanelles because they are the places on a newborn cranium that appear to pulsate. They do this because they (and especially the anterior fontanelle) transmit the pulsations of the intracranial arteries via the cerebrospinal fluid and the venous blood in the **dural venous sinuses**.

Fontéchevade (Location 45°40'43"N, 0°28'47"E, France; etym. named after a nearby village) History and general description This cave site in the Charente region was excavated by several amateurs since the 1870s, and then by Germaine Henri-Martin from 1937 to 1954. It is known as one of the reference sites for the Tayacian. The two recovered hominin fragments were thought to be quite old [approximately Oxygen Isotope Stage (OIS) 5e]; one fragment resembled *Homo neanderthalensis* traits but

the other appeared more modern and was thought to represent an early modern human population, and was part of the evidence used to support the **pre-sapiens hypothesis**. However, a program of excavation and a re-dating effort have shown that these fossils are more recent; the modern human-like fossil could even be an early **Upper Paleolithic** *Homo sapiens* individual. Temporal span and how dated? The lowest level was originally thought to date to the last interglacial (OIS 5e) based on the warm-climate fauna and the crude stone tools, but recent **radiocarbon dating** and **electron spin resonance spectroscopy dating** have suggested an age of *c.*33–60 ka (i.e., OIS 3) for the top of this level. Hominins found at site A fragment of a frontal bone [Fontéchevade (or Homo) I] and a partial calotte [Fontéchevade (or Homo) II] were both recovered near the top of layer E; Fontéchevade II was clearly Neanderthal-like but Fontéchevade I lacks a supraorbital torus and appears more modern. Archeological evidence found at site The lowest layer consists of a thick Tayacian deposit (a type of the **Mousterian**), but recent work at the site has shown that this "industry" is largely the result of taphonomic processes. This is overlain by a brecciated roof-fall, and then several thin archeological layers containing Mousterian, **Châtelperronian**, **Aurignacian**, and Bronze Age artifacts. Key references: Geology, dating, and paleoenvironment Chase et al. 2007; Hominins Henri-Martin 1957, Vallois 1949, 1958; Archeology Henri-Martin 1957, Chase et al. 2009.

food utility index *See* economic utility index.

foot The foot consists of seven tarsal bones, five metatarsals, and 14 phalanges (three for each toe, except for the big toe, or hallux, which has two) plus any sesamoid bones. The modern human foot differs considerably from the ape foot, reflecting a shift from a grasping appendage to a propulsive one. The most apparent differences are that in apes such as the chimpanzee, the foot is positioned in an "inverted set" (i.e., the sole of the foot is positioned with the lateral aspect of the foot on the ground) and it possesses an abducted (i.e., deviated away from the longitudinal axes of the other toes) grasping hallux, both features important for arboreal locomotion. In contrast the modern human foot has evolved a more everted "plantar" set (i.e., the sole of the foot is positioned with the bottom, or

plantar, aspect of the foot towards the ground), and the hallux is adducted (i.e., it is in line with the longitudinal axes of the other digits). Adaptations for habitual bipedality include a more robust calcaneus with a derived lateral plantar process. The modern human calcaneocuboid joint is unique among living taxa in possessing an interlocking facet that stabilizes the joint during the **push-off** phase of walking, and the tarsals are elongated (proximodistally), which increases the lever arm for efficient bipedal push-off. Metatarsal robusticity differs between modern humans and chimpanzee feet with the former typically having a $1 > 5 > (3,4) > 2$ formula and chimpanzees possessing a $1 > 2 > 3 > 4 > 5$ formula. The metatarsals of the modern human foot also have a distinct torsion (i.e., the long axis of the metatarsal head is not in line with the long axis through the articular surface at the base of the metatarsal) that allows the bases to form a transverse arch while all of the metatarsal heads lie squarely on the ground during the stance phase of the walking cycle. In contrast, the metatarsal torsion seen in the apes puts the lateral toes in opposition with the grasping hallux. While variation exists in the length and degree of curvature of ape phalanges, modern humans possess relatively short and straight phalanges compared to all apes. Modern human feet have a longer Achilles tendon and a thicker plantar aponeurosis (fascia) than ape feet. *See also* **bipedalism**; **walking cycle**.

foot arches The elevated midregion of the foot that results from the architecture of the hard-tissue skeleton in combination with soft-tissue structures. Modern humans, chimpanzees, gorillas, and orangutans possess a transverse arch, a mediolaterally oriented structure formed at the tarsometatarsal junction. Modern humans differ, however, from all other extant primates in also possessing a **longitudinal arch** that runs the length of the foot and serves both to stiffen the foot to make it an effective lever and to allow ligaments and the plantar aponeurosis to store elastic energy during the stance phase of walking. *See also* **longitudinal arch**; **transverse arch**; **walking cycle**.

foot function The modern human foot is stiff and straight and thus adapted for terrestrial bipedalism, whereas the extant ape foot is more flexible and adapted for a wider range of motion. Modern humans and nonhuman apes are both plantigrade; that is, they strike the ground with their heel (unlike monkeys, which are digitigrade or

semiplantigrade). During modern human walking forces are greatest at heel strike and again at **push-off**, producing a characteristic “double-humped” force/time curve in the **walking cycle**. During the stance phase of walking the modern human midfoot is normally elevated as a result of the **longitudinal arch**, maintained by ligaments and the plantar aponeurosis (fascia), whereas the ape midfoot is in contact with the ground during the stance phase. As the stance phase proceeds the foot undergoes **eversion**, due in part to the action of the fibularis muscles. Eversion helps transfer the weight-bearing function towards the robust hallux for push-off and it also keeps the transverse axes of the midtarsal joints roughly parallel and allows for some midfoot mobility, which is important for keeping the foot in contact with uneven substrates. Activity of the gastrocnemius-soleus complex at push-off plantar flexes the foot at the ankle, which causes inversion of the hindfoot. This motion twists the calcaneus against the cuboid in a close-packed position and this converts the midfoot into a structure that allows for uninterrupted weight transfer from the hindfoot to the forefoot. In apes such as the chimpanzee, the midfoot remains in contact with the ground after heel lift, the so-called “**midtarsal break**” or “**midfoot break**.” As the heel lifts in modern humans, the fulcrum shifts directly to the metatarsophalangeal joints and the resulting dorsiflexion of the phalanges tightens the plantar aponeurosis (the “**windlass effect**”), which helps convert the foot into a stiff and effective lever. *See also* **midtarsal break**; **walking cycle**.

foot movements The primary motions at the foot joints are dorsiflexion (extension) and plantarflexion (flexion) at the ankle (talocrural) joint that occurs around an approximately mediolateral axis, inversion and eversion, primarily at the subtalar joint, that occurs around an approximately antero-posterior axis, and internal and external rotation of the foot that occurs around an approximately superoinferior axis. The toes can also abduct and adduct with respect to the second digit; movement of the toes (other than the second) toward the second digit is **adduction**, and movement of the toes away from the second digit (or away from its normal longitudinal axis in the case of the second digit itself) is **abduction**. These motions often occur together as a result of the close articulation of the foot bones. Triplanar motion incorporating

these different foot movements is sometimes termed supination or pronation. Pronation involves external rotation, dorsiflexion, and eversion, and supination combines internal rotation, plantarflexion, and inversion. During the stance phase of locomotion, some pronation and some supination occur. At the very beginning of stance the hindfoot pronates slightly, allowing the midfoot to move. After this the foot is said to supinate, increasing stability of the foot during midstance. After midstance, the foot pronates slightly to absorb the forces of body weight in the arch and at the very end of stance phase the foot supinates slightly to create a rigid foot. That supination combined with the **windlass effect** promotes efficient propulsion by the plantarflexors.

footprints *See* **Koobi Fora hominin footprints**; **Lactoli hominin footprints**.

forager (OF *foufrage*=to search for food) The term used to describe societies that practice a subsistence strategy based primarily on the collection of wild plant foods, fishing, and the hunting and **scavenging** of animals. Contemporary foragers are of interest to paleoanthropologists because they provide the only means to directly observe behavioral patterns, subsistence strategies, and social interactions in the absence of horticulture, agriculture, or pastoralism. Studies of contemporary forager populations can provide insights into the selective forces that shaped the aboriginal modern human adaptation. In terms of caloric return, plant foods are generally the most important component of the contemporary forager diet, but plant **productivity** decreases with increasing latitude, so high-latitude foragers rely less on plant foods and more on animal foods than those living in the tropics. A predominantly foraging (hunting and gathering, or hunter-gatherer) lifestyle is practiced by a small number of groups today, including the **Hadza** of Tanzania, the **Aché** of Paraguay, the **San** of southern Africa, the Inuit of Canada and Alaska, and the **Mbuti** of the Democratic Republic of the Congo. Hunter-gatherers tend to forage in small, relatively egalitarian groups. Forager movements depend on the spatial distribution and seasonal availability of resources. In regions with a relatively low and even resource distribution, foragers live in mobile groups that move seasonally to exploit resources as they become available. Where resources are spatially and/or temporally more clumped (e.g., in regions with seasonal fish or large mammal

migrations), hunter–gatherers may reside in larger groups that do not need to move as frequently and small, special task groups may be sent out to obtain food for the group at large. Food storage is more likely in the latter context, where seasonal abundance may provide surpluses that can be stored for later consumption. Hunting and gathering was the predominant mode of subsistence before plant and animal **domestication** began *c.*10,000–12,000 years BP. Paleoanthropologists and archaeologists analyze the ways in which foragers produce and use tools in an attempt to glean how tool use developed in hominin evolution. Characteristics of certain tools used by contemporary foragers, such as wooden digging sticks and carrying devices used to transport infants and tools, remind us of the danger of interpreting the behavior of early hominins on the basis of durable (i. e., lithic) evidence, for the tools referred to above are typically constructed out of material that does not survive the archeological record. Recent hunting technology, such as iron-tipped tools, most likely replaced their bone and/or stone counterparts in most parts of the old world. The behavioral ecology of extant hunter–gatherer groups provides an indication of what the hunting and gathering adaptation might have been like for more ancient forms of *Homo*, although the extent to which this adaptive complex, including a sexual division of labor, extensive food sharing, and **central place foraging**, extends back into the **Pleistocene** is debated.

foraging (OF *foufrage*=to search for food) Foraging is an inclusive term for the search for and acquisition of food items. With respect to human evolution researchers use information about the foraging behaviors of extant organisms to develop **referential models** from which inferences can be made about the functional morphology of extinct hominin taxa. **Optimal foraging theory** involves setting the estimated energy expended in the search for food against the net energy yielded by ingesting the food. *See also* **extractive foraging**; **forager**.

foraging efficiency Refers to the efficiency with which foragers obtain calories from their food resources, often measured as the amount of energy obtained relative to the amount of time spent searching for and handling food. **Optimal foraging theory** assumes that the objective of all foragers is to maximize foraging efficiency with declines in foraging efficiency often signaled by an expansion

of **diet breadth** and increased utilization of **low-ranking prey**. Foraging efficiency can be affected by numerous factors including environmental change, technological innovation, and resource depression. The detection of changes in foraging efficiency through time in archeological contexts is central to understanding the factors mediating prehistoric human subsistence strategies.

foramen magnum (L. *foramen*=an opening and *magnus*=great) An unpaired opening in the occipital bone, this is the largest opening in the **basicranium** (hence its name). It transmits the spinal cord together with the **meninges** that cover it, the spinal contributions to the accessory (XI) cranial nerves, the vertebral and spinal arteries, and the thin-walled veins that connect the internal vertebral venous plexuses with the **dural venous sinuses** within the **endocranial cavity**. Two important midline cranial landmarks involve the foramen magnum; basion is defined by its anterior margin and opisthion by its posterior margin. Important variables associated with the foramen magnum involve its *location* relative to either the long (i. e., the **sagittal**) axis of the neurocranium or to axes defined by bilateral landmarks in the basicranium (e. g., bi-carotid, bi-tympanic, etc.), its *orientation* relative to horizontal planes such as the **Frankfurt Horizontal**, its *shape* described either non-metrically or metrically, and its *size* captured either by linear dimensions or by estimating or measuring its surface area. Location Interest in quantifying the location of the foramen magnum can be traced back to Bolk (1909) (see references in Luboga and Wood 1990), but the **head-balancing index** of Dart (1925), the index devised by Schultz (1942), and the **condylar position index** of Le Gros Clark (1950a) are among the best known of many attempts to locate the foramen magnum, or a proxy (e. g., porion or the occipital condyles) for the foramen magnum, along the midline axis of the cranium. But the utility of these indices is limited by the requirement that a well-preserved cranium is available. The realization that this is an unrealistic expectation for the early hominin fossil record provided the stimulus for researchers to investigate locating the foramen magnum with respect to transverse axes defined by bilateral landmarks within the basicranium (e. g., Dean and Wood 1981, 1982, Ahern 2005). The nonhuman great ape with the most anteriorly situated foramen magnum with respect to landmarks within the basicranium is *Pan paniscus*

(Luboga and Wood 1990) and there is overlap, albeit very limited, between the ranges of *Pan paniscus* and some modern human populations. Bolk (1915b) also noted that the position of the foramen magnum early in ontogeny in the nonhuman great apes resembled its location in adult modern humans. Among adult fossil hominins, the position of basion relative to the bi-tympanic line is most anterior in *Paranthropus boisei* but it lies close to this line in all specimens where this relationship can be assessed. Orientation Bolk (1910) was also a pioneer in the quantification of the orientation of the foramen magnum; much later Luboga and Wood (1990) showed that there is modest overlap of the ranges of the orientation of the foramen magnum in *Pan paniscus* and in modern humans. Shape A **cardioid foramen magnum** (i.e., heart-shaped) has been reported in several crania belonging to *P. boisei* and to the one cranium attributed to *Paranthropus aethiopicus* (Tobias 1967a, Leakey and Walker 1988). Size When the fossil record of a taxon is limited to the cranium at least one researcher suggested that the foramen magnum may be an appropriate and convenient proxy for body weight (Radinsky 1967), but subsequent research has shown that foramen magnum area has a relationship with **endocranial volume** that is independent of its relationship via body weight. *See also* **cranial venous drainage**.

foraminifera (L. *foramen*=an opening) An order of protozoans with many holes, or foramina, in their hard calcareous (Ca₂CO₃) shells. The oxygen in the **calcium carbonate** in the shells is the source of the oxygen isotopes used for **paleoclimate** reconstruction and the method of temporal correlation known as **orbital tuning**. Deep sea cores are extracted from ocean floors to sample the shells of ancient foraminifera along the sediment core. The ¹⁸O/¹⁶O ratios of the shells of deep sea, or benthic, foraminifera contain a temporal record of **deep sea temperature** and **glacial ice volume**. Often in the same cores planktonic foraminifera can be found, whose shells record **sea surface temperature**.

Forbes' Quarry (Location 36°08'N, 5°20'W, Gibraltar, UK; etym. named after the owner of the quarry) History and general description In 1848, the cranium of an early hominin was recovered from a limestone quarry on the north face of the Rock of Gibraltar, and in March of that year its discovery was the subject of a presentation to the Gibraltar Scientific Society by Lieutenant Flint.

The cranium was brought to the attention of Hugh Falconer, the paleontologist, and George Busk, a surgeon and paleontologist, when they visited the excavations at Gibraltar in 1862. In 1864 a report on the cranium was made to the British Association for the Advancement of Science and Falconer (1864) proposed it be referred to *Homo calpicus* (after Mons Calpe, the name for Gibraltar). This was the same year that the fossils from **Kleine Feldhofer Grotte** were published as *Homo neanderthalensis* and the significance of the Gibraltar 1 cranium was overlooked. Temporal span and how dated? The exact provenance of the fossil is unknown, and the fossil has not been directly dated. Hominins found at site The Forbes' Quarry Gibraltar 1 cranium is a small but nearly complete cranium, showing nearly all of the distinctive suite of Neanderthal characteristics; with hindsight it was the first adult cranium of *H. neanderthalensis* to be recovered. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment N/A; Hominins Busk 1865, Barton et al. 1999; Archeology N/A. *See also* **Gibraltar 1; Homo neanderthalensis**.

force (L. *fortis*=strong) The capacity to cause an object to change velocity. A force has both a magnitude and a direction, thereby making it a vector. Every force has an equal and opposite reaction force. Thus, if the foot applies a force to the ground the ground applies a reaction force of equivalent magnitude (and opposite direction) to the foot. Anatomical systems (e.g., the upper limb in tool making and the lower limb in running) must be constructed in a way that enables them to both apply and resist forces.

force plate A device that measures **force** using load cells (these are electronic devices used to convert, or transduce, a force into an electric signal). The simplest force plates measure only the force **normal** (i.e., perpendicular) to and in the center of the plate, much like a bathroom scale does. Most force plates used in biomechanical research calculate the force at the center of pressure and provide all three main directional components of force (normal, side-to-side, and fore-aft) over time. Most applications in **biomechanics** concern the force exerted by (and on) the hindlimbs (and forelimbs in nonhuman animals) during **gait**. For example, Kimura et al. (1985) used force plates to show how the **ground reaction force** (force at the foot) during **chimpanzee**

bipedal walking differs from the force profile during modern human walking. *See also* **kinetics**.

forcing *See* **climate forcing**.

forebrain (ME *fore*=the front and OE *braegen*=brain, most likely from the Gk *bregma*=the front of the head) The anteriormost of the three swellings or vesicles in the embryo that give rise to the brain. The forebrain is comprised of the **thalamus** (the diencephalic part of the forebrain vesicle), which lies close to the midline, and the two **cerebral hemispheres** (the telencephalic part of the forebrain vesicle), which are more laterally situated. The **basal ganglia** (i.e., the **striatum**, globus pallidus, substantia nigra, and subthalamic nuclei) develop during ontogeny deep in the wall of the part of the expanding forebrain that comes to rest up against the thalamus. In primates, but especially in the great apes and particularly in modern humans, it is the forebrain that undergoes the most expansion during development. This is an extension of the trend seen across a range of mammals, wherein increases in brain mass size are generally accompanied by the positive **allometry** of the growth of the forebrain components, particularly the **neocortex** and the striatum (Finlay and Darlington 1995).

forest (L. *foris*=outside) An assemblage of ecosystems dominated by trees and other woody vegetation. Within this broad category, there are several distinct forest biomes relevant to hominin evolution including **tropical dry**, tropical wet, **temperate deciduous**, montane, and gallery or riparian forests. In general, a forest is defined as a stand of trees, which can vary from 10 to 50 m or more in height, with interlocking crowns. Forests can have several layers, including shrub and ground layers, and in some forest biomes a grass layer may be present. The majority of African forests are evergreen or semi-evergreen, although localized patches of deciduous forests do exist.

forest hog The vernacular name for the taxa within the genus *Hylochoerus*. *See* **Suidae**.

form Objects (such as teeth, crania, long bones, etc.) have a number of spatial properties, including their location, orientation, size, shape, etc. Form refers to those aspects of an object that remain when all but **size** and **shape** are removed (e.g., ignoring

location in space, rotation, etc.). Form is often studied through the use of **geometric morphometrics** and/or **Euclidean distance matrix analysis**. Form and its subsets of size and shape are of great interest in human evolution: the analysis of similarity and variation in form, size, and/or shape are used in studies of topics such as **alpha taxonomy**, phylogenetic reconstruction, **sexual dimorphism**, developmental scaling, hormonal control of growth, and paleoecological reconstruction.

formation An inclusive term used in stratigraphy to refer to a set of strata whose upper and lower boundaries are evident. Formations are divided into **members** and members into **beds**. For example, the **Koobi Fora Formation** is divided into eight members: from oldest to youngest the Lonynun, Moiti, Lokochot, Tulu Bor, Burgi, KBS, Okote, and the Chari.

Fossellone (Location, 41°14'N, 13°05'E, Italy) History and general description This is one of the large cave sites in the **Monte Circeo** complex. Explorations by A.C. Blanc in 1937 revealed an **Upper Paleolithic** industry and he spent the next several seasons working there. It was not until 1954 that he found a **Mousterian** industry and hominin remains in level 4 of the Obermeier entry of the cave. Temporal span and how dated? Tool typology suggests a **Middle Paleolithic** date. Hominins found at site A fragmentary immature mandible and three teeth have been recovered from the Mousterian levels. Previously known as Circeo IV, this individual is now generally called Fossellone 3 and is identifiably *Homo neanderthalensis* in character. At least two other individuals (Fossellone 1 and 2) were found in the **Aurignacian** layers. Archeological evidence found at site A long Aurignacian (from the upper levels) and Mousterian (from the lower levels) sequence was recovered by Blanc, as well as a large sample of bone tools. Key references: Geology, dating, and paleoenvironment Blanc 1954; Hominins Mallegni 1992; Archeology Vitagliano and Piperno 1991.

fossil (L. *fossilis*=to dig) The word fossil now means a relic, or trace, of a formerly living organism, but in the past the term fossil was also applied to inorganic materials, such as rocks and crystals. In its modern interpretation, there are two categories of fossil. The first category comprises **true fossils**, which are remnants of the organism

itself, either in the form of hard (i.e., bones and teeth) or soft (i.e., skin, muscle, etc.) tissues. The latter are seldom preserved in the fossil record and in the case of human evolution soft-tissue fossils are confined to relatively recent and rare examples of bodies preserved in bogs, or within the ice of glaciers. The second category comprises **trace fossils** (also called **ichnofossils**). These provide direct evidence that an organism has been at a particular place at a particular time. Sometimes sediments function like casting material, retaining details of the surface of plant (e.g., leaves) and animal soft tissues or bones long after the individual, or its hard tissues, have disappeared. Footprints (e.g., the Laetoli and Ileret footprints) are an example of a trace fossil that preserves the impression of a soft tissue (i.e., the skin of the sole of the foot), and the natural endocranial casts that faithfully reproduce the inner (i.e., endocranial) surface of the missing parts of the brain case of the southern African fossil hominins (e.g., **Taung 1**) are an example of a trace fossil of a hard tissue. Other categories of non-cast-like trace fossils include coprolites (fossilized feces).

fossilization The process whereby organic materials (usually bones or teeth but other materials like wood) are transformed into a **fossil**. During life, the bones and teeth – the structures that make up the vast majority of the hominin fossil record – are made up of a mixture of organic **matrix** and inorganic material. The dense cortical bone that forms much of the **cranium** and **mandible** and the outer cortical bone of the long bones of the limbs are comprised approximately 70% by volume of mineral, or inorganic, material, and approximately 20% by volume of organic material. The inorganic component is mostly a complex of chemicals called hydroxyapatite. The organic material consists predominantly of **collagen** embedded within a matrix of other organic components (as well as the cells that resorb bone and secrete bone matrix). The balance (approximately 10% by volume) is made up of water. **Dentine** forms the core of mammalian teeth and has a chemical composition similar to that of bone. **Enamel** is the hard, white, outer covering of teeth; it consists of approximately 95% by weight inorganic material and less than 1% by volume organic material. Enamel is the hardest biological tissue known and is almost pure **apatite**. During fossilization the organic component of hard tissues degrades and is replaced either totally or partially by minerals from the surrounding rock. Many trabecular

spaces in bone become filled with deposits of, for example, calcite (calcium carbonate). The details of the fossilization process are site-specific and fossilization may result in the elimination of all of the original tissue and its replacement by minerals from the surrounding deposits; thus, fossils are effectively “bone-shaped” or “tooth-shaped” rocks. Plant fossils, for example, may become completely silicified but they can retain exquisite details of microstructure (e.g., Bamford 2005). Hydroxyapatite easily reduces to fluorapatite as the hydroxyl groups are replaced with fluoride from groundwater and it is this process that makes fossils extremely hard. Enamel, dentine, and bone may take up elements from the surrounding deposits (e.g., manganese and iron) which stain them brown or black. The chemicals in the inorganic component are exchanged with those in the rock to different degrees and in different ways. Some cells actually mineralize and preserve during life within bone and fossils bones can contain evidence of cells and even cell structure. Klinge et al. (2005, 2009) provide examples of the processes involved with respect to the fossilization of bone and dentine that have taken place at Koobi Fora, Kenya. The chances that the bones and teeth of a dead animal will end up in the fossil record are vanishingly small. Most of the animals that die in the wild are eaten by **scavengers**, their soft tissues are consumed or degraded by insects and bacteria and once the soft tissues that link the bones at joints are lost the bones are disarticulated and scattered. They are then reduced to small taxonomically unrecognizable fragments by a combination of the destructive effects of **diurnal** heating and cooling and by being trampled underfoot by large mammals. In all but a very few cases these processes effectively eliminate the soft and hard tissues thus removing any evidence that the animal had existed and denying it a place in the fossil record. If an animal does survive as a fossil it is usually because the remains were covered with **sediment** of some kind soon after death. These covering layers of sediment protect the skeletal remains from damage and the sediment moisture provides a medium for the exchange of chemicals between the sediments surrounding the fossil and the fossil itself. Intentional burial increases the chance that hard tissues will fossilize, which partially explains the increase in human fossils in later time periods. Higher population densities likely also contribute to this increase in numbers of fossils. Some of the organic material in bones is retained long enough to make it useful for dating (*see radiocarbon dating; amino acid racemization*

dating) and for helping to identify what type of animal the bone comes from (e.g., protein and DNA analysis). Researchers have been able to recover short fragments of DNA from relatively recent (<100 ka) fossil evidence such as that for *Homo neanderthalensis* and *Homo sapiens*, thus opening up a new line of evidence for scientists to use to assess the relationship between Neanderthals and modern humans. *See* ancient DNA.

Foster's island rule *See* island rule.

founder effect A concept developed by Ernst Mayr based on the foundational research of Sewall Wright. The term refers to the reduction in genetic diversity that occurs when a subset of the individuals belonging to a larger population forms the basis of (or "founds") a smaller subpopulation. The new subpopulation is likely to have allele frequencies that differ from those of the parent population and since this sampling event would also most likely change the gene frequencies in the parental populations, this phenomenon is often referred to as intra-generational genetic drift. In modern humans, founder effects can be seen in subpopulations such as the Amish, the Finns, and the French-Canadians, for each of these subpopulations has an increased incidence of particular inherited diseases. The founder effect very likely contributed to the genetic distinctiveness of subpopulations of early hominin taxa that formed the basis of new species. Often, founder populations become extinct, but occasionally they may survive and evolve into a new species via the process of **peripatric speciation**. *See also* *Homo floresiensis*.

fovea (L. *fovea*=a small pit) A depression on an otherwise smooth surface. **Teeth** The fovea anterior, or trigonid basin, is a depressed area of enamel between the **mesial marginal ridge** and the **trigonid crest**, and the fovea posterior, or **talonid basin**, is a depressed area of enamel between the ridge connecting the **entoconid** with the **hypoconulid** and the **distal marginal ridge**. **Bones** There is a fovea on the head of the **femur** (the fovea capitis) where the ligament of the head of the femur would have been attached. **Eye** There is a fovea in the central portion of the macula region of the retina of all haplorhine primates (called the fovea centralis retinae). This part of the retina has an extraordinarily high packing density of cone photoreceptors and makes high visual acuity possible.

fovea anterior (mandibular) Term used by Selenka (1898/1900) for the depression on the occlusal surface of a mandibular molar between the **mesial marginal ridge** and the **distal trigonid crest** of a mandibular molar (syn. anterior fovea, mesial pit, precuspidal fossa, prefossid, trigonid basin). *See also* fovea.

fovea anterior (maxillary) Term used by Selenka (1898/1900) for the depression on the occlusal surface of a maxillary molar between the **mesial marginal ridge** and the **epicrista** of a maxillary molar (syn. anterior fovea, mesial fovea, mesial pit). *See also* fovea.

fovea centralis (mandibular) *See* central fovea (mandibular).

fovea centralis (maxillary) *See* central fovea (maxillary).

fovea posterior (mandibular) A depression (sometimes a pit or a groove) in the talonid component of a mandibular molar crown between the ridge connecting the **entoconid** with the **hypoconulid** and the **distal marginal ridge** (syn. posterior fovea, postcuspidal fossa, post-talonid basin, distal pit). *See also* fovea.

fovea posterior (maxillary) Term used by Selenka (1898/1900) for the depression in the **trigon** component of a maxillary molar crown between the **hypocone**, the **distal marginal ridge**, and the **distal trigon crest** (syn. distal fovea, distal pit, distal triangular fossa, posterior fovea, oblique furrow, oblique groove, talon basin). *See also* fovea.

FOXP2 An abbreviation of forkhead box P2. The FOXP2 protein is a **transcription factor** that regulates **genes** involved in the development of the brain, lung, and gut. Evidence from songbirds and mice implicates FOXP2 expression in the brain with the production of vocalizations. In modern humans, expression of FOXP2 protein is important for the normal development of the neural circuits underlying language (Lai et al. 2001). There are two amino acid substitution differences between the FOXP2^{human} protein and the equivalent protein in chimpanzees, FOXP2^{chimp}. Researchers have speculated that these differences may be involved in the evolution

of complex language in modern humans. *See also FOXP2.*

FOXP2 An abbreviation of forkhead box P2. *FOXP2* (modern human genes are always italicized) is the shorthand for a **gene** that encodes a **transcription factor** important for the development of the brain, lung, and gut. Recent evolutionary changes in the *FOXP2* gene sequence are thought to be involved in the production of modern human **language**. Lai et al. (2001) showed that the gene had undergone a **mutation** in all of the members of a family of modern humans that were affected by the same dysfunction of orofacial movement and language. The affected family members, furthermore, showed functional and anatomical abnormalities in regions of the brain that are important in language processing, such as **Broca's area**, the striatum, and the cerebellum. When Enard et al. (2002) compared the product of the *FOXP2* gene in modern humans, the FOXP2^{human} **protein**, with the equivalent protein in chimpanzees, FOXP2^{chimp}, they found that two amino acid substitutions had occurred in the hominin clade sometime after hominins shared their most recent common ancestor with chimpanzees and bonobos, but Krause et al. (2007) showed that *Homo neanderthalensis* had the modern human-like form of *FOXP2*. Subsequently Konopka et al. (2009) showed that the “genes that are differentially regulated” by FOXP2^{human} and FOXP2^{chimp} include “some with functions critical to the development of the human central nervous system” and they claim that their study “reveals enrichment of differential FOXP2 targets with known involvement in cerebellar motor function, craniofacial formation, and cartilage and connective tissue formation” (*ibid.*, p. 217). They also comment that the “differences exhibited by humans and chimpanzees cannot be explained by differences in DNA sequence alone, and are probably due to differences in gene expression and regulation” (*ibid.*, p. 217). Congruent with this view of the differential gene regulation of FOXP2^{human}, Enard et al. (2009) showed that mice with insertion of FOXP2^{human} display differences from wild-type littermates in their vocal production, exploratory behavior, dopamine neurotransmission, and neuronal morphology in the striatum.

fractionation (L. *frangere*=to break) When small differences in mass cause pairs of **stable**

isotopes (e.g., ¹⁵N and ¹⁴N) to behave slightly differently during chemical and physical reactions, leading to different abundances of isotopes in the product and reactant or in multiple products. This is because isotopes of an atom have a different number of neutrons and thus different masses. There are two categories of fractionation: equilibrium and kinetic. Equilibrium fractionation leads to the concentration of isotopes in different components of a reversible system that is in equilibrium. The component, or phase, with relatively more of the heavy isotope is said to be “enriched” with respect to the heavy isotope and “depleted” with respect to the lighter isotope. Usually, the heavy isotope (e.g., ¹⁵N) concentrates in the component with the strongest bonds (see International Atomic Energy Agency; www.unu.edu/unupress/food2/uid05e/uid05e00.htm). Kinetic fractionation occurs when one isotope reacts more rapidly than the other in an irreversible system, or in a system in which the products are removed from the reactants before they have an opportunity to reach equilibrium. In general, the lighter isotope (e.g., ¹⁴N) reacts faster than the heavier isotope (e.g., ¹⁵N), leaving more of the heavy isotope in the reactant and more of light isotope in the product(s) (see International Atomic Energy Agency). In this case fractionation will *only* occur if the reaction does not reach completion, for if all of the reactant is turned into product there cannot be an isotopic difference between the product and the reactant. The isotopic offset, or fractionation, between two substances (a and b) is often expressed using Δ (or fractionation factor) notation (Martinez del Rio et al. 2009), where $\Delta^H X_{a-b} = \delta^H X_a - \delta^H X_b$. The Δ values are trivial to calculate and are accurate as long as the differences in δ values among tissues are small. However, Δ values become less accurate as the δ value differences among tissues increase. If the Δ values between substances are 10 or greater, it is preferable to calculate **fractionation factors** (α) and **enrichment** values (ε) instead of δ.

fractionation factor The fractionation factor (or α) provides the exact isotopic difference between a product and a reactant. The fractionation factor is similar to δ, but unlike δ it is not limited by the isotopic scale on which it is calculated (e.g., the Pee Dee Belemnite for carbon and Standard Mean Ocean Water for oxygen). The calculation for the fractionation factor, or α,

between two substances (a and b) is straightforward: $\alpha_{a-b} = (\delta^H X_a + 1000) / (\delta^H X_b + 1000)$. If the calculated fractionation factor is $>1\%$, the substance a is more enriched in the heavy isotope than substance b. Conversely, if α is $<1\%$, the substance a is less enriched (also called depleted) in the heavy isotope than substance b.

fracture and deformation biomechanics

The study of the way loads applied to a structure initiate and propagate irreversible damage (e.g., cracks). It focuses on the ways the shape and the material properties of a structure influence its response to such loads. These methods have been used to predict the ways the shape and internal structure of tooth crowns affect the ability of teeth to fracture food without themselves suffering irreversible damage (e.g., Lucas 2004, Lucas et al. 2008).

frameshift mutation A mutation within the **coding sequence** of a **gene** that involves changes other than the insertion or deletion of whole **codons** (i.e., other than multiples of three **nucleotides**). Such mutations disturb the **reading frame** of the gene and because of this they typically disrupt the **messenger RNA** (mRNA) produced by the gene, which can lead to a truncated version of the **protein** being translated, a protein with disrupted function, or no protein at all.

French-Chadian Paleanthropological Mission See Mission Paléanthropologique Franco-Tchadienne.

frontal lobe One of the four main subdivisions of the **cerebral cortex** of each **cerebral hemisphere**. It forms the anterior part of the cerebral hemisphere; the **parietal lobe** is immediately posterior to it. The most anterior point on the cerebral hemisphere, called the anterior pole, is formed by the frontal lobe. The frontal lobe is important for controlling movement and in planning and coordinating behavior. The frontal lobe contains the primary motor cortex, which lies in the **precentral gyrus** and is important for controlling voluntary movements of the body. Although neuroscientists traditionally believed that enlargement of the frontal lobe in modern humans was responsible for enhanced cognitive abilities in our species, recent studies have shown that the frontal lobe of modern humans comprises approximately the same propor-

tion of the cerebral hemisphere as in the great apes (Semendeferi et al. 2002).

frontal trigon The region, which straddles the midline between the **supraorbital tori** and the **temporal crests** or raised temporal lines. It can be either flat or hollowed and it is especially evident in some megadont archaic hominin crania (e.g., OH 5).

frugivory (L. *frug-*, *frux*=fruit, and *vorous*, from the stem of *vorare*=to devour) Literally, fruit-eating. Animals that eat fruit are frugivores. Most primates are frugivores to a greater or lesser extent. Primate frugivores may eat ripe or unripe fruits and seeds. **Hominoids** favor ripe fruits, whereas some monkeys can tolerate unripe fruits, which for them may be an important **fallback food**. Some have argued that the ability to eat unripe fruit is one important reason for the adaptive radiation of the Old World monkeys, and it may have helped them take over many of the niches previously occupied by hominoids in the late **Miocene** and **Pliocene**. Frugivory has been linked to the evolution of color vision and to the expansion of brain size through **extractive foraging** (Gibson 1986) via the need to exploit patchily distributed resources (Clutton-Brock and Harvey 1980), which may require mental maps for successful navigation (Milton 1988). In general, frugivorous primates have larger **brain** sizes and larger **home ranges** relative to body mass than do those relying on **folivory**.

FS Used in at least two senses in paleoanthropology. **Koobi Fora** In connection with **Koobi Fora**, Kenya, FS is used as the acronym for field surface. At the beginning of field research at Koobi Fora the recording system differentiated the fossils found on the surface (i.e., FS for field surface) from those found *in situ* (i.e., FI for field *in situ*). But because so few fossils were being found *in situ* the system was abandoned in favor of a single system (i.e., **KNM-ER** then the field catalogue number) that covered all the fossils that were recovered and catalogued (e.g., the cranium FS-158 became **KNM-ER 406**). **Sangiran** In connection with **Sangiran**, Java, **Ralph von Koenigswald** had given all of the isolated teeth recovered from Sangiran the prefix FS [i.e., fossils (from) Sangiran] followed by a number. Later the prefix S7 was introduced by Jacob (1975) for teeth subsequently recognized as hominin. In Jacob's scheme if teeth were recognized as hominin they carried

their FS number with them (e.g., FS 89 became S7-89). *See also* KNM-ER 406; Sangiran 7.

FS-158 *See* KNM-ER 406.

FS-210 *See* KNM-ER 407.

F_{ST} *See* *F* statistics.

Fuentenueva One of the sites of the Orce region. The latter is known for abundant faunal remains dating to the Plio-Pleistocene along with some potential stone tools. *See also* Orce region; Venta Micena.

fulcrum (L. *fulcire*=to support) A fulcrum is the point about which a lever pivots.

fulcrumate An antiquated term used by Morton (1924) to distinguish between “tarsi-fulcrumating” and “metatarsi-fulcrumating” primates. The former, exemplified by tarsiers and galagos, produce propulsion using an enlarged posterior tarsal region that acts as a lever about a fulcrum positioned anteriorly in the tarsus. Morton (1924) categorizes all anthropoids as “metatarsi-fulcrumating” primates that include the metatarsals as part of the propulsive lever. In these animals the fulcrum is positioned at the metatarso-phalangeal joints.

Fumane (Location 45°35'N, 10°54'E, Veneto, Italy; etym. after the nearby town. The site is also known as Stazione della Neve or Riparo Solinas) History and general description A rock-shelter/cave site in the Venetian pre-Alps. Excavations began in 1988 under A. Broglio and M. Cremaschi; so far, only the area at the front of the cave has been systematically excavated. Temporal span and how dated? One of the Upper Paleolithic levels, A2, was dated using radiocarbon dating to 40+4/-3 ka. Level S7, a Middle Paleolithic level, has a thermoluminescence dating age of 79±13 ka. Hominins found at site Three fragmentary hominin teeth were found, two of which are from the Middle Paleolithic levels and thus most likely belong to *Homo neanderthalensis*. Archeological evidence found at site Typical Mousterian artifacts with Levallois debitage characterize the lower occupation levels. The abundant faunal assemblage in the Mousterian levels are most likely due to hominin activity. Key references: Geology, dating, and

paleoenvironment Bartolomei et al 1992; Hominins Bartolomei et al. 1992; Archeology Fiore et al. 2004.

functional genomics The study of basic functional aspects of the genome. Functional genomics subsumes research topics such as the mechanisms of gene expression during development, gene network interactions, gene-protein interactions, and the epigenetic processes responsible for proteome production.

functional magnetic resonance imaging (or fMRI) A method commonly used to investigate brain activity in modern human subjects and occasionally in macaque monkeys. fMRI works by the external application of magnetic fields and electromagnetic pulses to manipulate the spins of atomic nuclei, inducing them to emit electromagnetic signals, which can be monitored to map the functional activity of living brains. This technique is based on the fact that changes in neural activity are accompanied by changes in regional blood flow and glucose utilization. Functional imaging maps these regional metabolic changes by tracking the different magnetic properties of oxygenated and deoxygenated hemoglobin present in the blood during regional activity.

furrow defects *See* hypoplasias.

FwJj14E (Location 4°18'44"N, 36°16'16"E, Koobi Fora, Kenya) A 1.5 Ma archeological and paleontological site within the Koobi Fora Formation in Area 1A at Ileret where hominin footprints have been discovered at two footprint surfaces vertically separated by 5 m and separated in time by c.10–20 ka (Bennett et al. 2009). The presence of animal footprints was recognized in 2005 and the first hominin footprints were exposed by excavation in 2007. In the upper footprint surface (which is less than a meter above the Ileret Tuff and about 2 m below the Northern Ileret Tuff) in addition to the prints of many nonhominin animals there are three hominin footprint trails (two trails of two footprints and one of seven footprints) plus several isolated single hominin footprints. In the lower surface (which is less than a meter above the Lower Ileret Tuff) there is one trail of two hominin footprints, plus one isolated hominin footprint. For details of their analysis and functional interpretation *see* Koobi Fora hominin footprints.

G

G-function *See* fitness-generating function.

Gadeb (Location 7°05'N, 39°21'E, Ethiopia; etym. named after the Plains of Gadeb, Ethiopia below the site) History and general description Gadeb is near the western edge of the South-East (or Somali) Plateau that borders the **Afar Rift System** near the headwaters of the Webi Shebeli River. It was initially explored in 1975–7 by international teams directed by Desmond Clark, but dam construction has since buried the excavations. Temporal span Artifacts occur within sediments of the Mio Goro Formation. Pumice at the base of the formation has a potassium-argon age estimate of 1.48 Ma and all sediments are normally magnetized, suggesting an age greater than the Brunhes-Matuyama boundary (i.e., >780 ka). An age range of *c.*1.5–0.78 Ma is supported by **tephra** correlated from the **Turkana Basin** (Silbo Tuff, Lower Nariokotome Tuff, and the Black Pumice Tuff) to stratigraphic sections near the Gadeb archeological sites, but because dam construction has buried the excavations, more precise correlation is impossible. How dated? **Potassium-argon dating**, **tephrostratigraphy**, and **magnetostratigraphy**. Hominins found at site None. Archeological evidence found at site Artifacts occur at a number of localities and stratigraphic levels in the Gadeb area have been provisionally attributed to the **Developed Oldowan** (but containing **handaxes**) and to the **Acheulean**. Analysis and publication focused on Locality 8 where more than 20,000 stone artifacts were recovered from a >115 m² excavated area. Notable are the abundant (approximately >450) handaxes and cleavers made from local **basalt** boulders and **ignimbrite** outcrops a few kilometers away, as well as a possible hippopotamus butchery site. The analysis of the recovered artifacts was conducted by H. Kurashina. Key references: Geology, dating, and paleoenvironment Eberz et al. 1988, Haileab and Brown 1994; Archeology Clark 1987, Clark and Kurashina 1979.

Gademotta (Location 8°03'N, 38°15'E, Ethiopia; etym. unknown) History and general description This artifact-bearing area on the flanks of a collapsed caldera approximately 5 km/3 miles west of Lake Ziway in the **Main Ethiopian Rift** includes the type section of the Gademotta Formation, which consists largely of **volcaniclastic** sediments and **paleosols** of approximately 40 m thickness. Gademotta and the slightly younger site of **Kulkuletti**, about 2 km/1.2 miles away, also within the Gademotta Formation, are correlated through shared **tephra**. Temporal span and how dated? **Argon-argon dating** of **sanidine** crystals in tephra and **tephrostratigraphy** suggest the Unit 10 tuff above the **Acheulean** and the oldest **Middle Stone Age** (or MSA) strata is *c.*280±8 ka and the tuffaceous Unit D that overlies it has an age estimate of *c.*180±10 ka. Hominins found at site None. Archeological evidence found at site Among the >40,000 recovered artifacts are **Levallois flakes**, **points**, **cores**, and **blades** (many of them large), unifacially and bifacially **retouched** points, as well as blades and blade cores. These are sufficient to attribute the four excavated strata from Gademotta to the MSA. Many of the points have **resharpening spalls** removed from the tip that are distinct from impact fractures; this, combined with **use wear** evidence, suggests the points may have been used for cutting and sawing rather than as projectiles. **Obsidian** from the *c.*1.3 Ma volcanics on which the Gademotta Formation sediments lie was used as the primary stone raw material and the site was likely either a **quarry**, or a near-quarry workshop. The recovered fauna are sparse and limited to hippopotamus, equid, and three varieties of bovid. The age estimates and numerous diagnostic artifact forms suggest that Gademotta is the oldest known MSA site. Key references: Geology, dating, and paleoenvironment Laury and Albritton 1975, Morgan and Renne 2008; Archeology Wendorf and Schild 1974, Schild and Wendorf 2005.

gait (ON *gata*=path) The way in which an organism (e.g., hominin, horse, etc.) uses its feet for locomotion. For example, the difference between a **bipedal** running gait and a bipedal walking gait is that in the latter one foot is in contact with the ground at all times.

GaJi10 (Location 3°44'15"N, 36°55'48"E, Koobi Fora, Kenya) A 1.43 Ma archeological site in Area 103 of the **Koobi Fora Formation**, Kenya, where a single footprint trail comprising seven hominin footprints were discovered in 1978 on a land surface (Behrensmeyer and Laporte 1981). Four of these seven footprints were recently re-excavated (Bennett et al. 2009) and an additional hominin footprint was exposed during that re-excavation. *See also Koobi Fora hominin footprints.*

Galeria (Location 42°21'09"N, 3°31'08"W, Spain; etym. karst gallery) History and general description One of the fossiliferous cave fillings in the **Sierra de Atapuerca**, a series of eroded, karstic, limestone hills 14 km/9 miles east of Burgos in northern Spain, which is permeated by sediment-filled cave systems. The largest is the Cueva Mayor-Cueva del Silo system, where the **Sima de los Huesos** is located, but just 1 km/0.6 miles away, in the Trinchera del Ferrocarril, is the Galeria (TG) site with 17 m of sediment. Excavations at Galeria, which is very close to **Gran Dolina** (TD), began in 1979. Originally the site of Galeria was included as part of a larger complex of karst infillings, taking the general name of Galeria-Tres Simas complex. Later on, the subsystem Galeria was in turn subdivided into three areas or sectors. The middle part was called Galeria *sensu stricto*, to the south is the Covacha de los Zarpazos (TZ), and to the north a vertical infilling called TN. All three sectors are connected but they apparently received distinct sources of sediments. The early terminology distinguished 12 geologic levels (TG1–12) (Aguirre et al. 1987), but these have subsequently been rationalized into six stratigraphic units, GI–VI (Carbonell et al. 1999); of these GIIa, GIIb, and GIII have produced stone tools and Middle Pleistocene faunal remains. Temporal span and how dated? Biostratigraphy, thermoluminescence, and uranium-series dating suggest the sediments range from 503±95 ka at the base of the lowermost “surface-inwash” facies to 185±26 ka at the top. Hominins found at site A mandible fragment with M₂₋₃ (AT76-TIH) was discovered in 1976 and a cranial vault fragment was found at the base of GIII

stratigraphic units. Archeological evidence found at site **Mode 2** artifacts in layers GIIa, GIIb, and GIII, plus clear evidence of butchering on many faunal remains. Key references: Geology, dating, and paleo-environment Aguirre et al. 1987, Rosas et al. 1998, Carbonell et al. 1999, Berger et al. 2008; Hominins Bermúdez de Castro 1992; Archeology Carbonell et al. 1999.

Galería del Osario *See* El Sidrón.

Galeria Musteriană *See* Baia de Fier.

Galili [Location, in the Mulu Basin, east of Gedameyto, 9°46'N, 40°33'E, Somali Region, Ethiopia; etym. the name of the site derives from Mount Galili, the hill in the center of the area (White Mountain in the language of the local nomads, the Issa). On official maps the hill is marked as Serkoma, but the locals refer to it as Galili (depending on transcription also Galila or Galilie)] History and general description The site is 30 km/18 miles to the west of the Mulu basin, and the latter is separated by several horsts from the Galili deposits. The Galili area drains not towards the Mulu, but into the Awash to the northwest. The Paleoanthropological Research Team began prospecting in the area in 2000 and they report a rich mammalian fauna including hominins from four members (Lasdannan, Dhidinley, Godifray, and Shabeley Laag) of the Mount Galili Formation. Two other members higher in the section (Dhagax and Caashacaado) have so far not yielded any fossil evidence except a bovid phalange from the Caashacaado Member; the total thickness of the deposits is probably close to 200 m. Temporal span and how dated? Biostratigraphic evidence suggests the fossil mammals are equivalent to those from the Kanapoi Formation, the uppermost part of the Apak Member at Lothagam, and the lower parts of the Kaiyumung Member of the Nachukui Formation (Kullmer et al. 2008, p. 461). Unpublished argon-argon ages suggest that the sediments at Galili date from *c.*5 Ma to *c.*3.4 in the lower (fossiliferous) part. Hominins found at site “Six hominid teeth and a proximal femur fragment” (Kullmer et al. 2008, p. 452), plus a distal humerus, a metatarsal, and four additional teeth; some of the possible hominin fossils are >4.4 Ma. Archeological evidence found at site The archeological evidence all postdates the deposits. The few handaxes recovered are from recent alluvium, and the **Middle Stone Age** and later lithic scatters are all on the surface; none of it is *in situ*. Key

references: Geology, dating, and paleoenvironment Kullmer et al. 2008; Hominins Macchiarelli et al. 2004b; Archeology N/A.

gallery forest (*L. galeria*=covering, as in the covering, or portico, over a door) Forests running alongside rivers or bordering wetlands. These strips of evergreen forest survive in environments that otherwise may have little forest, or even woodland, because of (a) the greater fertility of soils around rivers and wetlands, (b) the reliability of the water supply, and (c) the protection provided from natural fires by rivers and wetlands. Part of the woodland and/or grassland biome, these forest ecosystems border rivers and wetlands and although occasionally or seasonally flooded by river waters, they are dry for most of the growing season. The alluvial soils of these forests are high in nutrients and have better drainage than adjacent woodland and grassland ecosystems, thus hosting unique flora and fauna that are not present in drier forest types. A key characteristic is that they project into biomes such as woodland, grasslands, or deserts; the boundary between gallery forests and the surrounding woodland or grassland is usually abrupt. Gallery forests are important for primate biodiversity as they allow arboreal primates to survive in regions that would otherwise be suitable only for open-habitat adapted animals. Most early **hominins** were associated with tropical woodlands, but it is also likely that some (particularly those in the **Miocene** and **Pliocene**) existed in areas that contained tropical, and possibly gallery, forest. However, tropical forest is seen as a less favorable habitat for hominins than woodland because of the inaccessibility of fruits in the higher canopy and the cryptic nature of forest animals.

Galley Hill *See* fluorine dating.

Gamedah One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area**, Ethiopia.

gamete (Gk *gamos*=marriage) A reproductive or germ cell with a **haploid** (i.e., they only have one copy of each **chromosome**) complement of chromosomes. The gametes (i.e., the egg and sperm) pass genetic information from one generation to the next. All the other cells in the body are **diploid** (i.e., they have two copies of each chromosome) and are called **somatic cells**. *See also* germline.

gametic phase The term refers to combinations of **alleles** at different **loci** linked together on the same **chromosome**.

gamma taxonomy (Gk *gamma*=the third letter in the Greek alphabet and *taxis*=to arrange or "put in order") It is common for reference to be made to **alpha taxonomy**, but you very seldom read, or hear, any reference to "**beta**" or "**gamma taxonomy**." Mayr et al. (1953) is one of the few sources that define these terms [e.g., they do not appear in the index of Simpson's (1961) *Principles of Animal Taxonomy*]. Mayr et al. (1953) suggest that "the taxonomy of a given group, therefore, passes through several stages...informally referred to as alpha, beta, and gamma taxonomy" (*ibid*, p. 19). The distinction made by Mayr et al. is that whereas alpha taxonomy results in species being "characterized and named" and beta taxonomy refers to phylogenetic reconstruction, gamma taxonomy refers to the "analysis of intraspecific variation and to evolutionary studies" (*ibid*, p. 19). But Mayr et al. (1953) caution that it is "quite impossible to delimit alpha, beta and gamma taxonomy sharply from one another, since they overlap and intergrade" (*ibid*, p. 19). *See also* systematics; taxonomy.

Gánovce (Location 49°10'N, 20°18'E, Slovakia, etym. named after a local town) History and general description The site is in a travertine quarry 3 km/1.8 miles southeast of Poprad below the High Tatra Mountains. The first finds, including the hominin remains, were reported in 1926 and excavations were conducted in 1955. Temporal span **Oxygen Isotope Stage 5e**. How dated? **Uranium-series** dates on travertine (130, 105, and 84 ka years BP); **biostratigraphy**. Hominins found at site A natural endocast, cranial fragments, and natural molds of postcranial fragments attributed to *Homo neanderthalensis*. Archeological evidence found at site Artifacts described as Taubachian (**Mousterian**). Geology, dating, and paleoenvironment Hausmann and Brunacker 1986; Hominins Vlček 1955, Smith 1982; Archeology Vlček 1969.

Garrod, Dorothy Annie Elizabeth (1892–1968) Dorothy Garrod was born in London, England, and in 1913 was admitted to Newnham College, University of Cambridge, to study history. After graduating in 1916, Garrod joined the war effort, serving in the Catholic Women's League in France from 1917 to 1919 taking care of wounded soldiers. In 1919 she joined her father in Malta and he suggested that Garrod explore Malta's prehistoric ruins, a recommendation that sparked her interest in archeology. Garrod returned to England and enrolled in classes at the University of Oxford in 1921 to study anthropology with Robert R. Marett, who had excavated at the Paleolithic site of La Cotte de St. Brelade in France. Given Garrod's interest in prehistoric archeology, Marett suggested that she go to France to work with the eminent French prehistorian Abbé Henri Breuil. Garrod arrived in Paris in 1922 and studied with Breuil at the **Institut de Paléontologie Humaine** (Institute of Human Paleontology) until 1924. While in France, Garrod participated in excavations at the Paleolithic site of **La Quina** with Henri Martin and also worked at Les Eyzies. During this period Garrod also met George Grant MacCurdy, who taught anthropology and archeology at Yale University and who had just become the director of the newly founded American School of Prehistoric Research. With Breuil's encouragement, Garrod began working on a book that would synthesize what was known about the late Paleolithic in Britain. The book, *The Upper Paleolithic in Britain* (1926), earned Garrod an undergraduate degree from the University of Oxford. Breuil also arranged for Garrod to excavate a site in Gibraltar called the **Devil's Tower**. Excavations began in 1925 and soon Garrod found **Mousterian** tools and skull fragments belonging to a *Homo neanderthalensis* child. While Garrod was excavating Neanderthal remains in Gibraltar, fossil hominins were being unearthed by Francis Turville-Petre of the British School of Archeology in Jerusalem at Zettuphe cave in what was then Palestine. This discovery prompted George Grant MacCurdy to plan a joint Anglo-American archeological expedition to the region to be led by Garrod. Garrod arrived in Palestine in 1928 and began excavating at the cave of Skukbah where she discovered Levallois-Mousterian tools and a more recent Mesolithic tool type that she called **Natufian**. Also in 1928 Garrod was elected president of the Prehistoric

Society of East Anglia and in her presidential address entitled "*Nova et Vetera: a plea for a new method in Paleolithic archaeology*" she argued for a more phylogenetic approach in archeology that would focus on the inter-relationship of **Paleolithic** cultures globally which then would result in the construction of family trees showing how different cultures and archeological industries influenced each other. This would replace the more geological stratigraphic and primarily European approach developed by the French prehistorian Gabriel de Mortillet. Garrod began excavations at **Mount Carmel** in Palestine in 1929 and soon found Natufian-type tools and human remains. Her careful excavations of several caves at the site, including the **Tabun** and **Skhul** caves, allowed her to work out a stratigraphy of tool types ranging from the Mousterian to the Bronze Age that spanned about 600 ka of human prehistory. In 1932, while Garrod was away in Britain, the American paleontologist Theodore McCown discovered the remains of several burials in the Skhul cave. By the time excavations ended at Mount Carmel in 1934 Garrod and her team had recovered a substantial quantity of tools, animal fossils, and Neanderthal remains that provided a remarkably clear picture of the Paleolithic in Palestine. It was also clear that the stratigraphic sequence of Paleolithic cultures and industries originally developed from excavations in Europe did not correspond to the sequence discovered in western Asia. Some of the discoveries indicated that certain industries emerged in Asia earlier than they appeared in Europe and may have been introduced into Europe from western Asia. Garrod published the results of her research in Palestine in *The Stone Age of Mount Carmel* (1937). In recognition of this achievement Garrod was granted a doctorate by the University of Oxford. Garrod accepted the position of Disney Professor of Archaeology at the University of Cambridge in 1939, but the outbreak of WWII put an end to any prospects of continuing excavations in Palestine. In addition to her teaching, Garrod also served in the Women's Auxiliary Air Force from 1942 to 1945, interpreting aerial photographs of bomb damage. Garrod established anthropology and archeology as full-degree courses at Cambridge during her tenure and at the end of the war she returned to France to conduct excavations at **Fontéchevade** with Germaine Henri-Martin and at Angles-sur-l'Anglin with Suzanne de St. Mathurin. Garrod retired from teaching in 1952

and in 1954 she returned to western Asia to continue the research that had been interrupted by the war. Between 1958 and 1962 she excavated sites in Lebanon and she worked out the sequence of cultures and tool industries for the region, comparing them with the sequence established at Mount Carmel and correlating these with the corresponding sequences of prehistoric Europe. In addition to making significant contributions to prehistoric archeology, Garrod mentored a generation of women archeologists and strengthened the teaching of archeology at Cambridge. In 1968, shortly before her death, Garrod was awarded the Gold Medal of the Society of Antiquaries.

Garusi The name used by Ludwig Kohl-Larsen for the site now known as Laetoli. *See* **Laetoli**.

Garusi 1 Site **Laetoli**. Locality There are photos of the find spot of this early hominin maxilla as well as a map showing its approximate location (Protsch 1981) but it is not possible to relate these to the specific localities currently known at Laetoli. The Garusi 1 maxilla was recovered from sediments exposed at the head of the Garusi River Valley and the preservation of the fossil matches fossils recovered from the Upper Laetoli Beds. Surface/*in situ* Surface. Date of discovery February 8, 1939. Finders Members of the Kohl-Larsen Expedition. Unit N/A. Horizon N/A. Bed/member Laetoli Beds. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Given the preservation similarity noted above Garusi 1 is likely to have come from a horizon that is *c.* 3.7–3.59 Ma. Developmental age Adult. Presumed sex Unknown. Brief anatomical description A piece of the right maxillary bone extending from the midline to the distal aspect of the right P⁴. The crowns and roots of the P³ and P⁴ are preserved, but the alveoli are all that remain of the incisors and canine. The specimen preserves the junction of the floor and the right lateral margin of the nasal aperture. Announcement Weinert 1950. Initial description Weinert 1950. Photographs/line drawings and metrical data Weinert 1950, Puech et al. 1986. Detailed anatomical description N/A. Initial taxonomic allocation *Meganthropus africanus*. Taxonomic revisions *Praeanthropus afarensis* Strait et al. 1997. Current conventional taxonomic allocation *Australopithecus afarensis*. Informal taxonomic category Archaic hominin. Significance The Garusi 1 maxilla was an important part of

the evidence that led Johanson et al. (1978) to link the hominins from **Hadar** and **Laetoli** and to combine them into a single hypodigm as *Au. afarensis*. Location of original National Museum and House of Culture, Dar es Salaam.

Garusi Hominid 1 *See* **Garusi 1**.

Garusi River Series *See* **Laetoli**.

gas chromatography isotope ratio mass spectrometry Gas chromatography-coupled isotope ratio mass spectrometry (or GC-IRMS) uses a continuous flow of carrier gas over a solid surface with an absorptive coating to separate compounds by molecular weight and these compounds are supplied to the mass spectrometer. In this way the isotopic composition of individual compounds can be analyzed. This is important since different compound classes may have very different isotopic compositions as a result of differences in synthesis pathways, making the compound-specific isotopic analysis an advance over bulk isotopic analyses. Compounds can be combusted (for **carbon isotope analysis**) or pyrolyzed (for **hydrogen isotope analysis**) and supplied via continuous flow to the mass spectrometer for determination of isotope ratios of each sequentially eluting compound. This system can be used for stable isotope measurements on semi-volatile compounds (e.g., plant leaf waxes). *See also* C₃ and C₄; stable isotopes.

GATC Abbreviation for Gåala Tuff Complex. *See* **Aramis**.

Gause's Rule Also known as the principle of competitive exclusion, this states that two species cannot stably occupy an identical niche within the same ecosystem. *See also* competitive exclusion; niche.

Gauss chron *See* geomagnetic polarity time scale.

Gaussian distribution *See* normal distribution.

gazelle (Ar. *ghazal*=hoofed animals belonging to the genus *Gazella*) *See* **Antilopini**.

GB Abbreviation of the Galana Boi Formation, Turkana Basin, Kenya. *See* **Galana Boi Formation**.

GBY Acronym for **Gesher Benot Ya'akov** (*which see*).

GCM Acronym for **general circulation model** (*which see*).

Geißenklösterle (Location 48°23'53"N, 9°46'17"E, Germany; etym. Ge. *Geißen*=women, *klöster*=cloister) History and general description This cave site near Blaubeuren, in the Schwabian Jura, Baden-Württemberg, was first investigated in 1957 by G. Riek and from 1973 onwards excavated by J. Hahn, and, after his death, by Nicholas Conard and Hans-Peter Uerpmann. It is one of the most important **Aurignacian** sites in Europe, particularly for the evidence of art and symbolic behavior. Temporal span and how dated? The site ranges from the **Middle to Upper Paleolithic**. **Radiocarbon dating and electron spin resonance spectroscopy dating** have provided dates of *c.*40–29 ka for the Aurignacian deposits. Hominins found at site An unpublished deciduous tooth from the Aurignacian, and two deciduous teeth from the Gravettian deposit. Archeological evidence found at site The site contains Middle Paleolithic, Aurignacian, and Gravettian lithic industries. The Aurignacian is best known for its abundant ivory figurines and ivory and bone flutes, and for evidence of pigment use on the walls, which is otherwise rare in Germany. Key references: Geology, dating, and paleoenvironment Conard and Bolus 2008, Street et al. 2006; Archeology Hahn 1986; Hominins Street et al. 2006.

gel electrophoresis *See* electrophoresis.

gen. et sp. indet. (etym. *gen. et sp. indet.* is an abbreviation of “indeterminate genus and species”) When dealing with fragmentary specimens it is sometimes possible to identify the **higher taxon** a specimen belongs to, but it may not be possible to be sure what genus, and therefore, also what species it belongs to. In that case the taxonomic allocation researchers should use is *gen. et sp. indet.* (e.g., although some researchers are confident assigning the associated skeleton **KNM-ER 1500** to *Paranthropus boisei*, others are more cautious and refer it to **Hominidae** *gen. et sp. indet.*)

gene (Gk *genes*=to be born) A gene is a region of **DNA** that contains information for both the protein or RNA product it encodes and for regulating

the expression of messenger RNA. Thus, a gene includes both coding and non-coding DNA. The structure of a gene typically includes a **promoter** region. This is usually upstream (at the 5' end) of the gene sequence and it is where **transcription** is initiated and regulated. Most genes also have multiple **exons** and **introns**. Over evolutionary history genes (or parts of genes) can be highly conserved (i.e., they are resistant to change because they are subject to strong **purifying selection**) if change is highly detrimental or they may be less conserved if some change is compatible with preservation of protein function. Genes that have been subject to **directional selection** (e.g., *FOXP2*, which encodes a transcription factor linked to phenotypes of speech and language) have been used to reconstruct adaptive changes in the hominin clade. Gene regions, such as introns or third positions of codons, that are less conserved may effectively evolve neutrally and thus can be used to reconstruct population history. *See also* **neutral theory of molecular evolution**.

gene conversion The process whereby one copy of a **gene** is converted or changed such that it is identical to a **homologous** gene (either the **allele** of the same gene on the homologous chromosome or another gene from the same multigene family). This can occur during meiosis or mitosis as a result of the mismatch repair that occurs during **recombination**.

gene duplication If a **gene** is duplicated and if the additional copy of the gene is not selected against (for example, because of changes in the amount of protein produced), it may be free to mutate and that mutation may result in a change in function. This is one way many novel genes are created over deep evolutionary time. For example, the alpha and beta globin genes evolved via gene duplication from a myoglobin-like gene. Genes may also be duplicated because they are located in regions of the genome that are subject to **copy number variation**. For example, the salivary amylase gene, *AMY1*, which produces the enzyme responsible for starch hydrolysis in the mouth, has been duplicated such that five to seven copies are present on average in modern humans while only two copies are present in chimpanzees (Perry et al. 2007). It has been suggested that this is because modern humans, particularly agricultural populations, typically have diets that are high in starch,

while this is not usually the case with chimpanzees. *See also* **duplication**.

gene expression The process whereby the information encoded by a **gene** is used to make a gene product (e.g., a protein or one of the many kinds of RNA). Gene expression can be regulated in many ways including by **enhancers** and repressors as well as at different stages of **transcription** and **translation**. Gene expression may change during development, it may differ among the tissues of the body, and it may change according to environmental influences.

gene family A group of related (i.e., paralogous) **genes** that arose over time via **gene duplication** and thus are descended from a common ancestral gene. Members of the same gene family often have similar functions. For example, all the genes in the **globin** and **HOX gene** families are genes involved, respectively, in heme transport and development. A gene family may also be referred to as a multigene family.

gene flow The movement of alleles of genes from one population to another. Along with **genetic drift**, **mutation**, and **natural selection**, gene flow (also known as gene migration) is one of the four forces of evolution. High levels of gene flow cause two populations to become more similar (i.e., it decreases the **genetic distance** between them). In modern humans, culture, language, and geography are factors that may restrict gene flow. Gene flow can result when substantial numbers of people simultaneously migrate from one area to another in a single event or it can result when there are many episodes of smaller numbers of people moving from one place to another.

gene genealogy *See* **coalescent**.

gene networks Gene networks or gene regulatory networks are sets of genes that interact (usually via their products) to perform some physiological or developmental function. This is one of the core concepts of systems biology. The impetus behind the concept is that gene function can only be understood within the context of the larger system within which it operates.

gene pool The gene pool of a population consists of all the **alleles** present in that population.

gene tree A diagram that depicts the phylogenetic relationships among alleles or between homologues of the same gene. For example, Retief et al. (1993) analyzed the phylogenetic relationships of the protamine P1 gene in primates and found that the **chimpanzee** and **gorilla** protamine P1 genes are more closely related to each other than either is to modern humans or the orangutan. Note that one gene tree, such as that for protamine P1, can differ from the gene tree of another gene or from the structure of a multigene tree or from the species tree. Other gene trees, as well as phylogenies based on many genes, are consistent with the hypothesis that chimpanzees and modern humans are more closely related to each other than to any other taxon (Ruvolo 1997, Kumar and Hedges 1998).

general circulation model (or GCM) A type of climate model in which the initial and the external conditions (i.e., **insolation**, **sea surface temperature**, etc.) are set and then the model is run until it has reached equilibrium with the external **forcings** that influence it. An example of a GCM equilibrium experiment is the paired experiments for 105 ka BP run with the University of Victoria (UVic) Earth System Model to test the sensitivity of African climate to cooling and circulation changes in the North Atlantic as a result of freshwater inputs during **ice rafting** (sometimes called ice discharge) events known as **Heinrich events** (Carto et al. 2009).

generalist *See* **eurytopy**.

generation length The generation length, often symbolized as g or T , is the number of years that it takes a nonstationary population to grow or decline in size the amount given by the intrinsic rate of increase (r). The generation length is related to the **net reproductive rate** (or NRR), being $T = \frac{\ln(NRR)}{r}$. The generation length is difficult to estimate and is undefined when the population is stationary (i.e., the growth rate is zero). As a consequence, the mean age at childbearing is often used in place of generation length. For modern humans the mean age at childbearing (and hence the generation length) is around 25–7 years.

generation time The average interval between the birth of an individual and the birth of their offspring, or the average age of mothers giving birth in a given population.

genetic assimilation *See* canalization.

genetic bottleneck *See* bottleneck.

genetic code The genetic code is a three-nucleotide system (in DNA and RNA) that encodes genetic information. Each sequence of three nucleotides (also referred to as a **triplet codon**) defines either an **amino acid** or a punctuation message [i.e., the beginning or end of a messenger RNA (or mRNA) or protein sequence] for the processes of **translation** and **transcription**. Examples of DNA codons are AAA and AAG for phenylalanine (UUU and UUC are the corresponding mRNA codons) and ACC for tryptophan (UGG is the corresponding mRNA codon). Since there are four nucleotides, there are 64 possible three-nucleotide sequences. However, there are only 20 commonly occurring amino acids and thus the genetic code is redundant with many amino acids such as serine and leucine (as well as the "stop" punctuation) encoded by several different codons. The code used in the modern human genome is commonly referred to as the standard or universal genetic code and is shared among most organisms, but the genetic code can vary (e.g., the mitochondrial genome differs very slightly from the universal code and the mitochondrial code in mammals differs slightly from that in *Drosophila*).

genetic correlation A value that indicates how much of the genetic influence on two traits is common to both. Different traits in the same organism (e.g., length and mass) are often correlated. Typically, such correlations (also called phenotypic correlations) have genetic and environmental components. Genetic correlation is reflected in the proportion of variance that two traits share due to genetic causes (i.e., pleiotropy and gametic phase disequilibrium between genes affecting different traits). If the genetic correlation is greater than zero, this suggests the two traits are influenced by common genes.

genetic distance A statistical measure of the relationships among DNA sequences, protein sequences, or other genetic materials. Genetic distances can be then used to construct a phylogeny or other visual depiction of the relationships between **alleles**, **species**, or **populations**. The relationships among the DNA sequences, protein sequences, or populations determine genetic distance, but there are circumstances in which two

different sets of relationships can result in the same genetic distance.

genetic drift A random change in gene frequencies between generations. It occurs because the gametes produced by each parent contain a haploid genome that is a random assortment of chromosomes (i.e., for each type of chromosome an individual receives only one of the two chromosomes of that type within each parent). Genetic drift can also occur because of the **founder effect**. Genetic drift is more likely to be a significant factor in small populations because they have a smaller **effective population size** and it may have played an important role in shaping the diversity of past hominin populations (Ackermann and Cheverud 2004, Weaver et al. 2007). Along with **gene flow**, **mutation**, and **natural selection**, genetic drift is one of the four forces of evolution (syn. random drift, drift).

genetic hitchhiking *See* selective sweep.

genetic load A measure between 1 and 0 of the cost to the population of lost **alleles** due to **mutation** or **selection** (i.e., deaths due to deleterious alleles). It is the relative difference between the fitness of the "most fit" genotype and the mean population fitness for all the genotypes at that locus. If all the alleles in the population are of optimal fitness, then the genetic load is 0.

genetic map A map of the genome generated using a set of markers. The distance between markers is calculated not by the physical distance (that would generate a physical map) but by observing the number of **recombination** events that occur between them. For example, if two markers on the same chromosome are typically separated after each meiosis they are likely located on opposite ends of the chromosome, whereas two markers that are tightly linked (i.e., typically inherited together) are likely to be close to each other on the same chromosome. The distance between markers in a genetic map is measured in centimorgans. One centimorgan equals the distance between markers in which there is a 1% recombination frequency (i.e., one recombination event per 100 meioses). *See also* linkage.

genetic variation The genetic diversity present in a species. Genetic variation is created

through **mutation** and it is affected by **genetic drift**, **natural selection**, and **gene flow**. Patterns of genetic variation can thus inform researchers about the relative importance of these forces of evolution. They can also be used to infer demographic features of a species or population such as its **effective population size**, whether the population is expanding, stable or contracting, or hybridization patterns.

genome The complete DNA sequence of an organism. Traditionally the term genome is used to refer to the complete set of **chromosomes** in a **gamete** (i.e., one set of chromosomes) so somatic cells in primates, which have two sets of chromosomes, have a **diploid** genome. Organelles such as mitochondria have their own DNA complement that can also be called a genome (e.g., the **mitochondrial genome**).

genomic imprinting In **diploid** organisms, whether a gene is expressed or not depends on the parent from whom the individual inherited that gene's **allele**. So, for some genes, **gene expression** only occurs from the allele inherited from the mother (or vice versa). Genetic imprinting occurs in the **germline** cells (typically through methylation), and it determines for any particular allele whether it is the allele inherited from the mother or the one inherited from the father that is expressed in the offspring. Genomic imprinting is present in all marsupial and placental mammals. Hypotheses to explain its origins include the "parental conflict hypothesis," which states that differences in expression are related to an evolutionary conflict of interest between males and females over the growth of the fetus versus the conservation of resources by the mother for herself and for other offspring, and the "protection against foreign DNA hypothesis" which is that imprinting evolved to silence foreign DNA elements. In modern humans genomic imprinting explains why children with deletions in one region of chromosome 15 have different syndromes depending on which copy is deleted. Children who are missing the copy that is paternally imprinted have Prader-Willi syndrome while those without the maternally imprinted copy have Angelman syndrome.

genomics (Gk *genes*=to be born and *nomos*=to manage) An umbrella term that subsumes all of the activities involved in the study of the **genome** (e.g., mapping, sequencing, etc).

genotype (Gk *genes*=to be born and L. *typus*=form) The genetic composition of an organism (as opposed to its physical appearance or **phenotype**). The term is also used for the combination of allelic states of a locus (or of a set of loci) on a pair of homologous chromosomes. So, for example, a person with type A blood could have the genotype AO or AA for the ABO locus on chromosome 9.

genotype–environment interaction A technical term used in **quantitative genetics** to refer to the phenotypic effect of the interaction of variation in genotypes with variation in the environment (i.e., $G \times E$). This term encapsulates the consensus view that variation in traits is caused not by variation in genotype or by variation in the environment, but is rather the result of interactions between the two. The interactions between the genotype and the environment occur both prenatally (through the *in utero* environment) and in postnatal life. Phenylketonuria (PKU) is an example of such an interaction in modern humans. This metabolic disorder impairs proper breakdown of the amino acid phenylalanine and results in phenotypic effects such as mental retardation. However, avoidance of dietary items containing phenylalanine can prevent many of the major effects of this genetic condition.

genu valgum *See* valgus.

genus (Gk *genos*=race or stock) The next to lowest category in the original classificatory system introduced by Linnaeus in 1740. The most common contemporary understanding of a genus is the evolutionary systematic interpretation associated with Ernst Mayr. Mayr (1950, p. 110) suggested "a genus consists of one species, or a group of species of common ancestry, which differ in a pronounced manner from other groups of species and are separated from them by a decided morphological gap." He went on to state that the genus "has a very distinct biological meaning. Species that are united in a given genus occupy an ecological situation which is different from that occupied by the species of another genus, or, to use the terminology of Sewall Wright, they occupy a different adaptive plateau" (*ibid*). Thus, according to Mayr, a genus is as a group of **species of common ancestry** that is adaptively both homogeneous and distinctive. Mayr et al. (1953, p. 50) acknowledged the phylogenetic and functional

evidence may be in conflict if “unrelated species acquire a superficial similarity owing to parallel adaptations to similar environments” and in such cases they recommended that the phylogenetic evidence should be given precedence. However, it is implicit in Mayr’s (1950) definition that “common ancestry” subsumes both **monophyletic groups** and **paraphyletic groups**. It is one of the unfortunate aspects of taxonomy that except for the category species there are no objective criteria for taxonomic ranking. Goodman et al. (1998) suggested a time-depth criterion and proposed that a genus should be at least 4 million years old, but this idea has not attracted adherents. Wood and Collard (1999) proposed that a genus should be defined as a species or monophylum whose members occupy a single **adaptive zone**. It differs from Mayr’s (1950) concept in that it excludes paraphyletic taxa. It also differs from Mayr’s (1950) concept in that it does not require the adaptive zone to be unique or distinct (*contra* Leakey et al. 2001 and Cela-Conde and Altaba 2002). Rather, it simply requires the adaptive zone to be consistent and coherent across the species in the putative genus. Wood and Collard’s (1999) suggested definition allows for the possibility that species assigned to different genera may occupy the same adaptive zone, but it precludes species in the same genus from occupying different adaptive zones. Wood and Collard (1999) suggested two criteria for assessing whether or not a group of species has been correctly assigned to a genus. First, the species should belong to the same monophyletic group as the type species of that genus. Second, the adaptive strategy of the species should be closer to the adaptive strategy of the type species of the genus in which it is included than it is the type species of any other genus.

geochronologic units (Gk *geo*=earth and *kronos*=time) Intervals of time in Earth history. The geologic time scale has a dualistic character in which intervals of time share terms with the sequence of rock (strata) deposited in that interval. Geochronologic units are time-referenced and thus subdivisions are temporal (e.g., Early, Middle, and Late), whereas their rock equivalents are **chronostratigraphic units**, and their relative subdivisions are physically sequential (e.g., Lower, Middle, and Upper). In the hierarchy of terminology for the geologic time scale, geochronologic units are (from larger to smaller) eons, eras, periods, **epochs** and

ages (e.g., *Australopithecus afarensis* fossils from Laetoli date to the **Pliocene** epoch).

geochronology (Gk *geo*=earth and *kronos*=time) The umbrella term used for methods that can provide ages for rock layers or fossils. Traditionally, dating methods have been divided into two categories, relative and absolute. **Relative dating** methods date a horizon by finding similar horizons elsewhere that are part of an ordered and independently calibrated sequence. For example, the same fossil taxa preserved in the horizon being investigated and in the reference horizon, or the same sequence of magnetic reversals. **Absolute dating** methods are dating methods that use physical and chemical “clocks” that measure the passage of time in years (e.g., **potassium-argon** and **radiocarbon dating** methods). Colman and Pierce (2000) suggested that geochronological methods be divided up on the basis of the nature of the method and how the results of those methods are expressed. What follows is an adaptation of their terminology. Methods (a) **Sidereal dating** is based on counting annual events (e.g., dendrochronology); (b) **isotopic dating** measures changes in the absolute amounts or ratios of isotopes (e.g., **argon-argon dating**, radiocarbon, etc.); (c) **radiogenic dating** relies on measuring the effects of radioactive decay (e.g., **electron spin resonance spectroscopy dating**, **fission track dating**, etc.); (d) chemical and biological dating methods rely on measuring the progress of time-dependent processes (e.g., amino acid racemization); (e) **geomorphic dating** relies on processes that affect the landscape (e.g., sedimentation rates); (f) **correlation** relies on relationships established using differences that are themselves time-independent (e.g., **biostratigraphy**, **magnetostratigraphy**, **stratigraphy**, **tephrochronology**). Results Numerical-age methods provide an age in years (syn. absolute dating methods), and the term refers to methods a–c listed above; calibrated-age methods provide an approximation of the real age and the term refers to methods d and e listed above; **relative dating** provides an age via establishing links between the site in question and an age sequence established elsewhere, and refers to methods d and e listed above; correlated-age methods provide an age by relating the fossil or horizon to another independently dated sequence, and refers to methods in section f listed above.

geocline *See* **cline**.

Geological Survey of India (or GSI) An organization that undertakes the recovery of paleontological, including paleoanthropological, evidence within India and which is also a repository for fossils.

geological time An expression usually referring to long stretches of time, often on the order of many thousands or even millions of years across which evolution occurs. These long periods are "geological" in the sense that they are long enough to be detectable in the geological record.

geomagnetic anomaly (Gk *geo*=earth, *magnes*=magnet, and *anomalos*=uneven) A boundary between two prolonged periods during which the direction of the Earth's magnetic field has been consistent. These boundaries, or magnetozones, are between what were previously referred to as epochs and events, but contemporary geomagnetic columns now use numbered chrons and subchrons. Because the direction of the Earth's magnetic field reverses at these boundaries or anomalies, they are also known as **polarity reversals** or field reversals (syn. anomaly).

geomagnetic dating (Gk *geo*=earth and *magnes*=magnet) See **paleomagnetic dating**.

geomagnetic polarity time scale (or GPTS) Time scale based on past changes in the direction of the Earth's magnetic field. The liquid core of the Earth can be likened to a dipole magnet that generates a geomagnetic field. In the present day a magnetized needle will point to the North Pole (this is what we call the **normal** direction). However, at the beginning of the 20thC Bernard Bruhnes (1867–1910) showed that when a magnetized needle was placed in the magnetic field preserved by iron oxide in some older lavas the needle pointed to the South Pole (the **reversed** direction). Motonori Matuyama (1884–1958) demonstrated that the Earth's magnetic field had been reversed as recently as the early **Quaternary**. Scientists were initially unsure whether the lavas had been laid down during a global magnetic reversal ("field reversal"), or whether they had subsequently reversed their primary normal magnetism ("self reversal"). However, when **potassium-argon dating** began to be applied to the reversed rocks (Rutten 1959) it became clear that "field reversal" was a reality. The first published land-based paleomagnetic timescale was relatively

crude (Cox et al. 1963) but within a short time the basic structure of the GPTS (i.e., long periods of either normal or reversed magnetism, then called **epochs**, punctuated by shorter periods of the opposite magnetic direction, then called **events**) was established (Cox et al. 1964). Researchers then began the process of integrating the land-based record with magnetic anomalies detected in the ocean floor, and the fit was a good one (Vine 1966). By the late 1960s a geomagnetic reversal time scale was established with four epochs named after pioneer physicists (i.e., listed in order starting with the most recent: Brunhes, Matuyama, Gauss, and Gilbert) and events named according to the locations where they were first identified (e.g., Jaramillo, Cobb Mountain, Olduvai) (Cox 1969). Confusingly, any change of magnetic direction, either from normal to reversed or from reversed to normal, is referred to as a "reversal" of the geomagnetic field. The latest version of the GPTS has dropped the eponymous terminology (but see below) in favor of a numerical sequence adapted from the scheme used by scientists studying the magnetic anomalies associated with spreading from ridges in the deep sea floor. Epochs have been replaced by numbered **chrons** and events by **subchrons**. The most recent chron is 1 with the numbers increasing going back in time. A letter postfix is used to identify chrons that have been added since the scheme was adopted (e.g., 3A). A chron can have both normal and reversed components identified by lower case n or r (e.g., 3An and 3Ar). Subchrons within a chron are also numbered and their magnetic direction is identified using the same abbreviation system (e.g., the first reversed subchron in 3An is 3An.1r). The precision of the GPTS has been substantially increased by matching changes in geomagnetism with the increasingly detailed record of oscillations in the ¹⁶O/¹⁸O record. This in turn takes advantage of the correlations possible between such continuous geological records and the predicted ages derived from calculations using the known frequencies of the Earth's orbital components (eccentricity of the Earth's orbit, tilt, and precession of the Earth's axis), enabling the ages of geological transitions to be tuned to the astronomical signal; this is referred to as **orbital tuning**. Geomagnetic data are not by themselves sufficient evidence to provide ages for strata containing fossils. One of the other dating methods is needed to provide an absolute date so that the sequence of changes in magnetic direction in the sedimentary sequence can

be matched with the GPTS. When this is done the detailed sequence of magnetic reversals preserved in a section of sediments can then be used to date fossiliferous strata within it. The GPTSs change as the evidence they are based on is refined, with each scale having a title made up of the first letters of the author's names followed by the year of publication (e.g., HDHPL68, CK92). Initially they were based on assumptions about rates of seafloor spreading, but latterly astronomical, isotopic, and other evidence has been utilized to calibrate the timing and duration of the changes in the direction of the Earth's magnetic field. One of the first events to be recognized was a brief episode of normal magnetic direction at *c.*1.9 Ma within the Matuyama reversed epoch identified in the basalt underlying the fossiliferous sediments at **Olduvai Gorge**, Tanzania (Grommé and Hay 1963), and this was the first example of geomagnetic data being used to help date a hominin fossil site. It used to be called the **Olduvai event**, but it is now called the **Olduvai subchron**. The Cenozoic epoch boundaries are now tied to the GPTS chron system. The Cretaceous/Paleocene boundary lies in chron C29 at 65.5 Ma, Paleocene/Eocene in chron C24 at 55.8 Ma, Eocene/Oligocene in chron C13 at 33.9 Ma, Oligocene/Miocene in chron C6C at 23.0 Ma, Miocene/Pliocene in chron C3 at 5.3 Ma, and the Pliocene/Pleistocene either in chron C2 at 2.6 Ma or at the chron C2/chron C1 boundary at 1.8 Ma. *See also* **geomagnetic dating** (syn. magnetic anomaly time scale, magnetic polarity timescale, **magnetostratigraphy**).

geomagnetic reversal time scale *See* **geomagnetic polarity time scale**.

geometric mean A method for calculating the average of a set of numbers, it differs from the more commonly known **arithmetic mean** as follows. Rather than summing *n* values and dividing by *n*, the geometric mean calculates the product of *n* values then takes the *n*th root of the result. For example, the geometric mean of X_1 , X_2 , X_3 , and X_4 is $(X_1 \times X_2 \times X_3 \times X_4)^{1/4}$. The geometric mean may also be calculated as the antilog of the arithmetic mean of logged values; thus the geometric of the four measurements above could also be calculated as $e^{(\ln X_1 + \ln X_2 + \ln X_3 + \ln X_4)/4}$. The geometric mean of a set of values is always less than or equal to the arithmetic mean of those values. The geometric mean is often used to combine multiple measurements into a single measurement of **size**. *See also* **size**.

geometric morphometrics A family of methods for the analysis of **form** that preserve the original geometry of the measured objects during all the stages of the analysis. A second major strength of geometric morphometric methods is their ability to visualize shape differences and shape changes using deformation grids (i.e., morphing of two-dimensional images or three-dimensional surfaces). Geometric morphometrics is based on the coordinates of **landmarks**. Bookstein (1991, p. 2) defines landmarks as loci that are homologous across individuals in a sample (i.e., the landmarks have the "same" location in every other member of the sample being investigated). Coordinate data can be one-, two-, or three-dimensional. Two-dimensional coordinates are usually captured using a digitizing tablet or by measuring an image on the computer. Three-dimensional data can be captured directly using a coordinate digitizer such as a Microscribe or Polhemus or they can be measured on surface or volumetric scans. Surface scanners provide high-resolution three-dimensional representations of an object's surface using either laser or more traditional optical technology. Volumetric data are based on image slices from **computed tomography** (CT or μ CT) or **magnetic resonance imaging** (MRI or μ MRI) or, more recently, optical projection tomography. These slices contain gray values that correspond to tissue densities and they are concatenated to obtain a three-dimensional representation of an object; virtual surfaces can be generated from CT or MRI data. Most software packages allow landmark coordinates to be measured directly on these virtual surfaces or on volumetric objects. Statistical analysis in geometric morphometrics is performed using Procrustes shape coordinates (or their equivalent). In geometric morphometrics the shape variables all possess the same units so analyses are based on the covariance matrix and there exists a well-defined metric (the Procrustes metric) in shape space. Results of multivariate methods that preserve this metric (e.g., **principal component analysis**, multivariate regression, and partial least squares) can be visualized as actual shapes or shape deformations in the geometry of the original specimens. The algebra of the statistical methods is the same for two- and three-dimensional shape data. Principal component analysis (or PCA) is usually used to analyze the Procrustes shape coordinates and the principal components are computed in a way that preserves the Procrustes distances among the specimens.

Principal component scores are the projections of the shapes onto the low-dimensional space spanned by the eigenvectors. The weightings for linear combinations of the original variables can be visualized as actual shape deformations (called relative warps; see Bookstein 1991). However, the principal components are statistical artifacts and should not be interpreted as representing biologically meaningful factors (Mitteroecker and Bookstein 2007), with the exception that the first principal component of a species or population often represents the shape variation induced by overall size variation (i.e., allometry) (Klingenberg 1998). Partial least squares (or PLS) can be used to assess relationships among blocks of variables (Bookstein et al. 2003), and the results can be visualized as shape deformations (called singular warps). When the blocks of variables are shape coordinates, PLS can also be used to test hypotheses of **morphological integration** (Bookstein et al. 2003, Mitteroecker and Bookstein 2007, 2008) as well as functional, environmental, or behavioral influences (e.g., Bookstein et al. 2002, Frost et al. 2003, Manfreda et al. 2006). Many geometric morphometric analyses employ **randomization tests** (using permutations or bootstrapping) rather than parametric methods to assess the statistical significance level of a given hypothesis (e.g., Mitteroecker et al. 2005). See Good (2000) and Mitteroecker and Gunz (2009) for a more technical description and Mitteroecker et al. (2005) and Gunz et al. (2009a) for examples of its use.

geometric population growth Geometric population growth refers to an increase in population size as a fixed percentage per unit time. For example, if a population consists of 10,000 individuals on January 1 of a year and by December 31 the population consists of 10,100 individuals then it has grown in size by 1%. The growth rate must be given per unit time, so in this case the growth rate would be 1% per annum (per year). It is more common to give the growth rate on a basis of 1.0 rather than on a percentage basis, so a growth rate of 1% per annum would be given as 0.01. In an analogy to interest earned, geometric growth means that interest is earned at fixed periods, so that the compounding of interest (earning interest on previous interest) only occurs at a few fixed times (quarterly or annually). This can be contrasted with the exponential growth rate, where the time interval is infinitesimally small. Carrier (1958) was the first to suggest that a geometric

population growth model could be used in paleodemography to adjust **life tables** for population growth. Note that the population "growth" rate can also be negative if the population is in decline.

geophagy (Gk *geo*=earth and *phagein*=to eat) Literally, the consumption of clays and soils, but the term may also be extended in common usage to eating other organic or inorganic materials (such as charcoal). Several species of primates practice geophagy to help neutralize ingested secondary plant compounds (chemical deterrents produced by plants as a defense mechanism). Primate species differ in their ability to break down secondary compounds and what is poisonous to one may be edible by another. Colobines commonly use geophagy, presumably because their diets include mature leaves, which contain many alkaloids. Other primates minimize the effects of secondary compounds in their diets by adopting behavioral strategies, for example by varying their foodstuffs to avoid over-consumption from a single plant species (Strier 2000). Another function of geophagy is to balance mineral (including trace element) deficiencies; some primates and other mammals preferentially eat soils (e.g., salts at salt-licks) to add minerals which would otherwise be inadequate in their diets. Geophagy is also known to occur in modern human groups, especially in pregnant women. Studies of the evolution of hominin diets have not yet focused on how hominins procure important minerals, but this requirement must have played a role in food choice.

geophyte See **underground storage organ**.

"George" Nickname given by Louis and Mary Leakey to OH 16 from Olduvai Gorge.

George S. Huntington Collection See **Huntington (George S.) Collection**.

Georgian National Museum (or GNM) A network of 11 museums in the Republic of Georgia. It was established in its current form in 2004 by a Presidential decree, but the origins of the museum can be traced back to the Museum of the Caucasian Department of the Russian Geographic Society founded in 1852. The central branch, the Simon Janashia Museum of Georgia, is currently undergoing a large-scale reorganization and renovation. In addition to the hominin and faunal specimens from

Dmanisi, the Simon Janashia Museum houses a large collection of Bronze Age and Classical artifacts from around Georgia. A new branch of the GNM was recently opened in 2009 at the Dmanisi site, allowing visitors to view reconstructions of the hominins, casts of the fossils, and the excavation itself. Hominin fossil collections D211, D2280, D2282, D2600, D2700/D2735/D2724/D3160, etc., D3444/D3900, and D3900, among others. Comparative collections N/A. Contact department N/A. Contact person Teona Jakeli (e-mail teonajakeli@museum.ge). Postal address 3 Rustaveli Avenue, 0105 Tbilisi, Georgia. Website www.museum.ge. General e-mail info@museum.ge. Tel +995 32 99 80 22. Fax +995 32 98 21 33. *See also* Lordkipanidze, David.

germ cells Cells, also called gametes (i.e., egg and sperm) that have a **haploid** complement of chromosomes. *See also* **germline**.

germline (*L. germen*=offshoot) The gametes (i.e., egg and sperm) plus their immature precursors that have a **haploid** complement of chromosomes. The gametes are the cells that pass genetic information from one generation to the next. The remaining cells in the body are called **somatic cells**.

Gesher Benot Ya'akov (or GBY) (Location 33°00'28"N, 35°37'44"E, Israel; etym. He. literally "the bridge or crossing of Jacob's daughters." The name given from at least the time of the Crusaders to this point where the Jordan River can be crossed conveniently and the site of a battle called "Jacob's ford.") History and general description The GBY deposits stretch for approximately 3.5 km/2 miles along both sides of the Jordan River. They were first explored in a series of surveys in the 1980s and one area on the left bank of the Jordan River was excavated in seven seasons between 1989 and 1997 and again in the early 2000s. Temporal span **Oxygen Isotope Stages** 18–20 (i.e., at least 790 ka). How dated? Biostratigraphy and magnetostratigraphy. Hominins found at site None. Archeological evidence found at site GBY has at least 13 archeological horizons, which preserve fauna, plant remains, and **Acheulean handaxes** and **cleavers**. There is reliable evidence (perhaps the earliest reliable evidence) for the use of fire (Goren-Inbar et al. 2004), for nut-cracking (Goren-Inbar et al. 2002), and for a system of spatial organization (Alperson-Afil et al. 2009). Key references: Geology, dating, and paleoenvironment Goren-Inbar and Belitzky

1989, Goren-Inbar et al. 2000; Hominins N/A; Archeology Goren-Inbar et al. 1994, 1996, 2000, 2006, Alperson-Afil and Goren-Inbar 2010.

gestalt (*Ge. stellen*=place) A pattern that has properties or meaning(s) that are greater than the sum of its components (e.g., the distinctive overall appearance of the face of *Paranthropus boisei*).

gestation Gestation includes the period of time in which an embryo or fetus is carried inside a female in a species that gives birth to live young. During gestation, a fertilized egg develops into a neonate of varying levels of maturity (e.g., marsupials versus precocial mammals). Gestational age is typically calculated to include the time of the last menstrual period, although this is not always accounted for. Modern human pregnancy is divided into three trimesters: last menstrual period to 13 weeks, 14–27 weeks, and 28–40 weeks. Therefore, a full-term modern human birth occurs at 40 weeks' gestational age. However, birth occurring after 37 weeks is typically considered full term, and anything prior to 37 weeks is preterm. Preterm birth, together with the associated low weight and immature organ systems, comprises a large proportion of infant mortality.

gestation length The period of time between ovulation and birth. Gestation length varies widely among primate taxa. While there exists a within-order scaling of gestation length with body size in primates, the same is not true for mammals in general: bats have the longest gestation lengths for a mammal of their size. Within primates, mouse lemurs have a gestation period of *c.*60 days, lemurs *c.*133 days, macaques from 145 to 185 days (it varies across species), great apes between *c.*240 and 250 days, and modern humans average 267 days. Gestation length is an important component of reproductive investment. An active area of discussion in the past 30 years has involved the question of extended gestation length in *Homo neanderthalensis* with Erik Trinkaus proposing that Neanderthal gestation lasted 12 months based on aspects of pelvic morphology (from partial remains) that he suggested would have accommodated the birth of a larger-headed neonate. This was hotly debated, however, but evidence from subsequent finds of pelvic elements led to it eventually being discounted and recent work using reconstructions of Neanderthal pelvises and neonatal

head size suggest that brain size at birth was comparable in Neanderthals and *Homo sapiens*. Further, using information gleaned from virtual reconstructions of the passage of a Neanderthal head through a Neanderthal birth canal, this research also suggests that the obstetrical constraints for birthing a large-brained baby in Neanderthals were similar to those in modern *Homo sapiens*. Differences in adult brain size between Neanderthals and *Homo sapiens* are due, the authors suggest, to increased rates of brain growth in the early postnatal period in Neanderthals.

gesture A voluntary non-vocal action used to express meaning or significance in a socially specified manner. Gestures do not include various non-vocal signals such as smiling, laughing, and crying that index emotional states and serve important species-wide communication functions. Such affective or emotion signals are neither entirely voluntary nor are they socially specified. So, whereas everyone in the world expresses happiness with a smile (Ekman 1993), not everyone expresses approval with the “thumbs up” gesture. When defined this way, gesturing becomes an activity that is almost exclusive to modern humans (Tomasello and Call 1997). This is perhaps because gesture interacts with language in important ways, including the facilitation of language development (Goldin-Meadow 2007) and understanding (Skipper et al. 2009). There is some evidence that enculturated apes raised in modern human households use pointing gestures to refer to things out of sight and apparently comprehend the referential functions of another’s gesture as a means of directing one’s attention (Tomasello and Call 1997). However, work with non-enculturated apes supports the notion that the most basic type of gesture (e.g., pointing) is absent in chimpanzees, despite its presence in 12 month-old modern human infants (Liszkowski et al. 2009).

Geula (Location 32°40’N, 35°05’E, Israel; etym. named after the suburb in which it was found) History and general description Geula Cave, which is located on the northern slope of **Mount Carmel** in the suburbs of the city of Haifa, was excavated by E. Wreschner from 1958 to 1964. Despite the large faunal and lithic assemblages, relatively few **hominin** remains have been found. One of the more notable characteristics of the fauna from the cave is the abundance of porcupine remains. Temporal span c.41 ka. How dated? Conventional **radiocarbon**

dating of charred bones. Hominins found at site A total of six hominin bone fragments are known from the site. Their fragmentary nature hinders the ability to generate any reliable hypothesis about their taxonomy, but Arensburg (2002) notes that they have some affinities with hominins from both **Qafzeh** and **Tabun**. Raymond **Dart** (1967) suggested that at least one of the fragments had been fashioned into a tool. Archeological evidence found at site A typical Levantine **Mousterian** assemblage was found. Key references: Geology, dating, and paleoenvironment Vogel and Waterbolk 1963; Hominins Wreschner 1967, Arensburg 2002; Archeology Dart 1967, Wreschner 1967.

G.H. Abbreviation of Garusi Hominid and the prefix for fossil hominins recovered from **Laetoli**, Tanzania by the expedition by the 1938–9 Kohl–Larsen Expedition.

G.H. 1 *See* **Garusi 1**.

GI Acronym for **gyrification index** (*which see*).

Gibraltar A British overseas territory (a “Crown Colony”) on the southern coast of Spain, on a large limestone outcrop (“the Rock”) that juts into the Mediterranean. The cave sites in this outcrop preserve evidence of some of the latest-surviving *Homo neanderthalensis* in Europe, and its southern location and relative isolation on the far end of the Iberian peninsula are consistent with it being a **refugium**. Two Neanderthal fossils were found in the late 19thC and early 20thC. The first, a cranium from **Forbes’ Quarry (Gibraltar 1)** on the north side of Gibraltar was discovered during blasting for limestone in 1848. It was the first Neanderthal fossil to be discovered, but the importance of the find was not recognized until 1862, two years before the *H. neanderthalensis* fossils from **Kleine Feldhofer Grotte** were recognized as a distinct species. This discovery led several researchers to begin more concentrated examination of other Paleolithic sites on the Rock, and in 1926 Dorothy Garrod found the second Gibraltar fossil in Devil’s Tower, along with animal bones, charcoal, and other evidence of human occupation. Several other caves with **Mousterian** levels have since been discovered and documented, including **Ibex Cave**, **Vanguard Cave**, and **Gorham’s Cave**, but to date no fossils have been recovered.

Gibraltar 1 Site Gibraltar. Locality Forbes' Quarry. Surface/*in situ* Not known. Date of discovery 1848. Finders Military prisoners. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age N/A. Developmental age Adult. Presumed sex Female. Brief anatomical description Relatively well-preserved cranium. Announcement The discovery of the cranium was reported to the Gibraltar Scientific Society on March 3, 1848. Initial description The cranium was brought to the attention of Hugh Falconer, the paleontologist, and George Busk, a surgeon and paleontologist, when they visited the excavations at Gibraltar in 1862. Busk caused the cranium to be presented to the Royal College of Surgeons of England in 1868, where it remained until 1955 when it was transferred to what was then called the British Museum (Natural History) and is now the Natural History Museum in London. Photographs/line drawings and metrical data Morant 1927. Detailed anatomical description None. Initial taxonomic allocation *Homo calpicus* Falconer, 1864. Taxonomic revisions *Homo neanderthalensis* Keith (1911). Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance With hindsight, this was the first adult *H. neanderthalensis* cranium to be recovered. Location of original Natural History Museum, London, where it is on permanent loan from the Royal College of Surgeons of England.

Gilbert chron *See* geomagnetic polarity time scale.

giraffid The informal name for the artiodactyl family comprising the giraffes and their allies, whose members are found at some hominin sites. *See* Artiodactyla.

Giraffidae One of the artiodactyl families whose members are found at some hominin sites. *See* Artiodactyla.

GISP2 Abbreviation of the Greenland Ice Sheet Project Two (*which see*).

glabella (L. *glabellus*=smooth and hairless) The most anteriorly projecting point in the midline of the cranium between the superior orbital margins.

glacial cycles The term “ice-age” was apparently introduced by Goethe, but it became clear that it was not one monolithic event, but a series of colder glacial periods punctuated by warmer interglacial periods. These cold/warm cycles were originally identified and defined on the basis of lithological evidence, and before the use of Oxygen Isotope Stages the antiquity of a horizon or a site was reflected by it being linked with one of these named glacial cycles. There are several regional terminologies for glacial cycles, but the one with historical priority is the scheme developed for use in the Alps. This has named glacial periods and from recent to the oldest they are the Würm, Riss, Mindel, Günz, and Donau. The interglacial periods are named after the adjacent glacial periods, the older one first. Hence they are the Riss-Würm, the Mindel-Riss, the Günz-Mindel, and the Donau-Günz. Geologists in northern Europe used a different terminology, with separate terms for the glacial and interglacial cycles, hence the Würm glacial equivalent is the Weichselian, the Riss-Würm interglacial equivalent the Eemian, the Riss glacial equivalent the Saalian, the Mindel-Riss interglacial equivalent the Holsteinian, the Mindel glacial equivalent the Elsterian, the Günz-Mindel interglacial equivalent the Cromerian and the Bavelian, the Günz glacial equivalent the Menapian, the Günz-Mindel interglacial equivalent the Waalian, and so on. The British Isles had yet another scheme, with the Ipswichian interglacial equivalent to the Riss-Würm/Eemian, the Hoxnian interglacial equivalent to the Mindel-Riss/Holsteinian, and the Anglian glaciation equivalent to the Mindel/Elsterian. Around the time this latter scheme was introduced “cold stage” began to replace “glacial” and “temperate stage” replaced “interglacial.” But *all* of these named stages or cycles have been superseded by the numbered Oxygen Isotope Stages (OISs; *see* Gibbard and van Kolfschoten 2004 for a useful chart that matches the various named schemes of glacial cycles with OISs; for an updated version *see* Gibbard et al. 2007). *See also* Oxygen Isotope Stages.

glacial ice volume Glacial ice volume refers to the volume of ice locked up in continental glaciers and it may be usefully measured in sea-level-rise equivalent units. As the volume of continental ice has waxed and waned during glacial (cold) and interglacial (warm) cycles, the changing volume of continental ice has dramatically altered sea levels. The volume of continental ice locked up

in the East Antarctic Ice Sheet is equivalent to approximately 65 m of sea-level rise and in the West Antarctic Ice Sheet and the Greenland ice cap it is equivalent to approximately 8 and 6 m, respectively. All the other ice caps and valley glaciers are estimated to be equivalent to approximately 0.5 m of sea-level rise. At the **Last Glacial Maximum**, sea levels were about 120 m lower than they are today and this may have provided the opportunity for hominins to migrate out of Africa across the narrow, shallow, channel at the southern end of the Red Sea and out of Southeast Asia into Australasia. Lowered sea levels also provided new coastal habitats (e.g., around southern Africa) now presumably below sea level. Glacial ice volume can be roughly estimated from geomorphological evidence on land, **ice rafting** in the oceans, and most importantly the oxygen isotope ratio of **benthic foraminifera**.

glacial period *See* glacial cycles.

Gladysvale (Location 25°53'42"S, 27°46'21"E, Gauteng Province, South Africa; etym. named for Gladys, the daughter of former owner of the land in the 1920s) History and general description Cave system within Precambrian **dolomite** 13 miles northeast of **Sterkfontein** and approximately midway between **Drimolen** and **Gondolin**. Its **breccia** deposits were recognized as fossiliferous by Robert **Broom** in 1936 (in *Broom and Schepers* 1946, p. 43). Andre Keyser began the latest series of studies in 1988. In 1991–2, Lee Berger and Keyser analyzed breccia dumps scattered during mining of the cave that took place during the 1920s, eventually finding isolated hominin teeth. Berger took over excavations in 1993 when Keyser started looking for other sites (eventually finding **Drimolen**). The cave includes open de-roofed sections (called **GVED**), a smaller series of stratified deposits within the cave (**GVID**), and large series of underground chambers not yet formally described. Temporal span and how dated? **Biostratigraphy** based on faunal remains recovered from breccia dumps suggests the presence of deposits of an age comparable to **Sterkfontein Mb 5** and **Kromdraai A**. **Electron spin resonance spectroscopy dating** on tooth enamel from the **GVED** suggests an age of *c.*578–830 ka and all the **GVED** sediments are normally magnetized. Uranium-thorium dating of the **GVID** sediments provided a broad temporal range from

*c.*570 ka to the Holocene. Herries et al cite Curnoe (1999) as suggesting that the teeth assigned to *Au. africanus* may come from “interior deposits” in the cave that may be as old as *c.*2.4 Ma. Hominins found at site The first hominins, isolated teeth from breccia dumps, were assigned to *Australopithecus africanus*; a single phalanx assigned to *Homo* sp. was recovered from later *in situ* excavations. Archeological evidence found at site A single quartzite **handaxe** was recovered from just below the **flowstone** that marks the boundary between the **GVED** and a separate, and as yet undated, set of sediments called the South Western Cone (**SWC**). A probable human hair found in a hyaena coprolite was reported from **GVID** sediments dated to *c.*200 ka. Key references: Geology, dating, and paleoenvironment Lacruz et al. 2002, 2003, Pickering et al. 2007, Herries et al 2010; Hominins Berger 1992, Berger et al. 1993, Berger and Tobias 1994, Schmid and Berger 1997; Archeology Hall et al. 2006, Backwell et al. 2009.

glass An amorphous solid usually formed by the rapid cooling of magma. Volcanic glass forms when magma is quenched (i.e., it is rapidly cooled). It occurs in large volumes as **obsidian** and in small, microscopic volumes it forms the matrix of most lavas. Fragmented glass explosively erupted from a volcano is referred to as vitric tephra. Because the chemistry of a glass closely approximates the composition of the parent magma at the time of cooling, vitric tephra record a geochemical fingerprint of an eruption. Widely dispersed products of such an eruption can thus be correlated geochemically to provide an isochronous marker and in some cases these markers can be dated (e.g., by **argon-argon dating** of associated potassium-bearing **feldspars**). *See* **tephrostratigraphy**.

glia (Gk *glia*=glue) Refers to a diverse class of cells in the nervous system that surround and ensheath **neurons** (i.e., their cell bodies, **axons**, and **dendrites**). The functions of glial cells include providing structural and metabolic support for neurons, maintaining homeostasis, synthesizing **myelin**, signaling, and enabling the nervous system to respond to damage. Glial cells are classified according to their morphology, function, and location and the types include microglia, astrocytes, oligodendrocytes, and Schwann cells. Most types

of glial cells are derived from the neuroectoderm (one of the germ layers) but microglia are part of the immune system and enter the brain from the blood during development. Microglial cells engulf dead cells and neuronal debris and they have been implicated in the synaptic remodeling that occurs during development. Oligodendrocytes (in the central nervous system) and Schwann cells (in the peripheral nervous system) produce a lipid-rich membrane called myelin, which wraps around axons and insulates axonal segments, thereby speeding up the conduction of electrical impulses. Astrocytes provide neurons within the central nervous system with energy and substrates for neurotransmission. Their processes act as a physical barrier between neurons (the glial membrane), and between neurons and blood vessels (the blood-brain barrier), as well as removing excess neurotransmitter molecules from the extracellular space around the synapses that connect neurons. Recently, researchers have demonstrated that astrocytes are involved in the formation and modulation of synapses and that the astrocytes of the extant hominids have a distinctive morphology.

globins Globins form the protein component of two functionally important molecules: hemoglobin (the molecule that carries oxygen in blood) and myoglobin (the oxygen-storing molecule in muscle). The globin genes comprise three families: the myoglobin family (located on chromosome 22 in modern humans), the alpha globin family (on chromosome 16 in modern humans), and the beta globin family (on chromosome 11 in modern humans). Together they comprise the globin **gene family**. Mutations in the alpha globin or beta globin genes result in hemoglobinopathies such as sickle cell anemia. Deletions or regulatory changes in these genes result in thalassemias. These proteins and the genes encoding them have been intensively studied to understand modern human adaptation to **malaria**. *See also* **hemoglobin**.

gnathic (Gk *gnathos*=jaw) Anything that relates to either the upper (maxilla) or the lower (mandible) jaw.

Gomboré *See* Melka Kunturú.

Gompertz hazard model This model of adult **mortality** was proposed by Benjamin Gompertz (1825). Gompertz's model states that

adult mortality increases exponentially with age. A parameter in Gompertz's model, an initial hazard rate, is usually symbolized by α and the variable that specifies the increasing hazard of death that accompanies increasing age is usually symbolized by β . In the Gompertz hazard model the hazard of death at exact age t is $h(t)=\alpha e^{\beta t}$ and the **survivorship** to exact age t is $s(t)=\exp(\alpha/\beta(1-\exp(\beta t)))$. The **probability density function** for age at death is the product of the hazard and the survivorship: $f(t)=h(t)s(t)$. The logarithmic scale is particularly useful in examining the Gompertz model because the natural logarithm of the hazard is a straight line given by $\alpha+\beta t$, so that the Gompertz hazard plotted on a logarithmic scale is a straight line. In the **Siler hazard model** the Gompertz is the third (senescent) component of mortality, so it is often written with a_3 for α and b_3 for β . The Gompertz model is assumed whenever authors refer to a **mortality rate doubling time** and the model can have important implications when using age-at-death data to try to reconstruct the age distribution in the living. As such, the Gompertz model can be used to estimate the living age structure for fossil hominins based on the ratio of older to younger adults from the dead and the assumption of an initial mortality rate (α).

gomphoses *See* joint(s).

gomphothere The informal name for the taxa within the family Gomphotheriidae, which contains all the proboscideans with shovel-shaped tusks. *See* **Proboscidea**.

Gomphotheriidae (Gk *gomphos*=joint, *ther*=combining form, wild beast) A diverse family of extinct Proboscidea known from every continent except Australia and Antarctica. Their cheek teeth are relatively simple and bunodont, and many forms have both lower and upper tusks. Some species (e.g. *Anancus*) lack the lower tusks whereas in others (e.g. *Amebelodon*, *Platybelodon*) these were specialized and had an elongate, shovel shape. In Africa the family is known from the late Oligocene to the late Pliocene; their later distribution overlaps with that of the **Elephantidae**, which they gave rise to and which eventually replaced the Gomphotherids. Gomphotheres lived as far south as South America. They survived in Central America and Mexico until the end of the Pleistocene, and perhaps into the

Holocene. Gomphotheriidae remains are associated with early human occupation of the New World.

Gomphotherium See Gomphotheriidae.

Gona Palaeoanthropological Research Project This multidisciplinary field and laboratory project directed by Sileshi Semaw was established in 1997 to investigate the fossil- and artifact-rich deposits in the **Gona Paleoanthropological study area**, Afar Rift System, Ethiopia. Other researchers involved with the project include Michael Rogers, Dietrich Stout, and Dominique Cauche (palaeolithic archeology); Tesfaye Kidane, Naomi Levin, and Jay Quade (geology); Scott Simpson (hominin paleontology); Stephen Frost (non-hominin paleontology); and Manuel Dominguez-Rodrigo (zooarcheology). The local Afar contingent is led by AsAhmed Humet. Among the achievements of the Gona Palaeoanthropological Research Project are the recovery of evidence of early stone artifacts in association with deliberately fractured fauna (Semaw et al. 2003, Domínguez-Rodrigo et al. 2005), the recovery from sites in the **Western Margin** of the Gona Paleoanthropological study area of more than 30 hominin specimens (belonging to at least nine individuals) that have been assigned to *Ardipithecus ramidus* (Semaw et al. 2005), additional evidence of *Ar. ramidus* recovered during the 2003–8 field seasons, and a pelvis, BSN49/P27, whose "likely age" is "0.9–1.4 Ma" (Simpson et al. 2008, p. 1089). Simpson et al. (2008) assign it to a "short-statured *H. erectus* adult female" (*ibid.*, p. 1090) but Ruff (2010) suggests that the size of the pelvis as assessed from the diameter of the acetabulum is more consistent with it belonging to an archaic hominin, possibly *Paranthropus boisei*. Further, as yet unpublished, hominin remains have been also recovered from the Late Miocene deposits exposed in the Gona Western Escarpment and in sediments containing **Acheulean** artifacts.

Gona Paleoanthropological study area (Location 11°07'–08'N, 40°18'–19'E; Ethiopia; etym. the local name for the area) History and general description The Gona Paleoanthropological study area is located in the west-central section of the **Afar Rift System**; it is west of the **Hadar study area** and north of the **Middle Awash study area**. Initial fieldwork at Gona was carried out by Helene Roche and later by Jack Harris in the 1970s and collaborative work by Jack Harris and Sileshi Semaw

began in 1987. Systematic excavations at **Kada Gona** began in 1992 and these resulted in the recovery of the oldest known stone artifacts dated to 2.6 Ma (Semaw et al. 1997, Semaw 2000) and the **Gona Palaeoanthropological Research Project** began large-scale field investigations in 1999. The early Pliocene deposits exposed in the Gona section of the **Western Margin** have yielded hominins attributed to *Ardipithecus ramidus* (Semaw et al. 2005). The eastern and southeastern portion of the study area in the Kada Gona, Ounda Gona, and Dana Aoule drainages contain sediments of more than 80 m thick containing Plio-Pleistocene fossil fauna and **Oldowan** artifacts. In addition, several **Acheulean** occurrences estimated to be between 1.7 and 0.5 Ma have also been documented in these drainages and some of these have also yielded hominin fossils including a female pelvis (Simpson et al. 2008) and a cranium discovered in 2006. The Gawis drainage and the area the east of it contain late Acheulean, **Middle Stone Age**, and **Later Stone Age** sites. Temporal span and how dated? *c.*2.6–0.5 Ma determined by **argon-argon dating** and magnetostratigraphy. Hominins found at site More than 30 hominin specimens (belonging to at least nine individuals) that have been assigned to *Ar. ramidus* (Semaw et al. 2005), additional evidence of *Ar. ramidus* was recovered during the 2003–8 field seasons and a pelvis, BSN49/P27, whose "likely age" is "0.9–1.4 Ma" (Simpson et al. 2008, p. 1089); other hominins recovered from this time interval have yet to be published. Archeological evidence found at site Many levels in the *c.*2.6–1.5 Ma time interval contain **Oldowan** artifacts and the Gawis drainage and the area to the east of it has late Acheulean, Middle Stone Age, and Later Stone Age sites. Geology, dating, and paleoenvironment Semaw et al. 1997, 2003, 2005, Quade et al. 2004, 2008, Levin et al. 2004, 2008, Kleinsasser et al. 2008; Hominins Semaw et al. 2005, Simpson et al. 2008; Archeology Semaw et al. 1997, 2003, Semaw, 2000, Stout et al. 2005, Dominguez-Rodrigo et al. 2005.

Gona pelvis See BSN49/P27.

Gondolin (Location 25°49.837'S, 27°51.857'E, North West Province, South Africa; etym. named by a former owner of the farm where the site is located. He combined the names of his daughters – Gonda and Lynn – into the name "Gondalynn" but the site has only ever been published on with

the spelling “Gondolin”) History and general description The site is an abandoned limeworks based on a cave system within Precambrian **dolomite** near Broederstroom, 24 km/15 miles northwest of **Sterkfontein**. The potential of the site was noted in 1977 by MacKenzie and Elisabeth Vrba, who excavated there in 1979. Two *in situ* sequences are recognized at the site of the old cave, GD2 and GD1/3, along with extensive *ex situ* dumpsite deposits. Temporal span Fauna, specifically Stage III *Metridiochoerus andrewsi* recovered during the excavations at GD2, suggests an age for GD2 of *c.*1.5–1.9 Ma (equivalent to **Swartkrans Mb 1**) for the excavated breccia. The **normal** polarity of the GD2 sediments is consistent with their sampling the **Olduvai subchron** in which case the dates would be between 1.78 and 1.95 Ma but the **reversed** polarity recorded in GD1/3 suggests that other parts of the cave filling may be older or younger. How dated? Biostratigraphy and magnetostratigraphy. Hominins found at site Two hominin teeth, GA 1, a ?*Homo* left lower molar and GA 2, a large *Paranthropus robustus* left M₂, have been recovered from the site. Archeological evidence found at site None. Key references: Geology, dating, fauna, and hominins Menter et al. 1999, Adams and Conroy 2005, Heries et al. 2006, 2009, Adams et al. 2007, Adams 2010.

Gongwangling *See* Lantian Gongwangling.

Goodman, Morris (1925–2010) Morris Goodman was born in 1925 in Milwaukee, Wisconsin. In 1942, Goodman enrolled at the University of Wisconsin-Madison, but from mid-1943 to the fall of 1945 he served in the US Air Force flying as a navigator on bombing missions over Europe. He returned to the university as a sophomore in the winter of 1946 and became a research assistant to Harold Wolfe, Professor of Comparative Anatomy. After obtaining a BS in Zoology with a minor in Biochemistry in 1948, Goodman went on to receive his MS a year later and a PhD in Zoology with a concentration in biochemistry in 1951, all from the University of Wisconsin-Madison. Wolfe, a former student of Alan Boyden who was renowned for his work in comparative serology, influenced Goodman to concentrate on using molecular techniques to explore mammal relationships during the latter's master's degree. This influenced Morris Goodman's decision to focus on molecular

systematics and to examine the effects of salt concentration on the precipitin reaction in birds as the centerpiece of his PhD; it also helped foster Goodman's interest in immunology and protein chemistry. After his PhD, Goodman left Wisconsin to work at California Institute of Technology on a comparative study of hemoglobin with immunochemist Dan Campbell. Morris's interest in evolution was furthered during his subsequent work at the Detroit Institute of Cancer Research where he used the Ouchterlony method to make a comparative study of a range of proteins, including **albumin** (e.g., Goodman 1962). In 1962 Goodman proposed that chimpanzees and gorillas should be classified within the family Hominidae instead of the Pongidae because the comparative protein evidence suggested that chimpanzees and gorillas are more closely related to modern humans than to the other apes. On the basis of this evidence, especially that from albumin, Goodman also proposed the "hominoid slowdown hypothesis," the concept that rates of protein evolution had slowed down in the recent ancestry of modern humans and other hominoids. Goodman continued his work on serology and molecular taxonomy in the 1960s and 1970s, with work that focused on the evolutionary history of hemoglobin (Goodman et al. 1975). In the 1980s, Goodman used protein sequence data to reconstruct primate evolution and to inform primate classification. A 1988 paper published by Goodman's research group showed how important motifs in the non-coding DNA of genomes could be identified and in 1997 Goodman and Edwin McConkey lobbied for funding for an initiative to sequence the chimpanzee genome (McConkey and Goodman 1997). Goodman continued to work on evolutionary problems; until his death in 2010 his interests were placental evolution and the genetic changes responsible for enlargement of the **neocortex** and for **encephalization**. Morris Goodman, who was elected as a fellow of the American Academy of Arts and Sciences in 1996 and a member of the National Academy of Sciences in 2002, was a Distinguished Professor in the Department of Anatomy and Cell Biology and the Center for Molecular Medicine and Genetics at Wayne State University School of Medicine, where he had been for much of his career. He was also the chief editor of the journal *Molecular Phylogenetics and Evolution*.

Gorham's Cave *See* Gibraltar.

Gorilla The gorilla was first described by the Rev. Savage in 1847, as a new species of chimpanzee and called *Troglodytes gorilla* (at that time the generic name *Troglodytes* was used for chimpanzees), but the genus *Gorilla* was described for it in the 1860s. Paul Matschie and others in the early 20thC described a number of supposed new species of gorillas, but in 1929 Coolidge sank them all into a single species, *Gorilla gorilla*, with two subspecies (the western gorilla, *G. g. gorilla*, and the eastern gorilla, *G. g. beringei*). In the 1960s it became clear that eastern gorillas are divisible into two subspecies, the true mountain gorilla (*G. g. beringei*) and an eastern lowland or Grauer gorilla (*G. g. graueri*). Nowadays it is more usual to recognise two species of gorilla, *Gorilla gorilla* (western) and *Gorilla beringei* (eastern), as they have many absolute differences, both morphological and genetic. Each has two subspecies: the Cross River gorilla (*Gorilla gorilla diehli*) and the more widespread *Gorilla gorilla gorilla* in the west, and the Grauer gorilla (*Gorilla beringei graueri*) and the mountain gorilla (*Gorilla beringei beringei*) in the east. Pilbrow (2010) provides a useful map locating the various extant and historical gorilla populations and a comprehensive review of the molecular and morphological evidence. Her study of molar crown morphology supports a species-level distinction between *Gorilla gorilla* and *Gorilla beringei*.

gourmet strategy *See* economic utility index.

GPRP *See* Gona Palaeoanthropological Research Project.

GPTS *See* geomagnetic polarity time scale.

graben (Ge. *graben*=ditch) In structural geology a graben is a geological structure consisting of two (or more) inwardly directed **normal faults**, which form a trough-like feature. Because of their trough-like nature, grabens can become locations where potentially fossil-bearing sediments are preferentially deposited and preserved and thus grabens make obvious targets for geological and paleontological exploration. The rift valleys of East African are examples of grabens. *See also* **Afar Rift System**; **East African Rift System**.

grade (L. *gradus*=stage) Julian Huxley (1958, p. 27) introduced this term for what he called an “anagenetic unit.” Whereas a **clade** is analogous

to a make of car (e.g., all Rolls-Royce cars share a recent common ancestor not shared with any other make of car), a grade is analogous to a type of car (e.g., luxury SUVs made by Mercedes, Jaguar, and Lexus are functionally similar yet they have different evolutionary histories and therefore have no uniquely shared recent common ancestor). Thus, it is a category based on what an animal looks like and does, rather than on what its phylogenetic relationships are. Thus “leaf-eating monkey” is a grade that contains both Old and New World monkeys, but it is not a **clade** because the two groups of monkeys from the Old and New Worlds are components of different larger clades. Grades may also be clades, but they do not have to be. *See also* **adaptive zone**; **genus**.

graminivory (L. *gramen*=grass and *vorous*, from stem of *vorare*=to devour) Literally, the consumption of grass. This is a highly specialized primate dietary strategy, found only among primates in the genus *Theropithecus*. Today *Theropithecus gelada* live in the Ethiopian highlands, where their diet consists entirely of grasses of which they consume the leaves, rhizomes, stems, and seeds. *See also* **seed-eating hypothesis**.

Gran Dolina (Location 3°31'08"W, 42°21'09"N, Spain; etym. at the beginning of the investigation of this major European hominin site, it was thought the site was a large karstic doline, hence the name *Gran*=large and *Dolina*=doline, but now, even though it is a cave infill, the name persists) **History and general description** One of the fossiliferous cave fillings in the Sierra de Atapuerca, which is a series of eroded, karstic, limestone hills 14 km/8.5 miles east of Burgos in Northern Spain. It is permeated by sediment-filled cave systems. The largest is the **Cueva Mayor-Cueva del Silo** system where the **Sima de los Huesos** is located. Just 1 km/0.6 miles away in the **Trinchera del Ferrocarril** is the Gran Dolina (TD) with 18 m of sediment. Excavations began here in 1978 and seven levels (TD3-4, 5-7, and 10-11) have produced stone tools. In 1994 more stone tools and hominin fossils were recovered from the **Aurora stratum** (a conspicuous layer within the TD6 lithostratigraphic level). More hominins were recovered in 2003, including **ATD6-96**, and 25 additional hominin specimens were recovered between 2003 and 2008. In total the hominins from the TD6 sample came from at least 10 individuals. Researchers now recognize six lithostratigraphic

layers within the Aurora stratum, which they refer to as the Aurora archaeostratigraphic set (or AAS). Temporal span and how dated? **Magnetostratigraphy** points to an age >780 ka (it is in the **Matuyama** chron) and the best age estimate using **uranium series dating** and **electron spin resonance spectroscopy dating** methods is 731 ± 63 ka. Hominins found at site Between 1994 and 2008 more than 100 hominin fossils belonging to at least 10 individuals were recovered from the Gran Dolina cave. In 1997 they were assigned to a new species *Homo antecessor* on the basis of a hitherto unknown combination of a modern human-like midfacial morphology (e.g., a **canine fossa** and an acute zygomaticoalveolar angle) and a primitive *Homo ergaster*-like dental morphology. Critics suggest that the “modern” facial morphology is due to the immaturity of the ATD6-69 facial fragment. Archeological evidence found at site Mainly small, **Mode 1** artifacts, such as **flakes**, **denticulates**, **notches**, and **side scrapers**, many of which have been used for butchery and woodworking. The **cutmarks** on some of the hominin specimens shows that the hominins were being deliberately defleshed. Key references: Geology, dating, and paleoenvironment Parés and Pérez-González 1995, 1999, Cuenca-Bescós et al. 1999, Falguères et al. 1999, Berger et al. 2008; Hominins Carbonell et al. 1995, 2005, Bermúdez de Castro et al. 1997, 1999, 2008, Arsuaga et al. 1999a, Carretero et al. 1999, Lorenzo et al. 1999, Rosas and Bermúdez de Castro 1999, García-González et al. 2009, Gómez-Olivencia et al. 2010; Archeology Carbonell et al. 1995, 1999, Fernández-Jalvo et al. 1996, 1999 (syn. Trinchera Dolina).

Grande Grotte (Location 47°35'N, 3°45'E, France, etym. Fr. large cave) History and general description One of the largest caves of the **Arcy-sur-Cure** complex, the Grande Grotte is known for its many cave paintings and etchings, which include mostly animal forms, but also hand outlines and abstract symbols (points, wavy lines, etc.). The site has been extensively explored by a team led by Dominique Baffier and Michel Girard, who have painstakingly uncovered the artwork and performed a series of archeological excavations on the sediments below the artwork since they were discovered preserved under a thick layer of calcite in 1990. The site is currently open for tours. Temporal span and how dated? **Radiocarbon dating** of ochre-colored bones found at the base of some of the artwork in the cave provided dates of 26–28 ka, and

radiocarbon dates from torch smears over one of the friezes are about 27 ka. Hominins found at site N/A. Archeological evidence found at site An archeological layer was found below a 30 cm sterile surface deposit. This layer contained evidence of cave-painting activity, including pestles, colorants, lamps, and hearths. Key references: Geology, dating, and paleoenvironment Girard et al. 1996, Baffier et al. 2001; Hominins N/A; Archeology Baffier and Girard 1995.

grandmother hypothesis A model of human evolution introduced by Kristen Hawkes and colleagues (Hawkes et al. 1998) which emphasizes the important role played by post-menopausal women in helping to provide food for their daughter's children. This is an attempt to explain why in modern humans female **fertility** and **mortality** are decoupled so that modern human females have a long post-reproductive lifespan. The hypothesis suggests that post-reproductive adults and particularly grandmothers can continue to indirectly influence their own reproductive success (i.e., **inclusive fitness**) by contributing to the reproductive success of their daughters. The model suggests that grandmothers achieve this by **foraging** for foods such as **tubers** that their grandchildren would find difficult if not impossible to access on their own. This assistance increases the chances of existing offspring surviving and it also allows daughters to wean infants early, move on to the next pregnancy, and thus shorten the **inter-birth interval**.

granivory (L. *granum*=grain and *vorous*, from stem of *vorare*=to devour) Literally, the consumption of seeds. This term applies principally to rodents and insects that are exclusive seed-eaters, and whereas living primates consume seeds, particularly of flowering plants and sometimes grasses, as part of their diet (e.g., *Theropithecus*), no living primate has an exclusively granivorous diet. *See also* **graminivory**; **seed-eating hypothesis**.

grassland A biome with mean annual rainfall between 250 and 800 mm, a high rate of evaporation, periodic severe droughts, and a rolling to flat terrain, and where most animals are grazing or burrowing species. In Africa, grasslands can be completely devoid of woody plants, but in general grasslands are defined as those biomes with less than 10% cover of woody plants. The majority of

modern African grasslands are dominated by C₄ grasses. However, prior to 1.7 Ma, most of the fossil localities in East Africa characterized as grasslands were a mix of C₄ and C₃ plants, indicating that modern C₄ grasslands are a more recent phenomenon (Cerling 1992). Most grasslands require periodic fires for maintenance, renewal, and elimination of encroaching woody growth. Production in grasslands is positively correlated with precipitation. Whereas grasslands at one time are thought to have covered about 40% of the land surface on Earth, today they cover less than 12%. Much of the secondary grasslands in Africa would revert to woodland if not for overgrazing and fire (Pratt and Gwynne 1978). Grasslands tended to dominate at many hominin sites in Africa between 2.0 and 1.0 Ma, as evidenced by carbon isotopes in soils and deposits of mammalian grazer fossils. *Homo erectus* first appeared during this period and is thought to have existed in grasslands and lightly wooded habitats. Many of these grasslands became bushlands and woodlands after 1.0 Ma.

Gravettian An early Upper Paleolithic technocomplex found throughout Europe, dated to between 28 and 19 ka, a particularly cold phase during the last glacial maximum. It is characterized the appearance of diagnostic stone tools including burins and straight-backed points, the exploitation of large herd mammals, particularly mammoths, the expansion of long distance trade as evidenced by shells, and the production of ivory and clay stylized figures of women (known as Venus figurines) and animal designs. Sites in central and eastern Europe (e.g., Pavlov, Dolni Věstonice) show further technological specialization, including meat-storage pits, bone burning for fuel, and construction of shelters out of animal bones. A similar technocomplex from the same time period found only in central and southwestern France is known as the Perigordian.

gray matter A term that describes regions of the central nervous system that mainly comprise the cell bodies of neurons. There is gray matter in the cerebral cortex, the cerebellar cortex, the nuclei of the brain and the brain stem, and in the central portion of the spinal cord.

gray-scale image See computed tomography.

gray-scale values See computed tomography.

grazer An animal that feeds on ground-level vegetation (e.g., terrestrial or aquatic grasses). Grazers tend to have a relatively broad snout (e.g., extant hippopotami) so that the anterior teeth can trap as much grass as possible, whereas browsers have a narrower snout (e.g., modern giraffes) that allows them to select items in bushes and trees. In tropical environments, the vegetation that grazers feed on (i.e., grasses) uses the C₄ photosynthetic system and it has more ¹³C relative to plants that use the C₃ photosynthetic system; thus grazing animals have bones and enamel that have more ¹³C relative to the bones of browsing animals that consume plants using the C₃ photosynthetic system. See also C₃ and C₄; grazing.

grazing (ME *grasen*=to feed on grass) The consumption of the leaves and shoots of monocotyledonous plants (i.e., grasses and sedges having a single embryonic seed leaf or cotyledon) which grow at, or slightly above, ground level. Many antelopes, particularly the alcelaphines (i.e., wildebeest and allies that belong to the tribe Alcelaphini) and the antilopines (i.e., gazelles and allies that belong to the tribe Antilopini), graze on grasses. A grazing diet in extinct animals is usually inferred through studies of tooth morphology or stable isotope, usually carbon, geochemistry. Grazing on tropical grasses that have a C₄ photosynthetic pathway leaves a stable carbon isotopic signal that can be detected in tissues, including the enamel of fossil teeth. Grazing is important for understanding the environmental context of hominin evolution. Adaptive radiations of grazing ungulates occurred along with the reduction of forest and more wooded landscapes in Africa. The spread of grazing as a dietary strategy in the faunal community thus helps document changes in the environments inhabited by early hominins. See also ¹³C/¹²C; stable isotopes.

great ape (OE *great*=thick or large and *apa*=ill-bred and clumsy; literally the “large and clumsy” ones, as opposed to the “small and clumsy” ones, known as the “lesser apes”). Before the apes had been investigated scientifically and appreciated on their own terms, ‘apes’ were regarded as being ‘clumsy’ because they lacked dexterity) An informal taxonomic category that includes extant and fossil

taxa. The extant “great ape” taxa are chimpanzees/bonobos, gorillas, and orangutans; the fossil taxa are all the extinct forms that are more closely related to chimpanzees/bonobos, gorillas, and orangutans than to any other living taxon. In the traditional, pre-molecular, taxonomy the informal term “great apes” was equivalent to the family Pongidae. *See also* ape.

Great Cave of Niah *See* Niah cave.

Green Gully (Location 37°44'S, 144°50'E, Victoria, Australia) History and general description A soil pit 14.5 km/9 miles northwest of Melbourne and 1.6 km/1 mile south of Keilor. In 1965 hominin bones were accidentally uncovered during commercial sand-extraction operations. Temporal span and how dated? The direct **radio-carbon dating** of collagen from the skeletal suggests they are *c.*6500 years BP. Hominins found at site Most researchers suggest that the modern human remains from Green Gully represent two individuals, Green Gully 1, the partial skeleton of an adult female that includes portions of the cranium, thorax, and right upper limb, and Green Gully 2, the partial skeleton of an adult male that includes most of the left upper limb, a fragmentary pelvis, and both lower limbs. Archaeological evidence found at site Large and small **quartzite scrapers** and quartzite fabricators. Key references: Geology and dating Bowler 1970a; Hominins Macintosh 1967, 1970; Archaeology Mulvaney 1970.

Greenland Ice Core Project (or GRIP) A European initiative that complemented the US National Science Foundation-funded **Greenland Ice Sheet Project Two** (or GISP2) that drilled approximately 30 km/18 miles west of the site of the GRIP core. Between them, the GRIP and GISP2 provided a long, high-resolution record of past climate events. For more information see www.nerc-bas.ac.uk/public/icd/grip/griplist.html.

Greenland Ice Sheet Project Two (or GISP2) In late 1988 the Office of Polar Programs of the US National Science Foundation initiated GISP2 as part of its Arctic Systems Science Program that focused on environmental change in the Arctic. The aim of the project was to use a drill to recover an ice core that captured as much as possible of the history of the Greenland ice cap. After 5 years

of drilling, on July 1, 1993 the GISP2 drill penetrated the full thickness of the ice sheet and entered the bedrock. The ice core recovered was approximately 3050 m deep and at the time it was the deepest ice core ever recovered. The GISP2 drilling program complemented the European-funded **Greenland Ice Core Project** (or GRIP) that drilled approximately 30 km/18 miles east of the site of the GISP2 core. Between them the two projects provided a long, high-resolution record of past climate events. For more information see www.gisp2.sr.unh.edu/.

Grenzbank zone (Ge. for “border bed”) General description A 1 m-thick boundary layer between the underlying **Sangiran Formation** and the younger overlying **Bapang Formation** in the **Sangiran Dome** of central Java. This stratum is a calcareous **conglomerate** rich in fossil bone, including hominins. Sites where this formation is exposed **Blimbingkulon**, **Mojokerto**, and **Sangiran**. Geological age In 2001, published **argon-argon dating** suggested the lowermost Bapang hominins are 1.51–1.47 Ma and the youngest hominins from the Sangiran Formation are *c.*1.6 Ma so the Grenzbank is dated to *c.*1.51–1.6 Ma. Most significant hominin specimens **BK 7905**, **BK 8606**, **Sangiran 6** (“*Meganthropus A*”), and **Sangiran 9** (“*Mandible C*”). Key references: Geology, dating, and paleoenvironment Watanabe and Kadar 1985, Larick et al. 2001; Hominins Weidenreich, 1944, Sartono 1961, Kaifu et al. 2005a.

Grimaldi (Location 43°47'N, 7°37'E, Italy; etym. It. after the nearby village, or after the ruling family of Monaco, due to Prince Albert I having led the excavations in the **Grotte des Enfants**) History and general description The Grimaldi complex of sites consists of a series of limestone caves and rockshelters at the base of a cliff about 1 km/0.6 miles from the Italy/France border on the Mediterranean coast; it is also known as the “Balzi Rossi” or “Baousses Rousse” caves after the reddish color of the cliff. A number of these have yielded hominin fossils. From west to east they are **Grotte des Enfants**, **Riparo Mochi**, **Barma del Caviglione**, **Riparo Bombini**, **Barma Grande**, **Baousses da Torre**, and **Grotta del Principe**. Some of the excavations that took place in the latter quarter of the 19thC were undertaken by amateurs and even the remains and artifacts that were collected by trained

archeologists tended to be poorly looked after and were put in different museums. Most of the caves have since collapsed, making further inquiry logistically difficult. Temporal span and how dated? As many of the caves were explored before rigorous excavation techniques were developed, stratigraphic and chronologic questions remain unanswered. However, direct **radiocarbon dating** of a number of the skeletons gives an age of *c.*24 ka for the **Gravettian** layers and *c.*11 ka for the **Epigravettian**. Hominins found at site Many complete or near-complete skeletons are known from the **Paleolithic** deposits in the caves. All of the skeletons belong to modern *Homo sapiens* and appear to have been intentionally buried. Beginning with Verneau (1906), the lower burials of Grotte des Enfants 5 and 6 were regarded as “Negroid” in character. Boule and Vallois (1957) elaborate on this, stating that the Grotte des Enfants remains display affinities of South African Bushmen, even finding similarities between Grotte des Enfants 5 and 6 and the skeleton of the “Hottentot Venus,” which was at their disposal. These differences are now accepted as being within the normal range of anatomically modern human cranial robusticity, but the theories of Verneau, Boule, and Vallois were influential in eroding the Eurocentrism in physical anthropology. Archeological evidence found at site **Mousterian** assemblages occupy the lower **Middle Paleolithic** levels, while **Aurignacian** and Gravettian assemblages are known from the **Upper Paleolithic**. In addition to Gravettian lithic technology, a number of “Venus” figurines have been found in the Upper Paleolithic levels of the caves, but there is some confusion in a few cases as to which figurines come from which cave. Key references: Geology, dating, and paleoenvironment Formicola et al. 2004; Hominins Verneau 1906, Boule and Vallois 1957; Archeology Mussi 2001.

grindstone Stone tools used for cracking open or reducing the particle size of plant or animal foods, or of pigments. Grindstones usually appear in two forms; handheld grindstones are referred to as a hammer or mano, fixed or stationary grindstones are referred to as an anvil or metate. *See also* ground stone tool.

GRIP Acronym for the **Greenland Ice Core Project** (*which see*).

gross reproductive rate (or **GRR**) The integral of the age-specific fertility rate in a continuous age model and the sum of the age-specific fertility rates across the reproductive age intervals in a **life table**. The GRR is also sometimes referred to as the total fertility rate (or **TFR**) because it represents the expected total number of females born to a woman throughout her life, although some use GRR to refer to female births and TFR to refer to all births. The GRR should be contrasted with the **net reproductive rate** (or **NRR**), which is lower because it includes the mortality function for potential mothers.

Grotta Breuil (Location 41°14'N, 13°05'E, Italy; etym. It. *grotta*=cave and *Breuil*=for Henri Breuil, the French archeologist) History and general description One of the caves in the **Monte Circeo** complex, this site is a large karstic chamber located on the southwestern face of the promontory, just above the present sea level. The entrance opens towards the west, with a large central chamber extending to the east. Systematic excavations began in 1986 under the direction of A. Bietti. A few hominin remains and an abundance of associated stone tools and a rich faunal assemblage were found, and represent a late occurrence of *Homo neanderthalensis* in the Italian peninsula. Temporal span The hominin remains are dated to late **Oxygen Isotope Stage 3**, *c.*35–45 ka; How dated? Electron spin resonance spectroscopy dating, biostratigraphy. Hominins found at site Three fragments have been recovered: a portion of a left parietal, an adult left M₂, and a juvenile M₃. The remains are typical of *H. neanderthalensis*. Archeological evidence found at site A Pontian (local **Mousterian**) industry was found associated with the remains. Key references: Geology, dating, and paleoenvironment Bietti and Manzi 1991, Schwarcz et al. 1991b; Hominins Manzi and Passarello 1995; Archeology Bietti et al. 1991.

Grotta dei Fanciulli *See* Grotte des Enfants.

Grotta del Caviglione *See* Barma del Caviglione.

Grotta del Fossellone *See* Fossellone.

Grotta di Lamalunga (Location 40°52'21"N, 16°35'17"E, Italy; etym. It. *lama*=cave system in

the local dialect and *lunga*=long) A cave system in karstic limestone near Altamura, Bari, Apulia, where a hominin skeleton covered in a variably thick coating of calcareous material, **Altamura 1**, was found in 1993 by speleologists. *See also* **Altamura 1**.

Grotta Guattari (Location 41°14'N, 13°05'E, Italy; etym. It. *grotta*=cave; *Guattari*=from A. Guattari, the name of the discoverer of the fossils, the owner of the land where the site is and the owner of what used to be an eponymous hotel near the site, now called the Hotel Neanderthal) History and general description This, one of the many caves in the **Monte Circeo** complex, contained the most iconic of the hominin remains recovered from the Monte Circeo promontory. Alberto Carlo Blanc spent much of the late 1930s exploring the caves of Monte Circeo (e.g., **Grotta Breuil**, Fossellone, and many others). In 1939 Guattari, a local hotelier, told Blanc that he and his workmen had discovered a narrow entrance to a cave on his property and that there appeared to be a number of animal and human remains, including a cranium. The cranium had already been removed when Blanc arrived; it had been sitting on the cave floor, surrounded by a “circle of stones.” The following week one of Guattari’s staff who had explored the cave handed over a mandible that she had apparently found near the cranium. Another mandible was discovered in a breccia deposit outside the cave after WWII by A. Ascenzi and G. Lacchei. The remains were then given to Sergio Sergi for study. Temporal span and how dated? *c.*51–7 ka by uranium-series dating and electron spin resonance spectroscopy dating. Hominins found at site Three specimens were recovered: Guattari 1 (formerly Circeo I), a fairly complete cranium, and two fragmentary mandibles, Guattari 2 and 3 (formerly Circeo II/A and III/B), all attributed to *Homo neanderthalensis*. Archeological evidence found at site A Pontian (local **Mousterian**) industry was found. It was thought that Guattari 1 was the subject of a cannibalistic ritual, because of the damaged foramen magnum and the “circle of stones” surrounding the skull and other evidence. This is most likely not the case, since more thorough study in the 1980s suggests the cave was primarily a hyena den with only secondary occupation by hominins. Key references: Geology, dating, and paleoenvironment Schwarcz et al. 1991a; Hominins Bietti and Manzi 1991, Piperno and Scichilone 1991,

Sergi 1954; Archeology Taschini 1979, Bietti and Manzi 1991, White and Toth 1991.

Grotte des Contrebandiers *See* Smugglers’ Cave.

Grotte des Enfants (Location 43°47'00"N, 07°32'08"E, Italy; etym. presumably named after the infant skeletons found in the upper layers) History and general description The westernmost of the caves in the **Grimaldi** complex; it is also known as the Grotta dei Fanciulli. The cave was first excavated by Émile Rivière in the 1870s and subsequently by Prince Albert I of Monaco in the early 20thC. Temporal span and how dated? Direct radiocarbon dating of Grotte des Enfants 1 gave an age of 11,130±100 years BP. The older skeletons, Grotte des Enfants 5 and 6, are presumed to be *c.*24 ka, based on direct dating of remains from **Arene Candide** and **Barma Grande**, which can be biostratigraphically correlated. Hominins found at site Six complete or nearly complete skeletons are known from the site and were almost certainly intentionally buried. The first three can be chronologically grouped together and include two complete infant skeletons and one adult female. The second group of three are from the **Gravettian** layers (layer F) and consist of two males and one female. Ochre and marine shell ornaments were found decorating the burials. The hominins are all unquestionably *Homo sapiens*. Verneau (1906), and later Boule and Vallois (1957) thought the Gravettian remains Grotte des Enfants 5 and 6 to be “Negroid” in character. Boule and Vallois (1957) elaborate on this and stated that the Grotte des Enfants remains display affinities of South African Bushmen, finding similarities with the skeleton of the “Hottentot Venus.” Their morphology is now accepted as being within the normal range of anatomically modern cranial robusticity, but the “Negroid theory” was influential in eroding the Eurocentrism in physical anthropology of that time. Archeological evidence found at site Most of the **Upper**

Paleolithic artifacts were originally identified as **Aurignacian** but recent work has definitively attributed the industry to the Gravettian. Key references: Geology and dating Formicola et al. 2004; Hominins Boule and Vallois 1957; Archeology Mussi 2001.

Grotte des Fées (Location 47°35'N, 3°45'E, France, etym. Fr. *grotte*=cave and *fées*=fairies) History and general description The first among the **Arcy-sur-Cure** caves to be excavated was the Grotte des Fées, which was explored by Marquis de Vibraye in the 1850s and 1860s and later by the Abbe Parat and others until 1905, when the site was considered exhausted. de Vibraye never formally published his results, and instead gave a series of talks that were summarized by Parat (1903). Later researchers with more modern techniques subsequently excavated several of the nearby caves (e.g., Leroi-Gourhan 1950, 1958, Movius Jr 1969b), which helped to place the Grotte des Fées in context, although they raised several questions about the conclusions drawn from the earlier excavations. The Grotte des Fées consists of several chambers, with one long gallery running mostly north-south for nearly 150 m through the limestone cliffs. It contained several archeological layers, many faunal remains, and a mandible of questionable taxonomic status. Temporal span and how dated? The cave is only very approximately dated using **technostratigraphy**, especially with nearby caves, such as the **Grotte du Renne**. The stone tools are mostly **Mousterian**, suggesting a date of more than 35 ka. Hominins found at site de Vibraye found the only hominin remains, a mandible he attributed to *Homo neanderthalensis*, and a fragmentary atlas. Several authors have argued that the mandible is not ancient (de Mortillet and de Mortillet 1900, Leroi-Gourhan 1950, 1958). Leroi-Gourhan (1950) noted that the mandible lacked both the patina that marked the **Middle Pleistocene** bones from the site and the red ochre that marked the bones from the **Upper Paleolithic** layers. Furthermore, he argued the mandible lacked many of the distinctive traits of *H. neanderthalensis* and manifested many traits found in modern humans (Leroi-Gourhan 1958) and he suggested the mandible may have been a recent, perhaps **Neolithic**, burial. Archeological evidence found at site de Vibraye described three layers based on changes in the fauna, although Parat and others noted that the

bottom layer could be further subdivided. The few tools associated with de Vibraye's lower level were Mousterian, although some suggested **Acheulean handaxes** were found in the lowermost part of the excavation (Parat 1903). Key references: Geology, dating, and paleoenvironment Leroi-Gourhan 1950, 1958; Hominins Parat 1903, de Mortillet and de Mortillet 1900, Leroi-Gourhan 1950, 1958; Archeology Parat 1903.

Grotte des Fées de Châtel Perron *See* Châtel Perron.

Grotte des Pigeons (Location 34°48'38"N, 2°24'30"E, Morocco; etym. F. for "cave of pigeons") History and general description This large (>400 m²) cave formed in Permo-Triassic dolomitic limestone in the Beni Snassen mountains near the village of **Taforalt** was excavated discontinuously between 1944 and 1977 by Abbé J. Roche and since 2003 by N. Barton and A. Bouzzougar. The approximately 10 m-thick archeological sequence consists of **Aterian** and **Iberomaussian** artifacts as well as fossils within multiple layers of silt, silty loams, interstratified **speleothems**, and anthropogenic ashes and charcoal. The Aterian levels contain early shell beads with an age estimate of 82 ka, whereas the Iberomaussian strata include more than 180 Late Pleistocene (*c.*17–13 ka) hominin burials. Temporal span and how dated? Sediments at the Grotte des Pigeons are divided into six sediment groups (A–F, from top to bottom) bounded by erosive unconformities. Archeological strata at the Grotte des Pigeons are dated by **AMS radiocarbon**, **optical stimulated luminescence**, **thermoluminescence**, and **uranium-series dating** methods, with age estimates ranging from 10.94±0.04 to *c.* 95.4±0.90 ka. A **Bayesian age model** incorporating 13 age estimates constrains the age of the shell bead-bearing group E to between 73.4 and 91.5 ka with a most likely date of *c.*82.5 ka. Hominins found at site More than 180 modern human individuals from two necropolises have been reported for the Iberomaussian levels. Archeological evidence found at site Sediment group E contains **Middle Paleolithic** tools such as **scrapers**, small **Levallois cores**, and thin **bifacially worked** (Aterian) **foliate points**, well-defined **hearths**, and 13 small (<2 cm) *Nassarius gibbosulus* shells transported >40 km/25 miles to the site. Some of the shells may have been deliberately pierced, 10 show wear patterns suggestive of "string damage," and hematite is present on 10 of them. Older excavations recovered a

number of typical Aterian tanged or pendunculate points and other retouched implements, although the spatial and stratigraphic relation of these to the present excavations is unclear. Diverse Upper Paleolithic (including Iberomaurusian) flake, blade, and backed bladelet industries occur in sediment groups A–B. The abundance of cedar (*Cedrus*) charcoal fluctuates throughout the Pleistocene, and dates from some of the Iberomaurusian strata suggest the presumed modern human occupations coincided with Heinrich events. Key references: Geology, dating, and paleoenvironment Bouzouggar et al. 2007, Raynal 1980; Hominins Ferembach 1962, Irish 2000; Archeology Roche 1967, Barton et al. 2007, Bouzouggar et al. 2007.

Grotte du Hyène (Location 47°35'N, 3°45'E, France, etym. Fr. cave of hyenas, named for the most frequent fauna found during excavation) History and general description This name is given to two adjacent caves within the Arcy-sur-Cure complex. One cave, Hyène I, was systematically excavated by André Leroi-Gourhan between 1947 and 1957; Hyène II, was not formally excavated. Leroi-Gourhan described 16 layers in Hyène I numbered 14–30. Temporal span and how dated? Stratigraphic correlation to layers at the Grotte du Renne that have been radiocarbon dated suggests that the early Mousterian layers are considerably older than 39 ka, and the post-Mousterian layers may be c.33–5 ka. Hominins found at site Several isolated hominin remains were found in layer 20, which was assigned to the lower Mousterian period. These included a mandible with nearly complete dentition, a maxilla from a different individual, several isolated teeth, a fragmentary fibula, and a fragmentary occipital. Archeological evidence found at site The lower layers at the site contain a variety of Acheulean and Mousterian artifacts. There is a depositional hiatus between layers 16 and 15, and the two top layers (14 and 15) are from a more recent, post-Mousterian or possibly Châtelperronian period. These top layers contained ochre, shells, pyrite, and bolas stones in addition to flaked stone tools. Key references: Geology, dating, and paleoenvironment Leroi-Gourhan 1961; Hominins Leroi-Gourhan 1959, 1961; Archeology Leroi-Gourhan 1961.

Grotte du Loup (Location 47°35'N, 3°45'E, France, etym. Fr. cave of wolves, named after the

taxon found most frequently during excavations) History and general description This cave, part of the Arcy-sur-Cure complex, was covered by a rock-fall and thus was protected from looting and was first excavated by André Leroi-Gourhan in 1947. Compared to other caves in the complex, the Grotte du Loup is quite small, measuring roughly 4 m by 3 m. Leroi-Gourhan described six layers, two of which contained archeological material. One was assigned to the Châtelperronian, the other to the denticulate Mousterian. Temporal span and how dated? The archeological layers have been dated by correlation to those at the Grotte du Renne, where the Châtelperronian was dated using radiocarbon dating to c.33–5 ka, and the denticulate Mousterian to c.39 ka. Hominins found at site A molar and two incisors, along with a few fragmentary cranial pieces, were found in Layer IV. Leroi-Gourhan noted that the area immediately surrounding the remains had pieces of bones and flint, whereas the rest of this layer was devoid of cultural material. He suggested this was evidence of an intrusive burial from Layer III into Layer IV, but could not tell if the entire body had been buried (and subsequently decayed) or if the head only had been interred. Archeological evidence found at site A total of approximately 150 stone artifacts mostly from Layer III were assigned to the denticulate Mousterian; the rest were found in Layer I and the Upper Paleolithic layer assigned to the Châtelperronian. A few faunal remains – including reindeer, fox, cave bear, and wolf – were found, mostly in the Layer III. Key references: Geology, dating, and paleoenvironment Leroi-Gourhan 1950; Hominins Leroi-Gourhan 1950, 1959; Archeology Leroi-Gourhan 1950.

Grotte du Renne (Location 47°35'N, 3°45'E, France, etym. Fr. grotte=cave and renne=reindeer, named for the most frequent fauna found during excavation) History and general description This cave, which is part of the Arcy-sur-Cure cave complex, was excavated between 1949 and 1966 by André Leroi-Gourhan. The Châtelperronian levels are the subject of much debate, as they contain beads and other personal ornaments that are usually associated with modern human behavior (Leroi-Gourhan 1961), but the fragmentary hominin remains found in these layers are characteristic of *Homo neanderthalensis* (Hublin et al. 1996, Spoor et al. 2003, Bailey and Hublin 2006). Some argue this is evidence of Neanderthal social complexity either via acculturation from interaction with modern humans (Mellars

2005) or independent evolution of those traits (d'Errico et al. 1998). Others argue there is no stratigraphic integrity to these layers and that the tools are from the Aurignacian levels (White 2001). Temporal span and how dated? **Radiocarbon dating** on charcoal suggest the youngest layers at the site date to *c.*20 ka, while the oldest layers are more than 39 ka. The Châtelperronian levels date to between *c.*33 and 35 ka, with some much older and much younger dates. Hominins found at site Several teeth were found throughout the site and a partial skeleton of a juvenile Neanderthal was found in the bottom of the Châtelperronian levels (d'Errico et al. 1998). Archeological evidence found at site A total of 14 layers were found and these have been interpreted as representing a sequential progression from the Mousterian through Châtelperronian and Aurignacian to the Gravettian (Leroi-Gourhan 1961). Key references: Geology, dating, and paleoenvironment Farizy 1990, Hedges et al. 1994, Leroi-Gourhan 1961, 1988, Leroi-Gourhan and Leroi-Gourhan 1964; Hominins Hublin et al. 1996, d'Errico et al. 1998, Spoor et al. 2003, Bailey and Hublin 2006; Archeology Movius 1969b, Leroi-Gourhan 1961, Leroi-Gourhan and Leroi-Gourhan 1965, Farizy and Schmider 1985, Farizy 1990 and articles therein, Schmider and Perpère 1995, d'Errico et al. 1998, Mellars 2005, White 2001.

Grotte du Rhafas *See* Rhafas Cave.

Grotte Scladina *See* Scladina.

ground reaction force *See* force.

ground stone tool Any stone tool made by abrasion rather than by percussion. Ground stone tools include deliberately shaped implements (such as the stone adzes still used on Irian Jaya; Stout 2002) as well as those shaped by use, such as the upper and lower components (manos and metates, respectively) of **grindstones**. Deliberately shaped ground stone tools become common globally only in the **Holocene**, but the first grindstones appear in the archeological record in the **Middle Pleistocene** at sites such as **Twin Rivers**, Zambia.

group Formal geological term for a stratigraphic package comprised of several **formations**. The group is a useful comprehensive term to encompass related subunits that are closely related genetically and temporally (e.g., in the **Turkana**

Basin, the **Omo Group** includes the **Koobi Fora Formation**, **Nachukui Formation**, and **Shungura Formation**).

growth Growth is very broadly defined as an increase in size. During ontogeny, growth occurs in a number of dimensions, including mass (which represents the sum of lean and fat mass, water, organ weight, and skeletal weight), proportion, and linear dimensions. In modern humans pronounced growth in stature occurs shortly after puberty; this is unique in comparison to nonhuman primates. The end point of growth is the size attained by adulthood, and growth in various dimensions may reach this point at different times.

growth factors Substances, usually peptides or steroid hormones, that are capable of stimulating and regulating cellular growth, proliferation, differentiation, and maturation. They also play key roles in the growth rate of some cancers. Examples of these include the insulin-like growth factors, fibroblast growth factor, and epidermal growth factor, which regulate a wide variety of processes within organisms ranging from neural development and neuroprotection, to angiogenesis and embryonic development, to wound healing.

growth hormone (or GH) A peptide hormone released from the anterior pituitary gland. Release of GH is stimulated by growth hormone-releasing hormone (or GHRH) from the hypothalamus and it is downregulated (i.e., reduced in quantity) by somatostatin (or SST). GH exerts its potent effects on cell hypertrophy and differentiation both through direct effects at target tissue as well as through modulation of insulin-like growth factor I (or IGF-I), which is synthesized mainly in the liver. Body size dimorphism is regulated largely through different patterns of pulsatile secretion of GH in males and females, which are initiated at puberty under the influence of increasing levels of sex steroids. Abnormalities in GH secretion, or in receptors or binding proteins for GH, can result in dwarfism or gigantism.

growth plate Also known as the epiphyseal plate, the growth plate is a cartilaginous plate located at the ends of long bones in individuals who are still undergoing growth (e.g., juveniles, individuals with estrogen insensitivity). The chondrocytes of the growth plate undergo proliferation,

resulting in cells that eventually ossify and contribute to bone growth that occurs in a proximal–distal manner. Under the influence of increasing steroid hormones, the cartilage cells of the growth plate cease duplication and the whole area becomes ossified. The rate at which this occurs, and the relationship of this ossification to chronological age, can exhibit a great degree of variation among individuals. Methods that assess bone age based on degree of ossification of hands of the bone and wrist, include the Gruelich–Pyle method and the Tanner–Whitehouse method. The state of fusion of epiphyses from fossil hominins is used to estimate chronological age, although the efficacy of such methods will vary depending on the reference population used and the skeletal elements preserved.

growth spurt *See* adolescent growth spurt.

GRR Acronym for **gross reproductive rate** (*which see*).

GSI *See* Geological Survey of India.

GSI-Narmada Site Hathnora. Locality Hathnora. Surface/in situ Surface. Date of discovery 1982. Finder Sonakia. Unit N/A. Horizon N/A. Bed/member “ca. 4m thick boulder gravels and sandy-pebble beds” (Patnaik et al. 2009, p. 120) also referred to as the “Boulder Conglomerate” (*ibid*, p. 117). Formation Surajkund Formation. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age de Lumley and Sonakia (1985) suggested a Late Middle Pleistocene age on the basis of the presence of *Stegodon ganesa* and *Elephas hysudricus*; the combination of poorly constrained paleomagnetic and isotopic ages for equivalent sediments suggests an age range of 50 to more than 200 ka (Patnaik et al. 2009). Developmental age Adult. Presumed sex Initially male (Sonakia 1984), but subsequently revised to female (de Lumley and Sonakia 1985, Kennedy et al. 1991, Kennedy 1992). Brief anatomical description Almost complete right half of a calvaria to which part of the left parietal is attached. Announcement Sonakia 1984. Initial description Sonakia 1984. Photographs/line drawings and metrical data Kennedy 1991. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions *Homo sp. indet.* Current conventional taxonomic allocation *Homo sp. indet.* Informal

taxonomic category Pre-modern *Homo*. Significance It is the only significant fossil hominin evidence from the Indian subcontinent. Location of original Geological Survey of India, Calcutta, India.

Guattari Cave *See* Grotta Guattari.

gubernacular canal *See* gubernacular foramen; gubernaculum.

gubernacular foramen The opening of a gubernacular canal at the surface of the alveolar process. The opening communicates with the **dental crypt** that contains the developing **tooth germ**. *See also* gubernaculum.

gubernaculum (L. *gubernaculum*=a rudder or helm) Cords of connective tissue that play a role in the ontogeny of the testis (i.e., *gubernaculum testis*) or of a tooth (i.e., *gubernaculum dentis*). The *gubernaculum dentis* is a cord of fibrous tissue that connects the outer layer of the **dental follicle** (the fibrous sac surrounding the developing tooth germ in the bony crypt) with the mucous membrane that lines the mouth or oral cavity. This fibrous cord has a central epithelial strand and lies in a bony canal within the alveolar bone. Its function is to guide or direct the erupting tooth to its proper location in the **alveolar process**. The bony **gubernacular canals** containing the gubernacular cords of the permanent **anterior teeth** open on the lingual side of the erupted deciduous teeth at a **gubernacular foramen**, but those of the permanent molars (and sometimes the premolars) rise directly upwards through the opening in the roof of the bony crypt. During eruption the gubernacular cords decrease in length, increase in thickness, and become replaced at the surface by an epithelial plug, through which the tooth cusp(s) eventually emerge into the mouth.

gubernaculum dentis *See* gubernaculum.

guenon The informal name for the tribe Cercopithecini that includes the genera *Cercopithecus*, *Chlorocebus*, *Erythrocebus*, *Allenopithecus*, and *Miopithecus*. *See also* Cercopithecini.

guild (ON *gildi*=payment. Craftsmen or tradesmen had to pay dues to belong to their appropriate guild) In ecology the term guild is used to describe a group of species that exploit resources in a similar way. Overall body size and functional

GÜNZ

morphology-based interpretations of the type of resource consumed are considered when defining a guild. For example, dental morphology was used to identify four **carnivore guilds** at the Miocene hominoid site of Pasalar, Turkey.

Günz *See* glacial cycles.

Guomde cranium *See* KNM-ER 3884.

GVH Abbreviation of Gladysvale hominins and the prefix for fossils recovered from **Gladysvale Cave**, Blauwbank Valley, Gauteng, South Africa.

GWM Acronym for the Gona Western Margin sector of the Gona Paleanthropological study area. *See* **Gona Paleanthropological study area**.

gyri Plural of **gyrus** (*which see*).

gyrification index (or GI) An attempt to capture in the form of an index the amount of folding of the cerebral (or cerebellar) cortex. The method uses brain slices and for each slice the gyrification index is the total length of the cortex (i.e., including the part of the cortex buried in sulci) divided by the length of the cerebral or cerebellar cortical contour that is exposed on the surface of the hemispheres.

gyrus (Gk *gyros*=circle, or ring) The visible part of a fold in the cerebral (or cerebellar) cortex that can be seen on the surface of the brain.

H

$^2\text{H}/^1\text{H}$ Two stable isotopes of hydrogen. The relative ratio of $^2\text{H}/^1\text{H}$ (referred to as δD values; *see* δ) can be measured in plant and animal tissues and is used in **stable-isotope biogeochemistry**. Plants get all of their hydrogen from water. Water sources (e.g., groundwater, surface water, and rain water) have different δD values (Kendall and Coplen 2001), thus plants using different water sources due to differences in growing season or rooting depth may have different δD values. Evapotranspiration leads to increased δD values in leaves. This is because the lighter isotope (^1H) has a higher vapor pressure and evaporates first so that the remaining leaf water is enriched in ^2H . This process is exacerbated in windy or arid regions and is reduced in humid regions. Yakir (1992) provides an excellent review of hydrogen isotopes in plants. Among animals, δD is most commonly measured in hair or fur, feathers, and in bone **collagen**. Animals get their hydrogen from the water they drink and from the food that they eat. There is some disagreement over how much of the δD values in animals reflect diet versus drinking water. Interpretations of consumer δD therefore require a good understanding of both the δD values of potential water and food sources and the physiology of the organism of interest (Hobson et al. 1999).

H or H^2 Abbreviation of **broad-sense heritability**. *See* **heritability**.

h or h^2 Abbreviation of **narrow-sense heritability**. *See* **heritability**.

habitat (L. *habitare*=to dwell) The place where an organism, population, or community lives. Almost all habitats are shared by a range of taxa that together contribute to the community ecology of that habitat. Habitat differs from **niche** in that the former stresses location and the latter the environmental parameters.

habitat mosaic *See* **mosaic habitat**.

habitat theory hypothesis An overarching theory proposed by Elisabeth Vrba that seeks to explain how environmental change influences evolutionary patterns in the fossil record. Habitat theory is complex because it embraces no fewer than seven related hypotheses: (a) most species survive periods of environmental change by passively “tracking” the changing geographical distribution of their preferred **habitat** (e.g., as **savanna** conditions spread, so do the ranges of savanna-adapted mammals); (b) areas with irregular topography (i.e., peaks and valleys) will show higher rates of species’ ranges being split (this phenomenon is called **vicariance**) than will areas of gentle topography (i.e., smooth gradations in elevation) because irregular topography induces habitat fragmentation; (c) during periods in which global temperatures vary strongly by latitude, species living in equatorial latitudes should be more prone to vicariance, **speciation**, and extinction as a result of cyclical environmental change than species living at higher latitudes; (d) during extreme cooling trends, species’ extinctions should be concentrated at low latitudes because warm equatorial-type habitats are fragmenting or disappearing; conversely, extinctions should be concentrated at high latitudes during extreme warming trends; (e) speciation does not occur unless it is “forced” by environmental change; thus, most of the turnover in lineages (i.e., the extinction of species and the appearance of new ones) occurs simultaneously in multiple taxa in what is known as a “turnover-pulse”; (f) major global climatic changes are responsible for the majority of mammalian speciation events; (g) species whose ecological resources persisted even as the Earth oscillated between environmental extremes experienced low vicariance, speciation, and extinction rates. Persistent species will include both ecological generalists, **eurytopes**, who can exploit a variety of resources, as well as ecological specialists, **stenotopes**, whose preferred resource did not

diminish in the face of environmental change. Conversely, species whose ecological resources disappeared during periods of environmental change will have experienced more vicariance, and thus higher speciation and extinction rates. *See also* effect hypothesis; eurytope; macroevolution; stenotope; turnover-pulse hypothesis.

Hadar (Location 11°10'N, 40°35'E, Ethiopia; etym. Ahdi D'ar or Adda Da'ar is the local Afar (Danakil) name for the ephemeral stream central to what is now the Hadar Research Project area. The Afar name was transcribed by Maurice Taieb as "Hadar," which is now the widely accepted name for the area and formation that outcrops here) History and general description Maurice Taieb discovered fossils at the site of Hadar, which is 300 km/180 miles northeast of Addis Ababa in the **Afar Rift System**, in the 1960s while conducting a geological survey. In 1972 Taieb invited Donald **Johanson**, Yves **Coppens**, and Jon Kalb to join him for a field season and in 1973 the group formed the **International Afar Research Expedition**. The first fossil hominins were found at the site in 1973 and specimens were found each year until this first phase of intensive fieldwork at Hadar came to an end in 1977. Sustained fieldwork resumed from 1990 until 1994 and it has been ongoing since 1999. Temporal span The **Hadar Formation** is 3.4–3.0 Ma and the overlying **Busidima Formation** is c.2.4 to less than 2.0 Ma. How dated? **Biostratigraphy**, zircon fission track, **magnetostratigraphy**, **argon-argon dating**, and **potassium-argon dating**. Hominins found at site The vast majority of the many hominins found at Hadar have been attributed to *Australopithecus afarensis* on the basis of their dental and gnathic similarities to specimens from **Laetoli** (including the type specimen, **LH 4**). Since 1973 the site has yielded approximately 400 *Au. afarensis* specimens and the Hadar sample constitutes approximately 90% of all known *Au. afarensis* fossils. Teeth, jaws, and crania are the three largest specimen categories, but postcranial fossils make up approximately 38% of the site sample. The Hadar hominin sample includes **A.L. 288-1** ("Lucy"), a remarkably complete *Au. afarensis* associated skeleton and **A.L. 444-2**, a 75–80% complete *Au. afarensis* adult skull. The material from **A.L. 333**, comprising a rich assortment of adult and juvenile skull, skeletal, and dental remains, prob-

ably represents a single biological population of *Au. afarensis*. A small minority of the hominin fossils have been attributed to *Homo*, including **A.L. 666-1**, which has been referred to *Homo* aff. *Homo habilis* (Kimbel et al. 1997). Archeological evidence found at site **Oldowan** artifacts. Hadar Formation [Location 10°55'–11°20'N, 40°20'–40°50'E, Ethiopia; etym. Ahdi D'ar or Adda Da'ar is the local Afar (Danakil) name for the ephemeral stream central to what is now the **Hadar study area**. The Afar name was transcribed by Maurice Taieb as "Hadar," which is now the widely accepted name for the area and formation that outcrops here] History and general description A region of badlands in an incised channel of the Awash River exposes substantial thickness of sediments, which can be mapped throughout the region surrounding Hadar. Although the expeditions of both Nesbitt (in 1928; see Nesbitt 1930) and Thesiger (in 1933–4; see Thesiger 1996) both passed through the region, Maurice Taieb was the first to recognize the fossiliferous localities (in 1970; see Taieb et al. 1972). Taieb et al. (1972) initially designated four formations: Hadar, Meschelle, Leadu, and Haouna-Lédi. At least two of these formations (Hadar and Meschelle) are coeval, and all four can now be rationalized into a single unit called the Hadar Formation. The Hadar Formation was further subdivided into four members by the later description of Taieb et al. (1976) (i.e., the Basal, Sidi Hakoma, Denen Dora, and Kada Hadar Members). Although the boundaries of the uppermost and lowermost members were not originally defined, the three stratigraphic boundaries between the four members remain in use. Each of the members above the Basal Member is defined as the sediments between the base of a designated tuff and the base of an overlying designated tuff. The three designated tuffs forming the stratigraphic divisions are the Sidi Hakoma Tuff (SHT), Triple Tuff-4 (TT-4), and the Kada Hadar Tuff (KHT). The names of the members come from ephemeral streams near the most prominent outcrop of the sediments that defines the member. The Basal Member was originally defined as a

"catch-all" to include the sediments below the Sidi Hakoma Tuff, although this has been refined to the sediments between the uppermost surface of a basin-bounding weathered basalt flow (attributed to the Dahla Series Basalts; see Kalb et al. 1978a and Wynn et al. 2008). Likewise, the original definition of Kada Hadar Member had an undefined upper boundary and was a "catch-all" including all sediments above the Kada Hadar Tuff. This imprecise definition was problematic for dating sites in the upper part of the formation, and the upper boundary of the formation has since been refined to the level of a major unconformity with the overlying Busidima Formation (Quade et al. 2008). Temporal span and how dated? The oldest member, the Basal Member, includes sediments that date from an unconstrained lower age of less than 4 to 3.42 Ma, and the youngest, the Kada Hadar Member, dates from 3.20 to *c.*2.9 Ma. The sediments have been dated using the **argon-argon dating** and **potassium-argon dating** methods, as well as by **magnetostratigraphy** and **biostratigraphy**. Hominins found at site Fossil hominins recovered from the Hadar Formation, *sensu novo*, include only *Australopithecus afarensis*, of which much of the hypodigm is defined by specimens from the Hadar Formation; the AL-666 early *Homo* site was originally attributed to the Hadar Formation (Kimbel et al. 1996), although the upper formation boundary remained problematic. Archeological evidence found at site The Hadar Formation includes evidence of pre-Oldowan bone modifications (cutmarks and percussion marks), without accompanying stone tools; Gona archeology was originally attributed to the Hadar Formation (Corvinus and Roche 1976, Kimbel et al. 1996), although the definition of the upper formation boundary remained problematic. Key references: Geology, dating, and paleoenvironment Taieb et al. 1972, Taieb 1976, Tiercelin 1986, Walter 1994, Walter and Aronson 1993, Quade and Wynn 2008; Hominins Johanson et al. 1982a, Johanson and Coppens 1976, Alemseged et al. 2005, 2006, Kimbel and Delezene 2009; Archeology McPherron et al. 2010. *See also Gona Paleanthropological study area; Busidima Formation.*

Hadley circulation (or Hadley cell) Describes the general circulation of the atmosphere in the tropics. The equator-ward air supplied by the trade winds that rises at the **Intertropical Convergence Zone** (or ITCZ) is matched by high poleward air

that subsides in the subtropics. Rising air at the ITCZ accounts for high rates of precipitation there and the sinking air in the subtropics accounts for the global distribution of arid regions.

Hadza (etym. "Hadza" is short for "Hadzabe," the word that identifies the Hadza people in their own "Hadzane" language) The Hadza are one of the world's few remaining populations of hunter-gatherers. They live in a 4000 km²/1544 square-mile region of northern Tanzania, south of the Serengeti, in a savanna woodland habitat around the shores of Lake Eyasi. Approximately 300–400 individuals, out of a total population of 1000, depend on hunting and gathering wild foods for over 90% of their diet; the remaining members of the tribe combine foraging with trading and begging or gaining income from the tourist trade. The Hadza do not practice agriculture or animal husbandry and they do not participate in a market economy. They reside in camps whose average size is about 30 people. People frequently move between camps and this has been linked with the Hadza's lack of traditional land rights or sense of individual ownership of natural resources. Camps move approximately every 2 months in response to seasonal availability of water and foods. Distinct wet and dry seasons are associated with differences in subsistence behaviors and social arrangements. During the dry season (i.e., June to November) camp size is relatively large, due to the limited availability of drinking water and thus the greater concentration of animals near watering holes. During the wet season (i.e., December to May) drinking water is more freely available in many areas and camp sizes are smaller. The Hadza diet consists of a wide variety of plant and animal foods and is characterized by a distinct sexual division of labor. Men typically go hunting alone with poisoned tipped arrows and take a wide variety of birds and mammals. They also collect baobab fruit and honey. Women forage in groups and primarily focus on gathering plant foods such as baobab, berries, and tubers (underground storage organs). Observations about the Hadza enable researchers to test hypotheses about evolutionary ecology in the absence of agriculture. The Hadza collect and consume foods in an ecosystem that may have been quite similar to that of our early hominin ancestors.

haemoglobin *See* hemoglobin.

Hahnöfersand (Location 53°32'50"N, 9°43'38"E, Germany; etym. name of the island) History and general description A hominin skull fragment was recovered from the bank of the river Elbe just downstream of Hamburg in 1973, supposedly associated with Pleistocene fauna. **Radiocarbon dating** by Reiner Protsch, who is alleged to have falsified data, resulted in an age of (36.3 ka±300 years), suggested this specimen was the earliest anatomically modern human in Europe, but the specimen was recently redated by more precise **AMS radiocarbon dating** to the Holocene. Temporal span and how dated? Direct AMS radiocarbon dating to 7.5 ka±55 years (uncalibrated). Hominins found at site A single cranial fragment attributed to *Homo sapiens*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Street and Terberger 2002, Street et al. 2006; Archeology N/A; Hominins Bräuer 1980, Churchill and Smith 2000.

Haile-Selassie, Yohannes (1961–) Born in Adigrat, Ethiopia, Yohannes Haile-Selassie entered Addis Ababa University in Ethiopia in 1979 and graduated with a BA in history in 1982. From 1983 to 1985 he worked as a historian in the Center for Research and Conservation of Cultural Heritage in Addis Ababa and from 1986 to 1992 he was a research assistant at the Paleoanthropology Laboratory of the National Museum of Ethiopia, also in Addis Ababa. In 1992 Haile-Selassie enrolled in the University of California, Berkeley, USA where he studied for an MA and PhD. He received his MA in anthropology in 1995 and PhD in integrative biology in 2001 for a thesis entitled “Late Miocene mammalian fauna from the Middle Awash valley, Ethiopia.” In 2002 he was appointed Curator and Head of Physical Anthropology at the Cleveland Museum of Natural History. Yohannes Haile-Selassie has undertaken paleoanthropological fieldwork in Ethiopia, beginning in 1988–9, at **Kesem-Kebena**, Chorora, and Melka Werer, and later at **Fejej**, Burji, **Konso**, Galili, and **Middle Awash study area**. Latterly he surveyed and explored the north central Afar region. Haile-Selassie currently conducts fieldwork research at the **Woranso-Mille study area** and directs the Woranso-Mille Paleontological Research Project. He was the sole author of the paper that proposed the new taxon *Ardipithecus kadabba* (Haile-Selassie 2001) and the senior author on the paper that reported further evidence of that taxon (Haile-Selassie et al. 2004). An edited volume on *Ar. kadabba* (edited jointly with Giday WoldeGabriel) was published

in 2009. *See also* *Ardipithecus kadabba*; **Woranso-Mille Paleontological Research Project**.

half-life *See* radiometric dating.

Hamann-Todd Collection Taxa *Homo sapiens*, *Pan*, *Gorilla*, etc. History Collection of modern human, great ape, and monkey skeletons held at the **Cleveland Museum of Natural History**. The collection of modern humans was assembled at Case Western Reserve University (but at the time the collection began that institution was known as Western Reserve University). The initial collection of approximately 100 modern human skeletons was assembled by Carl Hamann but the majority of the specimens were added by Hamann's successor as Professor of Anatomy, T. Wingate Todd. The latter began his academic career with Sir Grafton Elliot Smith at what was then called the Victoria University of Manchester (now called the University of Manchester), but in 1912 Todd moved to Case Western Reserve University. The influence of Sir Grafton Elliot Smith on Todd is evident, for Todd collected not only modern human skeletons but also the skeletons of non-human primates. Curator/contact person Yohannes Haile-Selassie (e-mail yhailese@cmnh.org). Postal address Cleveland Museum of Natural History, 1 Wade Oval Drive, University Circle, Cleveland, OH 44106 USA. Relevant reference Hunt and Albanese 2005.

hammer As used in the analysis of stone tools made by **percussion**, a hammer refers to an object used to fracture rock. Hammers may be made of a variety of materials, including stone, bone, antler, or wood. *See also* **hammerstone**.

hammerstone A rock, often oval in shape, held in the hand and used for a variety of pounding tasks. In hard-hammer percussion, a hammerstone is used to strike flakes off a **core**. In combination with an anvil, a hammerstone may be used to flake rocks (**bipolar** technique) or to break open foods such as nuts, marrow bones, or shellfish. Hammerstones often develop characteristic pitting on one or both ends during use.

HAN Abbreviation of Hana Hari and the prefix for fossils recovered from Hana Hari, **Middle Awash study area**, Ethiopia.

hand The primate hand can be divided into the wrist, palm, the thumb (the first digit, also known

as the pollex), and the medial four fingers (digits two through five). The primate hand differs from that of most other mammals in its prehensile or grasping ability. The opposable thumb is also generally considered to be a specialized feature of primates, although only catarrhines have a truly opposable thumb. Opposability is accentuated in the modern human hand compared to other primates, especially apes, because the thumb is relatively long and the fingers relatively short, making touching the thumb to the finger tips relatively easy. In contrast, grasping by the flexed fingers or by the thumb against the side of the index finger is accentuated in apes; the fingers are remarkably long and the thumb relatively short. Because the ape hand is specialized for suspension and climbing, modern human hand proportions are most similar to those of a terrestrial Old World monkey, like the baboons and mandrills (Napier 1993). The modern human hand is composed of 27 bones: there are eight carpal bones in the wrist, five metacarpals that make up the palm, three phalanges (proximal, intermediate and distal) in each finger and two phalanges (proximal and distal) in the thumb. African apes and modern humans share the same number of hand bones. However, all other primates, apart from some lemurs, have an additional carpal bone, the **os centrale**. The wrist is generally divided up into two rows of bones: the proximal row including the radial to ulnar side, the scaphoid (and *os centrale* in nonhominid primates), lunate, triquetrum, and pisiform, and the distal row including the trapezium, trapezoid, capitate, and hamate. The pisiform is described in modern humans by some (Scheuer and Black 2000) as a sesamoid bone and not a “true” carpal because it is small and forms late in ontogeny within the tendon of the flexor carpi ulnaris. However, in all other primates the pisiform is a much larger bone that plays a more prominent functional role within the wrist (Lewis 1989). Both rows of carpals are connected by several interosseous ligaments, both within and across the two rows, which help maintain both mobility and stability within the wrist. The two carpal rows together form a mediolaterally concave arch on the palmar surface that creates the carpal tunnel. The “walls” of the carpal tunnel are formed on the lateral side by tubercles on the scaphoid and the trapezium and on the medial side by the pisiform and the “hook” or hamulus of the hamate, all of which

extend into the palm more than the other carpals. These anatomical “walls” serve as the lateral and medial attachment sites for the flexor retinaculum, a band of tough connective tissue that forms the palmar surface (or “roof”) of the carpal tunnel and keeps the digital flexor tendons from bow-stringing and buckling during flexion of the fingers. The attachments of the carpal tunnel are also the key areas of origin for the intrinsic thenar and hypothenar muscles of the hand (see below). The eight carpal bones of the modern human wrist form multiple complex articulations, some of which are relatively mobile (e.g., between the capitate and scaphoid) and others that are highly stable (e.g., between the capitate and hamate). In general the proximal row is more mobile than the distal row. However, most of the wrist bones function to create two main synovial joints, the radiocarpal joint and the midcarpal joint (see below), that permit the large range of mobility found in the wrist. The palm of the hand is comprised of five metacarpals, the first for the thumb and the fifth on the medial side of the palm. Each metacarpal articulates with at least one carpal bone at its proximal end and the corresponding proximal phalanx at its distal end. Several intrinsic muscles that move the thumb attach to the scaphoid and trapezium and create the muscular mass on the lateral side of the palm, called the thenar eminence. On the opposing medial side, several intrinsic muscles that move the fifth (or “pinky”) finger create a muscle mass called the hypothenar eminence. The **digits** can be divided into the thumb and four fingers. Each finger is comprised of a proximal, intermediate, and distal phalanx. The thumb is unique in lacking an intermediate phalanx. The metacarpal and corresponding phalanges of any digit are called a **ray**. For example, the second metacarpal and the proximal, intermediate, and distal phalanges of the index finger are together called the “second ray.” The joints between the phalanges are synovial and each ray receives at least one muscular tendon; many are independent but some have connections to the tendons of adjacent digits, making all of the digits of the hand highly mobile and capable of fine manipulation of objects. *See also* **opposable thumb**; **os centrale**.

hand, evolution in hominins Hominin hand fossils, especially early in hominin evolutionary history, are rare and, rarer still are hand fossils from the same individual. Much of what is known

about hominin hand evolution is inferred from only a few fossils from different individuals and thus our understanding of overall hand proportions and function is limited. The hand of the last common ancestor of modern humans and *Pan* is generally most parsimoniously considered to be similar to that of an African ape (Tocheri et al. 2008). However, fossil evidence from the time of divergence is scarce. The earliest evidence of hominin hand morphology are two phalanges associated with *Orrorin tugenensis* (c.6 Ma), the most notable of which is an adult distal phalanx of the thumb which is quite broad at its distal end and foreshadows the morphology of much later hominins (Gommery and Senut 2006, Almécija et al. 2010). However, the researchers who wrote the preliminary descriptions of two nearly complete hands of *Ardipithecus ramidus* (4.4 Ma) suggest it represents the morphotype of the last common ancestor of panins and hominins. *Ardipithecus* is interpreted as lacking evidence of specializations for suspension, climbing, or knuckle-walking found in extant African apes and instead is said to be similar to more generalized, arboreal, quadrupedal Miocene apes (e.g., *Proconsul*). The thumb is large and robust and the metacarpals and phalanges are relatively short, such that the hand proportions are more similar to Old World monkeys than to extant African apes (Lovejoy et al. 2009a). The researchers who discovered and analyzed these fossils (Lovejoy et al. 2009a) suggest that the morphology of the chimpanzee is too derived to be a good model for the hand of the stem hominin. Numerous hand bones of australopiths, including those of *Australopithecus anamensis*, *Australopithecus afarensis*, and *Australopithecus africanus*, shed light on Pliocene evolution of the hominin hand. Several hand fossils of *Au. afarensis* from Hadar, Ethiopia (c.3.2 Ma), indicate these hominins had relatively short fingers compared to the length of the thumb and a more derived capitate–trapezium–second metacarpal articulation; both lines of evidence suggest the ability to use some modern human-like precision grips (Marzke 1997). However, compared to later hominins and modern humans the phalanges are relatively more curved and the thumb is gracile with a more curved trapezial articulation. Hand fossils associated with *Au. africanus* and the nearly complete hand of Stw 573 from Sterkfontein in southern Africa suggest a similar derived morphology to that seen in *Au. afarensis* (Tocheri et al. 2008). Several isolated

hand bones from Swartkrans and associated hand fossils from Olduvai Gorge (OH 7) also demonstrate the mosaic nature of hominin hand evolution. However, the taxonomic attribution of these fossils to *Paranthropus* or early *Homo* (or another taxon) is uncertain as both taxa are found at each site. The most discussed fossils from Swartkrans include two first metacarpals, one that is very large and robust with a flatter, more modern human-like trapezial facet (SKX 5020), and one that is gracile with a more curved and primitive trapezial facet (SK 84). Some of the phalanges show a combination of features, such as being relatively straight like those of modern humans but with relatively larger flexor sheath attachments as seen in the extant apes. Thirteen bones are attributed to the immature OH 7 hand, including carpals, metacarpals, and phalanges. Again, some features of the hand are similar to African apes (e.g., the morphology of the scaphoid and the large flexor sheath ridges on the phalanges), while other aspects are more modern human-like, including the remarkably flat and broad metacarpal facet on the trapezium and the expanded apical tuft of the thumb's (pollical) distal phalanx (Susman and Creel 1979). The hand of later *Homo* species such as *Homo antecessor*, *Homo neanderthalensis*, and early *Homo sapiens* is well represented in the fossil record and their morphology can be generally described as fully modern. However, there are remarkably few fossils attributed to *Homo erectus* and this gap in the hominin fossil record makes it unclear exactly when and how a modern human-like morphology evolved (Tocheri et al. 2008). Nearly complete hands from Shanidar, in Iraq, and Kebara, in Israel, show that the biggest differences between Neanderthal and modern human hands are the robusticity of the bones and slight variations in the orientation of the carpometacarpal joints. The Neanderthal hand morphology is interpreted as having increased mechanical advantage of certain muscles and being well adapted for stronger grip strength, especially that of the thumb. The morphology of early modern human hands from Qafzeh and Skhul is interpreted as being more similar to that of modern humans than to Neanderthals, suggesting that these hominins were capable of the full repertoire of modern manipulative abilities and tool making. The discovery of the *Homo floresiensis* challenged traditional ideas of hominin evolution and the hand morphology is no different. Although *H. floresiensis* is a late

surviving hominin (0.018 Ma), its wrist bones are remarkably primitive. Five articulating wrist bones have been uncovered and all demonstrate more morphological similarities to African apes and early hominins, such as the OH 7 wrist bones, than to later *Homo* (Tocheri et al. 2007, 2008, Larson et al. 2009). Thus, this primitive morphology brings into question not only the taxonomy of *H. floresiensis* but also current ideas about what type of morphology is necessary for tool use and tool making.

hand function The modern human hand is capable of both prehensile and nonprehensile movements. Prehensile movements are often used when gripping or pinching an object and generally fall into one of two categories: **precision grips** and **power grips**. Nonprehensile movements include pushing, lifting, or tapping (Napier 1993). All of these movements are accomplished through complex, integrated actions of the numerous joints, muscles, and ligaments within the forearm, wrist, and hand. Muscles that move the joints of the hand can be divided into extrinsic and intrinsic muscles. Extrinsic muscles have proximal attachments outside of the wrist or hand, and most of these attach to the medial and lateral condyles of the humerus, but that insert (or distally attach) onto the digits. Intrinsic muscles have proximal attachments within the hand, most attaching to the carpals and inserting on the digits or running between two rays (e.g., the interosseous muscles). All of the articulations among the carpal bones (i.e., intercarpal joints), between the carpals and metacarpals (i.e., carpometacarpal joints), between the metacarpals and proximal phalanges (i.e., metacarpophalangeal joints), and, finally, between phalanges (i.e., interphalangeal joints) are synovial joints and are mobile, especially the radiocarpal, midcarpal, metacarpophalangeal, and interphalangeal joints. Intercarpal joints within each carpal row and some carpometacarpal joints are comparatively more stable. The functional axis of the hand runs along the middle finger (third ray), which is in line with the forearm; side-to-side movements of the digits, such as abduction and adduction, are made in reference to this axis. *See also* **abduction**; **adduction**.

hand, ray proportions Primate hands can be generally divided into three categories based on variation in ray proportions. Mesaxonic hands are

characterized by a longer third ray, which is found in most haplorhines. Ectaxonic hands are characterized by a longer fourth ray and are commonly found in most strepsirrhines. Finally, paraxonic hand describes a primate hand in which the third and fourth rays are relatively equal in length. This morphology is found in colobine monkeys, as well as some strepsirrhines (e.g., dwarf lemurs) and New World monkeys (e.g., spider monkeys) (Jouffroy et al. 1991).

hand, relative length of the digits Comparisons of relative digit lengths (within individuals) in the form of ratios potentially provide information on how early developmental processes can impact behavior and health (Manning 2002). Differences in length between the index and ring finger in male and female modern humans were described over 100 years ago (Ecker 1875, Casanova 1894), but it was not until the 1990s that John Manning rediscovered the trait and began his pioneering work on digit ratios (Manning et al. 1998). Sex differences in the ratio of the index (2D) to ring finger (4D), termed 2D:4D, are fixed early in life and it has been proposed that this reflects the effect of prenatal sex hormones on the fetus. Modern human individuals exposed to high prenatal androgens (masculine hormones) have longer ring fingers relative to their index fingers resulting in a lower 2D:4D ratio (<1). In contrast, estrogens (feminine hormones) appear to increase the length of the index finger relative to the ring finger making the digits more equal in length, resulting in a ratio that more closely approximates to 1 (Manning 2002). Although other digit ratios show sex differences, 2D:4D has become the preferred ratio as it tends to be the most sexually dimorphic. The links between prenatal sex hormones, sexual differentiation, and 2D:4D appear to be via shared developmental pathways. The formation of the fetal reproductive system (that produces sex hormones) and the development of the distal parts of the limbs (digits) are influenced by the same group of *HOX* genes (Zákány et al. 1997, Kondo et al. 1997). *HOX* genes are developmental regulators implicated in the expression of DNA and the action of *HOX* genes can be altered by sex hormones (Taylor 2002). The overarching theory is that 2D:4D acts as a biological marker for the effects of prenatal sex hormones on fetal tissues and thus for their subsequent influence on the body and brain during growth and into adulthood (Manning 2002).

Consequently, 2D:4D has been employed widely in the study of sex differences in modern human developmental psychology, behavior, and disease and these kinds of analyses are being extended to other animals (see Lombardo and Thorpe 2008, McIntyre et al. 2009). In primates, differences between ray proportions and relative digit length vary between taxonomic groups and are strongly linked to patterns of locomotion and hand posture (Susman 1979, Jouffroy et al. 1993). After controlling for possible functional effects on relative digit lengths, studies of primate 2D:4D indicate that evolutionary changes in prenatal sex hormones may be linked to important differences in social behaviors across species; lower 2D:4D is linked to promiscuous social systems while higher 2D:4D is associated with pair-bonded, monogamous social systems (Nelson and Shultz, 2010). These relationships also appear to be detectable in fossil hominoids (Nelson et al. 2010). *See also hand ray proportions.*

hand, tool use and tool making Traditionally, past research has generally focused on the length of the thumb compared to the fingers and the potential to form one type of **precision grip**, between the end of the thumb and distal pad of the index finger, as the key to tool-use and tool-making ability in humans and hominins. However, experimental research with modern humans making or using **Oldowan** tools reveals that three types of precision grip are primarily used: (a) the pad-to-side grip between the thumb and the side of the index finger, (b) the “baseball,” or three-jaw chuck, grip, and (c) a pinch grip between the thumb and the four finger pads (Markze 1997); **power grips** are not used (see below). These three precision grips allow for effective tool use and tool making while minimizing muscle fatigue and stress on the hand joints. Thus, researchers have looked for skeletal morphologies that facilitate these grips in modern humans and in the hominin fossil record to understand how and when tool use and tool making evolved (*see hand, evolution in hominins*). Kinematic studies of modern humans using tools have shown that the wrist plays a particularly important role in stone-tool production and the increased mobility in the modern human wrist relative to that of chimpanzees may have played a key role in the evolution of hominin tool use (Williams et al. 2010). Electromyographic studies of modern humans making

Oldowan tools have shown that muscles on both the radial (thumb) side and ulnar (fifth digit) side are used most consistently (Markze et al. 1998). Apes trained to use crude stone tools demonstrate that modern human hand morphology is not necessary for this behavior, but perhaps a key adaptation in hominins was the ability to use forceful manipulation of stone with one hand (instead of two). Modern human hand function during tool use and tool making differs from that of nonhuman primates in two distinct ways: (a) modern humans are able to apply more force to pinch, rather than hold, an object securely with precision grips; (b) because of the increased mobility of the digits, modern humans are able to accommodate the thumb and fingers to the shape of objects. In contrast to modern humans, the relatively short thumb and long fingers of chimpanzees are not able to create a stable, firm pinch of an object or to control it by the pads of cupped thumb and fingers, but recent research suggests they can maneuver objects within their hand.

handaxe Large (typically more than approximately 10 cm in length) bifacially flaked, oval or teardrop in plan view and lenticular in cross section, stone tools that are characteristic of the Acheulean industry. Handaxes can be made on cobbles, nodules, or large **flakes** and they were probably used for a wide variety of tasks, including butchery and perhaps woodworking. Handaxes occur in Africa and parts of Eurasia from *c.*1.6 Ma to perhaps as recently as 0.16 Ma.

hanging remnant *See Swartkrans.*

Hanoman 1 Site Bukuran. Locality Near the village of Bukuran in the **Sangiran Dome**. Surface/*in situ* Surface. Date of discovery 1989. Finder Local villager. Unit N/A. Horizon N/A. 1994. Initial taxonomic allocation *Homo erectus* Widiyanto et al. 1994. Taxonomic revisions None. Current conventional taxonomic allocation *H. erectus*. Informal taxonomic category Pre-modern *Homo*. Significance This specimen documents morphological variation in *H. erectus* crania from Java (i.e., it has a typical frontal with a **supraorbital torus** combined with a gracile occipital region that lacks a marked **nuchal torus**. Location of original **Palrad Laboratory**, Bandung, Indonesia.

haplogroup (Gk *haplo*=single and It. *gruppo*=group) A group of similar **haplotypes** that share a common ancestor. Haplogroups are commonly used in studies of **mitochondrial DNA** and the **Y chromosome**. For example, A, B, C, D, and X are the mitochondrial DNA haplogroups most commonly found in Native Americans.

haploid (Gk *haplo*=single and *oid*=like or resembling) Organisms or cells having only one copy of each **chromosome**. For example, sperm and egg cells, called gametes or germline cells, are haploid. The **Y chromosome** is also referred to as haploid since there is only one present in a normal male cell.

haplotype (Gk *haplo*=single and *typos*=figure or model) An abbreviation of “haploid genotype” that refers to a specified sequence of **DNA** that is confined to one **chromosome**. The term haplotype is also used to refer to sets of **single nucleotide polymorphisms** (or SNPs) or **short tandem repeats** (or STRs) found together (or linked) on the same chromosome (or the same part of a chromosome).

Happisburgh (Location 52°49'36"N, 1°31'58"E, England; etym. name of a nearby village) History and general description Changes in the level of the North Sea have recently re-exposed sections of the Hill House Formation (or HHF) just south of Mundesley on the Norfolk coast of eastern England. Temporal span and how dated? The artifacts and the fauna from Happisburgh Site 3 come from channel deposits that were laid down in the lower reaches of the proto-Thames that at the time flowed into what is now the North Sea at this location. The paleomagnetic signal is weak, but the sediments show reversed polarity, which constrains them to either the **Matuyama** epoch or to a period of reversed magnetism in the **Brunhes** epoch.

Biostratigraphy (e.g., *Mammathus meridionalis* and *Microtus arvalis*) and paleobotanical [e.g., *Tsuga* (hemlock) and *Ostrya*-type (hop-hornbeam)] dating evidence further constrains these age estimates and suggests the site was occupied between 0.99 and 0.78 Ma. **Hominins found at site None**. Archeological evidence found at site **Cores, flakes, and flake tools** ($n=76$) made of flint were found *in situ* at several levels in the site; there were no handaxes. Key references: Geology, dating, and paleoenvironment Parfitt et al. 2010; Hominins N/A; Archeology Parfitt et al. 2010.

HAR Abbreviation of Hargufia, one of three three-letter prefixes (e.g., **BOD** and **DAW** are the others) used for the paleontological evidence collected by the **Middle Awash Research Project**. Each fossil has a three-letter prefix that refers to the subdivision/drainage area where it was found followed by VP (for Vertebrate Paleontology), then the number of the collecting site within the area, and finally a number that places the fossil in the sequence of fossils recovered from that collecting site. Thus HAR-VP-1/1 is the first fossil to be found in the first collecting site to be recognized in the Hargufia drainage of the **Middle Awash study area**.

Hardy-Weinberg equilibrium (etym. Named after the English mathematician Godfrey Hardy and the German physician Wilhelm Weinberg) A principle in population genetics. Hardy and Weinberg pointed out that under the assumption of a randomly mating (the technical term is panmictic) population **allele** frequencies do not change from generation to generation (i.e., they are in equilibrium) unless the population is acted upon by one or more of the four forces of evolution (**mutation, genetic drift, natural selection, and gene flow**). In the simplest case of two alleles at a **locus**, the allele frequencies are represented by the equation $p+q=1$ (where p =the allele frequency of one allele and q =the allele frequency of the other; together their frequencies must equal 100% or 1.0) and the genotype frequencies are represented by the equation $p^2+2pq+q^2=1$. These equations can be used to calculate the expected frequency of carriers ($2pq$) of a recessive trait or to examine whether a particular locus is at Hardy-Weinberg equilibrium. But the above only applies so far as genotype frequencies are concerned if mating is random.

If mating is not random (e.g., if there is assortative mating or endogamy/exogamy the genotype frequencies will change and not in the way predicted by the Hardy–Weinberg equilibrium. If the mating is assortative the effect will influence the frequencies of the genotypes involved in determining the phenotypic character causing assortative mating and in the case of endogamy/exogamy the frequencies of all of the genotypes will be affected.

Hargufia One of the named subdivisions/drainage areas within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area**, Ethiopia. History and general description The drainage area was first explored for its paleoanthropological potential in 1981 by a multidisciplinary team organized by the **Ethiopian Ministry of Culture** and led by **Desmond Clark**, with more extensive excavations taking place in 1990. Temporal span A tuff exposed within Unit U of the Bodo-Dawaitoli-Hargufia sedimentary sequence has a suggested age of 0.64 ± 0.03 Ma and biostratigraphic evidence points to a **Middle Pleistocene** age for the sediments exposed at Hargufia. How dated? **Argon-argon dating** and **biostratigraphy** based on biostratigraphic correlation with **Olduvai Gorge Bed IV** and **Ologesailie**. Hominins found at site None. Archeological evidence found at site. **Mode 1 Acheulean** artifacts have been recovered from localities HAR-A2, HAR-A5, and HAR-A6 and **Mode 2 Acheulean** artifacts have been recovered from localities HAR-A1, HAR-A3, and HAR-A4. Key references: Geology, dating, and paleoenvironment Clark et al. 1994, de Heinzelin et al. 2000; Hominins N/A; Archeology de Heinzelin et al. 2000.

Harris lines Dense lines seen in plain radiographs of juveniles, subadults, and young adults that are orientated at right angles to the long axis of long bones. Insults such as serious infections apparently do not interfere with **mineralization** but they do cause **cartilage** growth to slow. Following such insults, **osteoblasts** produce horizontally orientated trabeculae that show up as lines of increased density.

HARs An acronym for **human accelerated regions** (*which see*).

Hathnora (Location $22^{\circ}49'14''N$, $77^{\circ}51'14''E$, India; etym. local name for a village close to the find site) There are several paleontological and arche-

ological localities at Hathnora in the **Narmada Basin**. Four are in the Surajkund Formation (Surajkund 1, 2, and 3, and **Hathnora 1**) and one is in the Baneta Formation (Hathnora 2). *See also* **GSI-Narmada; Hathnora 1**.

Hathnora 1 (Location $22^{\circ}49'14''N$, $77^{\circ}51'14''E$, India; etym. local name for a village close to the find site) History and general description Hathnora is one of several localities near the village of Hathnora on the northern bank of the Narmada River in Madhya Pradesh, India. The presence of Pleistocene sediments has been recognized since the late 19thC (de Terra and de Chardin 1936). Temporal span and how dated? Late **Middle Pleistocene** based on **biostratigraphy**, but **electron spin resonance spectroscopy dating** of “three mammalian teeth stratigraphically associated with the hominin calvaria” (Patnaik et al. 2009, p. 114) suggest a minimum age of *c.* 50 ka and a maximum age of *c.* 160 or more than 200 ka. Hominins found at site Hathnora 1, also known as the GSI-Narmada calvaria, plus Patnaik et al. (2009) suggest there are also two hominin clavicles and a partial hominin rib. Archeological evidence found at site **Quartzite hand-axes, flakes, etc.** and **flint and chert scrapers** were reported in the area near to the find site. Key references: Geology, dating, and paleoenvironment Sonakia 1984, Agarwal et al. 1988, Tiwari and Bhai 1997, Patnaik et al. 2009; Hominins Sonakia 1984, 1985, Kennedy et al. 1991, Sankhyan 1997; Archeology Sonakia 1985, Patnaik et al. 2009. *See also* **GSI-Narmada**.

Haua Fteah (Location $32^{\circ}55'12''N$, $22^{\circ}07'48''E$, Cyrenaica, Libya; etym. Berber for great cave) History and general description Haua Fteah (or Hawa Ftaih) is located 60 m above sea level on the northern slopes of Gebel el Akhdar (etym. Ar. green mountain) on the Mediterranean coast of Libya, east of the Gulf of Sirte. The site was discovered by Charles McBurney in 1948 during a geological survey and he returned to excavate the cave between 1951 and 1955. Despite excavating to 14 m depth in the deposits McBurney never reached an archeologically sterile layer. His 1967 monograph on the site was a landmark study in African archeology and incorporated some of the earliest uses of **Oxygen Isotope Stage** dating. The cave itself preserves one of the longest archeological chronologies in North Africa with deposits spanning the Historic period through the **Middle Paleolithic**. Temporal span and how dated? Dating of the site had been

somewhat controversial since the original **radiocarbon dates** published by McBurney (1967) have a high margin of error. More recent dating efforts using **biostratigraphy** and **geostratigraphy** have established the antiquity of the oldest deposits at *c.*200 ka while also indicating that the recent Holocene deposits are the result of many brief depositional episodes separated by hiatuses (Hunt et al. 2010). **Hominins found at site** Two hominin mandible fragments were recovered by McBurney from early Middle Paleolithic levels (McBurney et al. 1953a). The fragments represent two individuals, one young adult and one juvenile, from the same occupation period (McBurney 1967). Phillip Tobias, in his analysis in McBurney's 1967 text, assigned the mandibles to *Homo sapiens rhodesiensis*. The modern taxonomic equivalent would be *Homo heidelbergensis* or *Homo rhodesiensis*. **Archeological evidence found at site** McBurney divided the deposits into Phases G–A from youngest to oldest. The phases correspond respectively to Historic-Protohistoric, Neolithic of Libyco-Capsian Tradition, Libyco-Capsian, Eastern Oranian (Iberomaussian), Dabban, **Mousterian**, and **Pre-Aurignacian** (Lubell 2001, McBurney 1967). Faunal remains, both terrestrial and marine, are well represented at the site. Barbary sheep are present throughout the sequence of deposits, as are auroch and gazelle. Domesticated caprines first appear in the Libyco-Capsian levels (Lubell 2001). Sea shells in the pre-Aurignacian levels are among the earliest evidence for human exploitation of marine resources; land snail shells in the same deposits evoke the Capsian culture *escargotières* found to the west in the Maghreb. Key references: **Geology, dating, and paleoenvironment** Hunt et al. 2010, McBurney 1967; **Hominins** Tobias in McBurney 1967, McBurney et al. 1953a; **Archeology** Moyer 2003, Lubell 2001, McBurney 1967.

Haua Fteah I **Site** Haua Fteah. **Locality** N/A. **Surface/in situ** *In situ*. **Date of discovery** 1952. **Finder** Unnamed assistant to R. Hey. **Unit** Phase BI, 1st substage of the Levalloiso-Mousterian complex, 2.5 m below the earliest Upper Paleolithic deposits. **Horizon** Layer XXXIII, Spit 1952/32. **Bed/member** N/A. **Group** N/A. **Nearest overlying dated horizon** Layer XXVIII, dated to 41.45 ± 1.3 ka. **Nearest underlying dated horizon** N/A. **Geologic age** The layer containing the fossil (Layer XXXIII) is dated to 45.05 ± 3.2 ka by **radiocarbon dating**; however, more recent efforts at dating the site based on Mousterian artifact associations suggest that an

age between 130 and 50 ka is more likely (Hublin 2000, Klein 2009). **Developmental age** Young adult, 18–25 years old. **Presumed sex** Female. **Brief anatomical description** Virtually the entire left ramus, except for the lateral end of the condyle, and a part of the mandibular corpus as far forwards as the P₄; the second and third permanent molars are in place. **Announcement** McBurney et al. 1953a. **Initial description** McBurney et al. 1953a. **Photographs/line drawings and metrical data** McBurney 1967 (Appendix 1B by P.V. Tobias). **Detailed anatomical description** McBurney et al. 1953a, 1953b, Tobias 1967b. **Initial taxonomic allocation** *Homo sapiens neanderthalensis*, specifically described as having affinities to the **Tabun** *Homo sapiens* hominins (McBurney et al. 1953b). **Taxonomic revisions** *Homo sapiens rhodesiensis* (Tobias 1967b). Tobias notes similarities to sub-Saharan African specimens and suggests that Haua Fteah I represents an “advanced Afro-Asian Neanderthaloid population.” **Current conventional taxonomic allocation** *Homo heidelbergensis* or *Homo rhodesiensis* **Informal taxonomic category** Anatomically modern human. **Significance** Used to support McBurney's hypothesis that advanced **Neanderthaloid** populations, now generally assigned to archaic *Homo sapiens*, arose in the tropics of sub-Saharan Africa and moved northward into the Maghreb and southwest Asia. **Location of originals** University Museum of Anthropology and Archaeology, Downing Street, Cambridge, UK (Duckworth Laboratory reg. no. Af.8.7.1).

Haua Fteah II **Site** Haua Fteah. **Locality** N/A. **Surface/in situ** *In situ*. **Date of discovery** 1955. **Finder** C.M.B. McBurney. **Unit** Phase BI, 1st substage of the Levalloiso-Mousterian complex, 2.5 m below the earliest Upper Paleolithic deposits. **Horizon** Layer XXXIII, Spit 1955/110. **Bed/member** N/A. **Group** N/A. **Nearest overlying dated horizon** Layer XXVIII, dated to 41.45 ± 1.3 ka. **Nearest underlying dated horizon** N/A. **Geologic age** The layer containing the fossil (Layer XXXIII) is dated to 45.05 ± 3.2 ka by **radiocarbon dating**; however, more recent efforts at dating the site based on Mousterian artifact associations suggest that an age between 130 and 50 ka is more likely (Klein 2009, Hublin 2000). **Developmental age** Juvenile, 12–14 years old. **Presumed sex** Female. **Brief anatomical description** The left mandibular ramus is present though missing the lateral end of the condyle, as in **Haua Fteah I**. A small part of the corpus is present,

as far forward as the distal edge of the socket for M₂. Radiographs taken at the British Museum in 1955 indicated the presence of a developing M₃ within its follicle. This was subsequently extracted for further study. Announcement Described at the Neanderthal Centenary Symposium, Dusseldorf, Germany, in 1956. Initial description McBurney 1958. Photographs /line drawings and metrical data McBurney 1967 (see Appendix 1B by P.V. Tobias), McBurney 1958. Detailed anatomical description Tobias 1967b. Initial taxonomic allocation *Homo sapiens rhodesiensis*. Taxonomic revisions None. Current conventional taxonomic allocation *Homo heidelbergensis* or *Homo rhodesiensis*. Informal taxonomic category Anatomically modern human. Significance Used to support McBurney's hypothesis that advanced Neanderthaloid populations, now generally assigned to archaic *Homo sapiens*, arose in the tropics of sub-Saharan Africa and moved northward into the Maghreb and southwest Asia. Location of originals University Museum of Anthropology and Archaeology, Downing Street, Cambridge, UK (Duckworth Laboratory reg. no. Af.8.7.2).

Haupt knochen schicht (Ge. for "main bone layer") See Trinil; Trinil H.K. fauna.

Hay, Richard L. (1929–2006) Born in Indiana, USA, Richard Hay received his BA in 1946 and his MA in 1948, both from Northwestern University. He went on to receive a PhD in 1952 from Princeton University. Hay spent 2 years in the US Army before becoming an Assistant Professor at Louisiana State University in 1955. Two years later he went to the University of California at Berkeley where he became a Professor of Geology. At Berkeley Hay joined a group of the world's most distinguished petrographers, such as Howell Williams, Francis Turner, and Charles Gilbert. He studied mineral alteration in sedimentary rocks using petrographic analysis and emphasized integrating both analytical data and field relations with petrography. The skills he developed and used at Berkeley were the basis of many of his later achievements. In 1962 Mary and Louis Leakey invited Hay to work on the stratigraphy of Bed I at Olduvai Gorge. In the event he spent a total of 12 years there working out the stratigraphy, magnetostratigraphy, chronology, sedimentology and the Pleistocene paleogeography of the area. Hay's 1976 book, *Geology of the Olduvai Gorge*, was eminently accessible to non-geologists and it has had a lasting

impact among archeologists and anthropologists. When Hay and Mary Leakey moved the focus of their activities to Laetoli, he combined field studies and petrography with chemical, isotopic, and X-ray diffraction analysis to generate hypotheses about the nature of syndepositional volcanism that resulted in the unique record of footprints, including those of early hominins. In 1983, Hay became the Ralph E. Grim Professor in the Department of Geology at the University of Illinois at Urbana-Champaign. There he discovered the low-temperature megareplacement of uppermost Precambrian and Cambrian-Ordovician rocks of the US mid-continent by potassium-feldspar, a huge geochemical alteration still not quite understood in terms of its origin in the geological history of the North American continent. Hay retired in 1997 and moved to Tucson, Arizona, with his wife, Lynn, where he became an Adjunct Professor at the University of Arizona. In 2000 Hay was awarded the Rip Rapp Archaeological Geology Award from the Geological Society of America. A year later, in 2001, he shared the Leakey Prize with Garniss Curtis. See also **Laetoli hominin footprints; Olduvai Gorge**.

Hayonim (Location 32°56'N, 35°13'E, Israel; etym. He. *hayonim*=dove or pigeon) History and general description Cave site located in western Galilee on the left bank of a tributary of the Nahal Yassof river. The excavations were carried out in three phases, 1965–1971, 1974–1979 and 1992–1999. The uppermost Natufian layers possibly represent a permanent multiseasonal occupation. Temporal span and how dated? Thermoluminescence dating on burned flints gives an age of 230–140 ka for the lower Mousterian layers and electron spin resonance spectroscopy dating on teeth gives a range of 177–182 ka. Hominins found at site A large number of complete or nearly complete skeletons have been recovered from the Natufian layers of the site, many of which are burials. The hominin remains from the Acheulean and Mousterian layers are far more fragmentary and are unsuitable for taxonomic assignment; Arensburg et al. (1990) provide a list of the hominins recovered. Archeological evidence found at site An extensive lithic sequence is known from the site extending from Natufian in the upper layers to the Mousterian and Acheulean in the lower layers. The Mousterian assemblage includes early Middle Paleolithic blade tools. Key references: Geology, dating, and paleoenvironment Weiner et al. 2002, Rink et al. 2004, Mercier et al. 2007a; Hominins

Bar-Yosef and Goren 1973, Arensburg et al. 1990; Archeology Bar-Yosef 1991, Meignen 1999.

hazard rate The limiting value for the probability of an event (typically a death) within a time interval, divided by the width of the time interval. As the time interval becomes progressively shorter this probability divided by the interval reaches the instantaneous hazard rate. The average age at death for a constant hazard (also referred to as the residual component in a **Siler hazard model**) is the inverse of the hazard rate, so that a constant hazard of, for example, 0.02 gives an average age at death of $1/0.02 = 50$ years. The first graph in a series shows the probability of death within the first year, then within the first 2 years, and so on up to the probability of death within the first 80 years. The age-specific **probability of death** can be found by assuming a constant hazard of death within the interval (see Wood et al. 1992).

Hazorea (Location 32°39'N, 35°06'E, Israel; etym. He. *hazore'a* = the sower, named after the kibbutz on which it is located) **History and general description** Open-air site in the middle of a field on the Hazorea Kibbutz. The **Paleolithic** faunal and lithic assemblages came to light when a field was ploughed and because none of the recovered artifacts or bones were found *in situ*, it is difficult to judge the relative age of the specimens. Further excavations revealed numerous **Neolithic** and historical artifacts. **Temporal span and how dated?** The phenotypically Paleolithic assemblages are undated. **Hominins found at site** The more complete specimens, Hazorea 1 and 2, are nearly complete occipital bones and share morphological affinities with both *Homo erectus* and the **Steinheim** cranium. **Fluorine dating** revealed that the hominin remains belong to temporally separate groups, with Hazorea 2, 4, and 5 being older than Hazorea 1 and 3. **Archeological evidence found at site** Most of the flint tools found appear to be “typical of the Lower Paleolithic” (Anati and Haas 1967). Key references: **Geology, dating, and paleoenvironment** Anati et al. 1973; **Hominins** Anati and Haas 1967; **Archeology** Anati et al. 1973.

HCRP RC Acronym for the Hominid Corridor Research Project Ruasho and Chomolo and the prefix for fossils recovered by the **Hominid Corridor Research Project** from localities between the Ruasho and Chomolo Rivers (e.g., **HCRP RC 911** from Malema). *See* Malema.

HCRP RC 911 **Site** Malema. **Locality** RC 11. **Surface/in situ** *In situ*. **Date of discovery** 1996. **Finder** Stephen Mwanyongo. **Unit** Middle Sand at the base of the Bone Bed. **Horizon** Bone Bed. **Bed/member** Unit 3A. **Formation** Chiwondo Beds. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** *c.* 2.3–2.5 Ma. **Developmental age** Adult. **Presumed sex** Unknown. **Brief anatomical description** Alveolar process of the left side of the maxilla, including the heavily worn and badly damaged crown and the roots of M¹ and the even more damaged crown and roots of the M². No measurements are given, but the tooth crowns are estimated to be equivalent in size to those of KNM-ER 733 and 1804 (both belonging to *Paranthropus boisei*); they are substantially larger than the equivalent crowns of *Paranthropus robustus*. **Announcement** Kullmer et al. 1999. **Initial description** Kullmer et al. 1999. **Photographs/line drawings and metrical data** Kullmer et al. 1999. **Detailed anatomical description** N/A. **Initial taxonomic allocation** *Paranthropus boisei sensu lato*. **Taxonomic revisions** None. **Current conventional taxonomic allocation** *Paranthropus boisei*. **Informal taxonomic category** Megadont archaic hominin. **Significance** The value of this fragmentary specimen is that enough morphology is preserved to be sure that (a) it does not belong to *Homo* and (b) it belongs to an archaic megadont hominin. It is assumed to belong to *P. boisei* but the size of its tooth crowns is also consistent with it belonging to the *Australopithecus garhi*. Either way, its main significance is biogeographical, for it extends the range of either of these taxa more than 1000 km/620 miles to the south. **Location of original** **Cultural and Museum Centre, Karonga.**

HCRP UR Acronym for the Hominid Corridor Research Project Uraha and the prefix for fossils recovered by the **Hominid Corridor Research Project** from localities at Uraha, Malawi. *See* Uraha.

HCRP UR 501 **Site** Uraha. **Locality** U 18. **Surface/in situ** Surface, then *in situ*. **Date of discovery** 1991 and 1992. **Finder** Tyson Mskika. **Unit** Paleosol in the lower part of Unit 3. **Horizon** *See* above. **Bed/member** Unit 3A. **Formation** Chiwondo Beds. **Group** N/A. **Nearest overlying dated horizon** N/A. **Nearest underlying dated horizon** N/A. **Geological age** *c.* 2.3–2.5 Ma.

Developmental age Adult. **Presumed sex** Unknown. **Brief anatomical description** Adult mandibular corpus preserved in two nearly equally complete parts, the one on the left side extending to the distal border of the M₂ whereas the fragment of the right side of the corpus extends to the mesial plate-like root of the M₃. Parts of the crowns of the P₃s are preserved and the P₄ crowns are well preserved, as are the M₁ crowns. The right M₂ crown is well preserved, the left M₂ crown less so. **Announcement** Schrenk et al. 1993. **Initial description** Schrenk et al. 1993. **Photographs/line drawings and metrical data** Bromage et al. 1995. **Detailed anatomical description** Bromage et al. 1995. **Initial taxonomic allocation** *Homo rudolfensis*. **Taxonomic revisions** None. **Current conventional taxonomic allocation** *H. rudolfensis*. **Informal taxonomic category** Transitional hominin. **Significance** The value of this specimen is that enough morphology is preserved to be sure that (a) it does not belong to an archaic megadont hominin and (b) it resembles KNM-ER 1802, a mandible assigned to *H. rudolfensis*. The main significance of HCRP UR 501 is biogeographical, for if it does belong to *H. rudolfensis* it extends the range of that taxon more than 1000 km/620 miles to the south. **Location of original** **Cultural and Museum Centre, Karonga, Malawi.**

head-balancing index An index introduced by Raymond Dart (1925, p. 197) to provide a quantitative way of demonstrating the relatively anterior position of the **foramen magnum** in the **Taungs** child. It is the distance between basion and inion, divided by the distance between basion and prosthion, multiplied by 100. Dart cited index values of approximately 50 in *Pan*, more than 90 in modern humans, and he estimated its value in Taung(s) to be roughly 60.

hearth (OE *hoerth*) Following standard English usage, the hearth is the floor of a fireplace, but when the term is used by paleolithic archeologists it refers to visible evidence for the controlled use of fire. Fire use may be recognized through sediment colorization caused by high heat and oxidation or by the presence of large amounts of charcoal or wood ash (e.g., Meignen et al. 2007). Often, but not always, evidence of attempts to control a fire took the form of shallow pits or stone barriers (e.g., a ring of stones) recoverable

through careful excavation. The absence of such features at **Chesowanja** makes it difficult to be sure whether that site records a fire deliberately set by hominins or a natural fire (e.g., lightning setting fire to a tree resulting in a burned out tree stump).

heel strike *See* walking cycle.

Heidelberg mandible *See* Mauer mandible.

Heinrich events Heinrich events are ice-rafting events named after Hartmut Heinrich. They were identified by Heinrich on the evidence of “dropstones” (i.e., pebbles considerably larger than the ambient sedimentation) found in sediments on the floor of the North Atlantic Ocean (Heinrich 1988). Sea ice often forms in shallow waters and incorporates sediments from the continental shelf, and the subsequent movement of sea ice can transport these sediments (with their included dropstones) that fall to the sea floor when the sea ice melts. The morphology of ice-rafted sediments can be distinguished from other forms of transport (e.g., **fluvial** or **aeolian**), and the mineralogy, elemental, and isotopic composition of these dropstones can be used to infer their source. Six Heinrich events have been identified during the last glacial (i.e., between 60 and 17 ka), and they are numbered H1–H6, with H6 being the oldest. Some consider the **Younger Dryas** to be the most recent Heinrich event, in which case it would be H0. Climate shifts coinciding with Heinrich events have been reported in paleoclimate records well beyond the Atlantic. For example, cold **sea surface temperatures** in the North Atlantic associated with increased ice rafting may have altered patterns of precipitation in Africa (Carto et al. 2009).

Heinzelin, Jean de (1920–98) Born in Belgium to a family of noble descent, de Heinzelin attended the Université Libre Bruxelles (ULB) where he obtained his undergraduate degree in 1941, followed by a master’s degree in geology in 1946 and a doctoral degree in geology and the mineralogical sciences in 1953. He was also awarded a Diplôme d’Etat from the Sorbonne in Paris, France. In 1944 de Heinzelin became a scientist at the Belgian Natural Sciences Museum, where he eventually became deputy curator and assistant director of the laboratory from 1947 until 1951. He also taught geology, successively at ULB and the Vrije Universiteit Brussel, finally becoming a full Professor at the Royal

University in Ghent in 1964. de Heinzelin's involvement in archeology and prehistory began in the 1950s. While exploring in what was then the Belgian Congo in 1957 de Heinzelin discovered the Ishango bone, a baboon fibula bearing a series of tally marks engraved along it and having a piece of quartz fixed to one end. This instrument was dated to the Upper Paleolithic and is now thought to be more than 20,000 years old. From 1961 to 1966 he participated in a UNESCO project to rescue important archeological sites in the Nile Valley, and he also undertook field research in Sahabi (Libya) between 1977 and 1982. However, it was de Heinzelin's involvement with the **International Omo Research Expedition** with Clark Howell between 1967 and 1974, and subsequently with the **Middle Awash Research Project** with Desmond Clark and Tim White, that resulted in his seminal contributions to paleoanthropology. His detailed assessments of the stratigraphy of the Omo-Shungura Formation enabled the paleontologists working with the International Omo Research Expedition to locate fossils with precision and thus the Omo-Shungura Formation became an important reference for biostratigraphical studies at other sites in East and southern Africa. His contributions were recognized by the award of the V. Van Straelen and Adolphe Wetrems prizes in Belgium, as well as the Paris Prix des laboratoires. de Heinzelin was also a lifetime member of the scientific council for the Belgian Royal Institute for the Natural Sciences.

Helicobacter pylori (Gk *helix*=spiral, plus *L. bacter*=rod and *pylorus*=gatekeeper) Over half of all modern humans are infected by this Gram-negative bacterium, which, as its name implies, is found in the stomach. It is harmless in the short term, but its spiral structure allows it to burrow into the mucosa of the upper gastrointestinal tract, where it causes peptic ulcers in both the stomach and duodenum and it is a risk factor for gastric cancer. Its relevance for human evolution is that *Helicobacter pylori* is highly **polymorphic**, so there are more than 300 distinct strains of *H. pylori*. Linz et al. (2007) investigated 769 isolates of *H. pylori* from 51 different "ethnic" sources and used **Bayesian Markov chain Monte-Carlo cluster analysis** to investigate the relationship between the distribution of strains and the geographical locations of the samples. They found that 73% of modern human variation as assessed using **microsatellite** data could be explained by a linear relationship

with the variation among *H. pylori* strains. The geographical patterns of genetic isolation by distance (or IBD) assessed using *H. pylori* and modern human genetic diversity are a good match, both showing a continuous loss of genetic diversity with increasing geographic distance from East Africa. Simulations suggest that *H. pylori* migrated from East Africa *c.*58 ka, a time that is consistent with the estimated departure of modern humans from East Africa. The evidence suggests that modern humans have harbored *H. pylori* for at least 60 ka, and that modern humans and the micro-organism have been co-evolving ever since. More recently Moodley et al. (2009) used the distribution of *H. pylori* haplotypes to investigate the history of the peopling of the Pacific. They found that "a distinct biogeographic group" called hpSahul split from the main Asian populations of *H. pylori* *c.*31–7 ka and moved into **Sahul** (i.e., New Guinea and Australia) and they suggest those populations remained isolated there for *c.*23–32 ka. Much later a second biogeographic group of *H. pylori*, hpMaori, split off as a subpopulation of hpEastAsia *c.*5 ka and that subpopulation subsequently spread into Melanesia and Polynesia. The timing of the origin of hpSahul is consistent with the estimated age of the Q mtDNA **haplogroup** and the timing of the origin of hpMaori is consistent with the results of a computational linguistic analysis of the dispersal and development of the Austronesian language group (Gray et al. 2009).

helicoidal wear plane (Gk from *helix*=spiral) The pitch (i.e., the transverse orientation) of the occlusal wear plane is not the same along the tooth row. Wear is normally greater on the lingual, or tongue, side of the maxillary teeth in the anterior part of the postcanine tooth row, with the posterior part of the tooth row either showing less emphasis on the lingual side or more wear on the buccal, or cheek, side. Tobias (1980b) proposed that this twist in the pitch of the occlusal wear plane was not seen in hominins until the emergence of *Homo*, but Richards and Brown (1986) have shown that the twisting nature of the occlusal wear plane has no taxonomic value.

hematite (Gk *haimatites*=blood-like stone) Hematite (α -Fe₂O₃), the principal ore of iron, is a common component of metamorphic, igneous, and sedimentary rocks. It is the primary

component of (red) **ochre**, a common colorant found as an exotic material at many **Late Pleistocene** sites from southern Africa to France (see Watts 2002, White 2007). *See also ochre.*

hemispheric dominance Hemispheric dominance refers to an asymmetry of the structure or function of the **cerebral hemispheres** of the brain. For example, there is strong population-wide leftward functional hemispheric dominance among modern humans in the neural representation of **language**. Similarly, the modern human brain also displays anatomical hemispheric dominance as evident by **petalias** and by the leftward asymmetry of the **planum temporale**.

hemizygous (Gk *hemi*=half and *zygon*=yoke) The possession of only one copy of an **allele** or **chromosome** in a **diploid** organism. All mammals and thus all primates are diploid organisms and males are hemizygous for both the **X chromosome** and **Y chromosome**. If a gene is deleted on just one of the two autosomal chromosomes, then the individual is hemizygous for that gene. Because males are hemizygous for the X chromosome, recessive X-linked phenotypes are more common in males. This is also the case for X-linked recessive diseases and disorders such as hemophilia and color blindness.

hemoglobin (Gk *haîma*=blood plus L. *globulus*=globe and *in*=pertaining to) Abbreviation of hematinoglobulin (i.e., hematin plus globulin). It is the major **protein** in red blood cells and it carries oxygen from the lungs to the tissues. It is made up of two alpha globin and two beta globin protein subunits, which each contain a heme group. Each heme group can bind one oxygen molecule. The significance of hemoglobin for human evolution is that hemoglobins were some of the earliest and most extensively studied proteins in regional populations of modern humans. In addition, the alpha globin and beta globin protein subunits have been subject to selection for protection against malaria. *See also globins.*

Heoanthropus *See Sergi, Giuseppe (1841–1936).*

herbivore (L. *herba*=grass, plus *vorous*, from the stem of *vorare*=to devour) An animal that consumes plants. *See also herbivory.*

herbivory (L. *herba*=grass, plus *vorous*, from the stem of *vorare*=to devour) The consumption of plants. Herbivory is an inclusive term that may subsume a more specific dietary focus on a type of plant (i.e., grass, or **graminivory**) or a specific part of plants in general (i.e., fruit, or **frugivory**). Herbivory can be considered as a form of predation in which an organism consumes a plant.

heritability (L. *hereditare*=to inherit, from *heres*=heir) An individual's **phenotype** is determined by that individual's **genotype** and environment. Heritability is the proportion of phenotypic variation in a **population** that is attributable to **genetic variation** among individuals. The heritability of a particular **trait** may be different among populations because of both genetic and environmental factors. For example, the heritability of a complex trait such as stature might be high in a population that is well nourished and has access to health care and lower in a population where malnourishment and disease are common (i.e., the conditions that most likely prevailed in early hominins) even if the underlying genetic variation is the same. This is because in the latter population the environmental variance accounts for a higher proportion of the **phenotypic variance**. **Broad-sense heritability** (H or H^2) is defined as the total genetic variance divided by the phenotypic variance. It is called “broad-sense” because it reflects *all* possible genetic contributions to the phenotypic variance such as **additive genetic variance**, **dominance**, **epistasis**, and parental effects. **Narrow-sense heritability** (h or h^2) is the additive genetic variance divided by the phenotypic variance where the additive genetic variance is the weighted average of the squared values of the additive effects. In other words, the additive variance is variance due to differences among **alleles** only. Thus, narrow-sense heritability only refers to the portion of the phenotypic variation that is additive (or allelic) and does not take into account variation due to epistatic, dominance, or parental effects. However, the additive effects are important because this variation is the only variation that natural selection can act on. Narrow-sense heritability estimates are typically used in agricultural genetics to estimate how the mean of a trait of interest (such as milk production or size) will change in the next generation given how much the mean of the selected parents differs from the mean of the population.

heritable *See* heritability.

herpestid The informal name for the **Herpestidae** (mongooses and relatives), one of the **feliform** families whose members are found at some hominin sites. *See also* **Carnivora**.

Herpestidae The animal family that includes mongooses and their close relatives. It is one of the **feliform** families whose members are found at some hominin sites. *See also* **Carnivora**.

Herto (Location 10°15'55"N, 40°33'38"E, Ethiopia; etym. named after a nearby Afar village) History and general description The Herto locality was discovered as part of the **Middle Awash Project's** research efforts on the **Bouri Peninsula**. Prospecting in 1997 led to the discovery of six hominins, including three partial crania, and this intensified efforts to clarify the geology, archeology, and paleontology of the site. Two additional hominin fragments were recovered in 1998. All the hominins derive from the base of Upper Herto Member and were found on an **erosional surface** containing fossils, artifacts, and vertebrate fossils in a pebble **conglomerate**. Vertebrate fauna from the Upper Herto Member include taxa that are indicative of both grassland and aquatic habitats (e.g., *Hippopotamus*, *Thryonomys*, *Equus*, and *Connochaetes*). Temporal span and how dated? **Biostratigraphy** suggests a late **Middle Pliocene** age, and **argon-argon dating** of **amorphous** grains from **pumice clasts** from the sediments containing the hominins resulted in an age estimate of 163±3 ka. **Tephrostratigraphy** of an overlying volcanic ash (tephra) deposit has provided a correlation with an unnamed tuff at **Konso**, Ethiopia, that lies 6 m beneath the Konso Silver Tuff, which has been dated by argon-argon dating to 154±7 ka. The bounding tephra deposits suggest a very brief temporal span of *c.*160 ka. Hominins found at site **BOU-VP-16/1**, a large, well-preserved adult cranium and dentition, **BOU-VP 16/2**, a larger but fragmentary cranium, **BOU-VP-16/3**, a parietal fragment, **BOU-VP-16/4**, a parietal fragment, **BOU-VP-16/5**, a child's cranium, **BOU-VP-16/6**, a right M¹ or M², **BOU-VP-16/18**, vault fragments, **BOU-VP-16/42**, a left P⁴, and **BOU-VP-16/43**, a parietal fragment. These specimens are large and robust but their morphology is anatomically modern human. Archeological evidence found

at site As well as butchered faunal elements, numerous tools were found in the Upper Herto Member, including **handaxes**, **cleavers**, and other **bifaces** as well as **Levallois** flake tools. The bifaces were made from fine-grained **basalt**, but the points and light-duty blades are made from **obsidian**. The technology and typology of the tools most closely resemble those from **Garba III** and **Melka Kunturé** in Ethiopia. Key references: Geology, dating, and paleoenvironment Clark et al. 2003; Hominins White et al. 2003; Archeology Clark et al. 2003.

Hesperanthropus *See* **Sergi**, **Giuseppe** (1841–1936).

heterochromatin *See* **chromosome**.

heterochrony (Gk *hetero*=other and *kronos*=timing) Changes in the relative timing of the appearance or the rate of development of a feature in a descendant relative to the developmental timetable of the same feature in an ancestor. Heterochrony involves changes in ancestral developmental patterns that include shifts in rate and/or timing. Even when such shifts are apparently minor, they can produce significant alterations in morphology. Analyses of heterochronic transformations focus on the ontogeny of size and size-related changes, and explore the idea that selection may act on size through growth rates or timing, or on the rate or timing of growth itself. Since a large proportion of studies focus on adult morphologies and their presumed evolutionary transformations, and detailed studies of ontogeny permitting a comparative analysis of rate and duration of growth are relatively rare, it is important to discriminate between the results of heterochrony from the processes that generate the results. *See also* **acceleration**; **paedomorphosis**; **peramorphosis**; **hypermorphosis**; **hypomorphosis**; **neoteny**.

heteroplasmy (Gk *hetero*=other and L. *plasma*=form or shape) This term refers to the mixture of several different sequences of mitochondrial DNA in the same cell or individual. For example, individuals with mitochondrial diseases (e.g., Leber's hereditary optic neuropathy) are typically heteroplasmic since their mitochondria will contain a mixture of the wild-type DNA (i.e., mitochondrial DNA without the mutation) and some mtDNA with the deleterious mutation. The higher

the proportion of mitochondrial DNA with the deleterious mutation, the greater the severity of the disease. In the debate about “Mitochondrial Eve” (see **mitochondrial DNA**), the assumption that mitochondrial DNA was inherited strictly from the mother was questioned since occasional examples of heteroplasmy due to a paternal contribution were found in other animals. If this were true in modern humans, it would affect the coalescence time for mitochondrial DNA (i.e., the age of “Mitochondrial Eve”). However, subsequent research has failed to provide any evidence of a significant paternal contribution to mitochondrial DNA.

heterosis (Gk *heteroios*=different in kind) Heterosis can result from heterozygote advantage (overdominance) or recombinant hybrid vigor. In the skeleton heterosis is typically manifested as increased size. The role of **hybridization** in human evolution is currently poorly understood, though hotly debated (e.g., modern humans and Neanderthals) (syn. hybrid vigor). *See also* **hybridization**.

heterozygosity *See* **heterozygote**.

heterozygote (Gk *hetero*=other and *zygotos*=yoked) An individual organism that has two different **alleles** at a **diploid locus**. For example, an individual who has the genotype AB for the ABO locus and thus the blood type AB is referred to as being heterozygous. The significance of heterozygosity is that it is one of the sources of the variation that is necessary for evolution to occur.

heterozygous *See* **heterozygote**.

heterozygous advantage (Gk *hetero*=other and *zygotos*=yoked) The circumstance where it is advantageous to be heterozygous (i.e., have different versions of the allele on the two chromosomes) because the **heterozygote** has a higher fitness. An example in modern humans is the sickle-cell, or S, **allele** of the beta globin **gene**. In the **homozygous** form this allele is deleterious because it causes sickle-cell anemia, but in regions where malaria is endemic the heterozygous form protects against malaria. In such an environment, homozygotes for the wild-type allele are at a disadvantage because they are more susceptible to malaria. Thus, both alleles are maintained in the population (syn. heterozygote advantage). *See also* **balancing selection**; **hemoglobin**; **malaria**.

Hexian (和县) (Location 31°53'3"N, 118°12'18"E, eastern China; etym. named after the local county) History and general description The site of Longtandong (Dragon Pool Cave) is situated on the northern slope of Wangjiashan (“hill of Wang’s family”) just south of the town of Taodian, Hexian County, Anhui Province. Temporal span and how dated? **Thermoluminescence and uranium-series dating** methods of the fossil fauna yielded age ranges of 211–179 ka and 190–150 ka, respectively. Subsequent **electron spin resonance spectroscopy dating** and uranium-series analyses of rhinoceros and bovid teeth give a combined age estimate of 412±25 ka. This places Hexian equivalent to the base of layer 3 of **Zhoukoudian Locality 1**. Hominins found at site PA 830 (also known as **Hexian I**), a well-preserved calvaria, PA 831, a fragmentary left side of the mandibular corpus with M₂ and M₃, and PA 832, 833, and 834(1–2), four isolated teeth, were discovered in 1980. The Hexian (PA 830) calvaria is presumed to be a young adult male individual. In 1981, additional fossil material consisting of a frontal with part of the **supraorbital region** (PA 840), a parietal fragment (PA 841), and five isolated teeth (PA 835–839) were recovered. Archeological evidence found at site None. Repository **Institute of Vertebrate Paleontology and Paleoanthropology**, Beijing, China. Key references: Geology, dating, and paleoenvironment Chen et al. 1987, Grün et al. 1998; Hominins Wu and Dong 1982, Wu and Olsen 1985, Pope 1992, Wu and Poirier 1995, Brown 2001, Durband et al. 2005, Wu et al. 2006.

Hexian 1 Site Longtandong. Locality N/A. Surface/in situ Surface. Date of discovery 1980. Finders Unknown. Unit N/A. Horizon Near the top of Bed II. Bed/member Bed II. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age: The most recent electron spin resonance spectroscopy and uranium-series dates suggest an age of c.412±25 ka. Developmental age Adult. Presumed sex Unknown. Brief anatomical description The cranial vault is well preserved, but the only parts of the basicranium to be preserved are the temporal bones and the posterior border of the foramen magnum. Endocranial volume 1025 cm³. Announcement Huang et al. 1981. Initial description Huang et al. 1982, Wu and Dong 1982. Photographs/line drawings and metrical data Huang

et al. 1982, Wu et al. 2006. Detailed anatomical description N/A. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-modern *Homo*. Significance The Hexian calvaria is equivalent in age to Zhoukoudian X, XI, and XII and its endocranial morphology is closest to the Zhoukoudian sample (Wu et al. 2006). Location of original Institute for Vertebrate Paleontology and Paleoanthropology, Beijing, China.

High Cave, The *See* Mugharet el ‘Aliya.

high-ranking prey Within an **optimal foraging theory** framework high-ranking prey are those taxa or food resources that provide higher-than-average energetic returns. The **prey-choice model** predicts that high-ranking prey should always be pursued when encountered. Accordingly their abundances in archeological contexts should approximate their abundances on past landscapes. In archeological contexts prey rankings are often determined according to body size since larger taxa tend to provide greater energetic returns than small taxa. For example, large ungulates are typically regarded as high-ranking prey. However, a growing body of ethnographic evidence suggests that other factors (e.g., prey mobility) may play an important role in explaining human foraging decisions and prey rankings. *See also* **low-ranking prey**.

high-survival elements A subset of skeletal elements known to be resistant to destructive taphonomic processes. These include elements with substantial amounts of high-density cortical bone and relatively little cancellous bone (e.g., for most ungulates, these include the long bones, cranium, and mandible). Because high-survival elements provide the most accurate representation of those bones originally deposited by hominins, their study can be particularly useful when examining **carcass transport strategies** in bone assemblages that have been subjected to destructive processes. *See also* **skeletal element survivorship**.

high-utility bones *See* **economic utility index**.

higher taxon (Gk *taxis*=to arrange or “put in order”) Any **taxon** above (i.e., more inclusive

than) the level of the **genus**. Thus, the subtribe Australopithecina and the tribe **Hominini** are examples of higher taxa, whereas *Paranthropus boisei*, a **species** is not.

hindbrain (OE *hinder*=behind and OE *braegen*=brain, most likely from the Gk *bregma*=the front of the head) The hindbrain (or rhombencephalon) is the posteriormost, or **caudal**, of the three swellings, or vesicles, that give rise to the brain. The hindbrain is comprised of the medulla oblongata, the pons, and the cerebellum. The **cerebellum** is a dorsal outgrowth from the same embryonic brain subdivision that contains the pons. *See also* **brain**.

hippocampus (Gk *hippos*=horse and *kampos*=sea monster) A seahorse-shaped structure located in the medial part of the **temporal lobe** of the brain, adjacent to the **amygdala**. An important component of the **limbic system** the hippocampus is involved in functions such as spatial orientation, navigation, emotions, and the storage of **declarative memory** (i.e., the parts of the memory concerned with persons, places, and objects).

hippopotamid The informal name for the artiodactyl family comprising the hippopotami. *See* **Artiodactyla**.

Hippopotamidae The family that includes hippopotami and their close relatives. It is one of the **artiodactyl** families whose members are found at some hominin sites. *See* **Artiodactyla**.

histology The study of microscopic anatomy. Histology often involves generating a section of a tissue to visualize structures with light or transmission electron microscopy. Alternatively, a replica can be made for study with scanning electron microscopy or fractured or polished surfaces can be examined with **confocal microscopy**. For example, traditional approaches to understanding **enamel development** and **dentine development** involve preparing thin sections (approximately 100 m) (or **cross-sections**) to view them under transmitted or polarized light microscopy (e.g., Schmidt and Keil 1971).

H.K. Abbreviation for **Haupt Knochen schicht**. *See* **Trinil**; **Trinil H.K. fauna**.

HLA Acronym for human leukocyte antigens. See **major histocompatibility complex**.

Hoedjiespunt (Location 33°0'S, 17°57'E, Western Cape Province, South Africa; etym. named after the nearby peninsula) History and general description Fossiliferous Middle and Late Pleistocene dunes are well known in the area and they have provided evidence of shellfish collecting during Oxygen Isotope Stage 5 (Volman, 1978). Lee Berger collected the first hominin tooth in 1993 from the base of a 6 m-deep sequence of fossiliferous sands exposed by a road cut in a fossil dune deposit on the southern edge of Hoedjiespunt Peninsula, 6 m above sea level in Saldanha Bay. Further collection yielded additional vertebrate fossils and artifacts. The vertebrate fossils, including the hominins, derive from a brown hyena den. Temporal span and how dated? Middle Pleistocene based on associated fauna and Middle Stone Age (or MSA) artifacts and on geological evidence including foraminifera that are older than 78 ka. There is a uranium-series date of 300 ka for calcrete capping the deposit but Butzer (2004) argues the hyena burrow is intrusive and he favors a Late Pleistocene age for the site. Hominins found at site Four permanent teeth of a juvenile and a fragmentary right tibia that may belong to the same individual. The teeth are an upper left molar (HDP1-1), a right M³ (HDP1-2) that bears three cusps, and a left I₁ and I₂ (HPD1-3 and HDPI-4). Archeological evidence found at site MSA artifacts occur in the hominin level and in a sand and shell deposit at the top of the 6 m section. Key references: Geology, dating, and paleoenvironment Volman 1978, Berger and Parkington 1995, Churchill et al. 2000, Butzer 2004; Hominins Berger and Parkington 1995, Churchill et al. 2000, Stynder et al. 2001; Archeology Volman 1978, Berger and Parkington 2005, Stynder et al. 2001, Matthews et al. 2005.

Hofmeyr (Location 25°58'E, 31°34'S, South Africa; etym. after the nearby town of Hofmeyr, Eastern Cape Province, South Africa) History and general description The skull was recovered in 1954 from a dry channel bed of the Vlekport River, but erosional controls downstream have caused the location to be covered by silt. The endocranium was filled with a hard matrix of sand cemented with carbonate. The specimen was severely damaged in 1970 and comparison with photographs taken in

1965, reveal the loss of the anterior part of the face, the anterior teeth, and part of the ramus of the mandible. Temporal span and how dated? Optically stimulated luminescence and uranium-series dating suggest an age of 36.2±3.3 ka. Hominins found at site Hofmeyr 1, a skull comprising a partial cranium and a fragmentary mandible. Archeological evidence found at site N/A. Key references: Geology, dating, and paleoenvironment Grine et al. 2007; Hominins Grine et al. 2007, 2010; Archeology N/A.

Hofmeyr 1 Site Hofmeyr. Locality N/A. Surface/in situ In situ in a channel of the Vlekport River. Date of discovery 1954. Finder C. Hattingh, Jr. Unit N/A. Horizon The skull may have derived from another sedimentary context, but it shows no evidence of rolling. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Late Pleistocene. Developmental age Adult. Presumed sex Unknown, but its size and morphology suggest it may be male. Brief anatomical description A large cranium with a moderately strong supraorbital torus, a projecting glabella, square orbits, a slightly projecting, wide nose, and (in its pristine state) marked alveolar prognathism. Announcement Grine et al. 2007. Initial description Grine et al. 2007. Photographs/line drawings and metrical data Grine et al. 2007, 2010. Detailed anatomical description N/A. Initial taxonomic allocation *Homo sapiens*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo sapiens*. Informal taxonomic category Anatomically modern human. Significance Hofmeyr 1 (its catalogue number at the East London Museum is among the earliest evidence of late Pleistocene *Homo sapiens* in southern Africa. The results of a multivariate analysis show that Hofmeyr 1 falls closest to the centroid for European crania associated with the Upper Paleolithic, and is at the edge of the range of variation of recent sub-Saharan Africans. Thus, Hofmeyr 1 provides more evidence that at c.36 ka modern human crania resemble each other rather than specimens of modern *Homo* from the same region. These results fit predictions of the out-of-Africa hypothesis for the origins of modern humans. Location of original East London Museum, South Africa.

Hohle Fels Venus A carved ivory figurine recovered in six fragments between September

8 and 15, 2008, from the southern German **Aurignacian** site of **Hohle Fels**. The figurine depicts a female modern human that is lifelike, with the exceptions that it lacks a head, has de-emphasized limbs and it has exaggerated secondary sexual characteristics. It is in the tradition of the Venus figures from the **Gravettian** period such as the **Willendorf Venus** discovered in 1908. The Hohle Fels Venus (*c.* 35 ka calibrated radiocarbon years) is at least 5 ka older than other figurines and is the earliest known figurative image of a modern human (Conard 2009).

Höhlenstein-Stadel (Location 48°32'57"N, 10°10'21"E, Germany; etym. *Höhlen*=caves, *stein*=rock, and *stadel*=barn; presumably because it was used to house livestock) History and general description A cave site along the Lone river in the Ulm district that is just downstream from **Vögelherd** cave. It was excavated in the 1930s by Robert Wetzel, and several hominin specimens and archeological levels were recovered. Temporal span and how dated? Biostratigraphic correlation has suggested an age range from the Eemian or Early Würm to the Holocene. Hominins found at site Several hominin remains were found, including some Holocene *Homo sapiens*, but also a presumed **Upper Paleolithic (Aurignacian)** *H. sapiens* adult premolar, and a likely juvenile male *Homo neanderthalensis* right femoral diaphysis. Archeological evidence found at site The site is best known for a large anthropomorphic lion figurine carved from mammoth tusk that was found in the Acheulean levels. Key references: Geology, dating, and paleoenvironment Street et al. 2006; Archeology Hahn et al. 1985; Hominins Czarnetzki 1983, Kunter and Wahl 1992.

Holloway, Ralph (1935–) Born in Philadelphia, Pennsylvania, USA, Ralph Holloway began his undergraduate career in metallurgical engineering at the Drexel Institute of Technology in 1953, but after transferring to the University of New Mexico he received a BS in geology and engineering in 1959. He attended the University of California at Berkeley for his graduate studies and in 1964 he was awarded a PhD in anthropology for his thesis entitled "Some quantitative relations of the primate brain." Holloway joined Columbia University in 1964, where he is still on the Faculty; he became a Research Associate at the American Museum of Natural History in 2005. Holloway is a leading expert on hominin and comparative **endocranial morphology**. His important technical contribution

was to develop a method that uses latex to make an impression of the endocranial surface of relatively complete crania. The method involved stopping holes other than the foramen magnum, introducing a small volume of liquid latex, swirling it around so that it formed a thin coat against the endocranial surface, letting that cure, then repeating the process until the latex was thick enough to be used to make an endocranial cast and thin enough that it could be easily detached from the endocranial walls and removed via the foramen magnum. This technique gave Holloway a unique insight into hominin endocranial morphology and this led him to develop the hypothesis that early hominins underwent major neural reorganization (specifically a relative increase in the parietal association areas that resulted in the lunate sulcus being shifted posteriorly) *before* there was evidence of any significant increase in overall brain size. Ralph Holloway has also made major contributions to the interpretation of hominin endocranial morphology with regard to the evolution of cerebral asymmetry, the significance of encephalization, and the co-evolution of language and the brain. *See also* **encephalization**; **endocranial morphology**; **lunate sulcus**.

Holocene (Gk *holos*=whole and *kainos*=recent) The youngest (and current) epoch of the **Neogene** Period within the **Cenozoic** Era, spans the interval of time from 11.7 ka to the present. The onset of the Holocene follows the termination of the **Younger Dryas** stadial (i.e., cooling) event that punctuated the most recent deglaciation. The Holocene was previously thought to be a period of relatively monotonous interglacial conditions; however, much attention has recently been devoted to **proxy-based paleoclimate** reconstructions uncovering the climatic variability of the Holocene. For example, the early Holocene was much wetter, with a perhaps abrupt transition to drier conditions around 5 ka (deMenocal et al. 2005). More recently historical records have documented climatic swings during the Medieval Climate Anomaly (*c.* AD 1100–1300), marked by warm conditions in Europe and a northwards migration of agricultural zones, and the Little Ice Age (*c.* AD 1400–1900), a period of cooler conditions in Europe. These climate events identified as temperature excursions in mid and high latitudes may be regional or global in impact and in some low-latitude regions are instead felt as changes in aridity. For example, the Medieval Climate Anomaly, which is associated with a warming in Britain,

coincides with an arid shift affecting the Anasazi in the southwestern USA.

holotype (Gk *holos*=whole and *typus*=image) According to the **International Code of Zoological Nomenclature** a holotype is the specimen listed as the **type specimen** in the original description of a **taxon** (e.g., OH 7 is the holotype of *Homo habilis*). *See also* **type specimen**.

Holstein *See* glacial cycles.

Homa peninsula *See* Kanam; Kanjera.

home base hypothesis A model for Oldowan site formation developed by Glynn Isaac (1978a, 1981, 1984). It incorporated elements that were claimed to distinguish extant **hunter-gatherer** and African ape adaptations, including (a) the use of a central place from which hominins dispersed and returned on a daily basis, (b) a sexual division of labor whereby males hunted or scavenged for animal tissue and females gathered plant food resources, (c) delayed consumption, and (d) transport of food to the base where food sharing and social activities took place. Food sharing was a central element of the home base hypothesis and it was claimed that it could have provided the selective milieu for the further evolution of **cognition** and for the emergence of modern human **language**.

home range The total area exploited by an individual animal or a group of animals. Home range size varies between species and even between populations of the same species. It is influenced by a variety of factors including the **productivity** of the **habitat** and the dietary strategy of the animal: insectivorous and frugivorous primates tend to have relatively larger home ranges than primates that rely on more ubiquitous resources, such as grass or leaves. **Body mass** is also an important determinant of home range size; larger animals tend to need absolutely more food, so will have larger home ranges. Thus, the total population (or group) weight must also be considered. Estimates of hominin home ranges have been based on body mass within a model derived from foraging human populations (e.g., Antón and Swisher 2004).

homeobox genes (Gk *homoio* from *homos*=the same and “box” apparently because these genes have

a small enough sequence that it can be written in a “box” in a manuscript) A family of genes involved in **development**, specifically in the regulation of **morphogenesis**. *Homeobox* (also abbreviated to *Hox*) genes control spatial positioning for both the anterior–posterior and proximal–distal body axes. They are called *homeobox* genes because of a short 180 **base pair DNA** sequence that encodes part of a protein molecule called the homeodomain. Homeodomain molecules can bind DNA, so proteins that include a homeodomain can act as **transcription factors** and thus help regulate the **gene expression** of other genes. In modern humans, the 39 *HOX* genes are found in four clusters on chromosomes 2, 7, 12, and 17 (NB: the convention is that if the name of the gene is written with all capital letters it means the gene is a human gene, so *HOXA1* is a modern human gene, whereas the homologous gene in mice would be *HoxA1*).

homeodomain (Gk *homoio* from *homos*=the same and L. *dominium*=property) *See homeobox genes*.

hominid (L. *homin*=man or human being) Informal or vernacular name for a **species** (or an individual specimen belonging to a **taxon**) within the family **Hominidae**. *See Hominidae*.

Hominid Corridor Research Project A field and laboratory project that began in 1983 that addressed outstanding problems in the Plio-Pleistocene paleobiogeography of continental Africa (e.g., the origin and dispersion of Plio-Pleistocene faunas) by focusing on the region between the clusters of hominin sites in East Africa and those in southern Africa. Most of the project’s fieldwork was conducted in Malawi, specifically in the Chiwondo Beds in northern Malawi. The project, which was founded and co-directed by Friedemann Schrenk and Timothy Bromage (e.g., Bromage et al. 1987, Schrenk et al. 1993, Bromage and Schrenk 1995), recovered a hominin mandible (**HCRP UR 501**) from Uraha in 1991 and a maxillary fragment (**HCRP RC 911**) from Malema in 1996.

Hominidae (L. *homin*=man or human being) In the past the family Hominidae was interpreted to include only the modern human **clade** and it would have excluded all the non-human great apes. But given the copious morphological, molecular, and genetic evidence for a close relationship

between modern humans and chimpanzees/bonobos, some researchers now take the view that the former clade should be recognized at a lower level than that of the family. These researchers support a more inclusive interpretation of the family Hominidae so that it would include the three subfamilies, Ponginae, Gorillinae, and Homininae or just two subfamilies, Ponginae and Homininae. In this more inclusive interpretation the living representatives of the family Hominidae are, respectively, the orangutans, gorillas, **chimpanzees/bonobos**, and **modern humans**. Therefore, the fossil representatives of the family Hominidae are all those extinct taxa that are more closely related to the above living taxa than to any other living **taxon**. Some researchers still use the family name Hominidae for the modern human twig of the tree of life, but most are moving towards a usage that is consistent with modern biology (i.e., recognizing the modern human clade at the level of the tribe as the **Hominini**).

hominin (L. *homin*=man or human being) The informal or vernacular term for a specimen that belongs to a **taxon** within the tribe **Hominini**. For example, *Paranthropus boisei* is a hominin taxon and KNM-ER 406 is a hominin fossil.

hominin footprints Footprints are **trace fossils** (syn. **ichnofossils**) that provide a record of fossilized behavior on a relatively short time scale (on the scale of minutes to days). They provide unique information about gait in extinct hominin taxa in that they provide direct evidence of the shape of the soft tissues of the plantar surface of the foot and the manner in which the foot makes contact with the ground during the gait cycle. Modern human footprints are distinctive because they begin with a deep, rounded heel print, followed by an impression made by the lateral side of the foot, then a deep impression under the metatarsal heads as the center of pressure moves medially and the impression sequence ends with a relatively deep impression for the hallux in line with the other toes. Modern human footprints often lack an impression under the medial side of the foot where the longitudinal arch, if well developed, does not contact the substrate. The deepest part of the print often occurs below the medial metatarsal heads and hallux where the highest toe-off forces occur (Vereecke et al. 2003). However, footprint morphology shows

substantial variation due in part to variation in foot anatomy, walking gait, speed, and the properties of the substrate such as its firmness, particle size, and moisture content (Bennett et al. 2009). Footprints are rare in the hominin fossil record. The only hominin footprints in the Pliocene are those made by three individuals walking in a wet ash deposited 3.75 Ma in **Laetoli**, Tanzania (Leakey and Hay 1979). The **Laetoli hominin footprints** show compelling evidence that bipedal gait was well established in the hominins that made them, but ambiguities remain in the evidence of an arch and regarding the nature of gait (Stern and Susman 1983, White and Suwa 1987, Bennett et al. 2009). In the early Pleistocene, three instances of hominin footprints are known from the **Koobi Fora** (1.4–1.53 Ma). While they are distinguishable from modern human footprints, they show distinctive characteristics of a modern human style of gait noted above. Fossilized footprints are more common in the late Pleistocene and Holocene. A set of footprints in the Roccamonfina volcanic ash, southern Italy (Mietto et al. 2003) dates to 385–325 ka and appear fully modern human-like. Footprints from *c.*117 ka sediments in South Africa (Roberts and Berger 1997) and from 19–23 ka layers at **Willandra Lakes** in Australia (Webb et al. 2006) match those made by modern humans today.

Hominina If the tribe **Hominini** is interpreted to include both the **clade** that contains modern humans and the clade that contains extant chimpanzees/bonobos then some researchers (e.g., Andrews and Harrison 2005) discriminate between the two clades at the level of the subtribe. In which case the clade that contains modern humans would be called the **Hominina** and the clade that contains extant chimpanzees/bonobos would be called the **Panina**.

Homininae (L. *homin*=man or human being) A subfamily formally introduced by John **Robinson** (1972). He suggested that it contained just one genus, *Homo*, that subsumed “*Australopithecus*, *Meganthropus* from Africa, *Telanthropus*, *Sinanthropus*, *Pithecanthropus*, *Atlantropus*, and other supposed genera that are now generally treated as falling into either *H. erectus* or *H. sapiens*” (*ibid.*, p. 6). However, this was at a time when the family **Hominidae** was interpreted more exclusively and included only modern humans and all

the extinct taxa more closely related to modern humans than to any other non-human great apes.

homininan The informal term for individuals or taxa within the subtribe Hominina. See **Hominina**.

hominine (L. *homin*=man or human being) The informal or vernacular term for a specimen that belongs to a **taxon** within the subfamily **Homininae**.

Hominini (L. *homin*=man or human being) The tribe that includes modern humans and all the fossil taxa more closely related to modern humans than to any other living **taxon**.

hominoid (L. *homin*=man or human being and *oides*=resembling) The vernacular term for a member of the superfamily **Hominoidea**. The living hominoids (i.e., modern humans, chimpanzees/bonobos, gorillas, orangutans, and gibbons) all belong to the same **clade**. Fossil hominoids are all the taxa that are more closely related to living hominoids than they are to any other living **taxon**.

Hominoidea (L. *homin*=man or human being and *oides*=resembling) The superfamily comprising the following living taxa – modern humans, chimpanzees/bonobos, gorillas, orangutans, and gibbons – and all the fossil taxa that are more closely related to these taxa than to any other living **taxon**.

Homo See **Homo** Linnaeus, 1758.

Homo Linnaeus, 1758 (L. *homin*=man or human being) The genus introduced by Carl Linnaeus in 1758 to accommodate modern humans and which referred exclusively to modern humans. The history of the interpretation of the genus *Homo* since its introduction in the tenth edition of Linnaeus' *Systema Naturae* has been one of episodic relaxation of the criteria used for deciding what taxa should be included within the genus, with each episode resulting in one, or more, extinct taxon being added to *Homo*. As originally conceived by Linnaeus, the genus *Homo* incorporated two species, *Homo sapiens* (i.e., modern humans) and *Homo troglodytes*. William King was the first to suggest that an extinct hominin species, namely *Homo neanderthalensis*, should be included within *Homo* (King 1864). Researchers still argue about the taxonomic significance of the

differences between *H. sapiens* and *H. neanderthalensis* but the inclusion of the latter within *Homo* meant expanding the definition of *Homo* to included archaic and derived morphology (e.g., discrete and rounded supraorbital margins, midline facial projection, a distinctive parietal and occipital morphology, and robust limb bones with relatively large joint surfaces) either not seen at all, or not seen in this combination, in *H. sapiens*. The next modification of the interpretation of the genus *Homo* was in 1908 when *Homo heidelbergensis* was added to the genus (Schoetensack 1908). This meant that *Homo* now embraced at least one individual with a mandible that had a robust mandibular corpus and lacked a true chin. Then came the addition of *Homo rhodesiensis* (Woodward 1921) from the site now known as **Kabwe** and subsequently the addition of *Homo soloensis* from **Ngandong** (Oppenoorth 1937). The addition of the Ngandong fossils meant that crania substantially more robust than those of modern humans and *H. neanderthalensis* were now included in *Homo*. Nonetheless, the endocranial volumes of all the crania associated with *H. neanderthalensis*, *H. rhodesiensis*, and *H. soloensis* are still within, or close to, the modern human range. When Franz **Weidenreich** formally proposed that two existing extinct hominin hypodigms, *Pithecanthropus erectus* and *Sinanthropus pekinensis*, should be merged into a single species and transferred to *Homo* as *Homo erectus* (Weidenreich 1940) the addition of these taxa resulted in *Homo* subsuming an even wider range of morphology. Thereafter, the hypodigms of *Meganthropus*, *Telanthropus*, and *Atlantropus* were also transferred to *Homo* by, respectively, Mayr (1944), Robinson (1961), and Le Gros Clark (1964). The addition of the *H. erectus* hypodigm at this time, even though it was well before the discovery of the small *H. erectus* crania from East Africa (Anton 2004, Leakey et al. 2003, Potts et al. 2004, Spoor et al. 2007) and **Dmanisi** (Rightmire et al. 2006) substantially increased the range of endocranial volume within the genus *Homo*. Compared with most of the pre-1940 hypodigm of *Homo*, fossils attributed to *H. erectus* have a smaller neurocranium, a lower vault, a broader base relative to the vault, and more complex premolar roots. They also have a substantial, shelf-like torus above the orbits and there are often both sagittal and angular tori, although the expression of some, or all, of this morphology may be

size-related (Antón et al. 2007). The occipital sagittal profile is sharply angulated in *H. erectus*, with a well-marked supratoral sulcus and the inner and outer tables of the vault are thickened. The cortical bone of the postcranial skeleton is generally thick. The long bones are robust, and the shafts of the femur and the tibia are flattened from front to back relative to those of other *Homo* species. However, all the postcranial elements of *H. erectus* are consistent with a habitually upright posture and obligate long-range bipedalism. In 1964 the remains of *Homo habilis* from Olduvai Gorge were added to *Homo* (Leakey et al. 1964). The inclusion of this hypodigm (e.g., OH 7, 8, 13, 16) in *Homo* substantially expanded the range of morphology within the genus and meant that the Le Gros Clark (1955) diagnosis of *Homo* needed to be amended. To accommodate *H. habilis* in the genus *Homo*, Leakey et al. (1964) were forced to reduce the lower end of the range of brain size of fossils attributed to *Homo* to 600 cm³, but these authors claimed that other criteria, such as dexterity, an erect posture, and a bipedal gait, did *not* need to be changed because their interpretation of the functional capabilities of the type specimen and the paratypes of *H. habilis* was consistent with these functional criteria. Ultimately, however, fresh evidence and fresh interpretations of existing evidence have led others to offer rather different functional assessments of the same material. After the announcement of *H. habilis* in 1964, the next significant addition to the *Homo* hypodigm was the recovery of KNM-ER 1470 from the Upper Burgi Member of the Koobi Fora Formation (Leakey 1973) and the subsequent proposal to subsume *Pithecanthropus rudolfensis* into *Homo* as *Homo rudolfensis*. Morphologically, the latter taxon presented an apparently unique mixture of a relatively large *Homo*-like neurocranium, and a broad *Paranthropus*-like face, but it lacked the distinctive combination of small anterior and large postcanine teeth typical of *Paranthropus*, especially *Paranthropus boisei*. As a consequence, from 1972 onwards, the genus *Homo* subsumed a substantially wider range of facial morphology (Wood 1991) than it did prior to the discovery of KNM-ER 1470. Walker (1976) was alone among the early commentators to caution that KNM-ER 1470 may sample a large-brained australopith taxon and may not belong to *Homo*. The KNM-ER 1470 cranium was initially not allocated to a

species, but instead was referred to an informal category called "early *Homo*." In due course other cranial specimens from Koobi Fora (e.g., KNM-ER 1590, 1802, 1805, 1813, 3732) (Wood 1991) and Olduvai (e.g., OH 62) (Johanson et al. 1987) were added to the early *Homo* hypodigm, as were fossils from Members G and H of the Shungura Formation (Howell et al. 1976, Boaz and Howell 1977, Coppens 1980), Members 4 and 5 at Sterkfontein (Hughes and Tobias 1977, Clarke 1985, Kimbel and Rak 1993), Member 1 at Swartkrans (Clarke and Howell 1972, Grine and Strait 1994, Grine et al. 1993, 1996), the Chemeron Formation (Hill et al. 1992), Uraha (Bromage et al. 1995), Hadar (Kimbel et al. 1996), the Nachukui Formation in West Turkana (Prat et al. 2005), and Dmanisi in Georgia (Gabunia and Vekua 1995, Gabunia et al. 2000, Vekua et al. 2002, Lordkipanidze et al. 2005, 2006, 2007). These additions to "early *Homo*" subsumed a wide range of cranial and dental morphology. For example, the endocranial volumes of the specimens range from just less than 500 to around 850 cm³. The mandibles also vary in size, but all have relatively robust bodies (Wood and Aiello 1998) and premolar teeth with relatively complex crowns and roots (Bromage et al. 1995). The discovery of OH 62 provided the first unequivocal postcranial evidence for *H. habilis*, so it is significant that OH 62 has been interpreted as having limb proportions that are at least as ape-like as those of individuals attributed to *Australopithecus afarensis* (Johanson et al. 1987, Hartwig-Schrerer and Martin 1991, Richmond et al. 2002) and limb cross-sectional geometries that are unusual in a committed biped (Ruff 2008). It is also likely that the even more fragmentary KNM-ER 3735 associated skeleton belongs to *H. habilis* (Wood 1991). Some researchers have suggested that the inclusion of *H. habilis* and *H. rudolfensis* into *Homo* is unjustified on the basis that to do so weakens the case for recognizing *Homo* as a distinct grade. The most recent species to be added to *Homo*, *Homo floresiensis* (Brown et al. 2004) broadened the morphological scope of *Homo* even further. The specimens attributed to this species were recovered from deposits in the Liang Bua cave on the Indonesian island of Flores and are dated to between approximately 74 and 18 ka (Brown et al. 2004, Morwood et al. 2004, Morwood and Jungers 2009). Its small brain and body size

makes *H. floresiensis* a particularly significant addition to *Homo*. The endocranial volume of the partial associated female skeleton, LB1, was initially reported to be 380 cm³ (Brown et al. 2004), but Falk et al. (2005) increased this figure to 417 cm³. Even at 417 cm³, the endocranial volume of *H. floresiensis* is considerably smaller than those of the other species assigned to *Homo* for adult endocranial volume in *H. habilis* ranges between 509 and 687 cm³ (de Sousa and Wood 2006). However, the stature estimates of 106 cm for LB1 (Brown et al. 2004) and 109 cm for LB8 (Morwood et al. 2005) are only slightly smaller than McHenry's (1991) stature estimate of 118 cm for the *H. habilis* OH 62 partial skeleton. Some researchers have interpreted *Homo* more inclusively. For example, John Robinson proposed that *Australopithecus* be sunk into *Homo* (Robinson 1972). Curnoe and Thorne (2003) have proposed a much more radical scheme whereby they only recognize three species in the hominin clade and they include all three in *Homo*, as *Homo ramidus*, *Homo africanus*, and *Homo sapiens*. See **genus; *Homo africanus***.

***Homo africanus* (Dart, 1925)** (L. *homin*=man or human being and *africanus*=Africa) A new taxonomic combination introduced by John Robinson when he proposed that *Australopithecus* is a subjective junior synonym of *Homo* (Robinson 1972). Robinson (1967) suggested that *H. africanus* had been used by Broom (1918) for the Boskop associated skeleton, but Broom had assigned the latter to *Homo capensis* and not to *H. africanus*. Later Robinson realized that Giuseppe Sergi had introduced *Homo africanus* in 1908 and in deference to Sergi's prior use of the name Robinson used the next most senior synonym, *Australopithecus transvaalensis* Broom, 1936, and thus the binomen *Homo transvaalensis* in place of *Australopithecus africanus*. However, in his 1972 book Robinson judged that von Eickstedt (1937) was the first person to use *H. africanus* formally and so because *Australopithecus africanus* Dart, 1925 had priority he adopted *H. africanus* in place of *Homo transvaalensis*. Robinson (1972, p. 246) wrote that his inclusion of *Au. africanus* in *Homo* was the logical consequence of his belief that "a genus represents a clearly defined adaptive zone or way of life," and that the species within a genus should "represent no more than variations in detail on the basic adaptive theme" and he concluded that "the basic adaptation of *H. africanus* seems to me to be the same as that of

man, hence the two should be in the same genus." Wolpoff (1969) used *H. africanus* in place of *Homo habilis* when writing about OH 7, presumably because he saw it as a senior synonym of *H. habilis*. See also *Homo transvaalensis*.

Homo antecessor* Bermúdez de Castro et al., 1997 (L. *homin*=man or human being and *antecessor*=forerunner) Between 1994 and 1996 more than 80 hominin fossils were recovered from the Gran Dolina cave in the Sierra de Atapuerca. Their discoverers considered them too primitive to be allocated to either *Homo neanderthalensis* or *Homo heidelbergensis* so in 1997 they assigned them to a new species, *Homo antecessor* (Bermúdez de Castro et al. 1997), claiming that *H. antecessor* combines a modern midfacial morphology (a canine fossa, an acute zygomaticoalveolar angle, and a modern human nasal morphology) with primitive *Homo ergaster*-like dental morphology. Critics of the decision to recognize a new taxon suggest that the "modern" facial morphology is due to the immaturity of the ATD6-69 facial fragment. First discovery ATD6-1 (1994). Holotype The details of the holotype of *Homo antecessor* are given in note no. 5 of Bermúdez de Castro et al. (1997). They suggest that the holotype consists of all the remains belonging to an individual whose remains comprise the mandible ATD6-5, plus the isolated teeth listed as ATD6-1–ATD6-4 and ATD6-6–ATD6-12. Paratypes Listed in Table 2 in Carbonell et al. (1995, p. 1393). Main site Gran Dolina, Sierra de Atapuerca.

***Homo antiquus* Ferguson, 1984** (L. *homin*=man or human being and *antiquus*=former) Ferguson (1984) reviewed "14 hominoid fossil jaws" (*ibid*, p. 526) from Hadar and Laetoli and concluded that they should be distributed among three taxa: one unnamed pongid taxon and two hominin taxa, namely *Australopithecus africanus* for the larger hominin jaws (see also Ferguson 1999) and a new primitive *Homo* taxon, dubbed *Homo antiquus* for the smaller jaws. In doing so he claimed he was merely restoring "the original determination of A.L. 199-1 as belonging to the genus *Homo* (Johanson, Taieb and Coppens, 1982)" (*ibid*, p. 527). In a later paper Ferguson (1987) suggests that KNM-ER 1813 and KNM-ER 1501 should also be assigned to *H. antiquus*. Holotype A.L. 288-1 (1974). Paratypes A.L. 128-23, 198-1, 199-1, 207-1, and 333-2. Main site Hadar, Ethiopia. See also *Australopithecus afarensis*.

***Homo antiquus praegens* Ferguson, 1989**

(L. *homin*=man or human being, *antiquus*=former, and *praegens*=progenitor) A subspecies introduced by Walter Ferguson to accommodate the Tabarin mandible with KNM-TH 13150 (Ferguson mistakenly refers to it as “KNM-ER TI 13150”) as its holotype. No matter what anyone thinks of the logic behind the proposal for this new species the paper introducing it meets the criteria set out in the International Code of Zoological Nomenclature, and thus the name is available.

Homo calpicus* Falconer, 1864** See Gibraltar 1.Homo capensis* Broom, 1918** See Boskop; *Homo erectus capensis* (Broom & Robinson, 1949).***Homo cepranensis* Mallegni et al., 2003** See Ceprano 1.

***Homo erectus* (Dubois, 1893*)** (L. *homin*=man or human being and *erectus*=to set upright) Hominin species established by Eugène Dubois to accommodate fossil hominins recovered in 1891 at Trinil, Java. In his initial publication of the Trinil remains, published in 1893, Dubois referred the skullcap to *Anthropopithecus erectus*. The name reflected Dubois’ initial conviction that he had discovered the remains of a fossil ape, for at that time *Anthropopithecus* and not *Pan* was the preferred genus name for chimpanzees. But he changed his mind and a year later in 1894 he transferred the new species to *Pithecanthropus*. The discovery of the Trinil calotte was significant because of its small cranial capacity (approximately 940 cm³), its primitive shape with its low brain case, and quite sharply angulated occipital region, for in 1894 the only two hominin taxa known were *Homo sapiens* and *Homo neanderthalensis*. Discoveries made by Ralph von Koenigswald at Sangiran, also in Indonesia, were added to the hypodigm of *Pithecanthropus erectus*. Later additions came when the fossils recovered from what was then called Choukoutien (now called Zhoukoudian) and initially assigned to *Sinanthropus pekinensis* Black, 1927 were compared with the *P. erectus* hypodigm. The researchers responsible for analyzing the two collections suggested that the Indonesian and Chinese hypodigms were “related

to each other . . . in the same way as two different races of present mankind” (von Koenigswald and Weidenreich 1939, p. 928) and a year later Weidenreich formally proposed the two hypodigms should be merged in a single genus as *Homo erectus pekinensis* and *Homo erectus javanensis*, respectively (Weidenreich 1940). Subsequently the hypodigms of *Meganthropus* (Mayr 1944, p. 14, Le Gros Clark 1955, pp. 86–7), *Atlantropus* (Le Gros Clark 1964, p. 112), and *Telanthropus* (Robinson 1961) were transferred to *Homo* as *Homo erectus*. First discovery Kedung Brubus 1, Kedung Brubus, Java (1890). Holotype Trinil 2, adult calotte, Trinil, Ngawi, Java (1891). Paratypes None. Main sites Olduvai Gorge, Sambungmacan, Sangiran, Trinil, Zhoukoudian. See also *Homo ergaster*. (*NB: the year of publication is usually given as 1892, but this is incorrect. The publication was a report by Dubois of excavations carried out in 1892, but it did not become a public record until 1893, so this should be the year of its publication).

***Homo erectus capensis* (Broom & Robinson, 1949)** (L. *homin*=man or human being, *erectus*=to set upright, and *cape*=a reference to land that includes the Cape of Good Hope) A name combination introduced by Phillip Tobias (1968) for a subspecies of *Homo erectus* that presumably included specimens such as SK 15 and SK 45. The name is preoccupied by *Homo capensis* Broom, 1918.

***Homo erectus erectus* (Dubois, 1893)** (L. *homin*=man or human being and *erectus*=to set upright) A name combination introduced by Campbell (1973) as the nominotypical subspecies of *Homo erectus* for what most other researchers recognize as the temporally later part of the Indonesian hypodigm of *Homo erectus*.

***Homo erectus heidelbergensis* Schoetensack, 1908** (L. *homin*=man or human being, *erectus*=to set upright, and *heidelbergensis*=a city near the location of the holotype of *Homo heidelbergensis*) A name combination introduced by Campbell (1973) for what most other researchers recognize as either *Homo heidelbergensis* or the temporally early part of the hypodigm of an inclusive interpretation of *Homo neanderthalensis*.

Homo erectus javanensis (L. *homin*=man or human being, *erectus*=to set upright, and

javanensis=the name of the island where the holotype of *Homo erectus* was found) Name combination used by Franz Weidenreich (1940) for the hypodigm of what was then called *Pithecanthropus erectus*. It is derived from a poorly constructed name *Homo javanensis primigenius* Houze, 1896; the correct combination should have been *Homo erectus erectus*.

***Homo erectus leakeyi* (or *Homo leakeyi*) Heberer, 1963** (L. *homin*=man or human being, *erectus*=to set upright, and *leakeyi*=to recognize the contribution of Louis Leakey) A name combination introduced by Heberer (1963) for a subspecies of *Homo erectus* that accommodated OH 9. Campbell (1973) later used the same name combination for a subspecies that subsumed the temporally later part of the East African hypodigm of *Homo erectus*.

***Homo erectus mauritanicus* (Arambourg, 1954)** (L. *homin*=man or human being, *erectus*=to set upright, and *mauritanicus*=named after Mauritania, the name the Romans gave to the province that included the western part of modern Algeria and the northernmost part of Morocco. The name Mauritania come from the Gk *mauros*=black, from which the Moors took their name) A name combination introduced by Tobias (1968) and perpetuated by Campbell (1973) for what most other researchers recognize as the North African component of the hypodigm of *Homo heidelbergensis* or *Homo erectus* or the North African component of the temporally early part of the hypodigm of an inclusive interpretation of *Homo neanderthalensis*.

***Homo erectus olduvaiensis* Tobias, 1968** (L. *homin*=man or human being, *erectus*=to set upright, and *olduvaiensis*=named after Olduvai Gorge, the location of OH 9 and OH 12, see below) A name combination introduced by Tobias (1968) for a subspecies of *Homo erectus* that included specimens such as OH 9 and perhaps OH 12, but because it was proposed conditionally it has no standing.

***Homo (erectus or sapiens) palaeohungaricus* Thoma, 1966** A subspecies suggested by Thoma (1966) to recognize a subspecies of *Homo erectus* to accommodate the hominin remains recovered from Vérteszöllös, Hungary. The holotype is Vérteszöllös 2.

***Homo erectus pekinensis* (Black, 1927)** (L. *homin*=man or human being, *erectus*=to set upright, and *pekinensis*=named after the site where *Sinanthropus pekinensis* had been discovered) Name combinations suggested by Weidenreich (1940) and Campbell (1973) for what most other researchers recognize as the mainland East Asia part of the hypodigm of *Homo erectus*.

***Homo erectus reilingensis* Czarnetzki, 1989** A subspecies of *Homo erectus* proposed by Czarnetzki (1989) for the hominin remains recovered from Reilingen, Germany in 1978. The holotype is the Reilingen calvaria. See also Reilingen calvaria.

Homo erectus sinensis (L. *homin*=man or human being, *erectus*=to set upright, and *sinensis*=named after the country site where *Sinanthropus pekinensis* had been discovered) A name combination used by Weidenreich (1940) for a subspecies to recognize the hypodigm of what was then referred to as *Sinanthropus pekinensis*. The name derives from *Pithecanthropus sinensis* Weinert, 1931. See also *Homo erectus pekinensis*.

***Homo ergaster* Groves and Mazák, 1975** (L. *homin*=man or human being and *ergo*=work) A hominin species established by Colin Groves and Vratislav Mazák to accommodate fossil hominins recovered from Koobi Fora that in their judgment did not belong in the taxa that existed at the time. Wood (1994) used the taxon name *Homo ergaster* for East African hominin remains that are generally more primitive and lack the more extreme expressions of some of the derived features (e.g., thick inner and outer table, sagittal keeling, etc.) seen in Asian *Homo erectus*. Other researchers acknowledge these differences exist, but most are inclined to view them as regional variations within a single species, *Homo erectus*. First discovery KNM-ER 730 (1970). Holotype KNM-ER 992 (1971). Paratypes KNM-ER 730, 731, 734, 803, 806-9, 820, 1480, 1805. Main sites Koobi Fora, West Turkana.

***Homo floresiensis* Brown et al., 2004** (L. *homin*=man or human being and *flores*=the name of the island, Flores, where the type site is located) Hominin species erected by Brown et al. (2004) to accommodate LB1, a partial adult hominin skeleton and LB2, an isolated left P₃ recovered

in 2003 from the **Liang Bua** cave on the Indonesian island of Flores. More material belonging to LB1 and evidence allocated to LB4–9, including a second partial skeleton (but lacking a cranium), **LB6**, was recovered in 2004 (Morwood et al. 2005). The hypodigm now includes close to 100 individually numbered specimens that are estimated to represent fewer than 10 individuals. The taxon was immediately controversial for at least two reasons. First, its estimated geological age of between *c.*17 and *c.*74 ka substantially overlapped evidence of the presence of modern humans in the region. Second, while its discoverers and describers acknowledged its small overall size (the stature of LB1 is estimated to be 106 cm and its body mass to be roughly between 25 and 30 kg), its especially small brain (approximately 417 cm³) for an adult hominin and its primitive morphology were most parsimoniously interpreted to be evidence of a novel endemically dwarfed pre-modern *Homo* or a transitional hominin taxon. Other researchers have suggested that no new taxon needs to be erected because they claim the "*Homo floresiensis* hypodigm" has been sampled from a population of *Homo sapiens* – most likely related to the small-statured Rampasasa people who live on Flores today – afflicted by either an endocrine disorder or one, or more, of a range of syndromes that include **microcephaly**. Both explanations are exotic, but those who espouse a pathological explanation for the individuals represented by LB1–15 need to explain what pathology results in an early *Homo*-like cranial vault, primitive mandibular, dental, carpal and pedal morphology, and a brain that while very small apparently has none of the morphological features associated with the majority of types of microcephaly. Initially it was suggested that *H. floresiensis* was a dwarfed *Homo erectus*, but the burden of subsequent analyses suggest that it may be more closely related to a transitional hominin such as *Homo habilis* (Tocheri et al. 2007, Argue et al. 2009, Brown and Maeda 2009, Morwood and Jungers 2009). Aiello (2010) provides a useful review of the evidence and the controversy surrounding *H. floresiensis*. First discovery LB1 (2003). Holotype As above. Paratype LB2 (2003). Only site **Liang Bua**, Flores, Indonesia.

***Homo florissbadensis* Drennan, 1935** *See Florissbad 1.*

***Homo gautengensis* Curnoe, 2010** (L. *homin*=man or human being and *gauteng*=the name of the South African province within which are the caves of Sterkfontein, Swartkrans, and Drimolen) A hominin species established to accommodate fossil hominins recovered from Sterkfontein, Swartkrans, and Drimolen that Curnoe judged could not be accommodated within existing species within *Australopithecus*, *Paranthropus*, and *Homo*. The diagnosis stresses dental morphology and, in particular, the unusual combination of mandibular postcanine tooth crowns that are both buccolingually narrow and have a large talonid. First discovery **SK 15** (1949). Holotype **Stw 53** (1976). Paratypes The 21 paratypes listed in Curnoe (2010) include SE 255, SK 45, and DNH 70. Main sites **Sterkfontein** and **Swartkrans**, plus one specimen at **Drimolen**.

***Homo georgicus* Gabounia et al., 2002** (L. *homin*=man or human being and Georgia is the name of the country within which the **Dmanisi** site is located) A hominin species established in 2002 by Gabounia et al. (the spelling of Leo Gabounia's name in the 2002 reference is not the conventional one but according to the rules of the **International Commission on Zoological Nomenclature** (or ICZN) the spelling mistake has to be retained in the formal name of the species) for an adult mandible recovered from Dmanisi in 2000. Most researchers recognize that the vast majority of the hominin fossils recovered from Dmanisi belong to a taxon that shares features with both *Homo habilis* and *Homo erectus* (and with *Homo ergaster* if that taxon is recognized). However, at this stage few researchers (e.g., de Lumley and Lordkipanidze 2006 are an exception) are willing to assign this material to a novel taxon, but if that need arises in the future *Homo georgicus* is the species name that has priority. The workers who introduced the new taxon saw it as intermediate between *H. habilis* and *Homo rudolfensis* on the one hand and *Homo ergaster* on the other. First discovery **D2600** (2000). Holotype **D2600** (2000). Paratypes No paratypes were formally designated, but under the heading "Material," the mandible **D211**, the calvaria **D2280**, the cranium **D2282**, and the skull and associated skeleton **D2700** were referred to as evidence that "will complete the characteristics of the new species" (Gabounia et al. 2002, p. 244). Only site **Dmanisi**, Georgia.

Homo habilis Leakey, Tobias and Napier, 1964 (L. *homin*=man or human being and *habilis*=handy) A hominin species established by Louis Leakey, Phillip Tobias, and John Napier in 1964 to accommodate fossil hominins (OH 4, 6, 7, 8, and 13; OH 14 and 16 were not included as paratypes, but they were “referred” to *Homo habilis*) recovered between 1959 and 1963 from Beds I and II, Olduvai Gorge, Tanzania. Leakey et al. (1964) claimed that brain size, cranial, and dental morphology, and inferences about dexterity and locomotion, distinguished the new taxon from *Australopithecus africanus* and justified its inclusion in *Homo*. Subsequent discoveries at Olduvai (e.g., OH 24, 62, and 65) and from other sites (e.g., Koobi Fora: KNM-ER 1470, 1802, 1805, 1813, 3735; Sterkfontein: Stw 53; Swartkrans: SK 847; Hadar: A.L. 666-1) have also been assigned to this taxon. The hypodigm has a relatively wide range of cranial and dental morphology. Endocranial volume ranges from just less than 500 to approximately 800 cm³. All the crania in this group are wider across the base of the cranium than across the vault but facial morphology varies, with KNM-ER 1470 having its greatest width across the mid-face whereas KNM-ER 1813 is broadest across the upper face. Mandibles vary in size and robusticity, with those from the larger individuals having robust mandibular bodies. Postcanine teeth vary in size and crown morphology. Some mandibular premolars and molars are buccolingually narrow (e.g., OH 7), whereas larger mandibular premolar teeth within the hypodigm (e.g., KNM-ER 1802) have buccolingually broader crowns, complex talonids, and more complex root systems. Some researchers consider the cranial variation within a single taxon to be excessive in scale and unlike the pattern of intraspecific variation seen in the *Pan/Homo* clade. They suggest *H. habilis* subsumes two taxa, *Homo habilis sensu stricto* and *Homo rudolfensis*. First discovery OH 4 (1959). Holotype OH 7 (1960). Main sites Koobi Fora, Olduvai, Shungura Formation, ?Sterkfontein, ?Swartkrans. *See also* *Homo habilis sensu lato*; *Homo habilis sensu stricto*.

Homo habilis sensu lato A taxon whose hypodigm includes all the specimens referred to under *Homo habilis*. This is the sense in which *H. habilis* is used by researchers (e.g., Tobias 1991a, Suwa et al. 1996) who are content that

variation within that hypodigm is compatible with a single-species interpretation. *See also* *Homo habilis*; *Homo habilis sensu stricto*.

Homo habilis sensu stricto A taxon whose hypodigm includes a subset of the specimens referred to under *Homo habilis*. This is the sense in which *H. habilis* is used by researchers (e.g., Wood 1992, Stringer 1986a, Kramer et al. 1995, Grine et al. 1996) who suggest that the variation within that hypodigm is not compatible with a single-species interpretation. For Stringer the *H. habilis s. s.* hypodigm would consist of OH 7 and OH 24, but not specimens such as OH 13 and OH 16, but for Wood (1992) *H. habilis s. s.* comprises all the Olduvai hypodigm of *H. habilis*, plus a subset of the Koobi Fora site component of the hypodigm (e.g., KNM-ER 1805, 1813, 3785). *See also* *Homo habilis*; *Homo habilis sensu lato*.

Homo heidelbergensis Schoetensack, 1908 (L. *homin*=man or human being and *heidelbergensis*=because the holotype comes from the Grafenrain commercial sandpit, which is southeast of Heidelberg, Germany) This species name was created by Otto Schoetensack to accommodate a robust hominin mandible found in 1907 in a commercial sandpit at Mauer, near Heidelberg, Germany. The Mauer mandible lacks a chin and exhibits other traits Schoetensack interpreted as primitive, including a broad ramus and an anterior–posteriorly deep mandibular symphysis, but these are combined with modern human-like dental proportions, including reduced canines. In the light of this evidence Schoetensack concluded the Mauer mandible’s mosaic of primitive and derived traits was sufficient to distinguish it from *Homo sapiens*, *Homo neanderthalensis*, and what was then called *Pithecanthropus erectus* (Schoetensack 1908). However, until relatively recently the new species name attracted little interest. Howell (1960) does not mention it in his influential review of Middle Pleistocene hominins and Le Gros Clark’s (1955, 1964) only reference to *H. heidelbergensis* was to suggest that it is by no means certain the species belongs in *Homo*. Most European researchers described fossils with similar features and geological ages as belonging to a poorly defined group called “preneanderthals,” but did not refer to any specific taxa. In 1995 Rightmire suggested that *H. heidelbergensis* might

be the most appropriate species name for a group of Afro-European hominin fossils (e.g., Arago, Bodo, Kabwe, Mauer, Ndutu, and Petralona) that others were referring to as “archaic” *Homo sapiens* and in the same paper he considered the pros and cons of several hypotheses for the relationships among *H. heidelbergensis*, modern humans, and Neanderthals (Rightmire 1995, Fig. 4, p. 454). Mounier et al. (2009) provide the most detailed morphological and taxonomic analysis of the holotype of *H. heidelbergensis*. Their conclusion is that there are morphological grounds for recognizing *H. heidelbergensis* as a taxon separate from *H. neanderthalensis*, *H. sapiens*, and *H. erectus*, and they supply both a definition and a differential diagnosis for the taxon (*ibid*, pp. 243–4). They consider the mandibles from Arago, Montmaurin, Sima de los Huesos, and Tighenif to be conspecifics of the Mauer mandible and their conclusions about the taxonomic options for and the phylogenetic relationships of a *H. heidelbergensis* taxon include some of those reviewed by Rightmire (1995). The one Mounier et al. (2009) call the “Afro-European hypothesis” is that “*H. heidelbergensis* was a geographically widespread and diverse species that gave rise to *H. neanderthalensis* in Eurasia, and *H. sapiens* in Africa” (Stringer 2001, p. 568 and see Mounier et al. 2009, Fig. 6, p. 242). In what Mounier et al. (2009) call the “European hypothesis,” *H. heidelbergensis* is restricted to Europe and is only ancestral to *H. neanderthalensis*. In this hypothesis modern humans are descended from an African taxon that would be *Homo rhodesiensis* if that taxon’s hypodigm included Kabwe and Tighenif and *Homo mauritanicus* if it included the latter, but not the former. However, if, as some argue, *contra* Mounier et al. (2009), *H. heidelbergensis* represents an early stage in the accretion model of Neanderthal characteristics (e.g., Arsuaga et al. 1997, Dean et al. 1999, Carbonell et al. 2005) then *H. heidelbergensis* would be a junior synonym of *H. neanderthalensis*. However, if the latter view prevails then *H. heidelbergensis* would have priority as the name of the taxon that gave rise to *H. neanderthalensis* and *H. sapiens* (the “Afro-European hypothesis”) or just *H. neanderthalensis* (the “European hypothesis”). Until recently *H. heidelbergensis* was considered one of the oldest hominin taxa in Europe, but if *Homo antecessor* is a good taxon, then this would antedate it. First discovery Mauer mandible

(1907). Holotype As above. Paratypes None. Main sites Arago, Mauer, Mountmaurin, Sima de los Huesos, Tighenif. *See also pre-Neanderthal hypothesis.*

***Homo helmei* Dreyer, 1935** The taxonomic name assigned to a partial skull discovered in 1932 by T.F. Dreyer in Florisbad, South Africa. Some researchers interpret the Florisbad 1 cranium as being intermediate in morphology between *Homo heidelbergensis* and *Homo sapiens*. Its vertical facial dimensions, brow ridge size, and inclination of the frontal bone distinguish it from the former yet it retains primitive features (e.g., a large brow ridge, receding frontal and broad vault) that distinguish it from anatomically modern humans. While some suggest that Florisbad 1 could serve as the holotype of the taxon *Homo helmei* most researchers take the view that there is no satisfactory diagnosis for such a taxon. Other specimens that have been suggested as belonging to the same hypodigm as the Florisbad 1 cranium include Jebel Irhoud, Ngaloba (*see* LH 18), Omo II, and Singa (e.g., Group 2 in McBrearty and Brooks 2000, Fig. 2, p. 481).

***Homo kanamensis* Leakey, 1935** *See* Kanam.

***Homo leakeyi* Clarke, 1990** (*L. homin*=man or human being and *leakeyi*=to recognize the role of Louis and Mary Leakey in the recovery of OH 9) This name combination was suggested, but not formally proposed, as the binomial for OH 9 by Heberer (1963). Several authors (Simons et al. 1969, Harrison 1993, Groves 1999) have pointed out that Heberer’s name was unavailable in nomenclature and that Clarke (1990) was the first to use *Homo leakeyi* in a way that conforms with the requirements of the International Code of Zoological Nomenclature, but Groves (1989) points out that the introduction of *Homo (Proanthropus) louisleakeyi* by Kretzoi (1984) means that *Homo louisleakeyi* Kretzoi, 1984 would have priority.

***Homo louisleakeyi* Kretzoi, 1984** *See* *Homo (Proanthropus) louisleakeyi*.

***Homo (Proanthropus) louisleakeyi* Kretzoi, 1984** A name combination suggested by Kretzoi (1984) for the taxon of which OH 9 would be the type specimen. *See also* *Homo erectus*.

"Homo mauritanicus" (L. *homin*=man or human being and *Mauritania*=the name of a Roman province that is coincident with what is now Morocco and Algeria) Camille Arambourg (1955) provisionally suggested a new species and a new genus *Atlantropus mauritanicus* to accommodate three hominin mandibles and a cranial fragment recovered by Arambourg and Hoffstetter in June 1954 at Ternifine (now called Tighenif) near Mascara, in Algeria. *Atlantropus* was never widely adopted as a genus, and because Le Gros Clark (1964) formally suggested that *Atlantropus mauritanicus* is a subjective junior synonym of *Homo erectus* the new species was never formally incorporated into *Homo* as *H. mauritanicus*. Some suggest that if *H. heidelbergensis* is restricted to Europe and is only ancestral to *H. neanderthalensis* and if modern humans are descended from an African taxon that includes Tighenif but not Kabwe then *H. mauritanicus* would have priority as the name of such a taxon. However, that name is not available because its introduction was not associated with a formal description "giving characters purporting to differentiate the taxon."

Homo microcranus Ferguson, 1995 (L. *homin*=man or human being, *micro*=small, and *cranium*=brain case) In his 1995 review of the taxonomic status of KNM-ER 1813 Ferguson reiterates his earlier claim that the fossil is a male (Ferguson 1987) and because, in his opinion, the small brain size of KNM-ER 1813 precludes it from being included in *Homo habilis*, he sees the need to erect a new species, *Homo microcranus*, to accommodate KNM-ER 1813. He does not discuss the implications of this proposal for other early *Homo* specimens with a similar brain size. No matter what anyone thinks of the logic behind the proposal for this new species the paper introducing it meets the criteria set out in the **International Code of Zoological Nomenclature**; thus the species name is available. If it was judged that KNM-ER 1813 does not belong to *H. habilis* and that it belongs to a species other than *Homo rudolfensis* then *Homo microcranus* is a species name that is both valid and available. Holotype KNM-ER 1813 (1973). Paratypes None. Only site Koobi Fora. *See also* *Homo habilis*; KNM-ER 1813.

Homo modjokertensis von Koenigswald, 1936 (L. *homin*=man or human being and

modjokertensis from the name of a village in East Java near the site where the calvaria was discovered) The name given by Ralph von Koenigswald to a taxon he introduced to accommodate the juvenile Modjokerto calvaria, Modjokerto 1. Subsequently he and others transferred the taxon to *Pithecanthropus*. Harvati et al. (2010) show that some of the "characteristic morphology" of *H. neanderthalensis* is shared with African crania and they suggest that some of these features may be retained symplesiomorphies. First discovery Modjokerto 1 (1936). Holotype As above. Paratypes None. Only site Modjokerto.

Homo mousteriensis Forrer, 1908 [Homo mousteriensis hauseri Klatsch and Hauser, 1909] *See* Le Moustier I.

Homo neanderthalensis King, 1864 (L. *homo*=man or human being and *neanderthalensis*=literally "of Neander's valley", the Neander in question being Joachim Neander, a 17thC non-ordained Lutheran ecclesiastical poet and composer) A hominin species established in 1864 by William King for the partial skeleton recovered in 1856 from the Kleine Feldhofer Grotte in the part of the Düssel valley named after Joachim Neander. No faunal or archeological evidence was reported in the original publication. However, through careful archival research, Ralf Schmitz and Jürgen Thissen were able to identify what remained of the sediments from the Kleine Feldhofer Grotte at the base of the south wall of the Neander valley (Schmitz et al., 2002). Excavations of these sediments in 1997 resulted in the recovery of fauna, artifacts, and hominin bone fragments and "a small piece of human bone (NN 13) was found to fit exactly onto the lateral side of the left lateral femoral condyle of Neanderthal 1" (*ibid*, p. 13342). In 2000 more fauna, archeological, and hominin skeletal fragments were recovered and "two cranial fragments...were found to fit onto the original Neanderthal 1 calotte" (*ibid*, p. 13343). Some 80 fragments from at least two individuals have been recovered. Dates obtained from the sediments indicate an age of *c.*40 ka/Oxygen Isotope Stage (or OIS) 3 (*ibid*, p. 13345). King proposed the species name *Homo neanderthalensis* in a paper read to the British Association in 1863, but in the 1864 publication he apparently revised his assessment for he wrote that "I now feel strongly inclined to believe that it

(i.e., the Kleine Feldhofer skeleton) is not only specifically but generically distinct from Man.” However, King did not propose any new generic name for the specimen and the binomen *Homo neanderthalensis* is now well established. King’s conclusion about the taxonomic implications of the specimen’s distinctive morphology was in sharp contrast to workers such as Rudolf Virchow who considered it that of a recent individual affected by pathology, or others such as Hermann Schaaffhausen, Charles Lyell, and Thomas Henry Huxley who, while arguing for its antiquity and evolutionary significance, refrained from assigning it to a separate species. Discoveries made earlier, such as the infant’s cranium from Engis (1828) and the partial cranium from Forbes’ Quarry, Gibraltar (1848), were subsequently recognized as belonging to the same species. In the following half-century further Neanderthal remains were discovered at other European sites including La Naulette and Spy (Belgium), Šipka (Moravia), Krapina (Croatia, with over 900 specimens representing multiple individuals), and Malarnaud, La Chapelle-aux-Saints, Le Moustier (lower shelter), La Ferrassie, and La Quina, among others, in France. So by the early 20thC *H. neanderthalensis* was by far the best-known extinct hominin species. In 1924–6 the first *H. neanderthalensis* remains were found outside of western Europe at Kiik-Koba in the Crimea. Thereafter came discoveries at Tabun cave on Mount Carmel in the Levant, at Teshik-Tash in central Asia, and at two sites in Italy: Saccopastore and Monte Circeo. Further evidence was added after WWII, first from Iraq (Shanidar), then from additional Levantine sites in Israel (Amud and Kebara), and from Syria (Dederiyeh). New fossiliferous localities continue to be discovered in Europe and Western Asia (e.g., Saint-Césaire and Moula-Guercy in France, Zaffaraya in Spain, Mezmaiskaya in Russia, Vindija in Croatia, and Lakonis in Greece). To date, Neanderthal remains have been found throughout much of Europe below 55°N, as well as in the Near East and Western Asia, but no fossil evidence has been found in North Africa. Early views about Neanderthal morphology and phylogenetic status were based predominantly upon Marcellin Boule’s highly influential description of the La Chapelle-aux-Saints skeleton, which he reconstructed as massively built, with numerous primitive features including incomplete truncal erectness, no cervical

lordosis, a habitually flexed knee joint, and an abducted hallux. Boule argued that this morphology precluded Neanderthals from the ancestry of *Homo sapiens* and he concluded that the species became extinct at the end of the Mousterian. Even after Boule’s description a few workers continued to argue for a Neanderthal ancestry for modern humans (see Neanderthal phase hypothesis) but it was not until the mid-1950s that Boule’s reconstruction was shown to be anatomically incorrect and functionally impossible (Straus and Cave 1957). Many mid-20thC workers considered Neanderthals to be only subspecifically distinct from modern humans, as *Homo sapiens neanderthalensis*. This was likely due to the combination of a reaction against the “Boulean” view and the effect of the neo-Darwinian modern evolutionary synthesis with its emphasis on intra-specific variation and taxonomic lumping. By the 1980s the notion of conspecificity was increasingly challenged by the growing interest in punctuated equilibrium models and speciation as an evolutionary driver and by the growing evidence for an African origin for modern human (see out-of-Africa hypothesis). In the past decade or so there has been an increasing acceptance that the Neanderthals are morphologically distinctive, so much so that many consider it unlikely that such a derived form could have given rise to the morphology seen in modern humans (e.g., Stringer 1996, Tattersall 1986, Rak et al. 2003, Harvati et al. 2004). There is, however, another school of researchers (e.g., Wolpoff 1989, Frayer et al. 1993, Wolpoff and Frayer 2005) who point to, and stress, the morphological continuity between the fossil evidence for *H. sapiens* and the remains others would attribute to *H. neanderthalensis*. The inclusion of Neanderthals within *Homo sapiens* is consistent with the multiregional hypothesis for the evolution of modern humans. Yet another perspective is the assimilation model, first proposed in 1989 (Smith et al. 1989), which recognizes the African origin of modern humans but argues that a small amount of admixture occurred between expanding modern and indigenous archaic populations. This admixture is reflected only in certain morphological details that do not overshadow the basic differences between modern and archaic morphology (Smith, 2010). Some have argued that morphologically intermediate specimens are evidence of admixture between Neanderthals and modern humans (Duarte et al. 1999, Trinkaus

2005) but this argument has been challenged (Tattersall and Schwartz 1999, Pearson 2004, Harvati et al. 2007). Those who claim that *H. neanderthalensis* is specifically distinct from *H. sapiens* recognize morphological autapomorphies that distinguish the former from both earlier (e.g., *Homo erectus*, *Homo heidelbergensis*) and contemporary taxa (i.e., *H. sapiens*). These features are found in the cranium (e.g., large, rounded discrete brow ridges, projecting mid-face, inflated cheeks, small mastoid process, suprainiac fossa, and occipital bun), mandible (long corpus, retro-molar space, and asymmetric mandibular notch), dentition (e.g., large shovel-shaped incisors, occlusal morphology of molars and premolars, a high incidence of taurodontism), and the postcranial skeleton (e.g., long clavicle, teres minor groove extending onto the dorsal surface of the scapula, large infraspinous fossa, long, thin pubic ramus, and large joints). The taxon *H. neanderthalensis* is currently the only extinct hominin for which there is sound ancient DNA evidence. In 1997 Mathias Krings and his colleagues (Krings et al. 1997) announced they had recovered short fragments of the hypervariable region I (HVRI) of the mitochondrial DNA (or mtDNA) control region from a piece of bone taken from the right humerus of the Kleine Feldhofer Neanderthal 1 type specimen and 3 years later Krings et al. (1999) sequenced a 340 bp segment of a different part (HVRII) of the mtDNA control region of the type specimen. A year later two laboratories confirmed the extraction of a 345 bp sequence of HVRI from a rib fragment belonging to a Neanderthal from Mezmaiskaya (Ovchinnikov et al. 2000) and Krings et al. (2000) reported sequences obtained from a Neanderthal individual (Vi75; now Vi 33.16) from layer G3 at Vindija, Croatia. Schmitz et al. (2002) extracted mtDNA from the humeral shaft (NN 1) from a second individual at the Neanderthal type site. Serre et al. (2004) extracted mtDNA from four more Neanderthal individuals, two more from Vindija (Vi77 and Vi80), and one each from Engis (Engis 2) and La Chapelle-aux-Saints, as well as from five fossil *Homo sapiens* individuals. The Vi80 sequence was identical to that of the sequence reported for Vi75 (Krings et al. 2000) and none of the modern humans yielded any amplification products with the Neanderthal primers. The latest Neanderthal fossils to yield mtDNA is the evidence of HVRI that has been found in samples from the left femur of the Teshik-Tash Nean-

derthal from Uzbekistan and from the femur of the subadult individual from Okladnikov, a site in the Altai mountains in Western Asia (Krause et al. 2007). Subsequently the complete mtDNA of a specimen from Vindija has been sequenced (Green et al., 2008) and Briggs et al. (2009) reported the full mtDNA sequences of five individuals (Neanderthal 1 and 2, Sidron 1253, Vi33.25 from Vindija, and the Mezmaiskaya hominin). That study concluded that the genetic diversity within *H. neanderthalensis* was substantially less than that seen in modern humans. The results of the study of mtDNA by Serre et al. (2004) suggested that if Neanderthals made any contribution to modern humans then it was small one. This contribution was confirmed by the results of the analysis of the draft sequence of the Neanderthal nuclear genome (Green et al. 2010). The study focused on three individuals (Vi33.16, 25, and 26) from Vindija. Green et al. compared the draft sequence with smaller amounts of sequence data from Neanderthal specimens from El Sidron, Kleine Feldhofer Grotte, and Mezmaiskaya, as well as the sequenced nuclear genomes of five modern humans: two from sub-Saharan Africa, one each from Papua New Guinea and France, and a Han Chinese. The results show that whereas the modern humans from sub-Saharan Africa displayed no evidence of any Neanderthal DNA, the three modern humans from outside of Africa showed similar, low amounts (between 1 and 4%) of shared DNA with Neanderthals. These results are compatible with either a deep split within Africa between the population that gave rise to modern Africans and a second one that gave rise to present-day non-Africans plus Neanderthals, or with the hypothesis that there was hybridization between Neanderthals and modern humans soon after the latter left Africa, perhaps in western Asia. Overall, Smith's assimilation model and Bräuer's African hybridization and replacement model of modern human origins appears most compatible with the current morphological and genetic evidence on Neanderthal/modern human diversity. The combination of two distinctive morphologies with molecular evidence for gene flow – albeit partial and limited – points to a lack of congruence between *H. neanderthalensis* and *H. sapiens* defined as morphological species and biological species. A similar lack of correspondence has been demonstrated in other primates [e.g., baboons (*Papio*); Jolly 1993]. It has also been noted that the

projected time of the divergence between the Neanderthal and modern human lineages (see below) is probably not sufficient to establish reproductive isolation between them (Holliday 2006), but this may not be critical. Molecular and morphological evidence can also contribute to the debate about the origin of *H. neanderthalensis*. Nuclear and mtDNA have been used to generate estimates of the date of divergence of *H. sapiens* and *H. neanderthalensis*. A recent estimate using mtDNA and based on an assumed divergence time of *c.* 6–7 Ma for the modern human and chimpanzees/bonobo lineages suggests a divergence date of 660±140 ka (Green et al. 2008). Estimates of the divergence time of the ancestral modern human and Neanderthal populations based on the nuclear genome range from 440 to 270 ka; 440 ka is based on an early (8.3 Ma) divergence date for chimpanzees/bonobos and modern humans and 270 ka on a later (5.6 Ma) divergence date (Green et al. 2010). As far as the fossil evidence is concerned, the debate is about when the distinctive morphology of *H. neanderthalensis* first appeared in the fossil record. There is a growing literature about the distinctive morphology of *H. neanderthalensis* (see Wood and Lonergan 2008 for a brief survey of this literature) but there is no comprehensive review that brings together the cranial, dental, and postcranial evidence. The earliest fossils that most researchers would accept as *H. neanderthalensis* are from OIS 5 (i.e., *c.* 130 ka), but beyond that date there is contention. For example, some interpret the fossil evidence from Swanscombe (OIS 11) and the Sima de los Huesos (possibly as early as OIS 13) as showing enough *H. neanderthalensis*-like morphology to justify those remains being included in *H. neanderthalensis* (Hublin 2009), whereas others see a distinction between these specimens, which they would include in *H. heidelbergensis* and later “true” Neanderthals that they claim do not appear until OIS 6 (Rosas et al. 2006). These latter researchers see the evolution of *H. neanderthalensis* as a two-phase process and Hublin (2009) refers to this as the “two-phase model.” This contrasts with Hublin’s own “accretion model” (Hublin 1998, 2009), which suggests that after the first *H. neanderthalensis* apomorphies appear the process of accumulating further apomorphies is so seamless that there is no obvious species boundary after that time that can be identified using morphological evidence. First discovery Neanderthal 1 (1856).

Holotype As above. Paratypes No paratypes were formally designated. Main sites Many sites in Europe and the Western Asia.

***Homo neanderthalensis aniensis* Sergi, 1935** See Saccopastore 1.

***Homo neanderthalensis soloensis* Oppenoorth, 1932** See *Homo (Javanthropus) soloensis* Oppenoorth, 1932.

***Homo nocturnus* (L. *homin*=man or human being and *nocturnus*=of the night)** This is not a formal species name. See *Homo troglodytes*.

***Homo ramidus* (White et al., 1994)** See *Homo* Linnaeus, 1758.

***Homo rhodesiensis* Woodward, 1921** (L. *homin*=man or human being and *rhodesiensis*=from what was in 1921 the British protectorate of Northern Rhodesia – now Zambia – a country named after Cecil Rhodes) A pre-modern *Homo* taxon introduced by Sir Arthur Smith Woodward (1921) for the cranium and limb bones recovered from the site of Broken Hill lead mine at Kabwe. Woodward reasoned that a new species of *Homo* was needed for the specimen because it did not fit within any of the existing *Homo* taxa; it was not as primitive as *Homo erectus* and not as derived as either *Homo sapiens* or *Homo neanderthalensis*. Many researchers regard *Homo rhodesiensis* as a junior synonym of either an inclusively defined *H. sapiens* or *Homo heidelbergensis*. However, the taxon is used by researchers who see *H. heidelbergensis* as an exclusively European pre-modern *Homo* taxon. First discovery Kabwe 1 or E 686 (1921). Holotype As above. Paratypes None. Main sites Kabwe, Bodo.

***Homo rudolfensis* (Alexeev, 1986) Groves, 1989 sensu Wood, 1992** (etym. L. *homin*=man or human being and *rudolfensis*=after the old name, Lake Rudolf, for Lake Turkana) Hominin species formally established by Alexeev as *Pithecanthropus rudolfensis* and transferred to *Homo* by Groves (1989) and more comprehensively differentiated from *Homo habilis sensu stricto* by Wood (1992). Kennedy (1999) claims that the species name *Homo rudolfensis* is unavailable, but Groves (1989) and Wood (1999) point out that although Alexeev did not follow all the

recommendations of the **International Commission on Zoological Nomenclature** (or ICZN), he did follow its rules and thus the name is available. The differences between *H. rudolfensis* and *H. habilis sensu stricto* include that the crania of the former taxon are wider across the midface instead of the upper face, the mandibles are larger and more robust, the crowns of the postcanine teeth are larger and broader, and the talonids and the root systems of the mandibular premolars of the latter are more complex. Leakey and Walker (1989, pp. 212–13) consider that *H. rudolfensis* makes a more likely ancestor for *Homo erectus* than *H. habilis sensu stricto*. However, not all researchers recognize *Homo rudolfensis* as a separate taxon, with many preferring to include its hypodigm within a more inclusively interpreted *Homo habilis sensu lato*. First discovery KNM-ER 819 (1971). Lectotype KNM-ER 1470 (1972). Main sites Koobi Fora, Uraha. See also *Pithecanthropus rudolfensis*.

***Homo saldanensis* Drennan, 1955** See Saldanha 1.

***Homo sapiens* Linnaeus, 1758** (L. *homin* = man or human being and *sapiens* = to be wise) Hominin species established by Linnaeus to accommodate modern humans. The first discovery of a fossil modern human was made in 1822–3 in Goat’s Hole Cave in Paviland, Wales, but the first widely accepted evidence that modern humans were ancient enough to have fossilized representatives came when a series of skeletal remains were discovered by workmen at the Cro-Magnon rock-shelter at Les Eyzies de Tayac, France, in 1868. A male skeleton, Cro-Magnon 1, was made the type specimen of a novel species, *Homo spelaeus* Lapouge, 1899, but it was not long before it was realized that it was not appropriate to discriminate between this material and modern *Homo sapiens* (Topinard 1890, Keith 1912) and further discoveries of *H. sapiens*-like fossils were soon made elsewhere in Europe [e.g., Mladec (1881–1922), Predmosti (1884–1928), and Brno (1885)]. In Asia and Australasia similar fossils were recovered from Wadjak, Indonesia (1889–90), the Zhoukoudian Upper Cave, China (1930), Niah Cave, Borneo (1958), Tabon, Philippines (1962), and the Willandra Lakes, Australia (1968 and thereafter). In the Near East comparable fossil hominins have been recovered from sites such as Skhul (1931–2) and Djebel Qafzeh (1933 and 1965–75). The first African fossil evidence of populations that are difficult to

distinguish from modern humans came in 1924 from Singa in the Sudan. Thereafter comparable evidence has come from Dire-Dawa, Ethiopia (1933), Dar es Soltane, Morocco (1937–8), Border Cave, Natal (1941–2 and 1974), Omo-Kibish, Ethiopia (1967), Klasies River Mouth, Cape Province (1967–8), and Herto, Middle Awash study area, Ethiopia (1997). With the exception of Omo-Kibish (*c.*190 ka, McDougall et al. 2005) and Herto (*c.*170 ka, White et al. 2003), there is no firm evidence to suggest that any of the above sites are likely to be more than 150 ka, and most are probably less than 100 ka. Stringer (2002) provides an excellent overview of the fossil evidence for *H. sapiens* and the ways that the fossil evidence might be used to investigate modern human origins. All the fossil evidence referred to above has been judged to be within, or close to, the range of variation of living regional samples of modern human populations, and thus researchers concluded it is was not appropriate to distinguish it taxonomically from *H. sapiens*. But what are the features of the cranium, jaws, dentition, and postcranial skeleton that are only found in *H. sapiens*, and what are the limits of living *H. sapiens* variation? How far beyond these limits, if at all, should we be prepared to go and still be prepared to refer the fossil evidence to *H. sapiens*? These are simple enough questions, to which one would have thought there would be ready answers, but the assembly of a set of morphological criteria for “modern humanness” has proved to be a surprisingly difficult task. With respect to the cranium, little progress has been made since William (Bill) Howells’ seminal studies of modern human cranial variation. Howells (1973, 1989) carried out the most comprehensive sampling ($N=28$ groups and 57 measurements) of modern human cranial measurements and so he has, as well as anybody, captured the essence of modern human cranial variation. He showed that the totality of variation, as measured in Mahalanobis distance, among his 28 groups is comparable to the distance that separates all modern human crania from his small sample of *Homo neanderthalensis* crania. Small-bodied modern humans tend to have smaller crania, but overall there is very little among-sample difference in the overall size of the modern human cranium. Qualitatively, Howells comments that modern human crania share a “. . . universal loss of robustness,” and he goes on to write that within modern humans “variation in shape seems to be largely located in the upper face, and particularly the upper nose and the borders of the orbits”

(Howells 1989, p.83). A few attempts have been made to specify acceptable ranges of morphometric variation for the cranium of *H. sapiens* (e.g., Stringer et al. 1984, Day and Stringer 1991), but even these authors conceded that a sample need only comply with about 75% of the defining characteristics to qualify for inclusion in *H. sapiens*. In a review of variation in regional samples of modern human crania Lahr (1996) emphasized that regional peculiarities should not be incorporated into criteria for inclusion in *H. sapiens*. Lieberman (1998) distilled existing cranial definitions of *H. sapiens*, and suggested that to be regarded as “anatomically modern human,” crania need to have “a globular braincase, a vertical forehead, a diminutive brow ridge, a canine fossa and a pronounced chin” (*ibid*, p. 158). Others have suggested that all these features may be related in one way or another to a reduction in facial projection (Spoor et al. 1999) and Lieberman et al.’s (2002) conclusion was that all modern human crania have an unusually globular neurocranium. The most comprehensive survey of modern human dental metrics is still that of Kieser (1990). The equivalent source for non-metrical dental traits is Scott and Turner (1997) and a series of papers by Irish and colleagues (see Irish and Guatelli-Steinberg 2003). The post-canine teeth of modern humans are notable for the absolutely and relatively small size of their crowns, and for a reduction in the number of cusps and roots (Kraus et al. 1969, Hillson, 1996). There are no equivalent book-length surveys of the modern human postcranial skeleton. The postcranial skeleton of *H. sapiens* has limbs that are long relative to the trunk (Holliday 1995), elongated distal limb bones (Trinkaus 1981), a relatively narrow trunk and pelvis, and low estimated body mass relative to stature (Ruff et al. 1997). Many of these traits cause the earliest modern humans (e.g., those from Skhul and Qafzeh) to resemble extant people from hot, arid climates, and the contrasts in postcranial morphology between modern humans and Neanderthals probably have more to do with the uniqueness and distinctiveness of Neanderthal morphology than with the ability of researchers to define the distinctive characteristics of *H. sapiens* (Pearson 2000). The features of the postcranial skeleton that make extant and subrecent modern human populations distinctive have to be described in terms that encompass the full range of modern human climatic and altitudinal adaptations. In summary, compared to their more archaic immediate precursors, modern humans are characterized postcranially by their reduced body

mass (e.g., Kappelman 1996, Ruff et al. 1997), linear physique, and a distinctive pelvic shape that includes a short, stout, pubic ramus, and a relatively large pelvic inlet (Pearson 2004). In Africa there is fossil evidence of crania that are generally more robust and archaic-looking than those of anatomically modern humans, yet they are not archaic or derived enough to justify being allocated to *Homo heidelbergensis* or to *H. neanderthalensis*. Specimens in this category include Jebel Irhoud from North Africa, Laetoli 18 from East Africa, and Florisbad and the Cave of Hearths from southern Africa. There is undoubtedly a gradation in morphology that makes it difficult to set the boundary between anatomically modern humans and *H. heidelbergensis*, but the variation in the later *Homo* (i.e., post-*Homo erectus*) fossil record is too great to be accommodated in a single taxon. Researchers who wish to make a distinction between fossils such as Florisbad and Laetoli 18 and subrecent and living modern humans either do so taxonomically by referring the former specimens to a separate species, *Homo helmei* Dreyer, 1935, or they distinguish them informally as “archaic *Homo sapiens*.” A few researchers have suggested that *H. sapiens* should be a much more inclusive taxon. For example, because they could see no obvious morphological discontinuity between *H. sapiens* and *H. erectus*, Wolpoff et al. (1994) recommended the boundary of *H. sapiens* be changed to incorporate *H. erectus*, thus echoing a similar proposal made earlier by Mayr (1950). This taxonomy has received little support, but at least the authors made an explicit statement about the scope of the morphology they were prepared to subsume within *H. sapiens*. First discovery Goat’s Hole Cave, Wales, UK (1822–3). Holotype No holotype was nominated by Linnaeus. Paratypes None. Main sites Many sites in the Old World and some in the New World.

***Homo sapiens idaltu* White et al., 2003**

A subspecies of *Homo sapiens* established “because the Herto hominids are morphologically just beyond the range of variation seen in [anatomically modern *Homo sapiens*], and because they differ from all other known fossil hominids, we recognize them here as *Homo sapiens idaltu*” (White et al. 2003, p. 315).

***Homo sapiens shanidarensis* Senyürek, 1957** *See Shanidar 7.*

***Homo sapiens neanderthalensis* King, 1864** A name combination introduced by

Campbell (1973) for what most other researchers recognize as the European part of the hypodigm of *Homo neanderthalensis*.

***Homo sapiens palestinus* McCown and Keith, 1934** A name combination introduced by Campbell (1973) for what most other researchers recognize as the Near Eastern part of the hypodigm of *Homo neanderthalensis*.

***Homo sapiens protosapiens* Montandon, 1943** A new name combination suggested by Montandon (1943). *See Swanscombe 1.*

***Homo sapiens rhodesiensis* Woodward, 1921** A name combination introduced by Campbell (1973) for what most other researchers recognize as *Homo rhodesiensis*, or as the African part of either the hypodigm of *Homo heidelbergensis*, or the temporally earlier part of the hypodigm of an inclusive interpretation of *Homo neanderthalensis*.

Homo sapiens soloensis *See Homo (Javanthropus) soloensis* Oppenoorth, 1932.

***Homo sapiens soloensis* Oppenoorth, 1932** A name combination introduced by Campbell (1973) for what most other researchers recognize as the temporally later part of the Indonesian hypodigm of *Homo erectus*. *See Homo (Javanthropus) soloensis*.

***Homo sapiens steinheimensis* Linnaeus, 1758** A new name combination suggested by Weiner and Campbell (1964). *See Swanscombe 1.*

Homo-simiadae In his 1925 paper reporting the discovery of what was then called the Taungs skull, Raymond Dart proposed “tentatively” (Dart 1925, p. 198) that the novel taxon he announced, *Australopithecus africanus*, should be placed in a new family the Homo-simiadae. There is no evidence that Dart seriously pursued the proposal.

***Homo soloensis* Oppenoorth, 1932** *See Homo (Javanthropus) soloensis*.

***Homo (Javanthropus) soloensis* Oppenoorth, 1932** (L. *homin*=man or human being, *Java*=from the name of the island where

the fossils were found, Gk *anthropos*=human being and *solo*=refers to the river Solo in whose banks the site is located) Taxon introduced by Oppenoorth (1932) for the calvaria (Ngandong 1, 2, and 3) recovered from Ngandong in 1931. In that paper Oppenoorth compares the new calvaria with “Neanderalers,” the “Rhodesia-skull,” and “Wadjak man.” He does not specifically refer to Ngandong 1 as the holotype, but it is evident from the text that he regards it as such. In a later paper Oppenoorth (1937) jettisons the subgenus *Javanthropus* and just refers to the taxon as *Homo soloensis*. Since then researchers have either relegated the taxon to a subspecies of *Homo sapiens* as *Homo sapiens soloensis* (e.g., Dubois 1940, Tobias 1985), a subspecies of *Homo neanderthalensis* as *Homo neanderthalensis soloensis* (Weidenreich 1940), or it has been subsumed into *Homo erectus* (e.g., Santa Luca 1980) as either a junior synonym of *H. erectus* or as a recognized subspecies of that taxon (e.g., *Homo erectus soloensis*; Mayr 1944). Kaifu et al. (2008) support the use of separate subspecies for the Ngandong and Bapang-AG samples of *Homo erectus* and they also support Santa Luca’s conclusion that the Ngandong hominins are more derived than the Bapang-AG sample. First discovery Ngandong 1/Skull 1 (1931). Holotype As above. Paratypes None. Main Sites Ngandong, also called Solo, and some researchers also include the remains from Ngawi and Sambungmachan in this hypodigm.

***Homo spelaeus* Lapouge, 1899** *See Homo sapiens* Linnaeus, 1758.

***Homo spyensis* Krause, 1909** *See Spy.*

***Homo steinheimensis* Berkhemer, 1936** *See Steinheim 1.*

Homo sylvestris (L. *homin*=man or human being and *silva*=forest) This is not a formal species name. It was included in the discussion when the genus *Homo* was introduced in 1758 by Carl Linnaeus in the tenth edition of his *Systema Naturae*. It apparently referred to a mythical nocturnal cave-dwelling form from Java but the discovery of *Homo floresiensis* means that *Homo sylvestris* might not have been mythical after all (Collard and Wood 2006). *See Homo troglodytes*.

Homo transvaalensis (Broom, 1936)

(*L. homin*=man or human being and *transvaal*=the name of the state where the fossil site is located) Taxon used by Ernst Mayr (1950) for specimens then subsumed under the following taxa: *Australopithecus africanus*, *Plesianthropus transvaalensis*, *Australopithecus prometheus*, *Paranthropus robustus*, and *Paranthropus crassidens*. Apparently Mayr did not use the taxon with obvious priority, *Australopithecus africanus* Dart, 1925, because the type specimen belongs to a juvenile. In John Robinson's discussion of the relationship between *Homo habilis* and the southern African australopiths (Robinson 1965) he suggests that *Homo* should be divided into two taxa: *H. transvaalensis* for the "tool-using phase of the lineage" and *Homo sapiens* for the "tool-makers who possessed greatly improved means of communication and comparatively complex social structure" (*ibid*, p. 123). Robinson points out that his usage of *H. transvaalensis* differs from Mayr's in the sense that he would exclude the *Paranthropus* taxa because "their basic adaptation... was quite different from that of the *Homo* lineage" (*ibid*, p. 123). For Robinson, the genus *Homo* differed from earlier taxa and from *Paranthropus* because the component taxa had shifted to an omnivorous diet that included "a significant degree of carnivorousness" (*ibid*, p. 123). *See also Homo; Homo africanus.*

Homo troglodytes Linnaeus, 1758

(*L. homin*=man or human being and *troglydyta*=cave dwellers, from the Gk *troglos*=cave and *dtai*=those who enter) The second of two species of *Homo* coined by Linnaeus in the key tenth edition of *Systema Naturae* (the first species being *Homo sapiens*). He defined it as "*Homo nocturnus*" (=nocturnal humans), and as evidence for the existence of this species he cited "Homo sylvestris Orang Outang" from Jakob de Bondt, an early 17thC Dutch physician in Java and "Kakurlacko" from Kjoeping, a Swedish traveller, and evidence from Dalin, the president of the Swedish Royal Academy. De Bondt may have been describing a real orangutan, or maybe just a hypertrichous woman; Kjoeping and Dalin were describing albinos on the Indonesian island of Ternate, who hid away from the light in caves. Thus, *H. troglodytes* Linnaeus, 1758 is, in part or in whole, a synonym of *Homo sapiens*. Some authors have proposed that the chimpanzee should be placed in the genus *Homo*, in which case the name would be *Homo*

troglydytes (Blumenbach, 1785). On the face of it this name combination looks as if it should be preoccupied by *Homo troglodytes* Linnaeus, 1758, but the current (4th) edition of the *International Code of Zoological Nomenclature*, Article 23.9.1, states that "prevailing usage must be maintained" when "the senior homonym has not been used as a valid name after 1899, and the junior homonym has been used for a particular taxon, as it is presumed valid name, then at least 25 works, published by at least 10 authors in the immediately preceding 50 years." It is highly unlikely that the sporadic use of *Homo troglodytes* for the chimpanzee over the past half century qualifies, thus these criteria would appear to have been met; thus, Linnaeus' *Homo troglodytes* can be ignored.

homoiology (Gk *homoios*=similar) Despite the meaning of the Greek word on which it is based, homoiology refers to the part of the **phenotype** whose morphology is influenced by the type and level of activity undertaken (i.e., by environmental factors) (Remane 1961). Homoiology contributes to variation within a **taxon** and in theory homoiology can contribute to phylogenetically misleading morphological similarities among taxa when different genotypes express the same or similar phenotypes because of similar functional demands and not because of shared recent evolutionary history (i.e., they were present in the most recent common ancestor of the taxa concerned). Homoiologies are the result of a more inclusive phenomenon called **phenotypic plasticity**. *See also homoplasy.*

homologous (Gk *homologos*=agreeing, from *homo*=the same and *logos*=proportion) A structure, gene, or developmental pathway shared by more than one taxon that was inherited from the most recent common ancestor of the taxa concerned. For example, canine teeth are homologous across all primates but the eyes of vertebrates and cephalopods are not homologous. In genetics, the term homologous refers to DNA or protein sequences that share a common ancestry. *See also homology.*

homology (Gk *homologos*=agreeing, from *homo*=the same and *logos*=proportion) A term introduced by Richard Owen in 1843 that now refers to similar structures, or genes or developmental pathways found in more than one taxon whose similarity is due to their being inherited

from the most recent common ancestor of the taxa concerned. Homologies are the basis for assembling taxa into **clades** or **monophyletic groups**. For example, within the hominin clade the outcome of the debate about whether *Paranthropus* is a monophyletic group rests on resolving whether the distinctive facial and dental morphologies shared by taxa currently included in *Paranthropus* are homologies or are the result of parallel evolution. There are, however, cases where the structure remains homologous but the developmental processes change (e.g., the frontal is derived from the neural crest in some mammalian and bird taxa and from cranial mesoderm in others) but most researchers would retain the homology of the frontal across taxa. The way around this is to include Van Valen's addition of "continuity of information" to the processes that ground homology. Another nuance with respect to homology is that some people recognize degrees of homology whereas others argue that structures are either homologous or not. The term "deep homology" has been introduced for cases where even though organisms do not share the same morphology they do share the same genetic regulatory cascade (e.g., common photoreceptor precursors that result in differently structured eyes in arthropods, squids and vertebrates; Shubin et al. 2009). *See also* **homoplasy**.

homonym (Gk *homonymous*=the same name, from *homo*=the same and *onuma*=name) The same name used for more than one taxon. For example, the binomial *Meganthropus africanus* was introduced by Hans Weinert (1950) for the maxilla found by Ludwig Kohl-Larsen in 1939 at the site that was then called **Garusi** and is now called **Laetoli**. As long as *M. africanus* stays in a genus other than *Australopithecus* then there is no confusion with *Australopithecus africanus* Dart, 1925, but if *M. africanus* is transferred to *Australopithecus* (Senut 1996) then it becomes a secondary homonym. *See* **homonymy**.

homonymy In **nomenclature**, homonymy refers to a situation when two or more available names have the same spelling but they denote different nominal taxa. The **International Code of Zoological Nomenclature** stipulates that two different species or subspecies deemed to belong to the same genus may not have the same spelling, two different genera or subgenera in the Animal

Kingdom may not have the same spelling, and two different families, subfamilies, tribes, or subtribes may not have the same spelling or differ only in suffix (-idae, -inae, -ini, -ina respectively). The rules for homonymy between species or subspecies of the same genus are the most complex because some "different" spellings are deemed to be homonymous (*caeruleus*, *coeruleus*, and *ceruleus*, for example, are deemed to be "the same" spelling). Another category of problems are secondary homonyms. These are identical species or subspecies names that were initially used in different genera, but which later find themselves in the same genus because the two original genera were combined. In that case the junior homonym is dropped (and the species it represents renamed, if it is still thought to be a valid species), but if the two genera are then separated again, the two names are now no longer homonyms. Paleoanthropology provides at least two examples. The first is that, in 1950, Hans Weinert described Laetoli Hominid 1 (at that time known as "the Garusi maxilla") as a new species *Meganthropus africanus*. But most researchers consider LH 1 to be a member of the genus *Australopithecus* in which case the specific name "*africanus* Weinert" would be a junior secondary homonym of "*africanus* Dart, 1925", for there cannot be two species called *Australopithecus africanus*. Subsequently, in 1978 Johanson and colleagues gave the Laetoli species a new name, *Australopithecus afarensis*, but some researchers preferred to keep the Laetoli species in a different genus, in which case the name *africanus* Weinert would cease to be a junior secondary homonym. The case was referred to the **International Commission on Zoological Nomenclature** (or ICZN), which suppressed *africanus* Weinert. The second example is that of the **Omo 18-1967-18** mandible, which was made the holotype of a new genus and species *Paraustralopithecus aethiopicus* by Arambourg and Coppens in 1968. However, many researchers regard Omo 18-1967-18 as belonging to either *Australopithecus* or to *Paranthropus*. But in 1980 Tobias designated the Hadar hypodigm of *Au. afarensis* species as *Australopithecus aethiopicus*. So under the ICZN rules relating to homonymy, if Omo 18-1967-18 is included in *Australopithecus* it cannot retain its species name as *Australopithecus aethiopicus*, but if it is included in *Paranthropus*, it can retain its species name as *Paranthropus aethiopicus*.

homoplasy (Gk *homos*=same and *plasis*=mold) Introduced by Ray Lankester in 1870. He wrote “When identical or nearly similar forces, or environments, act on two or more parts of an organism. . . the resulting correspondences called forth in the several parts in the two organisms will be nearly or exactly alike. I propose to call this kind of agreement *homoplasis* or *homoplasy*” (Lankester 1870, p. 39). The contemporary interpretation is that homoplasy refers to resemblances between taxa that can be ascribed to processes other than descent from the most recent common ancestor of the taxa concerned and which imply phylogenetic relationships that conflict with the best estimate of phylogeny for the taxa. Several forms of homoplasy have been identified. Analogy and **convergence** are both caused by adaptation to similar environments. Natural selection operates on different developmental processes in the case of analogies but on the same developmental processes in the case of convergences. Parallelisms result from aspects of ontogeny that limit phenotypic diversity, but have no necessary connection with the demands of the environment. Parallelisms, in other words, are by-products of development, not adaptations. A fourth type of homoplasy is reversal, in which, for example, brain size increases and then decreases. Most cases of reversal are probably due to natural selection, but recent work on silenced gene reactivation suggests that some reversals may also be neutral with regard to adaptation. The last form of homoplasy is **homoiology**. Homoiologies are homoplasies attributed to non-genetic factors (e.g., activity-induced bone remodeling). Homoplasies can be mistaken for shared derived similarities or **synapomorphies**, which are the principal evidence for phylogeny. As such, homoplasy complicates attempts to estimate phylogenetic relationships. Indeed, if homoplasies are sufficiently numerous they can prevent a reliable phylogeny from being obtained. Homoplasy is also used to refer to a single trait shared by two or more taxa that was not inherited from the most recent common ancestor of those taxa. *See also cladistic analysis; homoiology.*

homozygote (Gk *homos*=the same and *zygotos*=yoked) A **diploid** organism that has the same **alleles** at a particular **locus** is referred to as being homozygous at that locus. For example, an individual who has the genotype AA at the ABO locus is homozygous and has type A blood.

homozygous *See* homozygote.

honing (OE *hān*=stone, from a whetstone used to sharpen knives or tools) Honing refers to teeth that rub together resulting in a sharp edge on one or both of them. In paleoanthropology it is used to refer to the honing complex made up of the upper canine and the anterior lower premolar that is found in apes and that is assumed to be the primitive condition for hominins. The loss of a honing complex is assumed to be related to a shift in behavior where males do not need to fight with their teeth to get access to mates, and thus the presence or absence of this feature in early hominins is much discussed. *See also sexual selection.*

Hoogland (Location 25°48.483'S, 28°0.204'E, Gauteng Province, South Africa; etym. Named by the landowner of the farm property). History and general description The site is an abandoned limeworks based on a cave system within Precambrian **dolomite** near the Hennops River, 22.5 km west of Pretoria in the Schurverberg Mountain Range. The site is consistent with field notes and descriptions by Broom (1936) as one of the localities he sampled to generate the ‘Schurverberg collection’ at the **Ditsong National Museum of Natural History** (formerly the Transvaal Museum), which includes the type specimen of *Papio (Dinopithecus) ingens*. Geologic description The cave system initially formed as a series of deep, vertical shafts that allowed exogenous materials to form a significant talus slope at the base of the entrance. A continuous record of intact *in situ* deposits on the cave wall records five ‘flowstone bounded units’ (FBUs), of which FBU 2–5 are fossiliferous. Fauna A diverse range of Neogene species, including *Theropithecus oswaldi oswaldi* and bovids similar to those recovered from **Makapansgat Member 3**. Temporal span Paleomagnetic sampling across the Hoogland deposits recorded a series of polarity reversals, indicating that the deposits span an extremely long time period. The densest fossil deposits (FBU4) occur during a normal polarity period. Initial analysis suggests deposition of FBU4 at the end of the Gauss Chron (C2An.1n; 3.03–2.58 Ma) normal polarity period given the morphology of the recovered bovids from the site. How dated? Biostratigraphy and magnetostratigraphy. Hominins found at site None. Archeological evidence found at site None; Key references: Geology and fauna Adams et al., 2010.

Hopefield *See* Elandsfontein.

Hopefield 1 *See Saldanha 1.*

hornfels A hornfels is a fine-grained, dark-colored metamorphic rock, formed by contact metamorphism adjacent to an igneous intrusion. Hornfels typically forms from high-temperature baking and recrystallization of a pre-existing rock, a process that usually removes features such as bedding planes. Its appearance is often similar to fine-grained basalt but it is much more brittle than basalt. This can make it a poor choice as raw material for **knapping** but it is selected where better options are unavailable (e.g., **Florisdad**).

horst Refers to an area of relative uplift between a pair of normal faults; the adjacent down thrown area is known as a **graben**. These faults tend to form in conjugate pairs within heavily faulted areas (e.g., parts of the floor of the East African rift valley) develop a landscape with relatively uplifted areas adjacent to relatively low-lying areas (e.g., the faulted margins of the **Ologesailie** paleolake basin). This can lead to substantial environmental heterogeneity over relatively short lateral distances. Horsts that form after deposition of sedimentary sequences can expose otherwise buried formations (e.g., **Bouri Formation** in the Middle Awash study area).

Hortus (Location 43°47'N, 3°50'E, France; etym. originally spelled Ortus, of unknown etymology) History and general description A cave site located high in a limestone massif in southeast France. Excavations by a series of professional and amateur scientists since 1908 focused on the superficial Late Bronze Age deposit. In the 1950s, Cazals and Audibert discovered deeper **Mousterian** layers and formal excavations of these layers were carried out by Henry de Lumley between 1960 and 1964. Temporal span and how dated? **Conventional radiocarbon dating** on bones from the Mousterian levels was unsuccessful. **Geochronology** suggests that the main deposition occurred during the Würm I and II cold phases. Hominins found at site The remains of between 20 and 36 individuals were recovered; there was no evidence of intentional burial. A high proportion of the individuals were young adults. The majority of the bones are maxillae or mandibular fragments, and de Lumley suggested they may be the result of cannibalism, but none show unambiguous cut-marks. Archeological evidence found at site

Mousterian artifacts in the lower levels. Key references: Geology, dating, and paleoenvironment de Lumley 1972; Hominins de Lumley 1972, Mann and Trinkaus 1973; Archeology de Lumley 1972.

Hotelling T^2 test A generalization of the *t* test used to test whether a vector of means of two or more continuous variables differ between two groups. For example, it can be used to test whether the **centroid** of two sets of cranial measurements differ from each other.

housekeeping gene A gene that is expressed in connection with the basic functions of a cell. For example, the genes involved with **transcription**, **translation**, energy production, and cell division would all be regarded as housekeeping genes.

Howell, Francis Clark (1925–2007) Francis Clark Howell was born in Kansas City, Missouri, USA, and grew up on a farm in Kansas. He was introduced to human prehistory by reading Henry Fairfield Osborn's *Men of the Old Stone Age* (1916) and William W. Howells' *Mankind so Far* (1944). During WWII Howell served in the US Navy in the Pacific from 1944 to 1946 and after his discharge he spent a short period at the **American Museum of Natural History** in New York where he met American paleontologist George Gaylord Simpson, as well as Franz **Weidenreich** and Ralph von **Koenigswald**. Howell wrote that "he had the humbling pleasure at the age of not yet 21, to meet von Koenigswald" and that the latter "was immensely kind to me, as was Franz Weidenreich, at a time that I only hoped for a career in human evolutionary studies" (Howell, 1994, p. 18). This experience strengthened Howell's conviction to pursue a career in paleoanthropology and he entered the University of Chicago where he studied anthropology with Sherwood **Washburn** and Robert J. Braidwood. After completing his BA in 1949 Howell decided to stay at the University of Chicago for graduate school where he conducted research on *Homo neanderthalensis*. Howell completed his MA in 1951 and his PhD in 1953. Howell claimed that it was the influence of the Spring Seminar Series organized by Sherwood Washburn that convinced him of the importance of the relationship between evolutionary biology, paleontology, and ecology. After completing his PhD Howell taught anatomy as an instructor at Washington University in St. Louis from 1953 to

1955. He also began to spend a portion of each year traveling to Europe to conduct excavations at prehistoric sites, and the latter led to early publications on Paleolithic archeology and fossil mammals. He also expanded upon his earlier research on Neanderthals by integrating the principles of the **modern evolutionary synthesis** with what was known about the climate of Europe during the Pleistocene, to explain the anatomical differences between the “classic” Neanderthals of Western Europe and the Neanderthals found in **Krapina** and in the Near East. In 1955 Howell accepted a position as Professor of Anthropology at the University of Chicago, but he continued to visit important prehistoric sites and museum collections throughout the world. Howell drew upon his broad knowledge of paleoanthropology to publish *Early Man* (1965), a popular synthetic work that appeared in revised editions in 1968 and again in 1980. Howell carried out important fieldwork at the **Acheulean** sites of **Isimila** in Tanzania, **Ambrona**, and **Torralla** in Spain, and at the **Lower Paleolithic** site of **Yarimbuzguz** in Turkey. However, his most influential fieldwork was carried out in the **Lower Omo Valley** in southern Ethiopia. The Borg de Bosas expedition in 1902 had shown that region to be fossiliferous and **Camille Arambourg** had assembled a substantial collection of mammalian fossils in 1933. **Clark Howell** had visited the Lower Omo Valley in 1959 and it was on the basis of this experience that in 1966 he was invited to join a team of researchers assembled by **Louis Leakey** and **Camille Arambourg** to re-explore the Lower Omo Valley. Howell emerged as one of the leaders of what came to be called the **International Omo Research Expedition** (or **IORE**), which brought together specialists from a variety of disciplines including geology, paleontology, archeology, and paleoanthropology between 1967 and 1976. The **IORE** was important because the **Omo** deposits, a mixture of river sediments and lava flows, were found to represent close to 3 Ma of evolutionary history during the **Plio-Pleistocene**. The presence of numerous animal fossils and volcanic layers dateable using the then newly devised **potassium-argon dating** and **magnetostratigraphy** methods meant that the Omo deposits could be used to calibrate the evolutionary and paleoenvironmental history of the past several million years. The site thus became an important focus of attempts to develop a comprehensive and reliable biostratigraphy of the Plio-Pleistocene. This careful

attention to stratigraphy and dating allowed the team to generate an absolute chronology for the evolution of many mammal groups. For example, correlation of the abundant fossil pig species with absolute dates from the volcanic deposits in the **Shungura Formation** at the Omo enabled researchers to date deposits elsewhere that contained similar fossil pigs but where reliable absolute dates were not available and this eventually helped resolve the **KBS tuff dating controversy**. Howell left his position at the University of Chicago in 1970 to move to the Department of Anthropology at the University of California at Berkeley, where he joined **Sherwood Washburn**, **Theodore McCown**, **Desmond Clark**, and **Glynn Isaac**, and together they formed an impressive human origins research group. There he co-founded with **Tim White** the Human Evolution Research Center in the Department of Integrative Biology. It is difficult to exaggerate the influence Howell had on paleoanthropology. He had an encyclopedic knowledge of both the human fossil record and the more general mammalian fossil record, especially that of carnivores and Old World monkeys. His seminal review of the Neanderthals (Howell 1951) stimulated much of the subsequent research eventually showing that Neanderthals were unlikely to have been the direct ancestors of modern Europeans and his review of hominin evolution in Africa was equally influential (Howell 1978). Finally, his insistence on scientific rigor meant that the Omo Shungura Formation became the reference for African mammalian biostratigraphy. Howell taught at Berkeley until his retirement from formal teaching in 1991. Thereafter, he was appointed emeritus professor, a position he held until his death in 2007.

Howells, William White (1908–2005)

William "Bill" Howells who was born in New York City obtained his BS in anthropology from Harvard University in 1930. He stayed on at Harvard to study with **Earnest Hooton** and completed his PhD in physical anthropology in 1934 with a dissertation entitled *The Peopling of Melanesia as Indicated by Cranial Evidence from the Bismarck Archipelago*. After graduating Howells accepted a research position at the **American Museum of Natural History** where he remained until 1937 when he left to become an Assistant Professor in the Department of Sociology and Anthropology at the University of Wisconsin. Howells served as an officer in Naval Intelligence

from 1943 to 1945 and at the end of the war he returned to the University of Wisconsin. Howells put this time to good use and his published first book, *Mankind So Far* (1944), was an overview of human evolution accessible for a general audience, that was followed by *The Heathens* (1948), a study of “primitive” religions, and *Back of History* (1954), a popular survey of prehistoric archeology. These and his most influential popular book, *Mankind in the Making* (1959), reflect Howells’ broad knowledge of cultural anthropology, physical anthropology, and archeology. When Earnest Hooton died Howells accepted an offer to succeed his mentor as Professor of Anthropology at Harvard in 1954. Howells, assisted by his wife Muriel, expanded upon his doctoral work by collecting measurements of crania from populations in **Oceania**, Europe, Africa, and Asia to understand the pattern and extent of the metrical variation in modern human populations. The results of his study, one of the first examples of the application of **multivariate statistics** in biological anthropology, convinced Howells that all living modern human populations represented a single homogeneous species and that the **Neanderthals** represented a distinctly different species. The results of these pioneering analyses were published in *Cranial Variation in Man* (1973) and the metrical data set accumulated by Howells has been used by many researchers. Howells used the conclusions drawn from this research to criticize the **Neanderthal phase hypothesis** of human evolution advocated by Aleš Hrdlička and others as well as the multiregional continuity model (later called by Howells the **candelabra model**) of human origins proposed by Franz **Weidenreich**, which argued that geographically distinct populations of anatomically modern humans had evolved relatively independently throughout the Old World from an original pre-*Homo erectus* population that had left Africa. He was also very critical of the ideas of Carleton **Coon** who had argued that regional populations of *H. erectus* evolved into the modern human races of *Homo sapiens* and therefore the races had been biologically separate for a long period. Howells instead promoted a view he called the Noah’s ark hypothesis where there were several migrations of hominins (only later did he specify that Africa was the most likely origin for all of these migrations) with the last migration comprising modern humans that then replaced the populations of more archaic hominins that

had formed the earlier migrations. The current version of this idea is referred to as the **out-of-Africa hypothesis**. During the 1960s Howells also helped to organize the Harvard Solomon Islands Project, an interdisciplinary study of the interaction of culture, natural selection, and disease and Howells’ own emphasis on the need to integrate biological anthropology, cultural anthropology, linguistics, and archeology are apparent in *The Pacific Islanders* (1973). That same year he also published *Evolution of the Genus Homo* (1973), a short overview of current theories of human origins. He was awarded the Viking Fund Medal in 1954 and was elected to the National Academy of Sciences in 1967. In 1978 he was awarded the Distinguished Service Award of the American Anthropological Association, and the American Association of Physical Anthropologists presented him with the Charles Darwin Lifetime Achievement Award in 1992. Howells retired from Harvard in 1974 but continued to conduct research and to write. In 1975 Howells was one of the first American paleoanthropologists to be allowed to visit China. He returned to the subject of craniometry and the evolution and migration of human populations in *Skull Shapes and the Map: Craniometric Analyses in the Dispersion of Modern Homo* (1989) and *Who’s Who in Skulls: Ethnic Identification of Crania from Measurements* (1995). His last popular book that surveyed human origins, *Getting Here: The Story of Human Evolution*, was published in 1993, with a second edition in 1997.

HOX genes An abbreviation of *homeobox*. See *homeobox genes*.

Hoxne See *Acheulean*.

HP Acronym for the Howieson’s Poort industry.

hpAfrica See *Helicobacter pylori*.

hpAsia See *Helicobacter pylori*.

hpMaori See *Helicobacter pylori*.

hpSahul See *Helicobacter pylori*.

Hrdlička, Aleš (1869–1943) Aleš Hrdlička was born in Humpolec, Bohemia (now the Czech Republic), but he immigrated with his parents to the USA in 1881. He entered the New York

Eclectic Medical College in 1889 to study medicine and graduated with honors in 1892. He continued his medical education at the New York Homeopathic College from 1892 to 1894 and after graduation he worked as a physician at the New York Homeopathic Hospital for the Insane and it was here that he became interested in anthropometry. In 1895 Hrdlička joined the newly founded Pathological Institute of the New York State Hospitals where he remained until 1899. To prepare himself for his new position, Hrdlička spent several months in Paris during 1896 studying anthropometry with the French physical anthropologist Léonce-Pierre Manouvrier at the École d'Anthropologie and the Laboratoire d'Anthropologie de l'École Pratique des Hautes Études. When he returned to the Pathological Institute, Hrdlička began to collect anthropometric data. In the course of these studies he met Frederic W. Putnam of the **American Museum of Natural History** who arranged for Hrdlička to join an expedition to Mexico in 1898 and this initiated his life-long interest in the native peoples of the Americas. Hrdlička resigned from the Pathological Institute in 1899 and joined Putnam at the American Museum of Natural History where between 1899 and 1902 he conducted several large anthropometric studies of the native peoples of the American Southwest and northern Mexico. Hrdlička's extensive research experience enabled his appointment as assistant curator of the Division of Physical Anthropology at the **National Museum of Natural History, Smithsonian Institution** in Washington DC in 1903, and then his appointment as curator in 1910. While at the Smithsonian, Hrdlička assembled an extensive collection of modern human skeletal material from around the world and thus made the Smithsonian a center for research in physical anthropology. He traveled widely, visiting many of the most important sites where hominin fossils had been discovered and examining many of the fossils himself and he was an ardent promoter of the science of physical anthropology, both in America and abroad. As part of this effort Hrdlička founded first the *American Journal of Physical Anthropology* in 1918, serving as its editor from 1918 to 1942, and then the American Association of Physical Anthropologists in 1930. The latter provided an institutional organization for the physical anthropology and contributed to its professionalization. For much of his life Hrdlička studied the ques-

tion of how and when the first humans had arrived in the New World. He spent many years inspecting much of the evidence that suggested the first humans arrived in the Americas before or during the "Glacial Epoch" (i.e., the Pleistocene). In *The Skeletal Remains Suggesting or Attributed to Early Man in North America* (1907) and *Early Man in South America* (1912) Hrdlička concluded that this evidence was suspect and that it was more likely that the first inhabitants of the New World had not arrived until the end of the Glacial Epoch and he remained a staunch supporter of this view throughout his life. These views were reiterated in *The Quest for Ancient Man in America* (1937) where Hrdlička argued that modern humans arrived in the New World from northeast Asia via the Bering Strait from where they migrated south to populate North and South America. In 1927 Hrdlička published an article in the *Journal of the Royal Anthropological Institute* entitled "The Neanderthal Phase of Man," in which he argued that all the modern human races had a common origin and that anatomically modern *Homo sapiens* evolved from Neanderthals. The extensive investigation of the hominin fossil evidence that formed the foundation for Hrdlička's theory was reflected in the *The Skeletal Remains of Early Man*, published in 1930, which at the time was one of the most comprehensive expositions of the fossil evidence for human evolution. Despite his many contributions to modern paleoanthropology, Hrdlička's methodology and outlook were rooted more in the 19thC than in the 20thC. He had little training in biology or evolutionary theory and the revolutions that were occurring in genetics largely passed him by. Some of his theories, especially the Neanderthal origin of modern humans, were controversial and not widely accepted, although his analysis and description of individual fossil specimens were of a high quality. Through his work at the Smithsonian and through works such as *Physical Anthropology: Its Scope and Aims* (1919), *Anthropometry* (1920b), and *Practical Anthropometry* (1939) Hrdlička helped to expand the scientific scope of physical anthropology as a discipline in the USA. Hrdlička retired from his position at the Smithsonian in 1942 and spent the last years of his life studying the native peoples of Alaska and the Aleutian Islands in search of support for his theories about the peopling of the Americas.

HSBC Acronym for Hunter-Schreger band curvature, which is defined as the "number of

cervically located **diazones** and **parazones**” crossed by the projection to the enamel-dentine junction of a line drawn “parallel to the H(unter) S(chreger) B(and)s in the outer enamel” (Beynon and Wood 1986, p. 182). *See also* **enamel microstructure**; **Hunter–Schreger bands**.

HSBW Acronym for Hunter–Schreger band width, which is defined as the average width of “at least ten alternating **parazones** and **diazones** in the occlusal one-third of the lateral enamel” (Beynon and Wood 1986, p. 181). *See also* **enamel microstructure**; **Hunter–Schreger bands**.

HTU Acronym for **hypothetical taxonomic unit** (*which see*).

Hublin, Jean-Jacques (1953–) Jean-Jacques Hublin was born in Mostaganem in former French Algeria. He gained a BA in Geology in 1975, an MA in Vertebrate Paleontology and Human Paleontology in 1976, and a third-cycle Doctorate in Vertebrate Paleontology and Human Paleontology in 1978, all at the University of Paris VI where his mentors were R. Hoffstetter and Bernard Vandermeersch. While working on his PhD Hublin focused on the anatomy of *Homo neanderthalensis* and one of his early papers was a cladistic investigation of the cranial morphology of *H. neanderthalensis* (Hublin 1978). In 1991 he was awarded a State Doctorate (Habilitation) in Anthropology from the University of Bordeaux. Hublin has conducted field work in North Africa (**Ternifine**, **Jebel Irhoud**), and Europe (**Zafarraya**). Much of his work has been on **Middle Pleistocene** and **Late Pleistocene** hominins, and his research demonstrated that *H. neanderthalensis* was older than initially thought, and that Neanderthals were unlikely to be ancestral modern humans. He is the contemporary proponent of the **accretion model** for the evolution of *H. neanderthalensis* (Hublin 1998). His research also suggests that assemblages considered as early **Upper Paleolithic** (such as the **Châtelperronian**) were actually produced by late Neanderthals, maybe as a result of an acculturation process (Hublin et al. 1996). He has also worked extensively on the origin of modern humans in North Africa and his research has provided evidence of *Homo sapiens* beyond sub-Saharan Africa and put the temporal origin of *H. sapiens* between 300 and 100 ka (Hublin and Tillier 1981,

Hublin 1992, Smith et al. 2007). He was also one of the first researchers to recognize the potential of imaging for the investigation of **life history** (e.g., Coqueugniot et al. 2004). From 1976 to 1978 he was under research contract with the French Ministry of Education and Research and then worked for the **Centre National de la Recherche Scientifique** (National Center for Scientific Research) from 1980 to 2000. In 2000 he succeeded Bernard Vandermeersch as Professor of Anthropology at the University of Bordeaux and in 2004 he was appointed Professor at the **Max-Planck Institute for Evolutionary Anthropology**, Leipzig, Germany, and the Founding Director of the Department of Human Evolution.

Hulu 1 *See* Tangshan Huludong.

human (L. *humanus*=people) This term is used in many ways but it should be reserved for referring to either the species taxa within the genus *Homo*, or to the species *Homo sapiens*, or to individuals within the those species.

human accelerated regions (or HARs) Regions of the **genome** that show relative conservation in vertebrates but which show changes in the lineage leading to modern humans subsequent to the most recent common ancestor of modern humans and chimpanzees and bonobos.

human anatomical terminology *See* anatomical terminology.

Human Genome Project An international, publicly funded, effort to produce the first sequence of the modern human genome initiated in the late 1980s by the US Department of Energy and the National Institutes of Health. The first published **draft sequence** (International Human Genome Sequencing Consortium 2001) covered 94% of the modern human genome. At the time of its publication only approximately 25% was considered **finished sequence**, but at present approximately 99% of the human genome sequence is finished sequence.

human leukocyte antigens *See* major histocompatibility complex.

Human Origins Program *See* National Museum of Natural History, Smithsonian Institution.

humerofemoral index Ratio of the lengths of the humerus and femur calculated as $100 \times (\text{humerus length} / \text{femur length})$. Like the **intermembral index** this index reflects major differences in locomotor strategies among primates. Because it requires fewer limb bones to calculate, it is more commonly used in studies of the hominin fossil record. Due to its relatively short femora *Australopithecus afarensis* (i.e., A.L. 288-1) has a humerofemoral index intermediate between Jungers (1982) and significantly different from Richmond et al. (2002), the high index of great apes and the low index of modern humans. The earliest evidence of a modern human-like humerofemoral index comes from associated limb bones from Bouri, **Middle Awash study area**, Ethiopia. By 1.8 Ma early *Homo* at Dmanisi has a modern human-like humerofemoral index, reflecting a relatively long femur that confers the locomotor benefits of speed and energetic efficiency. *See also* A.L. 288-1; Dmanisi.

Hungsugul *See* Turubong.

Hungsi-Baichbal valleys (Location 16°30'N, 76°35'E, India; etym. named after two towns) History and general description Over 200 **Acheulean** archeological sites located in two separate but interconnected valleys in the Gulbarga District, Karnataka, southern India. Surveys and excavations have been performed by K. Paddayya since the late 1960s, recovering information about Acheulean behavior. Joint research since the 1980s, with Michael Petraglia, examined the formation of the archeological sites and the stone tool technology. Temporal span and how dated? **Uranium-series dating** at several localities suggests an age of more than 350 to 166 ka. **Electron spin resonance spectroscopy dating** at **Isampur Quarry** suggests an age of 1.27 Ma (linear-uptake model) or 730 ka (early-uptake model). Archeological evidence found at site Acheulean localities contain handaxes, cleavers, choppers, picks, knives, polyhedrons, scrapers, discoids, and uni-faces. A variety of local materials were used for tool manufacture including limestone, quartzite, granite, dolerite, basalt, and schist. Variability in hard-hammer and soft-hammer techniques were observed between the localities. Technological variations, depositional contexts, and the range of chronometric ages suggest an earlier and later stage of the Acheulean. Specialized localities include a cluster of handaxes interpreted as a cache and dense

concentrations of limestone and basalt manufacturing debris at geological outcrops, interpreted as sources for stone-tool manufacture. Based on the distribution of archeological occurrences, the inferred paleomonsoonal climate, and the identification of seasonal springs and ponds, an Acheulean settlement model was proposed by Paddayya, consisting of wet-season dispersal of groups and dry-season aggregation. One notable discovery was the Isampur Quarry, a limestone source for the procurement and manufacture of stone tools. Key references: Geology, dating, and paleoenvironment Paddayya et al. 2002, Jhaldiyal 2006; Archeology Paddayya 1982, Paddayya and Petraglia 1993, Petraglia et al. 1999, Shipton et al. 2009a, 2009b.

hunter-gatherer A group of people, or a member of such a group, whose primary subsistence strategy is based on the hunting or gathering of wild plant and animal resources. Prior to the advent of **domestication**, virtually all hominin groups were hunter-gatherers and it is presumed that our more recent hominin ancestors (i.e., members of the genus *Homo*) had a hunter-gatherer subsistence economy. Present-day hunter-gatherers are of particular interest to paleoanthropologists because they provide an analogue for understanding past hominin subsistence strategies, behavioral patterns, and social interactions. For example, modern hunter-gatherers are known to obtain the majority of animal remains through hunting although they occasionally obtain meat from **passive scavenging** or **confrontational scavenging**. In an archeological context the identification of a subsistence strategy focused on scavenging rather than hunting therefore falls outside the realm of modern human behavior, which has implications concerning hominin social interactions and behavioral complexity. Ethnographic observations indicate that plant remains comprise the majority of food resources exploited by modern hunter-gatherers. In turn, this implies that plant resources likely made up a large portion of past hominin diets despite a strong paleoanthropological research bias towards the study of animal remains. *See also* forager.

Hunter-Schreger bands Structural microscopic features of tooth enamel that result from contrasting patterns of enamel prism decussation and named after two of the pioneers of dental microstructure, John Hunter (1778) and Heinrich

Schreger (1800) (reviewed in Boyde 1964 and Lynch et al. 2010). These bands are formed by successive layers of enamel prisms running in different directions, a phenomenon that results in patterns of light scattering that are particularly evident under reflected or polarized light microscopy. Attempts have been made to quantify differences in the degree of enamel prism decussation among hominins (e.g., Beynon and Wood 1986) and to model their formation (e.g., Osborn 1990). The latter has proven to be difficult because of the three-dimensional nature of these features. *See also* **diazone**; **enamel microstructure**; **parazone**.

hunting The pursuit and capture of wild animals for food or trade. Hunting is the primary carcass acquisition strategy of contemporary hunter-gatherer groups and is generally considered to be a basic constituent of aboriginal modern human behavior. In turn, the extent to which our hominin ancestors practiced a subsistence economy based on hunting, as opposed to scavenging, is of particular interest to paleoanthropologists since it implies complex social interactions and cooperation within hominin groups, but cooperative hunting is not confined to hominins, or indeed to primates. *See also* **carcass transport strategy**.

hunting and gathering *See* hunter-gatherer; forager.

Huntington (George S.) Collection Taxon *Homo sapiens*. History Collection of modern human skeletons assembled by anatomist George S. Huntington (1861–1927) based on cadavers used for dissection at the College of Physician and Surgeons, New York City. The Huntington Collection comprises the remains of immigrants and US citizens dying in New York City between 1893 and 1921. Many of the approximately 4054 individuals in this collection have documented sex, age, nationality, cause of death, and in some cases occupation and post-mortem anthropometrics. However, being from dissection cadavers, the skeleton is not always complete and few skulls are complete. It should also be noted that approximately 14% of the collection is commingled due to decades-old cataloguing errors. The demographic profile of this collection from the registered database of 4054 cataloged individuals is 71% male and 23% female. European and US Whites comprise 66.5% of the series,

while US Blacks are 7.6%, and individuals of unknown ancestry are 25.9%. Approximately 64% are immigrants (Irish 15%, Germans 10%, Italians 8%), and 36% are identified as US-born. The mean age at death is around 46 years (ranging from 5 to 96 years, with very few individuals under the age of 19). The collection is unique in the numerous excellent examples of trauma and occupational stress as well as infectious and congenital diseases. In the 1920s, before Huntington's death, one of his students, Aleš Hrdlička, arranged for the collection to be transferred to the Department of Anthropology at the **National Museum of Natural History, Smithsonian Institution**; this transfer was completed in 1927. Curator/contact David Hunt (e-mail hunt@si.edu). Postal address Department of Anthropology, National Museum of Natural History, Washington DC, USA. Website <http://anthropology.si.edu/cm/terry.htm>. Relevant references Hunt and Albanese 2005, Hrdlička 1937.

Huxley, Thomas Henry (1825–95) *See* *Evidence as to Man's Place in Nature*.

HWK Acronym for Henrietta Wilfrida Korongo, a locality at Olduvai Gorge. *See* **Olduvai Gorge**.

Hyaenidae The mammalian family containing the hyenas. *See* **Carnivora**; **hyenas**.

hyaline cartilage (Gk *hyalos*=glass and *L. cartilago*=gristle) *See* **cartilage**; **joint(s)**.

hybrid (*L. hybrida*, var. of *ibrida*=mongrel) The offspring resulting from the interbreeding of individuals from two different recognized species (interspecific hybridization) or from the interbreeding of individuals from two different subspecies, “races,” demes, or allotaxa (intraspecific hybridization). Hybridization can occur in areas where the ranges of two species overlap. For example, it has been demonstrated in the Awasha region of Ethiopia with respect to the gelada (*Theropithecus gelada*) and the Hamadryas baboon (*Papio hamadryas*) (Jolly et al. 1997) and in connection with the Hamadryas baboon and the olive baboon (*Papio anubis*) (Phillips-Conroy et al. 1991, Bergman and Beehner 2004). Hybridization is a feature of **reticulate evolution** and Jolly (2001) has been a proponent of the hypothesis that during the course of hominin evolution species may have

arisen as the result of hybridization as well as by classical processes such as **allopatry**. *See also* **reticulate evolution**; **speciation**.

hybrid zone A geographic region of contact and hybridization between two populations that are genetically distinct. Hybrid zones can be fleeting or stable; the latter has been demonstrated for well-studied Old World primates (Jolly 2001). *See also* **hybrid**; **hybridization**.

hybridization (L. *hybrida*, var. of *ibrida* = mongrel, Gk *izein* = to make) **Evolution** Interbreeding between individuals from genetically differentiated lineages or between local demes. The role of hybridization (and hence **reticulate evolution**) in human evolution is not well understood although there is considerable debate over whether certain groups (e.g., modern humans and Neanderthals) hybridized. By analogy to other living primates it has been argued that hybridization among distinct hominin taxa is likely (Jolly 2001) and emerging evidence from the broader literature also supports this conclusion (e.g., Arnold and Meyer 2006, Arnold 2009), but our understanding of how to detect this in the skeleton is still poor. Recent work suggests that hybrids may be detectable by the presence of skeletal developmental anomalies – especially sutural and dental abnormalities – or other signatures of breakdown in the coordination of early development (Ackermann et al. 2006, Ackermann 2007, Ackermann and Bishop 2010), but these traits have not been shown to have a fitness advantage or disadvantage. **Genetics and molecular biology** A molecular biology technique where two complementary strands of DNA are joined together. *See also* **DNA hybridization**; **hybrid**.

hydrogen The lightest of all elements, hydrogen is being increasingly used in **stable-isotope biogeochemistry**. There are two common hydrogen isotopes: ^1H (more common) and ^2H (less common); ^2H is commonly referred to as **deuterium**. Both of these isotopes are stable and do not decay. *See* $^2\text{H}/^1\text{H}$; **stable isotopes**; **hydrogen isotopes**.

hydrogen isotope analysis *See* **gas chromatography isotope ratio mass spectrometry**.

hydrogen isotopes Stable isotopes of hydrogen in water provide a useful tracer of changes in the hydrological cycle and they are increasingly

being incorporated into general circulation models (or GCMs). Hydrogen in cellulose from tree rings can be used to reconstruct past climate variations even in tropical trees which often lack the annual rings that facilitate dendroclimatology in temperate climates. Tree ring records of past climates can be used to reconstruct climate in the **Holocene** and hydrogen isotopes in leaf wax biomarkers can be used to reconstruct climate across millions of years.

hydroxyapatite One of the two common names (the other is apatite) for the dominant salt (also called the mineral phase) in **bone**, **cementum**, **dentine**, and **enamel**. *See* **apatite**.

hyenas (Gk *huaina* = swine) Hyenas belong to the mammalian family Hyaenidae, within the order **Carnivora**. The group includes the striped (*Hyaena hyaena*), the spotted (*Crocuta crocuta*), and the brown (*Parahyaena brunnea*) hyenas and the aardwolf (*Proteles cristata*). Hyenas are of particular interest from a paleoanthropological perspective for two reasons. First, in the **Plio-Pleistocene** hyenas were a prominent member of the **carnivore guild** and if, as some researchers suggest (Walker 1984), hominins became members of that guild as **scavengers** and/or hunters, then hyenas and hominins would have been in competition. The second reason is that like modern humans and early hominins hyenas are known to accumulate large collections of bones (i.e., **faunal assemblages**). In the absence of rigorous taphonomic investigations, hyena-accumulated bone concentrations can potentially be misidentified as the product of hominin activities, leading to erroneous behavioral interpretations. However, taphonomic observations suggest that hyena-accumulated faunal assemblages can be distinguished from hominin-accumulated assemblages because the former include large numbers of juvenile hyenas, high frequencies of tooth-marked long-bone shaft fragments, and a preponderance of limb bones with complete shafts, but lacking their epiphyses. In addition to accumulating faunal assemblages, hyenas are also known to modify or destroy skeletal remains discarded by modern humans and probably by early hominins, a phenomenon known as **carnivore ravaging**.

Hylochoerus (Gk *hulo* = woodlands, forest; *choerus* = pig) The giant forest hog, *Hylochoerus*

meinertzhageni is the sole species of the genus. The largest of all living pigs, it is thought to be a descendent of the *Kolpochoerus* clade. The earliest known representative is from the late to middle Pleistocene. Giant forest hogs prefer closed habitats when possible, but in parts of their range where forests and woodlands have been disturbed they have been seen to form large groups and graze in the open. Their range is restricted to tropical central Africa and they are patchily distributed from Guinea to Kenya. *See also* **Suidae**.

hyoid (Gk *hypooides*=shaped like the Greek letter hypsilon) Bone palpable in the midline of the neck, between the mandibular symphysis and the manubrium of the sternum. It consists of a central body and bilaterally the greater and lesser horns. With the mylohyoid muscle it forms the floor of the mouth and the base of the tongue. The strap muscles of the neck connect it to the thyroid cartilage and to the manubrium of the sternum. Hyoid bones occur occasionally in the hominin fossil record (e.g., **Dikika study area**, **Kebara**, **Sima de los Huesos**). Some researchers (e.g., Arensburg et al. 1989) claim that the morphology of the hyoid can be used to make inferences about the capacity for spoken language, but this claim has been disputed.

hypermorphosis (Gk *hyper*=over or beyond, *morphe*=form or shape) A **heterochronic** process that involves the extension of a shared ancestral trajectory to new size ranges in the descendants. Size and shape covariation found in the ancestors remains similarly associated in hypermorphic descendants; hypermorphosis requires a change to larger size of descendants to preserve the ancestral size/shape relationship. Hypermorphosis can occur two ways: by increasing the ancestral growth rate so that descendants grow beyond the ancestral size by the same age of maturity (rate hypermorphosis) or by extending the growth period of ancestors so that descendants maintain similar growth rates but reach maturation at later ages (time hypermorphosis).

hyperostotic *See non-metrical traits*.

hypervariable region *See mitochondrial DNA*.

hypocone (Gk *hypo*=under, below and *konos*=pine cone) The term proposed by Osborn

(1888) for the main cusp on the distolingual aspect of a maxillary (upper) mammalian molar. In some teeth its tip is lower than the tips of the **meta-**, **para-**, and **protocone** hence the prefix meaning "below." It is part of the **talon** (syn. endocone, distolingual cusp, tuberculum posterium internum).

hypoconid (Gk *hypo*=under, below and *konos*=pine cone) The term proposed by Osborn (1888) for the main buccal cusp situated distal to the **protoconid** on a mandibular (lower) (hence the suffix "-id") molar tooth crown. Its prefix is a misnomer in hominins because its tip is not usually lower than those of the other main cusps. It forms part of the **talonid** component of a mandibular postcanine tooth crown (syn. teleconid, distobuccal cusp, tuberculum mediale externum).

hypoconule The term proposed by Osborn (1888) for an accessory cusp on the occlusal surface of a maxillary molar that others more commonly refer to as a distostyle. *See distostyle*.

hypoconulid (Gk *hypo*=under, below and *konos*=pine cone) The term proposed by Osborn (1888) for the main cusp at the distal end of a mandibular (lower) (hence the suffix "-id") molar crown; it is wedged between the **hypoconid** on the buccal side and the **entoconid** on the lingual side. It forms part of the **talonid** component of a mandibular postcanine tooth crown. Modern humans may not have a hypoconulid but it is found in all archaic hominins and most pre-modern *Homo* taxa (syn. distostylid, tuberculum posterium internum, mesoconid).

hypodigm (Gk *hypo*=under, below and *deik*=to show) All the fossil evidence assigned to a taxon, but the term is usually used to refer to all the fossil evidence assigned to a **species**.

hypoglossal canal (Gk *hypo*=under, below and *glossa*=tongue) A bony canal that passes through the basioccipital bone just in front of the occipital condyles (hence its other name, the anterior condylar canal). It transmits the motor axons of the twelfth cranial or hypoglossal nerve, which innervate all of the intrinsic muscles of the tongue (i.e., the muscles that make up the tongue itself) plus all but one of the muscles that move the

tongue around in the mouth. It was suggested by Kay et al. (1998) that the size of the hypoglossal canal could be used as a proxy for the density of the nerve supply to the tongue muscles. The logic was that **speech** needs precise movements of the tongue, which are achieved by having smaller motor units (i.e., fewer muscle fibers supplied by each axon) thus more axons are required, and therefore the larger-diameter hypoglossal nerves needed for a hominin capable of speech compared to a hominin of the same overall mouth size that was incapable of speech would demand a commensurately larger diameter hypoglossal canal. Specifically, it was claimed that *Homo neanderthalensis* had similar speech capacities as modern humans on the basis of hypoglossal canal cross-sectional area relative to oral cavity size. However, subsequent recent studies have demonstrated that (a) the relative size of the hypoglossal canal shows too much within-species variability to be informative and (b) modern humans do not have a greater relative number of hypoglossal motor neurons relative to medulla size than do apes who do not use spoken language.

hypomorphosis (Gk *hypo*=under, *morphe*=form or shape) A **heterochronic** process that involves the truncation of ancestral growth trajectories resulting in descendant adults that resemble ancestral juveniles. As in **hypermorphosis**, size and shape covariation is maintained in descendants; hypomorphosis brings shape change through selection for reduced size growth. Hypomorphosis can operate by shortening the duration of growth in a descendant relative to an ancestor, while maintaining similar rates of growth (time hypomorphosis, also called progenesis), or by reducing the rates of ancestral growth together with similar duration of growth (rate hypomorphosis).

hypoplasia (Gk *hypo*=under, below and *plasis*=growth) Literally "arrested growth," the term refers to areas on teeth where the production of enamel matrix by ameloblasts has been disrupted by a non-specific stressor experienced during **tooth formation** (e.g., systemic infection, a deficient diet, or starvation), which results in a depression on the surface of a tooth. Witzel et al. (2008) have proposed three levels of disturbance of enamel matrix production: a reduction in volume, the formation of aprismatic enamel when one would expect prismatic enamel (this is due to

interference with the function of the distal portion of the Tomes' processes of ameloblasts), and a complete cessation of matrix production. Hillson and Bond (1997) classified areas of hypoplasia as either furrow defects or pit defects. Furrow defects are the most common type of hypoplasia and are the result of an interruption to enamel matrix production that affects many ameloblasts; they typically manifest as linear bands encircling a tooth crown (and possibly other teeth developing simultaneously). In pit defects the disturbance is more localized, appearing as an indentation or pit that does not include all simultaneously formed enamel. Because hypoplasias usually affect all the teeth in which enamel matrix formation is occurring, they can be used to compare the relative ontogeny of teeth along the tooth row. Guatelli-Steinberg (2001, 2003, 2004a, 2004b) has documented linear enamel hypoplasias in large samples of hominins and non-human primates, which show some differences in the frequencies and durations of stress.

hypostotic *See non-metrical traits.*

hypostyle A term introduced by Osborn (1892) for an accessory cusp others more commonly refer to as a distal accessory tubercle. *See distal accessory tubercle.*

hypothalamus (Gk *hypo*=under, below and *thalamus*=inner chamber, bedroom) The hypothalamus is situated inferior to the **thalamus**; together they form the **diencephalon**. The hypothalamus is involved in a diverse array of functions such as homeostasis, controlling the endocrine functions of the pituitary gland, and regulating emotional behavior and reproduction.

hypothesis testing The process of testing a specific relationship which has been identified *a priori*, as opposed to **exploratory analysis** in which multiple techniques are used to explore possible patterns within a data set.

hypothetical common ancestor When a cladistic analysis groups two taxa or two clades together as **sister taxa** or sister clades, certain assumptions can be made about the character states of the common ancestor of the two taxa or clades. These assumptions amount to a prediction about the morphology of the most recent common ancestor of the two taxa or clades. Researchers

HYPOTHETICAL TAXONOMIC UNIT

who are skeptical about the chances of ever finding an actual ancestor prefer to describe the predicted taxon as a hypothetical common ancestor.

hypothetical taxonomic unit A concept used in **phylogenetic comparative analysis** to refer to an internal branching node within a

phylogeny as opposed to an actual taxon from which data have been collected. *See also* **operational taxonomic unit**.

hystricomorphs The informal name for the suborder of the Rodentia that includes the porcupines and caviés. *See* **Rodentia**.

I

I.A.R.E. Acronym for the **International Afar Research Expedition** (*which see*).

IBD Acronym for **identical by descent** (*which see*).

Iberomaurusian (A combination of *Ibero-*, as in the Iberian Peninsula, and *L. Mauritania* = the name of a Roman province that is coincident with what is now Morocco and Algeria) A term that refers to **Late Pleistocene** artifacts and to the hominins that made them found at coastal sites in Morocco, Algeria, and Tunisia that date from *c.* 18 ka and 11 ka (Bouzouggar et al. 2008). Archeologically, Iberomaurusian stone artifact assemblages are dominated by **bladelets** and **microliths** with subsistence data suggesting the seasonal exploitation of coastal and interior habitats. Archeological evidence suggests there were evident technological and behavioral differences between the Iberomaurusian and its regional antecedents. In fact, Iberomaurusian strata often unconformably overlie **Aterian** ones, suggesting that the area may have been temporarily abandoned by hominins until settlement by Iberomaurusian populations (Close and Wendorf 1990). This hypothesis receives further support from the distinctive, skeletally robust "Mechta-Afalou" types found at sites with abundant burials such as **Grotte des Pigeons** (Tafoualt; Irish 2000) and genetic evidence linking the appearance of the U6 mitochondrial DNA clade with the spread of populations into North Africa from southwestern Asia at the time of the appearance of the Iberomaurusian (Maca-Meyer et al. 2003). High frequencies of dental evulsion and similarities in lithic technology suggest the presence of widespread social networks to maintain behavioral norms among Iberomaurusian populations (Close 2002, Humphrey and Bogaerts 2008).

IBS Acronym for **identical by state** (*which see*).

ice-rafting Ice rafting refers to the process of sediment transport via sea ice. Icebergs that calve off continental glaciers carry sediments from bedrock into the ocean and sea ice that forms in shallow waters incorporates sediments from the continental shelf. Icebergs calved from glaciers and sea ice are both transported by wind and ocean currents. Eventually the ice will start to melt and release its sediment load, which sinks and is then incorporated into ocean sediments. These ice-rafted sediments are known as dropstones (i.e., pebbles considerably larger than ambient sedimentation) (Heinrich 1988). The morphology of ice-rafted sediments can be distinguished from other forms of transport (e.g., fluvial or aeolian). The mineral, elemental, and isotopic composition of these dropstones can be used to infer their source. The extent of sea ice transport increases during times of glaciations and it is the sediments derived from sea ice that have provided evidence of abrupt climate change in the form of **Heinrich events**.

ichnofossils (Gk *ikhnos* = footprint) Evidence of one sort or another (e.g., footprints, tracks, burrows, leaf impressions, etc.) that an organism had been in that place at some time in the past. The **Laetoli hominin footprints**, **coprolites**, and leaf impressions are all examples of ichnofossils (syn. trace fossil).

ichnology The study of ichnofossils (i.e., fossilized footprints, tracks, burrows, leaf impressions, etc.) An analysis of the **Laetoli hominin footprints** would be an example of ichnology.

icons *See symbol; symbolic.*

ICZN Acronym for the **International Commission on Zoological Nomenclature** (*which see*).

ID Acronym for **immunological distance**. *See* **molecular clock**; Vincent M. Sarich.

-id (L. *-id*=source or origin) When this suffix is used after the name of a cusp it means it is a cusp on a mandibular (lower) tooth. Thus, **metaconid** is the term for the cusp mesial to the **protoconid** for the lower teeth whereas **metacone** is the term for the equivalent cusp in an upper tooth.

identical by descent The condition where two **alleles** are identical because they share a **common ancestry**; it is the genetic equivalent of a phenotypic **homology**.

identical by state The condition where two **alleles** are identical *not* because they share a **common ancestry** but because they have mutated independently to become identical to each other; it is the genetic equivalent of a phenotypic **homoplasy**. For example, **microsatellite** alleles are often identical by state because of the stepwise **mutation** process that produces the alleles. In this process a new allele is likely to have one additional repeat, or one less repeat, than the parent allele. Since microsatellites have high mutation rates, alleles with the same number of repeats are often created independently. For example, one allele with 14 repeats may have arisen from a gain of one repeat from a parental allele with 13 repeats while another allele with 14 repeats may have arisen because of a loss of one repeat from a parental allele with 15 repeats.

identification The process of allocating individual fossil specimens to an existing **taxon** or to a new taxon. Classification only applies to taxa; you identify an individual fossil, but classify the taxon it belongs to. *See* **classification**; **systematics**.

IHE Acronym for the **Institute for Human Evolution** (*which see*).

Il Dura One of the designated subregions of the Koobi Fora site complex. *See* **Koobi Fora**.

Il Naibar Lowlands One of the designated subregions of the Koobi Fora site complex. *See* **Koobi Fora**.

Ileret One of the designated subregions of the Koobi Fora site complex. *See* **Koobi Fora**.

image stack *See* **computed tomography**.

imbrication lines *See* **imbricational enamel**; **perikymata**.

imbricational enamel (L. *imbricatus*=roof made of tiles) Enamel formed after the cuspal (or appositional) enamel has been formed. The **striae of Retzius** within the imbricational enamel emerge on the crown surface as parallel ridges. They were called imbrication lines by Pickerill (1913) because especially towards the cervical region they can look like the edges of the tiles on a tiled roof. Their other name, **perikymata**, was given to them earlier by Gustav Preiswerk in his thesis on ungulate enamel structure (NB: Preiswerk is also responsible for the names **diazone** and **parazone** in enamel microstructure). *See also* **enamel development**; **incremental features** (syn. cuspal enamel).

imitation (L. *imitari*=to copy) The comparative study of imitation can be traced back to Thorndike (1858) who defined imitation as “learning to do an act from seeing it done” (*ibid*, p. 1911). In the *Poetics*, Aristotle noted that modern humans are “the most imitative creature[s] in the world and learns at first from imitation.” Modern human children imitate everything from the words used to describe new objects to actions with tools (e.g., telephones, brooms, and remote controls). As adults, modern humans from all cultures imitate everything from postures to styles of dress to conventions of affection, and most of this is done automatically. This phenomenon has been referred to as “the chameleon effect” (Chartrand and Bargh 1999). However, imitation may be divided functionally; that is, depending on the type of information that is being imitated (Subiaul 2010). For example, familiar imitation refers to the copying of actions that already exist in one’s behavioral repertoire (e.g., sticking out one’s tongue). Familiar imitation may be contrasted with novel imitation, which refers to the copying of novel actions or behaviors that do not already exist in the individual’s behavioral repertoire (e.g., riding a bicycle). Additionally, one can specify the type of information that is imitated. For example, vocal imitation refers to the imitation of specific sounds, motor imitation refers to the copying of actions, and cognitive imitation refers to the copying of abstract rules that are neither

motor nor vocal (e.g., social conventions or the order of events) (Subiaul et al. 2004). Motor imitation has been widely studied in both modern humans and non-human primates (Tomasello and Call 1997, Hermann et al. 2007). According to Call and Carpenter (2002) motor imitation has three components: (a) understanding the goals of a model or conspecific, (b) recreating the results of the event, and (c) using the model's actions rather than your own to achieve an end result. In this view, motor imitation is associated with high copying fidelity. This view of motor imitation is consistent with the notion that motor imitation is a specific form of social learning. But, as far as social learning mechanisms are concerned, motor imitation is considered to be the most cognitively sophisticated as it may require perspective taking, **self-awareness**, and **theory of mind** (or ToM). Certainly, various studies have demonstrated how ToM improves the flexibility and fidelity of imitation (Carpenter et al. 1998, Gergely et al. 2002, Meltzoff 1995). Arguably, the best examples of imitation come from animals that are believed to have a ToM (e.g., modern humans and chimpanzees). For example, chimpanzees have been shown to imitate novel actions of a modern human experimenter. In the "Do as I do" (DAID) paradigm (Hayes and Hayes 1952) chimpanzees were trained to respond to the phrase, "Do this!" followed by a range of behaviors, all of which are novel to the chimpanzee (e.g., touching an elbow, stomach, an ear, or nose, the latter of which are not visible). Chimpanzees were successful at imitating the modern human demonstrator, except they had difficulty matching behaviors that were visually opaque, such as facial gestures. In contrast, modern human children imitate touching both transparent actions (such as manipulating an object) and opaque actions (such as copying facial expressions). In the case of transparent actions, one can visually match one's own actions with those of others through a visual-visual match. But this is not possible in the case of opaque actions; for example, one does not have direct visual access to one's own face. Despite the differences of opinion regarding the nature of the heterogeneity of imitation competence in non-human apes, it is clear that from an early age the imitative skills of modern humans exceed those observed in apes. One possible scenario is that in the course of human evolution an elaboration of ToM (e.g., perspective taking, **intentionality**, reasoning about

belief) might have modulated imitation performance, eventually making modern human imitation more flexible and accurate than the predicted level of performance in the most recent common ancestor of chimpanzees/bonobos and modern humans (Tomasello 1999). Another possibility is that modern humans simply evolved more specialized imitation mechanisms than other apes. In this view, modern humans are exceptional imitators relative to other apes because we have learning mechanisms that allow our species to imitate more widely and flexibly (Subiaul 2007). There is debate about how well archeological evidence can track the evolution of imitative behavior from the level one would predict for the *Pan/Homo* common ancestor to the imitative capability of modern humans. *See also* **theory of mind**.

Imjin/Hantan river basins *See* Chongokni.

immunochemistry (*L. immunis*=an individual who is exempt from public service and *chemista*=alchemist, a person skilled in the art of alloying metals) A branch of biochemistry that investigates the components and chemical reactions of the immune system. Morris **Goodman** (1963) used the reactions between an antigen and an antibody to determine the relationships among the higher primates and showed that the patterns of agglutination produced by the reaction between specific antibodies and serum **albumin** were virtually identical in modern humans and chimpanzees. Others have tried less successfully to use the same techniques to investigate the relationships among fossil taxa. Immunochemistry has also been used to test whether a morphologically undiagnostic specimen claimed to be a hominin actually is a hominin, but these methods have not always proved to be accurate (see references in Martinez-Navarro 2002).

immunoglobulins *See* antibody.

immunological distance *See* molecular clock; Vincent M. Sarich.

imprinting *See* genomic imprinting.

in silico A term, equivalent to *in vivo* (i.e., an investigation made within a living organism) or *in vitro* (i.e., an investigation made outside of a living organism using isolated organs, tissues, or cells) for an investigation conducted by means of computer

simulation. Like “Silicon Valley” in California, USA, the term has its roots in the silicon that was used in the early integrated circuits.

in situ (L. *in*=in and *situs*=place) Fossils or artifacts found in their parent horizon either during the course of an excavation or in the process of eroding out of that horizon (e.g., KNM-ER 1813 was found eroding out of the sediments of the Upper Burgi Member of the Koobi Fora Formation and all the Dmanisi fossils have been recovered from excavations).

incertae sedis [L. *incertae sedis*=“of uncertain (taxonomic) position”] The phrase indicates that a particular specimen is difficult to assign to any taxon, and sometimes it is used to indicate that a named taxon may be difficult to assign to a higher taxonomic group. For example, the KNM-ER 1482 mandible from below the KBS Tuff at Koobi Fora, which when first described was not allocated to any taxon; the Ceprano 1 calvaria, which in some ways resembles *Homo erectus* and in others resembles later Lower Pleistocene African specimens such as Daka (Bouri) or *Homo heidelbergensis*. See also **taxonomy**.

increment (L. from *increscere*=to increase) The term means literally “a small increase.” The term is used in paleoanthropology when a large quantity is broken up into smaller ones. So, for example, when researchers count **perikymata** on the buccal surface of anterior teeth to compare details of enamel microstructure they break up the surface into smaller “increments.” If they break the height of the crown up into 10 equal increments, (e.g., Guatelli- Sternberg et al. 2005) they are called “10% increments” or deciles. Breaking the crown up into smaller increments allows researchers to investigate whether an overall increase or decrease in the rate of enamel deposition is distributed over all of the crown height or whether any change is focused on just one region of the total height of the crown.

incremental features (L. from *increscere*=to increase). Physical features in tissues such as **enamel**, **dentine**, and **cementum** that record their growth at regular, predictable time intervals. The growth of hard tissues is appositional in nature (i.e., one layer of tissue is deposited upon a previous layer) but the term “incremental” also

implies that the layers are deposited according to a periodic time scale regulated by an internal physiologic rhythm. Microscopic markings representing intrinsic temporal rhythms in hard-tissue secretion may be annual (e.g., cementum annulations, lines of arrested growth in bone), long-period (i.e., greater than one day; e.g., **striae of Retzius/perikymata** in enamel or **Andresen lines/periradicular bands** in dentine), short-period (i.e., 24 hours or circadian; e.g., **cross-striations** in enamel, **von Ebner’s lines** in dentine), or less than 24 hours (**intradial lines** in enamel and dentine; reviewed in Smith 2006). These increments of growth are preserved throughout life in mineralized tooth tissues because they are never replaced or “turned over.” For a long time it was widely believed that there were no equivalent preserved growth increments in bone. However, reports have demonstrated the presence of annual/seasonal and more recently possible long-period growth increments in the bone tissues of many vertebrates, including mammals (reviewed in Castanet 2006, Bromage et al. 2009). See also **enamel microstructure**.

incurvatio mandibulae A midline depression on the external aspect of the **symphysis** of the **mandible** between the **alveolar process** and the **base**. There needs to be an **incurvatio mandibulae** for a **mental protuberance** to qualify as a **true chin**.

incus (L. *incus*=anvil) One of the three **auditory ossicles** in the middle ear. The ossicles, including the incus, occasionally survive into the fossil record (e.g., SK 848, a *Paranthropus robustus* incus). See also **auditory ossicles**; **branchial arches**; **middle ear**.

indel Shorthand for insertion(s) and deletion(s). See **insertion**; **deletion**.

independent assortment The phenomenon observed by Gregor Mendel whereby the **alleles** of **genes** that are unlinked (i.e., they are on different **chromosomes** or located far apart on the same chromosome) assort independently during **meiosis** when gametes are formed. Independent assortment is one of the sources of genetic variation and therefore provides new combinations of variants upon which evolution can act.

independent contrasts See **phylogenetically independent contrasts**.

indexes *See* symbol; symbolic.

Indonesia (L. *Indus*=Indian and Gk *nesos*=island, literally "Indian Islands;" equivalent to the Malay Archipelago) Indonesia was a geographical entity before it became a political one. It includes the large and small islands that extend eastwards from the Malay Peninsula. The large islands include Borneo, Java, the Moluccas, Sulawesi, Sumatra, and Timor; the small islands include Bali, Flores, and Sumba.

industrial complex A higher-rank archeological taxonomic term defined initially by Clark et al. (1966). It defines an aggregate consisting of multiple related **industries** (e.g., the **Acheulean Industrial Complex**). This particular terminology is meant to both highlight the broad similarities among sites across the world that have **handaxes** and similar **Acheulean** tools, and emphasize local variation.

industry (L. *industria*=diligent) A spatially and temporally constrained collection of archeological assemblages, considered by some to represent the range of material items produced by a prehistoric group of people. Industries, particularly as defined and codified in the 1960s (Clarke 1968, Clark et al. 1999), came closest to archeological manifestations of the ethnographic ideals of "cultures" or "culture groups," despite the temporal resolution at most sites being too coarse to establish contemporaneity (a) among different artifacts deposited at a site and (b) between assemblages at two, or more, sites. The precise boundaries of an industry are rarely defined and usage varies among authors. The term is used informally as the archeological equivalent of a Linnaean taxonomic category – the genus is probably the best analogy – to highlight inter-assemblage similarities.

infant (L. *infans*=not being able to speak) Literally a child before it can talk, but normally used to refer to children when they are relatively helpless. There is no formal, more precise, definition.

inferior nuchal line A roughened line on the occipital bone that is produced by the attachment of the fascia between the biggest nuchal muscle, the semispinalis capitis, posterosuperiorly and a smaller nuchal muscle, the obliquus capitis superior, anteriorinferiorly.

infraorbital visor *See* facial visor.

inner ear A cavity medial to the middle ear within the petrous part of the temporal bone. It consists of a series of complex intercommunicating cavities referred to as the **bony labyrinth**. The bony labyrinth is filled with a fluid called perilymph and suspended in the perilymph is the membranous labyrinth, a smaller endolymph-filled facsimile of the bony labyrinth, in the walls of which are the hair cells that detect sounds, posture, and motion. The membranous labyrinth is divided into three functional components: the snail-shaped cochlea for sound, the saccule and utricle for posture, and the **semicircular canals** for motion. The relative size and shape of the semicircular canals of the bony labyrinth have proved to be taxonomically valid variables (Spoor and Zonneveld 1998). *See also* **semicircular canals**.

inner table *See* cranial vault.

innominate (L. *innominatus*=no name) The old name for what the *Terminologia Anatomica* encourages us to call the hip bone or pelvic bone.

insectivory (L. *insectum*=animal, derived from "a notched or divided body," literally "cut into," plus *vorous*, from stem of *vorare*=to devour) Literally, the consumption of insects. Insects are very high in energy and protein but can be rare, cryptic, and difficult to catch. Insectivory is therefore most common in the smallest primates, which require high-quality food because of their need for relatively more energy per unit body mass than large primates and because they are inefficient processors of low-quality foods. Generally insectivorous primates weigh less than 500 g, whereas folivorous ones tend to exceed this body mass: this is known as Kay's threshold. Insectivores often have teeth with high, sharp cusps that facilitate the penetration of the insect exoskeleton. Modern humans lack these dental specializations, but nonetheless they are known to consume insects (and insect products such as honey) opportunistically and it is likely that early hominins would have done the same.

Isernia la Pineta (Location 41°36'N, 14°14'E, Italy; etym. named after the nearby town) History and general description Road work outside of the town of Isernia uncovered paleosurfaces rich in

both faunal and artifactual assemblage. At least four layers have been identified. Temporal span and how dated? **Potassium-argon dating** and **magnetostratigraphy** suggest that the sediments immediately overlaying the archeological layers are 0.73 ± 0.04 Ma, but the **biostratigraphy**, particularly the micromammals, suggest an early Late Pleistocene date. Hominins found at site None. Archeological evidence found at site Flint choppers, flakes, and cores were all recovered from the site. Some of the faunal elements show signs of butchering. Key references: Geology, dating, and paleoenvironment Coltorti et al 1982; Archeology Mussi 2001.

insertion A mutation in the genome where one or more **base pairs** (i.e., one or more **nucleotides**) have been added, or inserted, into a sequence of nucleotides. An insertion can be as small as one base pair or it can encompass many thousands of base pairs. In a coding region any insertion that is not a multiple of three base pairs causes a **frameshift mutation**, which is typically deleterious. The significance of insertions for human evolution is two-fold. First, insertions can add genetic material that is functionally important, including genes. For instance, the *CCL3L1* gene has been duplicated (i.e., inserted) multiple times in some individuals. This gene encodes a protein that binds to the CCR5 receptor that is used by HIV to enter cells. Thus, individuals who have more copies of this gene have a lower risk of HIV infection and if they do become infected they have slower progression to AIDS (Gonzalez et al. 2005). Second, insertions can be used to understand the relationships among groups. For example, **Alu** insertions have been used to study population history and argue for a larger population size in Africa over most of human evolutionary history (Stoneking et al. 1997). Insertions and **deletions** are commonly referred to by the abbreviation indels.

insolation (*L. insolare* = in the sun) The amount of solar radiation reaching the Earth's surface. Solar radiation is more intense at or near the equator than at or near the poles. Changes in (a) the shape of the Earth's orbit (i.e., **eccentricity**), (b) the tilt of the Earth's axis (i.e., **obliquity**), and (c) the unsteadiness of that axis (i.e., **precession**), all of which take the Earth (or parts of the Earth in the case of changes in the tilt angle) nearer to or further away from the sun, affect climate by altering insolation.

Institute for Human Evolution (or IHE)

This institute, at the University of the Witwatersrand, was established in January 2004 under the interim Directorship of Professor Trefor Jenkins. The current Director, Professor Francis Thackeray, was appointed in February 2009. The objectives of the IHE include fieldwork and research focusing partly on South African Plio-Pleistocene hominin fossils and non-hominin fauna (from Gladysvale, Gondolin, Makapansgat, Malapa, Sterkfontein, Swartkrans, and Taung) and partly on late Pleistocene archeological sites (including Blombos Cave, Sibudu, and Rose Cottage Cave) associated with artifacts reflecting technological innovation in the **Middle Stone Age**. In addition to pursuing paleoanthropological research, the IHE's mission is to (a) promote South Africa's heritage to a wider audience, (b) stimulate a new generation of South African scientists with an interest in human evolution, and (c) contribute to the development of young researchers, especially from previously disadvantaged communities in South Africa, through outreach programs at the community, school, and university levels.

Institute for the Study of Man in Africa

(or ISMA) Established in 1963 to honor the contributions of Raymond **Dart**, who retired from the University of the Witwatersrand in 1958. It functioned as a focus within South Africa for educating the public about human evolution and for a brief period it ran the Museum of Man in Africa, but the collections have long since been subsumed into those of the Africana Museum that in 1994 was renamed in MuseuMAfrica. Currently the most visible manifestation of ISMA is the Dart Lecture series.

Institute of Human Origins (or IHO)

A research center in the School of Human Evolution and Social Change on the Tempe campus of Arizona State University (ASU), USA. The IHO was founded in 1981 by paleoanthropologist Donald **Johanson** as a non-profit research foundation in Berkeley, California, a still extant second identity, although all of its operations take place at ASU, where it has been headquartered since 1997. In 2009, Donald Johanson stepped aside as Director of IHO to become Founding Director; William Kimbel was appointed Director and Curtis Marean Associate Director. IHO's mission is three-fold: to recover and analyze the primary fossil and archeological evidence for human evolution and its

ecological and geological contexts, to advance scientific understanding of human origins and its contemporary relevance through focused public outreach programs, and to provide expertise that improves teaching of human evolution in primary- and secondary-school science classrooms (primarily through its website). IHO scientists have been involved in a number of field projects that have provided key evidence for early hominin evolution. The discovery of “Lucy” and other *Australopithecus afarensis* fossils by the **International Afar Research Expedition**, co-directed by Johanson at Hadar, Ethiopia, in the mid-1970s, provided the scientific centerpiece for the founding of IHO. After 15 field seasons research at **Hadar** is ongoing (directed by William Kimbel, Kaye Reed, and Chris Campisano), since 2007 as a biennial ASU-sponsored field school. More than 400 fossils of *Au. afarensis* have been recovered from 3.0–3.4 Ma sediments at the site, along with rare remains of early *Homo* and *Oldowan* stone tools dated to *c.*2.35 Ma. IHO’s research in Ethiopia’s Afar region expanded in 2002 with the launch of the **Ledi-Geraru Research Project** (directed by Kaye Reed and the late Charles Lockwood). From 1986 to 1988 an IHO/University of California Berkeley team (directed by Gerry Eck, Donald Johanson, and Tim White) worked at **Olduvai Gorge**, Tanzania, where, in 1986, a 1.7 Ma partial skeleton of a female *Homo habilis* (OH 62), was recovered. IHO research projects also address the later human record. From 1991 to 1994 William Kimbel collaborated with Israeli researchers (Erella Hovers and Yoel Rak) on IHO-cosponsored excavations at **Amud Cave**, in the northern Galilee, which produced several fossils of *Homo neanderthalensis*, including an infant’s skeleton, Amud 7, amid abundant Mousterian tools dated to *c.*57–60 ka. In 1998–9 this team conducted strategic survey across Israel for new sites, identifying several with paleoanthropological potential. Beginning in 2000 an IHO-led multinational team directed by Curtis Marean has conducted excavations at **Pinnacle Point**, near Mossel Bay, South Africa, where cave deposits dated to 72–164 ka have yielded evidence for human exploitation of marine resources, use of pigment, and heat-treatment of stone to enhance knapping ability, implying the early advent of “modern” cultural behaviors. IHO’s outreach programs include publically accessible print, web, and social media outlets, as well as lectures, symposia, and school tours. IHO’s website (becominghuman.org) pro-

vides news and information on human origins research and its Learning Center is a curriculum resource for primary and secondary school science teachers, a primary vehicle for IHO’s outreach into the educational community.

Institute of Vertebrate Paleontology and Paleoanthropology (or IVPP) Formed in 1957 in China when the **Laboratory of Vertebrate Paleontology** was renamed. It is an independent research institution under the **Chinese Academy of Sciences**. The IVPP conducts paleontological research in collaboration with local research entities and publishes the journal *Acta Anthropologica Sinica*. It is the repository of collections of vertebrate fossils, including many, but not all, of the hominins from Chinese sites.

Institutul de Speologie “Emil Racoviță”

The “Emil Racoviță” Institute of Speleology, which is part of the Romanian Academy, includes Departments of (a) Biospeleology and Karst Edaphobiology, (b) Geospeleology and Paleontology, and (c) Karstonomy, Karst Inventory and Protection. Hominin fossil collections **Oase 1**, **Oase 2**. Contacts Ioan Povara and Cristian Goran (e-mail iser_b@yahoo.com). Postal address 13 Septembrie Road, No. 13, 050711, Sector 5, Bucharest; note that the hominins are at the branch in Cluj-Napoca. Website www.iser.ro/index_en.php. Tel and fax +40 21 311 08 29.

integration See morphological integration.

interbirth interval The time between the birth of one offspring and birth of the following offspring of a different gestation. Interbirth interval is a crucial determinant of lifetime reproductive output in females. It can be affected by social elements, including group size, competition, and sex ratio. It is also influenced by ecological factors, including those affecting food availability (e.g., rainfall, altitude, seasonality), and maternal characteristics such as parity and survival of previous offspring. Three main phases have been proposed to make up the composition of primate interbirth intervals, some of which are more variable than others. The first phase consists of a period of postpartum amenorrhea, the length of which is related to the duration of lactation and patterns of nursing behavior (e.g., frequency and intensity). The second period is one in which ovulatory

cycling is resumed, and the duration of this can vary especially in relationship to food availability and maternal condition. The third period is defined by gestation of the subsequent offspring. The length of the interbirth interval, playing as central a role as it does in reproductive rate, is one of the primary life history variables that factor into discussions about “fast” and “slow” life histories. *See also* grandmother hypothesis; life history.

interglacial *See* glacial cycles.

intermembral index Ratio of upper-limb length relative to lower-limb length, calculated as $100 \times (\text{humerus length} + \text{radius length}) / (\text{femur length} + \text{tibia length})$. This index is the most common way researchers measure and compare limb proportions in primates and hominins and it reflects major differences in locomotor strategies among primates. Large-bodied primates (e.g., orangutans) tend to have high intermembral indices, their long upper limbs allowing them to reach across gaps between trees and hold onto multiple supports to distribute their weight. In contrast, many small-bodied primates (e.g., galagos) have low intermembral indices reflecting relatively long lower limbs that are mechanically advantageous for leaping. Modern humans are an exception to this trend, for although their body mass is large they have long lower limbs, which increase the speed and energetic efficiency of bipedal walking and running. *See also* humerofemoral index.

internal ear *See* inner ear.

International Afar Research Expedition (or I.A.R.E.) A collaboration among Maurice Taieb (its head), Yves Coppens, Donald Johanson, and Jon Kalb. Taieb and Kalb were to be responsible for the geology and Coppens and Johanson were to be jointly responsible for paleontology in general and hominid paleontology in particular. The arrangement persisted until the I.A.R.E. was disbanded in September 1974.

International Code of Zoological Nomenclature (current, fourth edition is Ride et al. 1999, with an online version available at www.iczn.org/iczn/index.jsp) Almost universally referred to as “the code,” published by the International Trust for Zoological Nomenclature on behalf of the International Commission on Zoological

Nomenclature (or ICZN) (for information about the latter see below or www.iczn.org/ICZNhomepage.htm). The code sets out rules and recommendations that help “promote stability and universality in the scientific names of animals and to ensure that the name of each taxon is unique and distinct.” If you name a new species you need to abide by these rules and it is also sensible to follow the recommendations.

International Commission on Zoological Nomenclature (or ICZN) Founded in 1895, its activities are supported by prominent national science societies and academies, and leading natural history museums and foundations. The ICZN is mandated by its scientific membership of the International Union of Biological Sciences (IUBS) and its members are elected by zoologists attending General Assemblies of the IUBS or other International Congresses. Its mission is “to create, publish and, periodically, to revise the International Code of Zoological Nomenclature. The ICZN also considers and rules on specific cases of nomenclatural uncertainty.” The rulings of the ICZN are published as “Opinions” in the *Bulletin of Zoological Nomenclature*. The code sets out rules and recommendations that help “promote stability and universality in the scientific names of animals and to ensure that the name of each taxon is unique and distinct.” For more information about the ICZN see www.iczn.org/ICZNhomepage.htm. *See also* International Code of Zoological Nomenclature.

International Louis Leakey Memorial Institute for African Prehistory *See* Leakey, Louis Seymour Bazett (1903–72).

International Omo Research Expedition (or IORE) A 1967 international expedition organized by Louis Leakey, Camille Arambourg, and F. Clark Howell to explore the fossiliferous sediments exposed in the Lower Omo Basin, that is the region just north of where the Omo River drains into what was then called Lake Rudolf and what is now called Lake Turkana. The Kenyan contingent consisted of Richard Leakey and Margaret Leakey, the French contingent was led by Camille Arambourg, and the American contingent by F. Clark Howell. In its first year, the three contingents of the International Omo Research Expedition worked in different geographical areas and therefore concentrated on different parts of the strata exposed in the area.

The Kenyan contingent (which only participated in 1967, and thereafter left to work further south on the east side of what was then called Lake Rudolf, at East Rudolf, now called **Koobi Fora**) worked in the north where they concentrated on the **Kibish Formation** and **Mursi Formation**. The US contingent focused on the Kibish and **Usno Formations** and the French contingent on the **Shungura Formation**, but thereafter the US and the French contingents concentrated on the Shungura Formation, the US working in the northern part of the type area north of the so-called "Watering Road" which ran between the combined Sectors 15 and 16 and Sector 17 and the French in the south. Full field seasons were worked until the mid-70s and thereafter research was mostly restricted to refining the geology. The fossiliferous sediments exposed in the Lower Omo Basin were assigned to formations in either the older **Omo Group** or the younger **Turkana Group**. Formations in the Omo Group in the Lower Omo Valley are the Usno, Mursi, Nkalabong, and Shungura Formations and in the Turkana Group they are the Bume, Kibish, and the Errum Formations. Compared with Koobi Fora, the geology in the Lower Omo Basin generally, and in the Shungura Formation specifically, was relatively simple. This relative simplicity combined with isotopic dates obtained from the tuffs that occur at frequent intervals in the Shungura Formation enabled the French and the US contingents to amass an impressive collection of well-dated mammalian fossils. This collection formed the basis of a reference biostratigraphy that has been and still is being used to date sites where there is no immediate prospect of obtaining absolute dates. Details of the history of the exploration of the Lower Omo Basin are given in Howell and Coppens (1983).

interproximal wear Wear between tooth crowns (also called approximal wear) that occurs when adjacent teeth move slightly against each other in the mouth during the process of **chewing**. In the early stages of the wear between two teeth in the same jaw that are in contact with one another (hence interproximal wear is also called interstitial wear) most of the wear occurs in the form of a concave wear facet on the proximal (i.e., mesial) face of the crown of the distal tooth (e.g., between the left P₄ and M₁ of **KNM-ER 992**), hence the emphasis in the term on proximal wear, but if the teeth wear against each other long enough a substantial wear facet also appears on the distal face of the crown

of the mesial proximal tooth (e.g., the left M₁ of **KNM-ER 1509** shows a distal interproximal facet). Some taxa (e.g., *Paranthropus boisei*) show marked interproximal wear that results in laterally and vertically extensive, more or less flat, interproximal wear facets. Marked interproximal wear can reduce the mesiodistal length and the overall occlusal area of a tooth crown, thus interproximal wear needs to be taken into account when comparing the size and shape of worn and unworn tooth crowns. *See also* **tooth size**; **tooth wear**.

interstadial *See* glacial cycles.

interspecific allometry *See* allometry; scaling.

interstitial growth *See* ossification.

interstitial wear Wear that occurs between two teeth in the same jaw and between adjacent bones (e.g., between adjacent metatarsals in the foot). In both cases the relative movement between the adjacent teeth or bones produces wear facets (e.g., interproximal wear facets between the teeth and smooth, eburnated, areas between the bones). *See also* **interproximal wear**; **OH 8**.

intertropical convergence zone (or **ITCZ**) Refers to the region where the trade winds converge and the air rises. The ITCZ migrates between the Tropics of Capricorn and Cancer as it follows the overhead sun with the seasons. A secondary control is contrasts between land and sea temperature and these are such that the migration of the ITCZ is not uniform around the planet. Seasonal variations in the position of the ITCZ influence the pattern of seasonal precipitation maxima across much of Africa. For example, East Africa receives most of its precipitation in April to March and in September to November, in association with the biannual movement of the ITCZ and with the seasonally reversing winds.

intracranial venous drainage *See* cranial venous drainage; intracranial venous system.

intracranial venous system The venous system that drains venous blood from the tissues that lie inside the bones of the **cranium** (e.g., the brain and the covering meninges) and from the cranial bones themselves. The intracranial venous system

consists of superficial cerebral veins that drain the surface of the brain, which, in turn, drain into a system of venous channels called the **dural venous sinuses** that run between the fibrous and endosteal layers of the outer of the three meningeal layers, the **dura mater**, and which leave impressions on the **endocranial** surface of the cranium. *See also* **cranial venous drainage**.

intradian line (L. *intra*=within and *dies*=day) An **incremental feature** found in **enamel** and **dentine** that shows a subdaily periodicity. Experimental evidence in primate enamel suggests that either one or two of these fine lines exist within a 24-hour period, and this is also supported by some studies of rodent dentine (reviewed in Dean 2000 and Smith 2006). Other rhythms, such as an 8-hour maturational rhythm, also occur in enamel formation. To date there is no experimental evidence to pin down the exact periodicity of these intradian lines but they can complicate counts and measurement of daily **cross-striations** in enamel. *See also* **enamel microstructure**.

intramembranous ossification (L. *intra*=within and *membrana*=membrane) *See* **ossification**.

intraspecific variation Variation within species due to differences in size, shape, or (almost always) a mixture of the two. The following factors may contribute to intraspecific variation in a collection of fossils assigned to a single species: (a) ontogeny, differences due to fossils coming from individuals at different stages of development, (b) geography, differences due to fossils coming from different regions of a species' range, (c) time, differences due to directional or random-walk changes through time, (d) sex, primary or secondary sexual differences in the hard tissues (this category of intraspecific variation is referred to as **sexual dimorphism** and in some extinct hominin taxa this can be a major component of intraspecific variation), and (e) intrasexual variation, differences between same-sex individuals within a species that are not due to (a)–(c). These intrasexual differences are sometimes due to **homoiology** (i.e., morphological variation that accrues due to differences in factors such as the activity levels among individuals).

introgression (L. *introgressi*=to step in) Gene flow between lineages whose individuals are hybridizing.

Introgression can result in **reticulate evolution**, best characterized as a “web-like” rather than a “tree-like” pattern of relationships through evolutionary time. *See* **hybrid**; **hybridization**.

intron An abbreviation of intragenic region. It refers to the non-coding regions of genes between the **exons**. After **transcription** the introns are removed from the pre-mRNA by a process called **splicing**. Introns may contain regulatory elements such as **enhancers**. Mutations in intronic splice sites can lead to human diseases such as β^0 -thalassemia.

intrusive (L. *intrudere*=to thrust in) Fossils or artifacts that have been secondarily introduced into sediments either naturally (e.g., by burrowing rodents) or deliberately (e.g., by ritual burial).

inversion A foot movement around an anteroposterior axis in which the sole of the foot turns inward to face the midline of the body. Although some of this motion can occur at the ankle (talocrural joint) during extreme inversion, inversion is primarily a motion between the calcaneus and the talus (i.e., at the subtalar joint). Often incorrectly used interchangeably with supination (see **foot movements**), inversion refers only to rotation about the long (anteroposterior) axis of the foot. This movement is limited in modern humans by joint morphology, and by tension in the fibularis muscles and in the anterior talofibular ligament, which is one of the most often-sprained ligaments in the modern human body. Nonhuman primates have a greater range of rear-foot inversion due to an inverted set to the ankle, increased mobility at the subtalar joint, and the absence of an anterior talofibular ligament.

IORE Acronym for the **International Omo Research Expedition** (*which see*).

Irhoud 1 Site **Jebel Irhoud**. Locality N/A. Surface/in situ *In situ*. Date of discovery 1961. Finder Mohammed Ben Fatami. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 190–90 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Cranium lacking base, nasal cavity structures, posterior portion of orbits, and all teeth; its endocranial volume is estimated to be 1305 cm³ (Holloway et al. 2004). Announcement Ennouchi 1962a. Initial

description Ennouchi 1962b . Photographs/line drawings and metrical data Ennouchi 1962b, Hublin 2001. Detailed anatomical description Hublin 2001, Rightmire 1990. Initial taxonomic allocation *Homo neanderthalensis* (Ennouchi 1962b). Taxonomic revisions *Homo sapiens* (Hublin 2001). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern human. Significance Among the earliest *H. sapiens* in North Africa. Location of original Musée Archéologique, Rabat Chellah, Morocco.

Irhoud 2 Site **Jebel Irhoud**. Locality N/A. Surface/in situ *In situ*. Date of discovery December 23, 1963. Finders Mohammed Ben Fatami and Carlton Coon. Unit N/A. Horizon N/A. Bed/member Ashy level C. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age 190–90 ka. Developmental age Adult. Presumed sex Male. Brief anatomical description Calvaria, but all of the face below the brow ridges missing; a metopic suture divides the frontal bone. Cranial capacity estimated to be 1400 cm³ (Holloway et al. 2004). Announcement Ennouchi 1963. Initial description Ennouchi 1968. Photographs/line drawings and metrical data Ennouchi 1968. Detailed anatomical description Hublin 2001, Rightmire 1990. Initial taxonomic allocation *Homo neanderthalensis* (Ennouchi 1963). Taxonomic revisions *Homo sapiens* (Hublin 2001). Current conventional taxonomic allocation *H. sapiens*. Informal taxonomic category Anatomically modern humans. Significance Among the earliest *H. sapiens* in North Africa. Location of original Musée Archéologique, Rabat Chellah, Morocco.

Isaac, Glynn Llywelyn (1937–85) Glynn was born in Cape Town, South Africa, to two botanists: his mother was the flowering-plant botanist at Cape Town's Bolus Herbarium and his father a marine ecologist and Professor of Botany at the University of Cape Town (UCT). Glynn's interest in archeology began at an early age as he and his identical twin, Rhys, explored ancient outcrops near the Cape, and investigated castles, cathedrals, and museums together on their first trip to Britain as 9-year-olds. When Glynn finished secondary school in South Africa he returned to England where he worked on Bronze Age and late Mesolithic digs, and in 1955 he successfully completed a 6-month

diploma course in archeological techniques at the University of London. He returned to South Africa to study geology, zoology, and archeology/ethnography at UCT and received a BSc with distinction in 1958. In the summer of 1956 he hitchhiked up to Zambia to study the collections at the Rhodes-Livingstone Museum, thus beginning his longstanding relationship with Desmond Clark. His mentors at UCT were John Goodwin and Monica Wilson, and when Professor Goodwin fell gravely ill, Isaac, just 21, was invited to take over his courses. Isaac's accumulated experience prepared him well and he was awarded an Elsie Ballot Scholarship to study at the University of Cambridge, England. He studied Paleolithic Archaeology with Charles McBurney from 1959 to 1961, taking the Archaeology and Anthropology honors degree examination (tripos) in 2 years and thus completing his second undergraduate degree. During his time at Cambridge he participated in a number of different field projects at sites in England and Jersey, a survey in Libya with Eric Higgs, and excavations at the site of **Abri Pataud** in France with Hallam Movius Jr. Eager to return to Africa to pursue field research, Isaac accepted Louis Leakey's invitation to become the Warden of Prehistoric Sites of the Royal National Parks of Kenya. As Warden (1961–2) and subsequently as Deputy Director of the Center for Prehistory and Paleontology at the **Coryndon Museum** (1963–4) Isaac was responsible for the museum's oversight of several prehistoric sites in Kenya, including **Kariandusi** and **Hyrax Hill**. Louis Leakey encouraged Isaac to visit **Olduvai Gorge** and consult with Mary Leakey as her archeological excavation program developed. In 1964 Isaac also co-led a field expedition to the remote exposures west of Lake Natron in Tanzania, in collaboration with Richard Leakey. The team surveyed sediments and discovered several promising archeological localities with distinctive early **handaxes**, as well as a massive hominin mandible from the site of **Peninj**. Isaac focused most of his scientific energies during this period on new investigations at the Acheulean site complex of **Olorgesailie**. He developed the project in close intellectual partnership with his new wife Barbara Miller and their professional collaboration grew to become a central and enduring pillar of his career. The impressive concentrations of Acheulean artifacts and faunal remains at this site had been initially discovered by Louis and Mary Leakey

during WWII, yet it took Isaac's detailed and problem-oriented research to reveal their true potential for understanding Acheulean tool use during the Middle Pleistocene. Ologesailie became Isaac's PhD dissertation project and in it he began to formulate research questions and develop methodological approaches that became hallmarks of his later research programs, including a focus on site-formation processes, artifact function and design, and hominin hunting abilities and social organization. For example, in an early example of taphonomic research, Isaac began a program of experimental layouts of bones and stone tool replicas to evaluate sedimentary processes that may have led to the unusual concentrations of large **bifaces** and bones at Ologesailie. He also developed innovative multivariate approaches to analyze attributes of handaxes and **cleavers**. In 1965 Isaac returned to the University of Cambridge to spend a year analyzing the results of his Ologesailie research and he was awarded his PhD in 1968. A monograph based on this work, *Ologesailie: Archaeological Studies of a Middle Pleistocene Lake Basin*, was published in 1977. Desmond Clark recruited Isaac to the faculty of the University of California at Berkeley in 1966, where he joined a group of colleagues, Sherwood Washburn, Phyllis Dolhinow, Theodore McCown, Elizabeth Colson, Richard Hay, and Garniss Curtis, with special interests in Africa and human evolution. At Berkeley, Isaac and Clark worked closely together to establish what quickly became the preeminent program in African prehistory and the archeology of human origins. In 1970 Clark Howell joined the program followed by Tim White in 1977. Isaac returned to Kenya to begin field research in the Late Pleistocene deposits in the Naivasha-Nakuru basin of the eastern Rift Valley in 1969–70. Also during this period, Richard Leakey invited Isaac to be co-director of the **East Rudolf Research Project**, later renamed the **Koobi Fora Research Project**. Although he was focused on documenting and interpreting the archeological record in the region, Isaac's field experience and training in geological and evolutionary sciences shaped his leadership of what became a collaborative and interdisciplinary investigation. Isaac, Kay Behrensmeyer, and a small team discovered **Oldowan** artifacts associated with the remains of a variety fossil animals in relatively undisturbed channel fill and deltaic deposits. These archeolo-

gical sites, particularly **KBS** (FxJ1) and **HAS** (FxJ3), led Isaac to formulate his **food sharing/home base hypothesis** and began a decade of empirical investigations into the technological abilities, subsistence patterns, ranging behavior, and social strategies of early Oldowan tool makers. Isaac's archeological teams grew to involve colleagues from many other institutions and provided dissertation topics and support for a large number of students at Berkeley and other schools. Much of the research was later published as Volume 5 of the *Koobi Fora Research Project* monograph series. The KBS and HAS sites were initially thought to be close to 2.6 Ma because of their stratigraphic relationship to the **KBS Tuff**, potentially making them the oldest evidence of stone tools and animal butchery. These early dates stoked a debate, however, because they placed the sites and other hominin remains much earlier than comparable finds at the nearby **Omo Shungura Formation**. Ultimately, a comprehensive reanalysis of **chronostratigraphy** in the **Turkana Basin** resolved that the Koobi Fora sites were closer to 1.9 Ma. During this dating controversy, Isaac was a strong advocate for collegial dialogue and the importance of undertaking new research and analyses to test the divergent dating hypotheses and resolve the scientific uncertainty. Isaac moved from Berkeley to Harvard University in 1983 but his intellectual home base remained in Africa. He prioritized African scholarship, training students and expanding international scientific collaboration. One of his last publications *Ancestors for us All: Towards Broadening International Participation in Paleoanthropological Research* (Isaac 1984) focused optimistically on the ethical responsibilities and potential of integrative human origins science. Pursuing new international collaboration was one motive for his trip to China in 1985, sponsored by the National Academy of Sciences. Tragically he collapsed from an illness shortly after arriving in Beijing, an illness that resulted in his untimely death at the height of his powers.

Isampur Quarry (Location 16°30'N, 76°29'E, India; etym. after nearby village) History and general description A significant **Acheulean** quarry consisting of more than 15,000 excavated artifacts in the **Hunsgi-Baichbal** valley of southern India. Discovery of the stone-tool quarry was made in 1994 during a survey to locate stratified sites. Temporal span and

how dated? **Electron spin resonance spectroscopy dating** ages on two herbivore teeth suggest an age of 1.27 Ma (linear-uptake model) or 730 ka (early-uptake model). Archeological evidence found at site The artifact assemblage is mostly limestone and includes giant cores, flakes, and bifacial and unifacial tools. Hammerstones are made from a variety of raw materials, some of which were imported into the site. The entire biface-manufacturing sequence was carried out at the limestone source, from the extraction of the bedrock to the creation of finished handaxes and cleavers. Two main reduction strategies were identified, consisting of the manufacture of handaxes from thin slabs and the production of cleavers from large flakes struck from prepared cores. Analysis of the stone-tool reduction sequences indicates that hominins were engaged in repeated imitative behaviors, while demonstrating a long sequence of hierarchically organized cognitive actions. Key references: Geology, dating, and paleoenvironment Paddayya et al. 2002; Archeology Paddayya and Petraglia 1997, Petraglia et al. 1999, 2005, Shipton et al. 2009a, 2009b, Shipton 2010. *See also* **imitation**.

Isenya (Location 1°40'S, 36°50'E, Kenya; etym. named after a nearby small trading village) History and general description A large open-air **Acheulean** site characterized by its dense archaeological levels (particularly its abundance of **cleavers**) and a rich fossil fauna. More than 300 m² were excavated from 1983 to 1988 by a team led by Hélène Roche, revealing five archaeological strata within fluvial sediments some 55 km/34 miles south of Nairobi in the Eastern Highlands and approximately 45 km/28 miles east of Acheulean sites of the **Ologesailie Formation**, Kenya. Temporal span and how dated? Isenya is estimated to be **Early to Middle Pleistocene** in age. **Tephrostratigraphic** correlation to Member 10 of the Ologesailie Formation (Roche and Texier 1995, p. 157) suggests an age greater than c.0.6–0.7 Ma although the data supporting this correlation have yet to be published. **Biostratigraphical** evidence suggests similarities with Bed IV at **Olduvai Gorge**, Tanzania, with extinct taxa including *Elephas recki*, two species of the genus *Metridiochoerus*, and *Hipparion* sp. Hominins found at site Brugal and Denys (1989) report a small shaft of right fibula, which they attributed to *Primates gen. et sp. indet.* that may be hominin. Archeological evidence found at site The excavated assemblage includes more than 17,000 arti-

facts. Larger tools such as the 1300 cleavers and 800 **handaxes** were made primarily of locally available lavas, with smaller tools primarily made of **chert** from sources approximately 3 km/1.8 miles upstream of the site. The more than 2000 faunal elements in the bovid-dominated fauna indicate a savanna habitat. Cut and percussion marks are rare but they suggest that hominins were involved in the accumulation of some of the faunal remains. Key references: Geology, dating, and paleoenvironment Roche et al. 1988, Roche and Texier 1995; Hominins Brugal and Denys 1989; Archeology Brugal and Denys 1989, Roche et al. 1988, Roche and Texier 1995.

Ishango (Location 0°8'S, 29°36'E, Democratic Republic of the Congo; etym. the name means “confluence” in KiNande, referring to the place where the Semliki River exits from Lake Edward) History and general description The site complex is on the right bank of the Semliki River at its exit from Lake Edward, approximately 6 km/3.5 miles south of Katanda. The terraces were explored briefly by H. Damas in 1935, in 1950–7 by a Jean de Heinzelin-led expedition, and again in 1983–4 by Noel Boaz. From 1985 to 1990 Alison Brooks, John Yellen, and Kanimba Misago conducted further excavations both at the original site (Ishango 11) and at a second site further downstream (Ishango 14). The main artifact- and bone-bearing levels at Ishango were deposited on an eroded bench of Plio-Pleistocene-age deposits (Lusso beds, formerly equated with the Kaiso beds of Uganda). These latter were then covered by at least two later Pleistocene to Holocene depositional episodes. An erosional unconformity separates the lower, later Pleistocene deposits, capped by a cemented layer (“terrasse tufacée” or “Tt”), from the later or Holocene deposits (“Terrasse postérieure” or “Tp”). This terrace sequence is approximately 10–12 m above the current river level and is banked up against a much higher and older Middle Pleistocene to early later Pleistocene terrace series (“Terrasses supérieures” or “Ts”) that contains the Semliki and Katanda Beds. Terrace Tt, which lies 10.5 m above the present lake level, includes a fining-upward sequence consisting of a lower gravel deposit (GI), the Principal Fossiliferous Layer (NFPr) of fine sands and small gravels, and the uppermost cemented tufaceous levels (NT). A Holocene-age catastrophic flood removed most of the massive ashfall from the early

Holocene volcanic eruption of the Katwe volcano (Uganda) which underlies the modern soil elsewhere in the region. Terrace Tp, which consists of **midden** deposits in fine sands and volcanic ash, was deposited on top of the NT. It contains both the later Holocene Post-Emersion Zone (P-EZ) and several dark soil horizons of Neolithic and Iron Age materials above it. Cultural materials from the Belgian expeditions and the hominins Ishango 1–8 are curated at the Institut Royal des Sciences Naturelles de Belgique, Brussels, Belgium. Temporal span and how dated? Initial **radiocarbon** ages of 18 and 21 ka on mollusc shell were not regarded as accurate. Citing comparisons of the material with European post-Pleistocene fishing industries, it was suggested that most of the hominin remains were *c.*9 ka (de Heinzelin 1962). New chronometric dates suggest that the “Tp” and the zone post-emersion post-date 7 ka BP, based on an **AMS radiocarbon date** on charcoal, while the NFPr and other deposits of the Tt date to between 25 and 20 ka BP, based on new AMS radiocarbon dates on mollusc shell and ostrich eggshell, and amino acid racemization ages on both mollusc shell and ostrich eggshell. Hominins found at site Ishango 1, a right mandibular ramus. Ishango 2–4 derive from NFPr and comprise three partial mandibles, 10 cranial fragments, assorted teeth, dens, atlas, cervical vertebra, adult left humerus, juvenile right humerus, three left (one is juvenile) and one right ulnae, three right radii, two metacarpals, nine manual phalanges, three femoral fragments, left patella, right tibia, left talus, 20 metatarsals, and three pedal phalanges. Ishango 5–8 and unnumbered individuals derive from P-EZ and comprise six mandibular fragments, some with teeth, a fragmentary left ulna and left radius, four metacarpals, two manual phalanges, three patellae, proximal epiphyses of a right and a left tibia, left talus and calcaneus, and one pedal phalanx, plus Boaz et al. (1990) recovered 19 additional hominin fragments from NFPr. All of the hominin remains are anatomically modern, but the molar teeth are strikingly large and the mandibular symphyses are deep but the shafts of the limb bones are straight and slender. Archeological evidence found at site NFPr to NT contained **Later Stone Age** artifacts including microlithic scrapers and backed crescents, harpoons with barbs on two sides in the earlier level gradually replaced by those with barbs on only one side, grindstones, but no pottery.

Cultural material from P-EZ contained a microlithic Later Stone Age industry, with bone artifacts that include harpoons with barbs on one edge, but no pottery or grindstones. Key references: Geology and dating Damas 1940, Lepersonne 1949, 1970, 1974, de Heinzelin 1955, 1957, 1962, Helgren 1997, Brooks and Smith, 1987, Brooks et al. 1991, Verniers and de Heinzelin 1990, Peters 1990, de Heinzelin and Verniers 1996, Brooks et al. 2008a; Hominins Twisselmann 1958, de Heinzelin 1962, Boaz et al. 1990, Brooks et al. 1991, Crevecoeur 2008b; Archeology de Heinzelin 1955, 1957, 1961, 1962, Brooks and Smith 1987, Stewart 1989, Boaz et al. 1990, Peters 1990, Yellen 1998, Mercader and Brooks 2001, Brooks et al. 2008b.

Isimila (Location 7°53'48"S, 35°36'12"E, Tanzania; etym. meaning unknown) History and general description This rich open-air **Acheulean** site located in the Iringa Highlands (outside of the Rift Valley) was discovered in 1951, with extensive excavations beginning in 1957 under the direction of F. Clark **Howell** together with Glen Cole and Maxine Kleindienst. The excavations at Isimila are an important early example of landscape-scale excavations to look at spatial and temporal variation in the **Early Stone Age** archeological record. Temporal span and how dated? **Uranium-series dates** on bone fragments (a poor material for this method) from Sands 4 range from more than 170 ka to *c.*330 ka, but these may well be underestimates. Although fauna is sparse, the presence of the **suid** *Metridiochoerus compactus* is consistent with an older, perhaps **Early Pleistocene** age. Hominins found at site None. Archeological evidence found at site Gully erosion has exposed sediments of the >18 m-thick Isimila Beds, a series of five sand deposits (Sands 1–5 numbered from top to bottom) overlying a paleosol developed on bedrock. The Isimila Beds are exposed over an area of at least 2 km², and were the subject of numerous large-scale excavations (some apparently as large as 620 m²) from laterally continuous deposits. Excavation results were important in demonstrating both the presence and absence of **handaxes** and similar implements in Acheulean stone tool assemblages and the importance of environment and hominin activity differences in explaining this variation. All of the fauna, mainly dental specimens of elephant, rhino, equids, suids, and bovids, plus some small taxa, derive from Sands 4. Key references: Geology, dating, and paleoenvironment Hansen and Keller 1971, Harris and White 1979, Howell et al. 1962, 1972; Archeology Cole and

Kleindienst 1974, Coryndon et al. 1972, Hansen and Keller 1971, Howell 1961, Howell et al. 1962.

island rule Proposed by Foster (1964), who suggested that island populations of mammals tended towards either gigantism or dwarfism depending on the original size of the organism. According to the island rule, if a mammal was on average smaller than a rabbit it will get larger, and if it is larger than a rabbit then it will tend to dwarf. The logic is that in the absence of mainland predators organisms no longer need to be small in order to be cryptic. Similarly, larger organisms, especially herbivores, would have access to less forage on an island and in the absence of mainland predators there is no need for them to resort to a large body mass to avoid predation, and so will get smaller.

ISMA Acronym for the **Institute for the Study of Man in Africa** (*which see*).

Isoberlinia *See* miombo woodland.

isochron (Gk. *isos*=the same and *kronos*=time) Refers to events happening at the same time, or to what a complex surface (e.g., a land surface or the outer enamel surface of a developing tooth) looks like at a point in time. It is also used in connection with potassium-argon dating.

isocortex (Gk *iso*=same or equal) The isocortex is synonymous with the **neocortex**. *See* **cerebral cortex**; **neocortex**.

isometric relationship (Gk *iso*=same or equal and *metron*=measure) *See* **isometry**.

isometry (Gk *iso*=same or equal and *metron*=measure) A change in size without an associated change in shape. Isometry is identified in scaling analyses when variables of equivalent **dimension** (i.e., both variables are lengths, or areas, or volumes/masses) are log transformed and plotted against each other and the first variable changes at the same rate as the second so that the slope (α) of the regression line is equal to 1. The objects on the regression line change their size, but not their shape. If the variables are of different dimensions then the isometric slope is equal to the ratio of the y -axis dimension to the x -axis dimension. For example, if a log-transformed area measurement (dimension=2) is plotted against a log-transformed

volume measurement (dimension=3) then the isometric slope is 2/3. It should be noted that if the y -axis variable is not a size variable but a shape variable (e.g., an angle or a ratio of size measurements) then the isometric slope is equal to zero (i.e., a change in size with no change in shape).

isotope (Gk *iso*=same or equal and *topos*=place) One of two or more atoms that have the same atomic number but different atomic masses. Because they have the same atomic number (i.e., the same number of protons) they occupy the same place in the periodic table (hence the name "isotope") and have the same element name, but because they differ in the number of neutrons they will have a different number superfix (atomic mass). Contrast this with what happens in non-isotopic decay. The daughter product has the same atomic mass, but one less proton than the parent isotope. This changes its atomic number and thus its place in the periodic table (e.g., when ^{40}K decays to ^{40}Ar). Many isotopes of the lighter elements such as carbon, nitrogen, and oxygen do not decay. Instead their proportions are determined by processes such as photosynthesis (e.g., $^{13}\text{C}/^{12}\text{C}$), climate or diet (e.g., $^2\text{H}/^1\text{H}$, $^{13}\text{C}/^{12}\text{C}$, $^{15}\text{N}/^{14}\text{N}$, and $^{18}\text{O}/^{16}\text{O}$). These isotopes are called **stable isotopes** and researchers use them to reconstruct diet, habitat, and migration in modern and extinct animals.

isotropy (Gk *iso*=equal and *tropus*=direction) Meaning, literally, equal in all directions. Within paleoanthropology, isotropy is used most commonly in reference to the material properties of a substance (e.g., **bone** or **enamel**) or to **dental microwear** textures. Materials are isotropic when their material properties, particularly their various measures of material behavior (stiffness as reflected by the **elastic modulus** or **Young's modulus**, shear stiffness as reflected by the **shear modulus**, and the relationship between axial and lateral strains as reflected by **Poisson's ratio**) are the same in all directions. Moreover, in isotropic structures those measures are related to each other in a mathematically predictable fashion such that the elastic modulus is equal to one plus the Poisson's ratio, multiplied by twice the shear modulus. Bone, like many other biological materials, is not isotropic, but it is often assumed to be so as a simplifying assumption in biomechanical analyses (e.g., **finite element analysis**). Regarding dental microwear, isotropy is a term used to describe the orientation of microwear features. Microwear is

isotropic when the features are not consistently aligned in any given direction (i.e., feature alignment varies without patterning). The opposite of isotropy is **anisotropy**, although additional terms are used in materials science (e.g., **orthotropy**, **transverse isotropy**) also denote departures from isotropy. *See also* **dental microwear**.

Istállóskő (Location 48°04'18"N, 20°25'08"E, Hungary etym. inversion of Hu. *kő istálló*=stone barn, since the cave was used to house pigs in historic times) History and general description This cave site in the Bükk Mountains, near Szilvásszék, was excavated throughout the 20thC. It preserves evidence of one of the oldest examples of the **Aurignacian** in Europe, suggesting a long period of overlap between **modern humans** and *Homo neanderthalensis*. However, some suggest there are more recent dates for the site. Temporal span and how dated? Early **radiocarbon dating** of bone provides an age of *c.*40 ka (uncalibrated); more recent dating has given a range of *c.*33–28 ka (uncalibrated). The anatomically modern human tooth has been directly dated to *c.*39 ka, although this date is questioned by some. Hominins found at site The germ of a right M₂ that is assigned to *Homo sapiens*. Archeological evidence found at site Aurignacian I and Aurignacian II lithic technology. Key references: Geology, dating, and paleoenvironment Allworth-Jones 1990, Vogel and Waterbolk 1972, Adams and Ringer 2004; Archeology Vértes and Vries 1952, Adams and Ringer 2004; Hominins Malán 1954, Thoma and Vértes 1971.

Isturitz (Location 43°21'10"N, 1°12'21"W, France; etym. Basque, name of the nearby town) History and general description This cave site located in a limestone hill near Bayonne on the Atlantic Coast of France has been known since at least the late 1700s when it was explored for potential gold deposits and then in the late 1800s it was partially excavated for phosphate. Organized amateur and professional archeological excavations in the main area of the cave (Salle d'Isturitz or Grande Salle) and in a second, smaller chamber (Salle de Saint-Martin) began in 1912 and the current excavations directed by Christian Normand have been underway since 1999. This is one of very few sites with well-dated *Homo sapiens* fossils in association with an early **Aurignacian** deposit. Temporal span and how dated? The earliest Aurignacian levels have been dated using **AMS radiocarbon**

dating to 41,355–42,625 cal. radiocarbon years BP. Hominins found at site 119 fragments and isolated teeth were found, all from the Upper Paleolithic levels. All of material is assigned to *H. sapiens*, even those from the earliest Aurignacian. Archeological evidence found at site Most deposits are **Upper Paleolithic**, with some evidence of the **Middle Paleolithic**. The Salle d'Isturitz has thin Aurignacian and **Solutrean** layers and thick **Magdalenian**, and **Gravettian** deposits, all capped by Bronze Age sediments and burials. Perforated human teeth were found in the upper levels. Amber pendants were found in the earliest Aurignacian deposits and whale bone artifacts were found in the Magdalenian layers. The **Mousterian** deposits in the Salle de Saint-Martin are topped by Aurignacian and Magdalenian; there is no evidence of the Châtelperronian. Key references: Geology, dating, and paleoenvironment Normand 2002, Szmíd et al. 2010; Hominins Gambier 1990/1991; Archeology Normand 2002, Szmíd et al. 2010.

IVPP Acronym for the **Institute of Vertebrate Paleontology and Paleoanthropology** (*which see*).

Iwo Eleru (Location 7°26'N, 5°8'E, Nigeria; etym. unknown) History and general description A large rock-shelter in the rain forest of western Nigeria excavated by Thurstan Shaw in 1965. Temporal span and how dated? Conventional **radiocarbon dating** on charcoal suggests and age of 2.52±0.07 ka and 11.25±0.2 ka. Hominins found at site Iwo Eleru 1, a tightly contracted fragmentary skull and skeleton was excavated from the bottom of the sequence and Shaw reported he was confident from the stratigraphy that the burial was not intrusive. The cranium preserves much of the vault, which is long, low, and narrow. Its markedly receding frontal aligns it with "archaic" crania in **multivariate space** and the **chin** is weakly developed. Archeological evidence found at site A **Later Stone Age** sequence containing more than half a million artifacts. Key references: Geology, dating, and paleoenvironment Shaw 1965, 1968, Brothwell and Shaw 1971; Hominins Brothwell and Shaw 1971, Stringer 1974, Bräuer 1984; Archeology Shaw 1965, 1968, Brothwell and Shaw 1971.

Iwo Eleru 1 *See* Iwo Eleru.

J

jackknife A **resampling** procedure similar to the **bootstrap** that can be used to calculate a confidence interval and/or the degree of bias for any sample statistic (e.g., mean, variance, median, correlation coefficient, regression slope, etc.). In its simplest application, the jackknife is conceptually more difficult than the bootstrap and it is also a less flexible technique than the bootstrap. For these reasons, and because the computing power necessary for performing bootstrap analyses is now readily available, the jackknife is not often used. For a sample of size n , the statistic of interest is calculated n times, each time leaving out one measurement. For example, for a sample of 10 endocranial capacities, the median can be calculated for all but the first measurement, all but the second measurement, and so on. These calculated values are known as partial estimates. For each partial estimate a quantity known as a pseudo-value can be calculated using the following formula: $\hat{\theta}_1^* = n\hat{\theta} - (n-1)\hat{\theta}_1$, where $\hat{\theta}$ is the statistic of interest (e.g., median) calculated for the full sample and $\hat{\theta}_1$ is the partial estimate calculated by leaving out the i th value. In our example, the first pseudo-value would be calculated as 10 times the median for the whole sample, minus nine times the median calculated for the sample without the first measurement. This equation takes into account the fact that the partial estimates are calculated on samples that are smaller than the full sample. The resulting pseudo-values are equivalent to the values that are generated in a bootstrap distribution. The mean and standard deviation of these pseudo-values can be treated as the jackknife estimate of the statistic and the standard error of the jackknife estimate can be used to generate a confidence interval. The pseudo-values can also be used to estimate bias in the jackknife estimate of the statistic. Manly (2007) provides further detail.

Jacob, Teuku (1929–2007) Teuku Jacob was born in Peureulak, Aceh, in what was then

the Dutch East Indies (now Indonesia). During the late 1940s he participated in the Indonesian independence movement and remained an ardent nationalist throughout his life. He entered **Gadjah Mada University** in Yogyakarta in 1953 to study anatomy in the university's School of Medicine and completed his medical degree in 1956. He became an assistant in anthropology at the university in 1954 and became a lecturer in anthropology at the university in 1962. He continued his studies in anthropology at Howard University in Washington DC in the USA where he completed a Master's degree in 1960. He then went to The Netherlands where he studied paleoanthropology with **Ralph von Koenigswald** at the Rijksuniversiteit in Utrecht, completing his doctorate "Some problems pertaining to the racial history of the Indonesian region" in 1967 that included a study of the small-statured modern humans from Flores, including the negritos from Liang Toge. When he returned to Gadjah Mada University after completing his studies in The Netherlands, Jacob accepted a position as Professor of Anthropology and was appointed to head the Laboratory of Bioanthropology and Paleoanthropology at the university, serving as the Dean of the School of Medicine from 1975 to 1979. He was also involved in Indonesian politics, serving as a member of the Indonesian People's Consultative Assembly from 1982 to 1987. Throughout his career at Gadjah Mada University, Jacob pursued studies of Indonesian *Homo erectus* fossils and rose to considerable prominence in Indonesian paleoanthropology. Early in his career, in 1962, he conducted excavations at **Sangiran** where he later found *Homo erectus* and early *Homo sapiens* fossils and stone tools. It was most likely Jacob's familiarity with the small-statured modern humans from Flores, including the negritos from Liang Toge, that caused him to involve himself centrally in the debate about *Homo floresiensis*, joining those who strenuously opposed the proposal that the **Liang Bua** fossils represent a novel species

of dwarfed primitive hominin. Jacob proposed a very different interpretation, namely that the Liang Bua fossils were only 1300–1800 years old, that they sample an "Australomelanesid race" of modern humans. He also suggested that the unusually small skull could be explained as being the result of a congenital abnormality called **microcephaly**.

Jacovec Cavern *See* **Jakovec Cavern**.

Jakovec Cavern (etym. Justin Wilkinson, who explored the Sterkfontein Cave system, named this particular cave after a friend whose family name was Jakovec) Part of the **Sterkfontein** cave system containing breccia equivalent in age to Sterkfontein Member 2. In 1995 two of the charges laid to blast the breccia in the **Silberberg Grotto** were detonated, but no breccia was removed. This indicated to one of the miners laying the charges that the force of the charge must have dissipated into a cavity on the other, eastern, side of where the charges had been laid. Ron **Clarke** knew the Jakovec Cavern was east of the Silberberg Grotto and he surmised that the breccia in the grotto might also be exposed in the nearby cavern. Meshaka Makgothoko, Stephen Motsumi, and Nkwane Molefe were sent to search the walls of the Jakovec Cavern for signs of fossils, and within a day they had located a section of the brain case of a hominin. This was the first of the 12 hominins recovered in 1995 that were reported in Partridge et al. (2003). *See also* **Sterkfontein**.

Jaramillo *See* **geomagnetic polarity time scale**.

Jarman/Bell principle A model that relates dietary quality, metabolism, and body size. The model was initially derived from studies of antelopes (Bell 1970, Jarman 1974), but it has also been shown to be applicable to primates (Gaulin 1979). The Jarman/Bell principle suggests that because large-bodied animals require less energy per unit body mass than smaller-bodied ones, they can exist on lower-quality diets. However, although the relative energy intake of large-bodied animals is lower compared to small-bodied animals, their food consumption is still absolutely greater than that of smaller-bodied animals and if they focused on less abundant, high-quality foods (such as ripe fruits and insects, for example) large-bodied animals may not be able to meet their daily energy needs. The Jarman/Bell principle provides a useful basis

for investigating the relationship between body mass, diet, and metabolic rate in studies that examine the role energetics may have played in hominin evolution.

jasper A characteristically reddish variety of cryptocrystalline silica (SiO₂) (i.e., chert). The distinctive color is due to the presence of trace amounts of iron oxide. Nodules of jasper have the hardness and **conchoidal fracture** properties typical of siliceous materials and at some **Middle Stone Age** sites it was the selected raw material for flaking.

Javanthropus Oppenoorth, 1932 (*Java* = from the island and *Gk anthropos* = human being) A subgenus of the genus *Homo* introduced by Oppenoorth (1932) to accommodate the new species *Homo soloensis*. In a later paper Oppenoorth (1937) suggested the subgenus should be abandoned and nearly all researchers (e.g., Le Gros Clark 1955) took his advice.

jaw (E *jome* or *joue* = cheek) Refers to either the maxilla (i.e., upper jaw) or the mandible (i.e., lower jaw).

Jebel Irhoud (Location 31°51'36"N, 8°52'12"W, Morocco; etym. unknown; alternate spellings **Jebel Ighoud**, **Djebel Irhoud**) History and general description Discovered during mining, this cave site has produced several **Middle Paleolithic** hominin fossils. It was originally excavated by Ennouchi, and subsequently by Tixier and de Bayle des Hermens in 1967 and 1969. Much of the recent analysis, including new excavations beginning in 2004, have been done by an international group led by Jean-Jacques **Hublin** and Abdelwahed Ben-Ncer. Temporal span and how dated? **Electron spin resonance spectroscopy (ESR) dates** on horse teeth provide a range of 90–125 ka assuming an early-uptake model or 105–190 ka assuming a linear-uptake model. More recent uranium-series and ESR dates on one hominin tooth suggest an age of 160±16 ka. Hominins found at site The remains of at least four individuals have been recovered. They were originally attributed to *Homo neanderthalensis* or were at least considered to possess some Neanderthal traits, but reanalysis suggests that similarities to early European fossils may be due to shared ancestral traits and that the Irhoud material displays more similarities with early modern humans from the

Near East. **Irhoud 1** and **Irhoud 2** are mostly complete fossil crania. Irhoud 3 is a juvenile mandible with a well-preserved dentition. A study of dental microstructures suggest that this individual experienced a prolonged life history, in which case it would be among the earliest evidence of a modern human-like life history. Many authors consider these fossils to be the predecessors of the later individuals found at **Dar es Soltane II** in Aterian context. Archeological evidence found at site A Middle Paleolithic stone tool technology with use of Levallois technique and a high proportion of scrapers, which has been named "Irhoud Mousterian." Faunal remains are poorly preserved but dominated by gazelles. Key references: Geology, dating, and paleoenvironment Hublin 1992, Grün and Stringer 1991, Smith et al. 2007; Hominins Hublin 1992, Hublin and Tillier 1981, Hublin et al. 1987, Tixier et al. 1998, Smith et al. 2007; Archeology Hublin et al. 1987.

Jebel Qafzeh *See* Qafzeh.

Jebel Sahaba (Site 117) (Location 21°59'N, 31°20'E, Sudan; etym. Arabic, "mountain of the companion of the Prophet," a local geographical feature) History and general description This site, 3 km/1.8 miles north of Wadi Halfa, was discovered and excavated during the rescue archeological efforts that preceded the construction of the Aswan Dam. The existence of the site was first noted in 1962, but the first skeletal and archeological evidence was recovered in 1965 by a team led by Fred Wendorf. Tony Marks conducted additional excavations in 1966, recovering nine more skeletons of a total for the site of 58. The burials were in flexed positions, heads to the north, and faces turned east. Most of the skeletons were partially mineralized and 24 were associated with microlithic artifacts that had apparently been attached to darts or arrows shot into their bodies. Temporal span and how dated? Associated, possibly Qadan (Nile Valley Later Stone Age, or LSA) lithics and conventional radiocarbon dating of the skeletons suggest an age of 12–14 ka. Hominins found at site Anderson (1968) analyzed 52 of the 58 skeletons and that subsample included 19 adult males, 17 adult females, seven adults of indeterminate sex, and nine juveniles. The crania are large and robust with strong supraorbital tori and some are prognathic; the mandibular bodies are robust with large teeth. Morphologically, the crania

closely resemble those from **Wadi Halfa**, and recall the Metchoid people from the **Ibero-Maurusian** of North Africa. The dental morphology resembles that of West Africans rather than the later agricultural populations of Nubia. Archeological evidence found at site 110 microlithic artifacts, possibly from the Qadan (Nile Valley LSA). Key references: Geology, dating, and paleoenvironment Wendorf 1968a; Hominins Anderson 1968, Turner and Markowitz 1990, Irish and Turner 1990, Irish 2005; Archeology Wendorf 1968a.

JHS Acronym for John's Hominid Site. *See* **Omo-Kibish**.

Jinniushan (金牛山) (Location 40°34'40"N, 122°26'38"E, northeastern China; etym. named after a local hill) History and general description The fossil-hominin-bearing locality (Site A) is one of several breccia-filled fissures located in an isolated karst tower locally known as Jinniushan (Golden Ox Hill), 1 km/0.6 miles west of Sitian Jiatun village and about 20 km/12 miles southeast of the city of Yingkou, Liaoning Province. Archeological survey and excavation began in 1974 and three potential localities, Site A (located on the eastern slope), Site B (located 20 m north of A), and Site C (located on the western slope), were discovered. In 1984, archeology field school students from Peking University, under the direction of Professor Lü Zun'E, discovered a partial hominin skeleton in layer 7 (not in layer 6 as originally reported) of Site A. Although Jinniushan is one of the most important paleoanthropological sites in China, most of the excavated materials (fauna, hominin, and lithics) have not been widely studied and results have mostly been published in Chinese. Temporal span and how dated? Chen et al. (1994) report a mean of 237 ka from uranium-series dating and a mean electron spin resonance spectroscopy (early-uptake model) date of 187 ka for Jinniushan based on five fossil mammalian teeth. Taken together, the authors suggest a conservative, minimum age of *c.*200 ka. Lü (1985) reports another uranium-series date of 280 ka for layer 7. However, both Wu Ru-kang (1988) and Geoffrey Pope (1992) have called the reliability of the older date into question on stratigraphic grounds. Hominins found at site A partial skeleton belonging to a male around 20 years of age. The cranium was reconstructed by Wu Xin Zhi and Zhao Zhong Yi of the **Institute of Vertebrate**

Paleontology and Paleoanthropology from over 100 broken fragments. It is thin-vaulted and has an endocranial volume of about 1300 cm³. The postcranial elements include six vertebrae (one cervical and five thoracic), two left ribs, a complete left ulna, a complete left os coxa, a complete left patella, and numerous articulated bones of both wrists, hands, ankles, and feet. Archeological evidence found at site Only two lithic artifacts were reported from the seven layers (numbered from top to bottom) of excavated deposits at Site A. From the dense accumulations of well-stratified **microfauna**, Pope (1992) suggests that Site A was likely a natural faunal trap not an occupation site. At Site C, 15 small stone artifacts were recovered from layers 4–6 (the Lower Cultural Zone of presumed **Early Paleolithic** antiquity) of six layers in 1975. These are dominated by **scrapers** and most show **retouching** by simple direct percussion. Abundant mammalian fossils and evidence of fire utilization (details unclear) have also been reported from the Lower Cultural Zone. Repository Beijing University Department of Archaeology. Johanson, Donald Carl (1943–) Donald Johanson was born in Chicago, Illinois, USA. He became interested in anthropology as a child and after initially choosing chemistry as his major at the University of Illinois at Urbana–Champaign he later changed to anthropology and received his BA in 1966. Johanson entered The University of Chicago to study with paleoanthropologist Clark **Howell**, completing his MA in 1970. Johanson began his graduate studies and took part in the 1970, 1972, and 1973 fieldwork seasons of the **International Omo Research Expedition** that was exploring the deposits of the Omo River Basin in Ethiopia. While working in the Omo, French geologist Maurice Taieb invited Johanson to join him in examining some promising deposits located in the **Afar Triangle** region in northeast Ethiopia and when Taieb, Johanson, French paleoanthropologist Yves **Coppens**, and American geologist Jon Kalb explored that region in 1972 they came to realize the potential of the site now known as **Hadar**. The first formal expedition to Hadar in

1973 resulted in the recovery of a large quantity of mammal fossils along with an early hominin knee joint. The following year an even more remarkable hominin discovery was made when Johanson and Tom Gray recovered a substantially complete associated skeleton, **A.L. 288-1**, to which they gave the nickname “Lucy.” Fieldwork continued at Hadar and in 1975 the team unearthed the remains of at least 13 hominin individuals, about 200 fossils in all, at locality 333. Johanson began working in the Department of Physical Anthropology at the **Cleveland Museum of Natural History** in 1972. Upon completing his PhD on variation in chimpanzee dentition at the University of Chicago in 1974, he became Curator of Physical Anthropology at the Cleveland Museum. Since it was impossible to continue fieldwork at Hadar, Johanson began to examine the Hadar fossils with the assistance of William Kimbel, Owen Lovejoy, Bruce Latimer, and Tim White among others. There was initially uncertainty as to whether the Hadar specimens represented *Homo* or *Australopithecus*, and whether they sampled one, or more, species. Johanson and his team became convinced that all the Hadar remains belonged to one, novel, species of *Australopithecus*, and in 1978 they proposed that the Hadar hominin fossils should be referred to new taxon *Australopithecus afarensis*. In 1981 Johanson left his position at the Cleveland Museum of Natural History (as well as the adjunct faculty positions he held at Case Western Reserve University and Kent State University) and founded the **Institute of Human Origins** (or IHO) in Berkeley, California, to promote and facilitate further multidisciplinary research into human origins. He also wrote, with Maitland A. Edey, a popular book titled *Lucy: The Beginnings of Humankind* (1981), which described the discoveries at Hadar and his interpretation of the role played by *Au. afarensis* in hominin evolution. Johanson and his team returned to Africa in 1985 when he received permission from the Tanzanian government to excavate at **Olduvai Gorge** where Louis and Mary Leakey had worked. In 1986, Tim White found a 1.8 Ma associated hominin skeleton (**OH 62**) that White and Johanson argued belonged to *H. habilis*. In addition to directing the IHO, conducting field research in the Hadar study area and contributing to the analysis of the Hadar hominins Johanson was a Professor of Anthropology at Stanford University from 1983 to 1989 and also continued to write books for a popular audience. Johanson collaborated with Maitland Edey to write *Blueprints: Solving the Mystery of Evolution*

(1989), with J. Shreeve to produce *Lucy's Child* (1989), and with Blake Edwards to produce *From Lucy to Language* (1996). Johanson and the IHO moved from Berkeley to Tempe, Arizona, in 1997, where it is affiliated with Arizona State University and where Johanson is a Professor and still occupies the Virginia M. Ullman Chair in Human Origins. In July 2008 Johanson stepped down as director of the IHO.

joint (ME *joint*=junction) A discontinuity between two bones. Joints are classified according to whether the tissues that separate the bones are solid (i.e., fibrous and cartilaginous joints) or have a cavity (i.e., synovial joints). There are three types of fibrous joints: suture joints between flat cranial bones (e.g., the sagittal **suture** between the parietal bones), gomphoses joints that keep teeth in their sockets, and syndesmoses fibrous bands of collagen that join two, or more, bones (e.g., the sacro-iliac, tibio-fibular, and interspinous ligaments). Cartilaginous joints are of two types: primary cartilaginous joints (also called synchondroses) in which hyaline cartilage covers the surfaces of the bones involved in the joints and secondary cartilaginous joints (also called symphyses) in which each bone is covered by a plate of hyaline **cartilage** with fibrocartilage between the plates. Synchondroses are what we all have before the ends of our long bones (i.e., epiphyses) fuse with the shaft (i.e., diaphysis). They are also found at the lateral ends of ribs and between some cranial bones (e.g., between the sphenoid and the ethmoid and between the sphenoid and the occipital) formed from the **chondrocranium**. All secondary cartilaginous joints are in the midline (e.g., the intervertebral discs and the pubic symphysis). The surfaces of the bones involved in synovial joints (like those involved in synchondroses) are covered with hyaline (called articular) cartilage and the bones are connected by a fibrous capsule lined with synovial membrane. The space between the membrane and the cartilage contains synovial fluid and may also include a flat meniscus made of fibrocartilage. Synovial joints are usually protected by ligaments. These may be thickenings of the capsule (e.g., the ilio-femoral ligament) or they are non-capsular. Non-capsular ligaments may be within the capsule (e.g., the cruciate ligaments of the knee joint) or outside the capsule (e.g., sacro-iliac ligament). Tension in ligaments is one of the main factors restricting movement at synovial joints.

Jones, Trevor See Robert Broom; Sterkfontein.

jugal (L. *iugum* or *jugum*=yolk, as in what is worn by beasts of burden) The name of a cranial bone in amphibians, reptiles, and birds; the equivalent in mammals is the zygomatic bone. The term jugal is used in old anatomy books (e.g., the 7th edition of Buchanan's *Manual of Anatomy* refers to what Martin calls the "fronto-malare temporale" as the "jugal point") and some researchers refer to the postcanine teeth as the "jugal" teeth. However, all told jugal is an arcane term that is best avoided. See also **malar**.

"Jonny's Child" The nickname given by Louis and Mary Leakey to OH 7 from Olduvai Gorge that became the holotype of *Homo habilis*.

jugular bulb See cranial venous drainage.

Julbernardia See miombo woodland.

jump dispersal A type of dispersal that occurs when a subpopulation of a larger population of organisms crosses an existing barrier to dispersal. Stochastic processes may play an important role in generating jump dispersals, or novel adaptations may allow individuals to traverse regions that had previously been impassable. A particularly dramatic example of jump dispersal is the colonization of South America by African **anthropoids** during the early **Miocene**, in which the founding populations of **platyrrhines** may have crossed the Atlantic Ocean on mats of floating vegetation that functioned as rafts. Jump dispersal may be an important process leading up to **allopatric speciation** and involuntary jump dispersal may have been how hominins reached islands in South Asia. Once hominins were able to build seagoing craft they were effectively able to undergo jump dispersal either by accident or by choice.

jumping genes See transposition; transposon.

junior synonym A name for a taxon that has been superseded by a different name that has historical priority. The junior synonym may be an objective synonym (when two taxa have been erected with the same type specimen) or a subjective synonym (when two taxa, formerly thought to be different, have been synonymized). For example, the names *Homo neanderthalensis*

King, 1864, *Homo primigenius* Schwalbe, 1903, and *Palaeanthropus europaeus* Sergi, 1910 were all given to a taxon whose type specimen was the calvaria from the Kleine Feldhofer Cave and the latter two names are consequently objective junior synonyms of *H. neanderthalensis*. The name of *Australopithecus transvaalensis* was given by Broom, 1936 to a specimen from Sterkfontein, and later transferred to a new genus *Plesianthropus*; most authorities since then have considered that the Sterkfontein fossils are the same species as represented by the Taung skull, which was described as *Australopithecus africanus* Dart, 1925. Consequently the specific name *transvaalensis* is considered a junior subjective synonym of *africanus*, and the generic name *Plesianthropus* is considered a junior subjective synonym of *Australopithecus*.

juxtamastoid eminence A bony process that is seen in some, but not all, modern human crania. When present, it lies between the digastric fossa laterally and the groove for the occipital artery medially and it probably owes its presence to bone being pushed up between the two aforementioned structures, especially when the occipital artery takes a course lateral to the occipitomastoid crest and the occipitomastoid suture. A juxtamastoid eminence is present in early hominin crania such as SK 27 and SK 847 and the combination of a large juxtamastoid eminence but small mastoid process is one of the distinctive features of *Homo neanderthalensis*. The juxtamastoid eminence is probably equivalent to Franz Weidenreich's *crista paramastoidea* (syn. juxtamastoid process).

juxtamastoid process See juxtamastoid eminence.

Jwalapuram (Location 15°19'20"N, 78°08'01"E, India; etym. named after a local village)
History and general description A group of archeological sites located in the Jurreru River Valley, Kurnool District, southern India. Surveys and excavations were performed between 2003 and 2010, identifying rock-shelters and open-air sites, some in association with the Toba super-eruption event.
Temporal span and how dated? **Radiocarbon dating** (AMS) and optically stimulated **luminescence dating** suggest an age of c.78–10 ka. Hominins found at site Four fragmentary and burned (calcined) cranial fragments and a tooth attributed to *Homo sapiens*, and dating to 20–12 ka at Jwalapuram Locality 9 rock-shelter. Archeological evidence found at site Jwalapuram Locality 3 contains **Middle Paleolithic** assemblages in association with Toba ash. The 511 artifacts excavated from Jwalapuram Localities 3 and 23 are made of limestone, chert, quartzite, quartz, chalcedony, and dolerite. The assemblage includes multi- and single-platform cores and **Levallois** cores for the production of flakes and blades, and diverse retouched pieces, including scrapers, notches, and points. The assemblages are notable for showing technological continuity after the Toba event. Discriminant core analysis indicates that the Jwalapuram cores are similar to sub-Saharan **Middle Stone Age** industries. The Jwalapuram Locality 9 rock-shelter dates up to 35 ka, and contains 53,000 excavated lithic artifacts, beads, and worked bones. The transition from the Middle Paleolithic to Microlithic at Jwalapuram occurs c.35 ka, and has been attributed to innovations arising from environmental deterioration and demographic increase. Key references: Geology, dating, and paleoenvironment Jones 2010, Petraglia et al. 2007, 2009; Hominins Clarkson et al. 2009; Archeology Petraglia et al. 2007, 2009, Haslam et al. 2010.

K

K-selection See *r/K-selection*.

K/Ar See *potassium-argon dating*.

ka (L. *kilo*=thousand and *annum*=year) The abbreviation for an age determination or **age estimate** expressed in thousands of years. For example, “the date of the anatomically modern human crania from the Omo is *c.*190 ka.” The term “ky” or “kyr” should be used to describe periods of time as in “30 kyr have elapsed since anatomically modern humans first reached Europe.” See also *age estimate*.

Kaalam See *Shungura Formation*.

Kabua (Location 3°27'N, 35°47'E, Kenya; etym. named after the water-hole) History and general description The site is 1143 m south-southeast of Kabua water-hole on the west side of Lake Turkana. A fossilized hominin skull was found *in situ* in Late Pleistocene lacustrine deposits that outcrop near Kabua Gorge by T. Whitworth and a research group from the University of Durham in September 1959. Temporal span and how dated? Association with an elevated lake level suggests a **Late Pleistocene** or **Holocene** age. Hominins found at site A fragmentary skull comprising a calotte, right half of the mandible with M₂–M₃ and fragments of I₂–P₄, two isolated upper molars, and a right maxillary fragment with I¹–I² and P⁴. The calotte is long and somewhat low but anatomically modern. The large mandible has a deep corpus, a **retromolar gap**, and the signs of a strong chin. Archeological evidence found at site No artifacts in close association, but a large, fossilized hippopotamus skeleton was found *in situ* from the same level nearby. Key references: Geology, dating, and paleoenvironment Whitworth 1965a, 1966; Hominins Whitworth 1960, 1966; Archeology Whitworth 1965b, 1966.

Kabuh Formation See *Bapang Formation*.

Kabwe (Location 14°27'S, 28°26'E, central Zambia; etym. Kabwe is the name of the nearest village. The site, formerly known as **Broken Hill**, was named after a circular depression that divided the artifact- and fossil-bearing hill or kopje and apparently also because it resembled the mines at Broken Hill, Queensland, Australia) History and general description Fossils and artifacts were discovered in 1921 during lead and zinc mining operations at Number 1 Kopje, a dolomitic outcrop containing an approximately 30 m-long, clay- and breccia-filled cavity. By 1930 Number 1 Kopje had been leveled and the precise provenance of the recovered fossils and artifacts remains uncertain, although mineralogical and chemical analyses suggest that most derive from the lower portions of the cavity. Subsequent excavations by Desmond Clark in 1953 targeted surficial deposits some 200 m from Number 1 Kopje. Temporal span and how dated? The more than 23 large mammal species from Kabwe include extinct large baboons, saber-toothed cat, warthog, giraffid, and giant buffalo, and show a general similarity to fauna from Bed IV at **Olduvai Gorge** and thus the assemblage is estimated by some authors to be as old as 0.78–1.3 Ma. However, the precise association of the extinct taxa with the hominin remains is unclear and such a date is at odds with the **Middle Stone Age** (or MSA) attribution of the (equally poorly provenanced) artifacts recovered with the fossils, as elsewhere the MSA dates to <300 ka. Hominins found at site **Kabwe 1** (British Museum of Natural History registration no. E686 and formerly Broken Hill 1) is a nearly complete cranium found by T. Zwigelaar in 1921. The specimen became the holotype for *Homo rhodesiensis* but is attributed by many authors to *Homo heidelbergensis*. Additional hominin remains recovered from Kabwe include a left tibia (no. E691), distal right humerus (no. E898), fragment of a femoral shaft (no. E793), cranial fragment (no. E897), right maxilla (no. E687),

fragmentary right and left innominates (nos. E719–20), sacrum (no. E688), proximal right femur (no. E907), proximal left femur and distal left femur (no. E689), and left femoral diaphysis (no. E690). Most of these specimens were also collected in 1921 and mineralogical analyses and comparisons of the chemical compositions of hominin and non-hominin fossils (as well as sediment adhering to artifacts) suggest that most derive from the lower portions of the sediment-filled cavity, but Hrdlicka (1930) reported finding the distal end of a humerus and a parietal fragment on a nearby bone pile. Archeological evidence found at site The majority of the artifacts from Kabwe have been lost, although some lithic artifacts and putative bone tools have been preserved. Artifacts associated with the hominin fossils recovered from Number 1 Kopje include **flakes with faceted platforms**, discoidal and perhaps **Levallois cores**, **hammerstones** and possible **anvils**, as well as three shaped bone tools that Desmond Clark attributed to the MSA. Clark's 1953 excavations revealed more than 2 m of stratified sediments that contained a sequence of **Acheulean**, **Sangoan**, and MSA artifacts, but unfortunately no fauna was preserved for comparison with the fauna from Number 1 Kopje. Key references: Geology, dating, and paleoenvironment Clark et al. 1947, Klein 1973, McBrearty and Brooks 2000; Hominins Woodward 1921, Pycraft 1928, Clark et al. 1968, Kennedy 1984b, Stringer 1986b, Trinkaus 2009; Archeology Clark et al. 1947, Clark 1950, Barham et al. 2002.

Kabwe 1 Site Kabwe. Locality Discovered during lead and zinc mining operations at Number 1 Kopje, a dolomitic outcrop containing an approximately 30 m-long cavity filled with clay and breccia. Surface/in situ *In situ*. Date of discovery June 17, 1921. Finders A.S. Armstrong and A.W. Whittington. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age **Biostratigraphy** suggests a general similarity to fauna from Bed IV at **Olduvai Gorge** and thus the assemblage is estimated by some authors to be as old as 0.78–1.3 Ma. Developmental age Adult. Presumed sex Male, based on its massive brow ridge and large face. Brief anatomical description A cranium including the worn maxillary dentition except for the right I² and the crown of the right M³. Endocranial volume Approxi-

mately 1280 cm³ (Rightmire 2004). Announcement Woodward 1921. Initial description Woodward 1921, Pycraft 1928. Photographs/line drawings and metrical data Pycraft 1928, Rightmire 1990. Detailed anatomical description Rightmire 1990. Initial taxonomic allocation *Homo rhodesiensis* Woodward, 1921. Taxonomic revisions *Cyphanthropus* (Pycraft 1928), *Homo erectus* (Coon 1962), *Homo sapiens rhodesiensis* (Campbell 1964, Rightmire 1976). Current conventional taxonomic allocation *Homo heidelbergensis* or *H. rhodesiensis*. Informal taxonomic category Pre-modern *Homo*. Significance Kabwe 1 resembles **Bodo 1**, **Arago**, **Petralona**, and **Saldanha**, and many regard it as consistent with the hypothesis that these specimens all belong to the hypodigm of *H. heidelbergensis*, or *H. rhodesiensis* if the former taxon is interpreted as having some *Homo neanderthalensis* autapomorphies. If Kabwe 1 is the same age as Olduvai Gorge Bed IV then it is possibly the earliest evidence for *H. heidelbergensis* and *H. rhodesiensis*. Location of original **Natural History Museum**, London, UK.

KAI Abbreviation of the Kaitio Member in the Nachukui Formation, **West Turkana**, Kenya.

Kaitio [etym. Named for an ephemeral river system (laga) in whose drainage the localities are located] (or KI) Refers to a complex of fossil localities in the Nariokotome, Natoo, Kaitio, and Kalochoro Members of the Nachukui Formation within the Kaitio drainage in West Turkana, Kenya. *See also* **West Turkana**.

KAL Abbreviation of the Kalochoro Member in the Nachukui Formation, **West Turkana**, Kenya.

Kalahari Dune Expansion In southern Africa, fossil dunes in the Mega Kalahari dated by **luminescence dating** (Stokes et al. 1998) indicate arid conditions and dune expansion between 95 and 115 ka, 41 and 46 ka, 20 and 26 ka, and post-20 ka. Comparable periods of aridity are also seen in the **paleoclimate reconstruction** from the **Tswaing Impact Crater** (Partridge et al. 1997).

Kalokodo (etym. Named for an ephemeral river system (laga) in whose drainage the localities are located) (or KK) Refers to a complex of fossil localities in the Kalochoro Member of the Nachukui Formation within the Kalokodo drainage in West Turkana, Kenya. *See also* **West Turkana**.

Kalaloo One of the named drainages/subdivisions within the **Bodo-Maka** fossiliferous subregion of the **Middle Awash study area**, in Ethiopia.

Kalam *See* Shungura Formation.

Kalambo Falls (Location 8°30'S, 31°15'E, Zambia; etym. unknown) History and general description Desmond Clark directed intermittent excavations between 1953 and 1966 in sediments of the Kalambo Falls Formation. Kalambo Falls Formation sediments crop out immediately upstream of the falls of the Kalambo River, which drains into Lake Tanganyika approximately 6 km/3.6 miles downstream. Although no fauna is present, the waterlogged conditions at the site preserved abundant organic remains including wood and pollen. The composite stratigraphic sequence of the different excavations provides a crucial benchmark for the cultural historical succession of southern and East Africa, from the **Early Stone Age** (e.g., **Acheulean**) to the Iron Age. Temporal span and how dated? Uranium-series dating on fossil wood, a material for which the uranium and thorium geochemistry remains poorly understood, may underestimate the true sample age. They suggest an age of 76 ± 10 ka for the **Sangoan** levels, 182 ± 10 ka for the Upper Acheulean level, and 182 ± 16 ka for the Lower Level Acheulean. **Radiocarbon dating** estimates from the 1950s suggest that that the **Later Stone Age** and Iron Age strata may be as old as *c.*25 ka, although most are **Holocene** in age. Hominins found at site None. Archeological evidence found at site Stone artifacts likely spanning much of the Pleistocene occur at Kalambo Falls, from Early Stone Age (i.e., Acheulean), **Middle Stone Age** (i.e., **Lupemban**), to the Later Stone Age as well as “intermediate” industries (i.e., Sangoan and “**Magosian**”). Most are made from locally available **quartzite**, **mudstone**, or **silcrete**. These stratified stone-tool assemblages in alluvial and colluvial sediments have provided a fundamental relative dating tool used throughout much of Africa, although many of them have undergone **winning** or otherwise been reworked by **fluvial** processes. The typology developed for their study by Desmond Clark and Maxine Kleindienst enjoyed widespread use beyond Kalambo Falls. Waterlogged conditions, particularly in the lowermost strata, assist in the preservation of pollen that suggests fluctuations in the mosaic of

forest and swamp environments in the area, an interpretation supported by preserved seeds, tree bark, and wood charcoal. A number of wood specimens that suggest hominin modification and use occur in Acheulean and Sangoan strata. They include a number of pointed pieces that may have functioned as **digging sticks** but smoothing by stream flow has removed many of the fine traces necessary for confirmation. Key references: Geology, dating, and paleoenvironment Clark 1969, 2001; Archeology Clark 1969, 1974, 2001, Sheppard and Kleindienst 1996.

Kalochoro (etym. Named for an ephemeral river system (laga) in whose drainage the localities are) History and general description Complex of fossil localities within the Kalochoro, Kaitio, Nattoo, and Nariokotome Members of the Nachukui Formation in the vicinity of the Kalochoro drainage in **West Turkana**, Kenya. The **Koobi Fora Research Project** conducted surveys between 1980 and 1983 and more intensive fieldwork began in 1984. By 1988 six vertebrate fossil localities had been identified (Harris et al. 1988) but no hominin remains have been recovered to date. Archeological excavations have been undertaken by the West Turkana Archaeological Project and have continued since 1994. Temporal span and how dated? The localities occur in two blocks separated by a major fault, and are well constrained by **argon-argon dating**. The western sequence spans from the Kalochoro Tuff (2.32 Ma) to well above the KBS Tuff (1.87 Ma), and includes most of the paleontological localities. The archeological sites lie east of the fault, and are immediately above the Lower Nariokotome Tuff that is *c.*1.3 Ma. Hominins found at site None. Archeological evidence found at site Test excavations were undertaken at Kalochoro 1 (KL 1) in 1994 and Kalochoro 2 (KL 2) in 1996. Surface lithic assemblages have been found in four localities, but no *in situ* material has been recovered to date. Key references: Geology and dating Harris et al. 1988, Kibunjia 2002; Hominins N/A; Archeology Kibunjia 2002. *See also* **West Turkana**.

Kamoya *See* Kimeu, Kamoya.

Kanam (Location 0°21'S, 34°30'E, Kenya; etym. named after the Kanam Beds exposed at the site) History and general description A fossilized hominin mandible was found at the site in an erosion gully on the south shore of the Kavirondo Gulf, Lake Victoria, in 1932 by Juma Gitau, a member of Louis Leakey's

East African Expedition. Temporal span and how dated? Inferred to be late **Pliocene** or early **Pleistocene** based on correlations (later doubted) with the Kanam Beds. Hominins found at site Kanam 1, the anterior portion of a mandible with pathological anterior surface of the symphysis (causing it to superficially resemble a chin) and the right P₃ and P₄. The mandible is the holotype of *Homo kanamensis*. Archeological evidence found at site None found with the mandible, but there are **Oldowan** tools from the Kanam Beds. Key references: Geology, dating, and paleoenvironment Leakey 1935, Cooke 1963; Hominins Woodward 1933, Leakey 1935, 1936b, Tobias 1960; Archeology Leakey 1935.

Kanapoi (Location 2°19'N, 36°04'E, Kenya; etym. the site was apparently misnamed by Bryan Patterson; the local name for the area is Kanapunyi) History and general description The site located southwest of Lake Turkana and just north of the Kakurio River was discovered in 1965 by Bryan Patterson's team. The Kanapoi sediments were deposited in a channel of the Kerio River that drained northwards into the paleolake Lonyumun. Temporal span and how dated? Three stratigraphic intervals are represented in the Kanapoi exposures. All lie beneath the *c.*3.4 Ma Kalokwanya basalt and all but one of the hominin fossils were recovered from sediments dated to between 4.17±0.03 and 4.07±0.02 Ma by **argon-argon dating**. Hominins found at site The first hominin fossil recovered from Kanapoi was a distal left humerus found by Bryan Patterson's expedition in 1965 (Patterson and Howells 1967). Eight more hominins were recovered in 1994 (Leakey et al. 1995) and a further 24 more hominins recovered between 1994 and 1997 were reported in Leakey et al. (1998). The initial humerus was regarded as *Australopithecus* sp. but a mandible found in 1994, **KNM-KP 29281**, was made the holotype of *Australopithecus anamensis* and this is the taxon to which the 1965 humerus and all the subsequent (i.e., 1994 and thereafter) discoveries have been allocated. All of the hominins except a mandible come from the interval between the Kanapoi Tuff and a tephra layer called the "lower pumiceous tuff." Archeological evidence found at site Mary Leakey reported on Oldowan-style artifacts recovered from Kanapoi, but they are not associated with the Pliocene fossils. They are believed to be of recent derivation and remain somewhat enigmatic (Leakey 1966b).

Key references: Geology and dating Leakey et al. 1995, 1998, Feibel 2003; Hominins Leakey et al. 1995, 1998, Ward et al. 1999b.

Kanapoi Hominoid 1 *See* **KNM-KP 271**.

Kangaki (etym. Named for an ephemeral river system (laga) in whose drainage the localities are located) (or KK) Refers to a complex of fossil localities in the Kalocho Member of the Nachukui Formation within the Kangaki drainage in West Turkana, Kenya. *See also* **West Turkana**.

Kangatukuseo (etym. Named for an ephemeral river system (laga) in whose drainage the localities are located) (or KU) Refers to a complex of fossil localities in the Upper Lomekwi Member of the Nachukui Formation within the Kangatukuseo drainage in West Turkana, Kenya. The early hominin mandible **KNM-WT 16005** was recovered from Kangatukuseo III. *See also* **West Turkana**.

Kanjera (Location 0°20'S, 30°02'E, Kenya; etym. unknown) History and general description The site of Kanjera, a series of erosion gullies 500 m from the south shore of the Kavirondo Gulf, Lake Victoria, was initially explored by Louis Leakey's East African Expedition, which recovered anatomically modern-looking hominins in 1932. Kanjera comprises several collection areas around Kanjera North (KN) and Kanjera South (KS). The apparent association of anatomically modern humans with Acheulean tools, along with Hans Reck's discovery of an anatomically modern skeleton (**OH 1**), erroneously associated with **Pliocene** fauna at **Olduvai Gorge**, formed the basis of Louis Leakey's view that modern humans had a long, separate, lineage in East Africa extending back to **Oldowan** times. Subsequent excavations at Kanjera have shown the hominins to be from much more recent contexts or probably intrusive burials into geologically older strata. Temporal span and how dated? Behrensmeyer et al. (1995) restudied the approximately 37 m of deposit and divided the sequence into three units, the Kanjera Formation (*c.*1.5–0.5 Ma), the **Apoko Formation** (<0.5 Ma), and the Black Cotton Soil (terminal Pleistocene–Holocene). Behrensmeyer et al. concluded that all the hominins except Kanjera 3 derived from the Black Cotton Soil, and that Kanjera 3 was probably an intrusive burial in the Kanjera Formation at KN-2t. Subsequent geological work and paleomagnetic sampling by Plummer et al.

(1999) and Ditchfield et al. (1999) demonstrated that sediments at Kanjera South extend back to 2.2 Ma. The strata exposed in the Kanam and Rawi Gullies have been divided into the Rawi Formation, Abundu Formation, and Kasibos Formation (*c.*3.0–1.0 Ma based on faunal and paleomagnetic correlations). Today, Kanjera is chiefly notable for its faunal sequence and for the archeological evidence that samples activities in a more open environment than at most Oldowan sites. Hominins found at site Five fragmentary hominins, mostly surface finds; Kanjera 1, fragmentary cranium; Kanjera 2, parietal and rib fragments; Kanjera 3, a partially *in situ* cranium and femoral fragments; Kanjera 4, two frontal fragments; Kanjera 5, two fragmentary femora. The cranial fragments are clearly anatomically modern. Archeological evidence found at site None in direct association with the hominins, but Leakey emphasized that the Kanjera Beds contain evolved **Acheulean** bifaces. The site of Kanjera South also preserves strata containing Oldowan artifacts. The importance of Kanjera is that it provides evidence about how hominins contemporary with the Oldowan artifacts procured raw material. Key references: Geology, dating, and paleoenvironment Leakey 1936, Kent 1942, Oakley 1962, Cooke, 1963, Plummer and Potts 1989, Behrensmeyer et al. 1995, Plummer et al. 1999, Ditchfield et al. 1999; Hominins Woodward 1933, Leakey 1935, Tobias 1962; Archeology Leakey 1935, Cooke 1963, Plummer and Potts 1989, Behrensmeyer et al. 1995, Plummer et al. 1999.

Kapcheberek (Location 00°45'N, 35°52'E, Kenya; etym. the local, Tugen, name for the area) History and general description Locality within the **Lukeino Formation** in the eastern foothills of the Tugen Hills, Baringo District, Kenya. It is one of four localities from which remains attributed to *Orrorin tugenensis* have been recovered. Temporal span and how dated? *c.*6–5.7 Ma based on a combination of **argon-argon dating, potassium-argon dating, and magnetostratigraphy**. Hominins found at site The only specimen recovered to date is BAR 349'00, a manual phalanx found in 2000 and assigned to *O. tugenensis*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Deino et al. 2002, Hill et al. 1985, Pickford and Senut 2001, Sawada et al. 2002; Hominins Senut et al. 2001; Archeology N/A.

Kapedo Tuffs (Location 1°04'N, 36°05'E, Kenya; etym. named after the nearby trading village

of Kapedo) History and general description Deposits of volcanic **tuffs** and intercalated fluvial **conglomerates** and **sands** with a maximum thickness of 20 m, discontinuously exposed over an area of approximately 50 km²/19 square miles west of Silali, the largest **Quaternary** volcano in the Kenyan section of the **East African Rift System**. Temporal span and how dated? Electron probe microanalyses of glass from several of the tuff layers suggest the sediments exposed at Kapedo Tuffs are equivalent to the Upper **Pyroclastic** Deposits exposed in the caldera of Silali and the latter have **argon-argon dating** estimates of 132 ± 3 and 135 ± ka. The Arzett Tuffs, with ⁴⁰Ar/³⁹Ar age estimates of 123 ± 3 ka, are also exposed on Silali but they are not represented at Kapedo Tuffs; this suggests the latter site has an age range of *c.*135–123 ka. Hominins found at site None. Archeological evidence found at site The sparse archeological record includes surface and excavated **lithic** assemblages made predominantly of locally available lavas that include rare **Levallois flakes** and **cores** and retouched or deliberately shaped pieces, attributed to the **Middle Stone Age**. No fauna was recovered. Key references: Geology, dating, and paleoenvironment Dunkley et al. 1993, Macdonald et al. 1995, McCall 1999, Smith et al. 1995, Tryon et al. 2008; Archeology Tryon et al. 2008.

Kapsomin (Location 00°45'N, 35°52'E; Kenya; etym. the local, Tugen, name for the area) History and general description Locality within the **Lukeino Formation** in the eastern foothills of the Tugen Hills in the Baringo District. It is one of four localities from which remains attributed to *Orrorin tugenensis* have been recovered. Temporal span and how dated? It and other nearby sites have been bracketed *c.*6–5.7 Ma based on a combination of **argon-argon dating, potassium-argon dating, and magnetostratigraphy** but it is suggested that “the Kapsomin hominid specimens that are the most important” can be bracketed to 5.9–5.8 Ma (Sawada et al. 2002). Hominins found at site All specimens were recovered in 2000 and have been assigned to *O. tugenensis*. **BAR 1000'00**, comprising two mandibular fragments, is the **holotype** of *O. tugenensis*. Other important finds include BAR 1001'00, an upper central incisor, BAR 1002'00, a left femur, BAR 1003'00, a proximal left femur, BAR 1004'00, a right humeral shaft, BAR 1390'00, a P₄, BAR 1425'00, an upper right C, BAR 1426'00, a left M³, and BAR 1900'00, a right M³. Archeological evidence found at site None. Key

references: Geology, dating, and paleoenvironment Deino et al. 2002, Hill et al. 1985, Pickford and Senut 2001, Sawada et al. 2002; Hominins Senut et al. 2001; Archeology N/A.

Kapthurin Formation (Location 00°47'N, 36°5'E, Kenya; etym. named after the Kapthurin River where sediments are best exposed) History and general description An approximately 125 m-thick sequence of **tuffaceous**, predominantly **lacustrine**, and **fluvial** sediments exposed over an area of about 150 km²/58 square miles, west of Lake Baringo, Kenya, the **Middle Pleistocene** portion of the Tugen Hills sequence. The sediments are divided into five geological members numbered K1–K5 from bottom to top. The 1966 discovery of an adult hominin mandible, postcranial remains, and **lithic** artifacts led to additional geological mapping in the area under the aegis of William (Bill) **Bishop** and Basil King of the **East African Geological Research Unit**. The **Baringo Paleontological Research Project** has conducted research in the region since 1980 and in 1982 John Kimengich found another hominin mandible during archeological investigations in the area directed by Francis Van Noten. Since 1990, the area has been studied by Sally McBrearty with notable fossil finds including the first fossil chimpanzee remains and the discovery of blades in sites that are *c.*500 ka. Temporal span and how dated? **Argon-argon dating** of lavas and tephra and tephrostratigraphic correlation by electron probe microanalysis suggest an age bracket of 780 to less than 200 ka, with the lower Kasurein Basalts within K1 dated to 610 ± 40 ka and upper portions of K4 (the Bedded Tuff Member) dated to 235 ± 20 ka. Hominin evidence An adult hominin mandible, KNM-BK 67, was discovered in 1966. Subsequently two manual phalanges, a right metatarsal, and a right ulna (KNM-BK 63–66) were recovered from excavations. A second mandible, **KNM-BK 8518**, from a second individual was found in 1982 by John Kimengich. The individual represented by KNM-BK 63–67 was referred to *Homo cf. erectus* by Leakey et al. (1969), while KNM-BK 8518 was referred to *Homo sp. indet.* (Wood and van Noten 1986). The **panin** remains comprise eight dental specimens (**KNM-TH 45519–45522** and KNM-TH 46437–46440), and all but one undiagnostic root fragment are maxillary. There is no duplication so the eight teeth may sample one individual. Archeological evidence Sediments of the Kapthurin Formation contain numerous archeological sites across the extent of the exposures and

throughout much of its temporal sequence. The richest and best-studied sites occur in members K3 and K4. Interbedded tephra have been dated and correlated, permitting an understanding of temporal and spatial variation among multiple surface-collected and excavated **Acheulean** and **Middle Stone Age** (or MSA) archeological sites. Particularly notable are the presence of large **Levallois flakes** in Acheulean strata at sites LHA and LHS (*c.*250–500 ka) and diverse methods of Levallois flake production at MSA strata at Koimilot (*c.*250 ka). The Kapthurin Formation sequence is unusual in showing complex temporal patterning in Acheulean and MSA artifacts, inconsistent with simple replacement scenarios during the early appearance of MSA lithic technology. The Kapthurin Formation also includes early traces of the use of **ochre** and **blade** production. Key references: Geology, dating, and paleoenvironment Leakey et al. 1969, McCall et al. 1967, Deino and McBrearty 2002; Hominins Leakey et al. 1969, Wood and van Noten 1986, Solan and Day 1992, McBrearty et al. 1996, McBrearty 1999, 2005, Wood 1999, Hill 2002; Archeology McBrearty et al. 1996; McBrearty 1999, Tryon and McBrearty 2002, 2006, Tryon et al. 2005, Tryon 2006, Johnson and McBrearty 2010.

Karari Ridge One of the subregions of the Koobi Fora region. *See* **Koobi Fora**.

Karonga Alternative name used by Richard Hay for a small valley at **Olduvai Gorge** that Louis and Mary Leakey refer to as a **korongo**. *See also* **Olduvai Gorge**.

Karonga Museum *See* **Cultural and Museum Centre, Karonga**.

karst (Ge. *karst*=kras, after the “kras” region in Slovenia not far from Trieste, where this geological feature is common) Limestone deposits that have been affected by water rich in carbonic acid. This mildly acidic ground water produces small (e.g., flutes), medium (e.g., sinkholes), or large-scale (e.g., limestone pavements) surface features, and underground the water action leads to fissures and solution cavities and when breccia and bones fill these solution cavities the process results in cave sites like those in the Blaauwbank valley (e.g., **Sterkfontein, Swartkrans**).

karstic A landscape typically dominated by small, medium, and large-scale karst features on

the surface and by channels and cavities within the rock. *See also karst.*

karyotype (Gk *karyon*=nut, kernel and *typos*=impression, mark, figure, or original form) The complement of **chromosomes** found in an individual or normally found in a taxon. The modern human karyotype has 46 chromosomes including 22 pairs of autosomes and one pair of **sex chromosomes**. The techniques used to investigate karyotypes are called cytogenetic. The most common cytogenetic technique is Giemsa staining (also called G-banding) that reveals specific banding patterns on each chromosome, but other dyes or fluorescently labeled probes can also be used. Karyotypes are used to detect chromosomal abnormalities in fetal cells (amniocentesis) and cancer cells. Karyotypes have also been used to study the evolution of chromosome number and structure. For example, the karyotypes of modern humans and the great apes show that they have 46 and 48 chromosomes, respectively. The banding patterns reveal that sometime during hominin evolution chromosomes 2a and 2b found in the great apes fused to form modern human chromosome 2. Prior to the availability of large amounts of DNA data, differences in chromosomal number and pattern were often used to determine the relatedness between species (e.g., Yunis and Prakash 1982).

Katanda (Location 0°06'N, 29°35'E, Democratic Republic of the Congo; etym. denotes a resting place by a ford in KiNande) History and general description Katanda, which incorporates three sites exposed on the eastern bank of the Semliki River, was first explored by Jean de Heinzelin in the 1950s and was excavated by John Yellen and Alison Brooks from 1986 to 1990. The excavations at Katanda 2 (108 m² excavated, 21 m² of them in the Katanda beds), Katanda 9 (35.2 m²), and Katanda 16 (11 m²) focused on the Katanda Beds, alluvial sediments attributed to lateral fills along an ancient floodplain margin and the valleys of ephemeral tributary streams, 34–41 m above the current Semliki river. The Katanda beds unconformably overlie the ASB paleosol complex and are themselves overlain by the Holocene-aged Katwe Ashes whose base is dated to 6.89±0.75 ka by AMS radiocarbon dating on charcoal. Yellen (1996) argues from spatial patterning in artifacts and fauna that the Katanda 9 excavations reveal a short-term occupation or base camp. The range of radiometric age estimates by multiple methods

allow for a considerably longer period of sediment accumulation and site burial. Original **thermoluminescence** estimates on sands overlying the artifact horizon at Katanda 9 yielded an estimated age of 82.8±8 ka, while a second series of optically stimulated **luminescence dating** determinations on the 20 sand samples suggested an age range of 65–90 ka in all but one of the results. **Electron spin resonance spectroscopy dating** age estimates on fossil *Hippopotamus* teeth from Katanda 9 range from 89±22 ka (early uptake) to 155±38 ka (late uptake) whereas **uranium-series dating** on the teeth was more-or-less consistent with the older determination (140±4 ka, 174±1 ka). None of the dating results suggested an age younger than 50 ka. Because of the broad similarity of recovered bone harpoons at the Katanda sites with younger examples from **Ishango**, and differences in Katanda 9 faunal preservation states, Klein (2008) among others contends that the true age of the sites remains unresolved. However, the Ishango sites are located on a terrace some 24–8 m below the level of the Katanda sites and the bone points there are smaller, manufactured by a different process and used a different shape for both the barbs and the base. Hominins found at site None. Archaeological evidence found at site The Katanda sites contain 12 worked bone tools, including seven barbed points or harpoons, five unbarbed pointed pieces, and one “knife,” plus approximately 16,000 lithic artifacts composed primarily of quartz, quartzite, and chert flaking debris, including discoidal and single and multi-platform cores. Rare rubbing or grinding stones are also present. The approximately 19,000 faunal elements include a diverse mammalian taxa that suggests a riverine setting with a gallery forest fringed by a savanna. Of the minimum number of individuals of identified fish remains, 65% are catfish (*Clarias* sp. and *Synodontis* sp.) whose size and age profiles suggest they were acquired during spawning, which today is limited to the rainy season. The spatial distribution of artifacts and fauna at the Katanda 9 excavation have been argued to reflect an anthropogenic feature or “pavement” similar to nuclear family areas ethnographically documented among the Kalahari San and other groups. KB Prefix used for fossils from two locations, the Kossom Bougoudi “fossiliferous area,” **Chad Basin**, Ethiopia, and Kromdraai B, South Africa.

KBS Acronym for the Kay Behrensmeyer site at **Koobi Fora** and used for the KBS Member in the **Koobi Fora Formation**, **Koobi Fora**, Kenya.

KBS CC Abbreviation of the KBS Channel Complex in the **Koobi Fora Formation**, **Koobi Fora**, Kenya. See also **KBS**.

Kebara (Location 32°34'25"N, 34°58'08"E; etym. Hebrew, פְּעֵרַת בְּכָאֲרָה, *Me'arat Kebara* or Arabic, مغارة الكبارة, *Mugharat al-Kabara* both mean “the great cave”) History and general description Kebara is located on the western escarpment of Mount Carmel in Israel and has undergone several phases of excavations. The first, by Dorothy **Garrod** and Francis Turville-Petre in the early 1930s examined the **Natufian**, **Kebaran**, and **Upper Paleolithic** layers. Stekelis, who was the next to work at the site from 1951 to 1965, focused on the **Upper** and **Middle Paleolithic** layers and it was during his excavations that the fossil neonate (**KMH1**) was found. The latest excavations by Ofer **Bar-Yosef** and colleagues (1982–90) further explored the Middle Paleolithic and recovered more hominin remains (Bar-Yosef et al. 1992). Temporal span and how dated? The Mousterian levels have been dated by **radiocarbon dating**, **electron spin resonance spectroscopy dating**, and **thermoluminescence dating** methods (Bar-Yosef et al. 1996, Schwarcz et al. 1989, Valladas et al. 1987); the Upper Paleolithic levels have been dated by radiocarbon (Bar-Yosef et al. 1996). The Middle Paleolithic levels have been dated at 62–48 ka, the transition between the Upper and Middle Paleolithic has been assigned a date of *c.*45 ka, and the Upper Paleolithic levels have been dated at *c.*36–32 ka. Hominins found at site The excavations of Garrod and Turville-Petre recovered the remains of at least 15 individuals from the Upper Paleolithic layers, but these have not been formally described in detail. The later excavations of Stekelis and Bar-Yosef yielded the remains of approximately 29 individuals, most of which are from the Middle Paleolithic layers; all belong to *Homo neanderthalensis*. The remains are mostly craniodental frag-

ments, but include a nearly complete skeleton of an infant (**KMH1**) as well as the nearly complete torso of an adult (**KMH2**). Archeological evidence found at site The Upper Paleolithic levels include Bronze age, Lower Natufian, **Kebaran**, **Aurignacian**, and **Ahmarian** industries. The Middle Paleolithic levels contain Levantine Mousterian tools. There is fauna from all layers and several studies have suggested that fluctuations in occupation frequency may be related to environmental change as well as to human demographic change (Davis 1977, Speth and Tchernov 2002). Charred macrobotanical remains and **phytoliths** from the Middle Paleolithic levels have been interpreted as evidence of broad-spectrum plant foraging by Neanderthals, as well as for the controlled use of fire (Lev et al. 2005, Albert et al. 2000). Key references: Geology, dating, and paleoenvironment Bar-Yosef et al. 1996, Valladas et al. 1987, Schwarcz et al. 1989; Hominins Smith and Arensburg 1977, Rak and Arensburg 1987, Bar-Yosef and Vandermeersch 1991; Archeology Garrod 1954, Bar-Yosef et al. 1992, Schick and Stekelis 1977.

Kébibat (Location 34°02'N, 6°51'W, Morocco; etym. named after the nearby city) History and general description This site and its hominin cranial specimen were discovered in 1933 by workmen with M. Alenda at Mifsud-Guidice Quarry in the suburb of Rabat. It was subsequently studied by J. Marçais. The first Middle Pleistocene hominin found in North Africa; its fragmentary nature (23 fragments) is due to dynamite blasting and subsequent reburial by quarry workers. Temporal span and how dated? Biostratigraphy and uranium-series dating on overlying shell suggest 200–130 ka; it is assigned to the middle Tensiftian local Maghreb continental stage. Hominins found at site Mandible with left I₁–M₁ and right I₁, P₃₋₄, and M₃; left maxilla with I²–M²; parietals and occipital fragments of an adolescent assigned to what Saban (1977) called “evolved *Homo erectus*.” Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Hublin 2001, Stearns and Thurber 1965; Hominins Hublin 2001; Archeology N/A.

Kedung Brubus (Location 7°30'S, 111°54'E, Indonesia; etym. named after a local village) History and general description An exposed river-bed deposit 35 km/22 miles southeast of **Trinil** where Eugène **Dubois** discovered a fragmentary fossil hominin mandible on November 24, 1890. The fauna from

Kedung Brubus, including the hominin mandible, comes from the sandstones of the Trinil beds of the **Bapang Formation** (formerly called Kabuh). Temporal span and how dated? There has been debate in the literature concerning the relative age of Kedung Brubus. Leinders and colleagues contend that the Trinil mammals are older than those from Kedung Brubus, whereas Hooijer's interpretations of these faunas lead to the opposite conclusion. **Argon-argon dating** of volcanics from breccias and tuffs at and near Kedung Brubus suggest a latest Pliocene/earliest Pleistocene age for these deposits. Hominin found at site Kedung Brubus 1 is a right mandibular fragment containing part of the canine and P₃ roots that most likely represents a juvenile *Homo erectus*. Dubois (1935) described what he rather confusingly referred to as “the sixth (fifth new) femur of *Pithecanthropus erectus*”, and he suggested that there is “some probability that this fossil was found at Kedung Brubus” (*ibid.*, p. 852). However, when Day and Molleson (1973) examined all of the Trinil femora (i.e., Femora I–VI) in detail (using radiography and microscopy) they concluded that “Femur VI is not hominine, hominid or even primate” (*ibid.*, p. 151). Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Hooijer 1983, Hooijer and Kurtén 1984, Leinders et al. 1985, Bandet et al. 1989; Hominins Dubois 1892, 1935, Tobias 1966b, Day and Molleson 1973.

Kedung Brubus 1 Site **Kedung Brubus**. Locality N/A. Surface/in situ Not known. Date of discovery November 24, 1890. Finder Eugène Dubois. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age Latest Pliocene/earliest Pleistocene. Developmental age Probably juvenile. Presumed sex Unknown. Brief anatomical description Small fragment of a right mandibular corpus that extends from the region of the canine posteriorly to include the anterior margin of the mental foramen. It preserves the base of the crown and the root of the right P₃ and the tip of the root of the right canine. Announcement Dubois 1891. Initial description Dubois 1924a. Photographs/line drawings and metrical data Dubois 1924b, Tobias 1966b. Detailed anatomical description Tobias 1966. Initial taxonomic allocation *Homo sp. indet.* Taxonomic revisions *Pithecanthropus erectus* Dubois (1924a, 1924b). Current conventional taxonomic allocation *Homo erectus*. Informal taxonomic category Pre-

modern *Homo*. Significance As poorly preserved as it is, Kedung Brubus 1 was the first early hominin to be recovered from Java. Location of original Geological Research and Development Center, Bandung, Indonesia.

Keilor (Location 37°42'S, 144°51'E, Australia; etym. named after a local town) History and general description An adult probable male cranium and a fragmentary femur were discovered in 1940 during quarrying operations on a river terrace about 16 km/10 miles northwest of Melbourne. The specimen was recovered from a silt deposit, below a minor disconformity. Secondary carbonates adhering to the cranium suggest it was deposited into a paleosol. Temporal span and how dated? Radiocarbon dating of the bone suggest an age of 12 ka while dates from the adhering carbonates cluster around 6.8 ka. Hominin found at site The Keilor cranium is anatomically modern human, but it is unlike its more robust contemporaries from **Kow Swamp** in that it is relatively orthognathic, has moderately sized teeth and a curved frontal region. Archeological evidence found at site Quartzite flakes. Key references: Geology, dating, and paleoenvironment Brown 1987; Hominins Wunderly 1943, Brown 1987; Archeology Simmons and Ossa 1978.

Keith, Arthur (1866–1955) Arthur Keith was born in Old Machar, near Aberdeen in Scotland and entered the University of Aberdeen in 1884 to study medicine. He completed his studies in 1888 and the following year accepted a post as a medical officer for a gold-mining company in Siam (now Thailand). While there Keith dissected monkeys to see if they carried malaria and this led to a lifelong interest in the comparative anatomy of primates. Keith returned to Britain in 1892 where he studied anatomy with George D. Thane at University College London and with Robert W. Reid at the University of Aberdeen and it was there that Keith completed his MD in 1894. His thesis, entitled ‘The myology of the Catarrhini: a study in evolution’ was based on the numerous dissections he had conducted in Siam. Keith became a Fellow of the **Royal College of Surgeons of England** in 1894 and after spending a brief period in 1895 working with the Swiss anatomist and embryologist Wilhelm His in Leipzig, Germany, he returned to Britain to accept an appointment as Senior Anatomy Demonstrator at the London Hospital Medical

College. Keith conducted a study of primate skulls in 1895 and in 1896 he published *An Introduction to the Study of Anthropoid Apes*. Keith's professional success led to his appointment as Head of the Anatomy Department at the London Hospital Medical College in 1899 where he combined his primate research with a detailed study of the conducting tissue of the heart. The latter resulted in the recognition of one of the two foci of electrical activity in the heart and his contribution is recognized in the eponymous name for the atrio-ventricular node, which is called the node of Keith and Flack. In 1908 Keith resigned from the London Hospital Medical College to become conservator of the Hunterian Museum of the Royal College of Surgeons of England, and thereafter his research focused on physical anthropology. Keith published a paper on the evolution of the orthograde posture in 1903 and in *Ancient Types of Men* (1911) Keith first expressed his opinion that the modern human type was at least as old as extinct hominins such as *Homo neanderthalensis*. This view, later referred to as the **pre-sapiens hypothesis**, had an important influence on theories of human evolution and on the interpretation of hominin fossils during the early 20thC. Keith was influenced by discoveries such as the **Galley Hill** skeleton, an anatomically modern human discovered in 1888 in geological deposits in southern England that appeared to be very old (the skeleton was later shown to be a more recent intrusive burial). It was perhaps Keith's view that the modern human type evolved very early that led him to be an ardent supporter of Piltdown Man (*Eoanthropus dawsoni*). The controversy surrounding the competing interpretations of Piltdown Man and Keith's own investigations of the fossils prompted him to publish *The Antiquity of Man* in 1915 in which he examined the existing fossil evidence for human evolution and discussed the pre-sapiens hypothesis. Over the following decades Keith gradually modified his views, and this is reflected in the views expressed in *New Discoveries Relating to the Antiquity of Man* (1931). Keith collaborated with American anthropologist Theodore McCown between 1933 and 1937 on studies of the archeological and hominin skeletal material excavated at the **Mount Carmel** sites in Palestine by the American School of Prehistoric Research and the British School of Archaeology in Jerusalem. This resulted in the publication in 1939 of the second of the two volumes entitled *The Stone Age*

of Mount Carmel. Keith retired as Conservator at the Royal College of Surgeons of England in 1933, but in the same year he was appointed the first Master of the Royal College of Surgeons of England's Buckston Brown Research Farm located at Downe, in Kent, and he lived in Charles Darwin's old home, Down House. Keith had been instrumental in the establishment of the Buckston Brown Research Farm and he lived there until his death in 1955. Keith was elected a Fellow of the Royal Society in 1913 and he served as President of the Royal Anthropological Institute from 1914 to 1917. Keith was also the editor of the *Journal of Anatomy* from 1916 to 1936 and in recognition of his accomplishments he was knighted in 1921. During the last decades of his life Keith continued to write, focusing on the issue of race and the mechanisms of evolution. He published *A New Theory of Human Evolution* (1948), *An Autobiography* (1950), and *Darwin Revalued* (1955).

Kelsterbach (Location 50°03'N, 8°31'E, Germany; etym. named after the nearby town) History and general description A hominin calvaria found in Kelsterbach, near Frankfurt, was dated by Reiner Protsch to *c.*32 ka. The specimen is currently missing so redating is impossible, but many other fossils dated by Protsch's lab (e.g., **Paderborn**, Hanöfersand) have been recently redated to much more recent times, making this Upper Paleolithic date highly questionable. Temporal span and how dated? Probably Holocene. Hominins found at site A calvaria attributed to *Homo sapiens*. Archeological evidence found at site None. Key references: Geology, dating, and paleoenvironment Street et al. 2006; Archeology N/A; Hominins Protsch and Semmel 1978.

Kendeng Hills A range of hills on the south side of the Solo River in the northern part of central Java. The Kendeng Hills were explored by Eugène Dubois and fossil sites in that region include **Kedung Brubus**, Pati Ajam, Teguan, and **Trinil**.

Kenya National Museum See National Museums of Kenya.

***Kenyanthropus platyops* Leakey et al. 2001** (Gk *anthropos*=human being, *platus*=flat, and *opsis*=face; etym. *Kenya*=Kenyan) A hominin genus and species established in 2001 by Meave

Leakey and colleagues to accommodate cranial remains recovered from the *c.*3.5 Ma Kataboi Member at Lomekwi, West Turkana. The initial report lists the holotype cranium and the paratype maxilla plus 34 specimens that include three mandible fragments, a maxilla fragment, and isolated teeth some of which may also belong to the hypodigm, but the researchers reserved their judgment about the taxonomy of most of these remains (Leakey et al. 2001), some of which had only recently been referred to *Australopithecus afarensis* (Brown et al. 2001). The main reasons Leakey et al. (2001) did not assign the Lomekwi material to *Au. afarensis* are its reduced subnasal prognathism, anteriorly situated zygomatic root, flat and vertically orientated malar region, relatively small but thick-enameled molars, and the unusually small M¹ compared to the size of the P⁴ and M³. Some of the morphology of the new genus, including the shape of the face, is *Paranthropus*-like yet it lacks the postcanine megadontia that characterizes *Paranthropus*. The authors note the face of the new material resembles that of *Homo rudolfensis* (see below), but they point out that the postcanine teeth of the latter are substantially larger than those of KNM-WT 40000. *K. platyops* apparently displays a hitherto unique combination of facial and dental morphology. White (2003) has taken the view that the new taxon is not justified because the cranium could be a distorted *Au. afarensis* cranium, but even if this explanation is correct (see Spoor et al. 2010 for a response) it would not explain the small size of the postcanine teeth. First discovery KNM-WT 8556 (1982). Holotype KNM-WT 40000 (1999). Main site West Turkana.

Kesem-Kebena (9°13'N and 39°58'E, Ethiopia; etym. from the names of two nearby rivers) History and general description Area located on the Awash River upstream from the Middle Awash study area in the northern sector of the Ethiopian section of the East African Rift Valley. It was explored between 1988 and 1989 by the Paleanthropological Inventory of Ethiopia. Eleven localities were identified, two of which have yielded lithic assemblages. Temporal span and how dated? Potassium-argon dating of Tuff K-K2E overlying the deposits at locality K-K2 provided a date of 3.76 ± 0.6 Ma. Tuff K-K6G is just above the deposits at locality K-K6 and argon-argon dating provided an age

of 1.002 ± 0.041 Ma. Thus, the age of these Plio-Pleistocene sediments date is $>3.75\text{--}1.0$ Ma. Hominins found at site None. Archeological evidence found at site Localities K-K6 and K-K7 have yielded Acheulean assemblages and K-K5 Later Stone Age assemblages, but the artifacts at locality K-K3 were in a secondary context. Key references: Geology, dating, and paleoenvironment WoldeGabriel et al. 1992; Hominins N/A; Archeology WoldeGabriel et al. 1992.

key innovations Evolutionary innovations that allowed a lineage to exploit a new adaptive zone. Taxa that share these innovations are normally recognized as occupying the same grade (Miller 1949, Jensen 1990, Hunter 1998).

Keyser, André W. (1938–2010) *See* Drimolen.

keystone resource (ME *key(e)*=central and *stan*=stone; it refers to the central wedge-shaped stone in an arch that locks the other stones in place) A taxon that has a major impact on community structure through its consumption by other organisms, even though a keystone resource might not itself be a consumer. The effect of a keystone resource is measured by quantifying the taxon's community importance (or CI) (Power et al. 1996). Robert Paine introduced the term keystone species in 1969 to refer to species that have a disproportionate effect on their environment and on local biodiversity. Paine focused on the impact two species of starfish, *Pisaster ochraceus* of California and *Acanthaster planci* of the Great Barrier Reef, have on their local intertidal zones. Closer to paleoanthropology Terborgh (1986) applied the term to the figs produced by trees in the genus *Ficus*. During periods of low fruit availability, primates, marsupials, birds, and many other frugivorous animals rely on figs for a significant portion of their energy. Keystone resources have been documented and studied in all of the world's major ecosystems (Power et al. 1996).

KGA Abbreviation of Konso-Gardula, the original name for the site now known as Konso, Ethiopia. Thus it is the prefix used for fossils from Konso. *See* Konso.

KGA 10-1 Site Konso. Locality KGA 10. Surface/in situ Surface, then excavation from a

lag deposit. Date of discovery 1991. Finder Gen Suwa. Unit N/A. Horizon N/A. Bed/member Kayle Member. Formation Konso Formation. Group N/A. Nearest overlying dated horizon By stratigraphic correlation, the Karat Tuff (or KRT) is the closest overlying dated tuff at 1.41 ± 0.02 Ma. Immediately above KRT lies the Bright White Tuff, also dated to 1.40 ± 0.02 Ma. The latter corresponds to the Chari Tuff at **Koobi Fora** in its major and minor element compositions of glass shards. Nearest underlying dated horizon Leahyte Tuff inferred to be $c.1.42$ Ma based on 1.47 ± 0.07 Ma age on plagioclase and stratigraphically underlying Trail Bottom Tuff dated to 1.43 ± 0.02 . Geological age Lower Pleistocene. Developmental age Adult. Presumed sex Male, based on large size. Brief anatomical description The left side of the mandibular corpus including P_4 - M_3 and the left ramus and condyle. Announcement Asfaw et al. 1992. Initial description Asfaw et al. 1992. Photographs/line drawings and metrical data Asfaw et al. 1992, Suwa et al. 2007. Detailed anatomical description Suwa et al. 2007. Initial taxonomic allocation *Homo erectus*. Taxonomic revisions N/A. Current conventional taxonomic allocation *Homo erectus* or *Homo ergaster*. Informal taxonomic category Pre-modern *Homo*. Significance The molar crown morphology of KGA 10-1 resembles that of **KNM-ER 992**. The tooth crowns have inter-proximal grooves that resemble those made by modern humans who habitually use tooth-picks or sinews and the KGA 10-1 mandible is associated with **Acheulean** artifacts. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

KGA 10-525 Site Konso. Locality KGA 10. Surface/in situ Surface. Date of discovery 1993. Finder A. Amzaye. Unit N/A. Horizon N/A. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon Karat Tuff, $c.1.41$ Ma. Nearest underlying dated horizon Trail Bottom Tuff, $c.1.43$ Ma. Geological age $c.1.4$ Ma. Developmental age Mature adult. Presumed sex Male. Brief anatomical description A skull comprising a well-preserved **calotte** lacking the frontal and the anterior part of the cranial base and much of the lower face along with the lateral parts of both sides of the upper face. The remarkably complete mandible preserves the worn crowns of all tooth types other than the incisors. Announcement Suwa et al. 1997. Initial description Suwa et al. 1997. Photographs/

line drawings and metrical data Suwa et al. 1997. Detailed anatomical description N/A. Initial taxonomic allocation *Paranthropus boisei*. Taxonomic revisions N/A. Current conventional taxonomic allocation *P. boisei*. Informal taxonomic category Megadont archaic hominin. Significance The well-preserved first skull of *P. boisei* and although its describers claimed that KGA 10-525 shows “striking deviations...from the known Olduvai/Turkana *A. boisei* condition” (Suwa et al. 1997, p. 492), other researchers have concluded that most of the morphology of KGA 10-525 can be accommodated within the morphological range of the pre-Konso hypodigm of *P. boisei*. Location of original National Museum of Ethiopia, Addis Ababa, Ethiopia.

KHS (Location $5^{\circ}24.152'N$, $35^{\circ}55.812'E$, Ethiopia; etym. acronym for “Kamoya’s Hominid Site”) History and general description The site was discovered by Kamoya Kimeu in 1967 during the surveys carried out by Richard Leakey’s Kenyan component of the **International Omo Research Expedition** to the **Lower Omo Basin**. The site is located on a hill overlooking an erosional gully leading to the Omo River. Geological work by Karl Butzer and colleagues placed the site in Member I of the **Kibish Formation**. The site provided the earliest date for anatomically modern human based on two infinite (>39.9 ka) radiocarbon dates and a uranium-thorium (or $^{240}\text{Th}/^{234}\text{U}$) date of $c.130$ ka on Nile oysters from unit f above the hominin. Skepticism among anthropologists over these dates led to renewed work led by John Fleagle and Frank Brown in the Kibish Formation in 1999, 2001, 2002, and 2003. The new excavations relocated KHS, clarified the site’s stratigraphic position, and determined **Omo I** to be even older than previously claimed; thus if the age of Omo I is correct it is currently the earliest evidence of anatomically modern humans within *Homo sapiens*. Temporal span and how dated? **Argon-argon dating** suggests an age of 195 ± 5 ka on an underlying tuff combined with correlation with Mediterranean **sapropels**. Hominins found at site Omo I, a fragmentary skull and skeleton. Archeological evidence found at site A small sample of **Middle Stone Age** stone artifacts made of fine-grained silicate rocks including **chert**, **jasper**, and **chalcedony** as well as some made of **ryolite** or **basalt**. Of the artifacts, un-retouched **flakes** predominate but 24 small **cores**, 20 retouched

pieces, and two **hammerstones** were recovered. Scattered faunal remains were also recovered, including a complete bird. Key references: Geology, dating, and paleoenvironment Butzer 1969, Butzer et al. 1969, Butzer and Thurber 1969, McDougall et al. 2005, 2008, Brown and Fuller 2008, Feibel 2008; Hominins Day 1969a, Stringer 1974, Day and Stringer 1982, 1991, Kennedy 1984b, Day et al. 1991, Pearson et al. 2008a, Voisin 2008; Archeology Leakey 1969, Shea 2008, Assefa et al. 2008, Louchart 2008.

Kibish *See* Omo-Kibish.

Kibish Formation A formation in the Lower Omo Basin, Ethiopia, that takes its name from a local village. Its main outcrops occur along the Omo river, where it skirts the west side of the Nkalabong mountains about 100 km/60 miles north of the northern end of the present Lake Turkana. It overlies, but is not continuous with, the sediments belonging to the **Omo Group**. In the north, near the village of Kibish, it overlies the **Nkalabong Formation** and **Mursi Formation** but further south it overlies the **Usno Formation** and **Shungura Formation**. Karl Butzer divided the Kibish Formation into four Members (Mb. I–IV). Three absolute dates are available for the Kibish Formation. Single crystal **argon-argon dating** provide ages for Mb. I and Mb. III tuff feldspars of 196 ± 2 and 104 ± 1 ka respectively and **radio-carbon dating** on molluscs from Member IV gives ages in the range of *c.*3250 to *c.*9500 years ago. The three hominin individuals, **Omo I**, an associated skeleton including a fragmentary skull of a young adult, **Omo II**, an adult calvaria, and **Omo III**, fragments of an adult cranial vault, are judged to have come from Mb. I and their ages have been estimated at *c.*195 ka (McDougall et al. 2005).

Kiik-Koba (Location $45^{\circ}03'N$, $34^{\circ}18'W$, Ukraine; etym. Turkik phrase for mountain goat cave) History and general description This **Middle Paleolithic** cave site in the Crimea was excavated by Gleb Bonch-Osmolovskii in 1924–6, who found the skeletons of an adult and child buried close to each other. Temporal span and how dated? The site has never been absolutely dated; but the presence of cold-phase fauna and technostratigraphy has suggested an age around the end of **Oxygen Isotope Stage (OIS) 5** or the beginning of OIS 4 for the layer containing

the hominins. Hominins found at site Kiik-Koba 1 is the remains of an adult, probably a male. Its grave was disturbed in antiquity, removing all but a few teeth, portions of both hands, the right lower leg, and both feet. Kiik-Koba 2 is the remains of a very young child, less than a year old. Most of the postcrania are preserved. Both individuals are assigned to *Homo neanderthalensis*. Archeological evidence found at site Three Middle Paleolithic layers were recovered, and the site is the type site for the Kiik-Koba **Mousterian**. Key references: Geology, dating, and paleoenvironment Bonch-Osmolovskii 1940; Hominins Trinkaus 2008b, Trinkaus et al. 2008; Archeology Bonch-Osmolovskii 1940.

Kilaytoli Tuff A 3.57 ± 0.014 Ma (Deino et al. 2010) vitric tuff found in several collection areas in the **Woranso-Mille study area**. Its geochemistry matches that of the **Lokochot Tuff** known from the **Koobi Fora Formation**.

Kilombe (Location: $0^{\circ}6'S$, $35^{\circ}53'E$, Kenya; etym. the site is about 4 km/2.4 miles southeast of a mountain of the same name) History and general description Kilombe is an **Acheulean** site complex which lies on the western flank of the Rift Valley in Central Kenya. The site was discovered by W.B. Jones in 1972 and its geological context was first described by William (Bill) **Bishop** (1978). Fossiliferous brown clays (with a sparse fauna including *Elephas recki*, hippopotami, suids, and a range of bovids) formed on top of trachyphonolite lava that is approximately contemporary with the *c.*1.8 Ma trachyte lavas of the Kilombe volcano (Jones and Lippard 1979). The main archeological horizon at Kilombe accumulated on a clay surface during a pause in deposition in what was probably a broad drainage way or lakeside environment. Temporal span and how dated? Reversed paleomagnetization in layers immediately overlying the main artifact horizon indicates a probable age of more than 0.8 Ma. The sequence resumes with deposition of weathered tuffs and airfall tuffs through a depth of about 15 m and it is capped by an ashflow tuff or agglomerate several meters thick. Finds of occasional bifaces have been made up to the base of this tuff which probably derives from Menengai (*c.*0.35 Ma). Hominins found at site None. Archeological evidence found at site The extensive exposures of its main biface horizon at Kilombe can be traced horizontally for more than 200 m.

It provides exceptional opportunities for comparisons of contemporaneous local occurrences at points more than 100 m apart on the same horizon. Its geological context is very unusual for East Africa in that the artifacts are on a clay surface rather than in a sandy channel. Small flakes found with the bifaces indicate some local resharpening and are evidence that the material was not redeposited. Some biface cores have been found, but most of the most of the biface blanks were probably made at nearby lava exposures and imported. Several **obsidian** bifaces indicate transport over long distances. The bifaces are most similar to those from **Kariandusi**, **Ologesailie**, and **Olduvai Gorge Bed IV**. **Cleavers** occur across the surface but not in high frequencies. Details of the Kilombe bifaces differ from area to area within the relatively small site. For example, their relative thickness varies markedly (the mean thickness/breadth ratio ranging from 0.30 to 0.56) whereas the breadth/length ratio is a closely controlled **allometric** relationship. The former observation calls into doubt the notion that the thickness/breadth ratio of bifaces has any chronological significance. Cluster analyses indicate that biface morphology is correlated with location within the site and in some areas of the site **Developed Oldowan**-like small bifaces are found alongside large classic Acheulean specimens. The size (approximately 60–250 mm in length) and weight (about 50–2000 g) range of the latter is striking and suggests that no single function is likely to account for the large biface accumulations of the East African Acheulean. As at Ologesailie, some artifact occurrences at Kilombe do not include bifaces. Key references: Geology, dating, and paleoenvironment Dagley et al. 1978, Jones and Leat 1985; Hominins N/A; Archeology Gowlett 1988, 2005, 2006, Crompton and Gowlett 1993, Lycett and Gowlett 2008.

Kimeu, Kamoya (1940–) A renowned fossil hunter and field director of numerous expeditions, Kamoya Kimeu (universally referred to as “Kamoya”) began his career working for Louis and Mary Leakey at **Olduvai Gorge** in 1960. Trained in excavation by Mary Leakey, he quickly learned to recognize hominin fossils and in 1964 made his first major discovery with the **Peninj 1** mandible. Working with the Kenyan contingent of the **International Omo Research Expedition** in 1967 he discovered the **Omo I** cranium at **Omo-Kibish**. Kamoya was a member of Richard

Leakey’s first expedition to **Koobi Fora** (then East Rudolf) in 1968, and continued working there over four decades, making numerous important hominin finds. Over the years Kamoya was regularly dispatched with a small field crew to investigate potential new localities, and in the process he became familiar with sites all over Kenya. He worked extensively in Miocene localities of western Kenya as well as in the Turkana Basin. During early exploration of **West Turkana** he discovered the first fragments of the Nariokotome Boy (**KNM-WT 15000**), and directed the subsequent 5 years of excavations at that site. During the expeditions to **Kanapoi** and Allia Bay he was responsible for the discovery of important specimens attributed to *Australopithecus anamensis* including the tibia **KNM-KP 29285**. In 1985 Kamoya was awarded the LaGorce Medal of the National Geographic Society by President Ronald Reagan in a ceremony at the US White House, in recognition of his contributions to the understanding of human evolution.

kind (OE *gēcȳnd*=race or offspring) A group made up of individuals that share one, or more, traits. Kind is also used in connection with the philosophical distinction between “degree” and “kind,” as in the following quote from Charles Darwin’s *The Descent of Man*: “the difference in mind between man and the higher animals, great as it is, is one of degree and not kind.”

kinematics (Gk *kinesis*=movement and *kinein*=to move) A branch of **biomechanics** that describes the motion of objects (kinematics sounds like, but should not to be confused with, **kinetics**, which describes the effects of forces on objects, particularly the effects of forces on the motion of objects). Kinematics includes information on the position, the **velocity** (speed) and accelerations (rate of change of velocity) of an animal or of an anatomical element (e.g., the hand) or of an object. Kinematic data are collected using **motion analysis** equipment, accelerometers, or other movement-measuring devices and these data are often collected in concert with data on kinetics. For example, building on Jenkins’ (1972) landmark observations about how **chimpanzee** bipedalism involves movements that differ from those of modern humans, D’Août et al. (2002) measured the kinematics of the trunk and hind limb of nine **bonobos** during **knuckle-walking** and bipedal walking. They showed that, unlike modern humans, when bonobos walk bipedally they use flexed hips and

knees throughout the **stance phase** and the knee joint rarely passes behind the hip joint. This **bent-hip bent-knee walking** gait prevents bonobos and chimpanzees from enjoying the energetic efficiency that characterizes the **gait** of modern humans (Sockol et al. 2007). It is probable that these efficiency gains were critical for the origin and/or later evolution of **obligate bipedalism** in later hominins.

kinetics (Gk *kinesis*=movement) A branch of **biomechanics** describing the effects of forces on objects, particularly the effects of forces on the motion of objects. Kinetic data are collected with **force plates**, **pressure pads**, or with other force-measuring devices, and such data are often collected in concert with data on **kinematics**. For example, Kimura (1985) used a force plate to measure the vertical force (i.e., **ground reaction force**) generated by the foot of **chimpanzees** during bipedal walking. In contrast with the double-peaked force pattern of **modern human** walking they found that in chimpanzees the vertical force remains at or slightly above body weight throughout the **stance phase**. This indicates that chimpanzees do not enjoy the energy-saving benefits of the oscillation between potential and kinetic energy that characterizes the **inverted-pendulum** type of bipedal walking in modern humans.

K-K Acronym for **Kesem-Kebana** (*which see*).

KL Abbreviation of Kollé and the prefix for fossils from the Kollé “fossiliferous area,” Chad Basin, Ethiopia. *See* **Kollé**.

Klasies River (Location 34°06'S, 24°24'E, Eastern Cape Province, South Africa; etym. named after the outlet of Klasies River approximately 500 m to the east) History and general description The Klasies River Main Site on the Tsitsikamma coast of South Africa between Klasies River and Druipkelder Point comprises several caves and shelters (Caves 1 and 2, Shelters 1a, 1b, and 1c). They were initially excavated by John Wymer and Ronald Singer in 1967–8 and they were subsequently intensively investigated from 1984 onwards by Hilary Deacon. The excavations revealed a long **Middle Stone Age** (or MSA) sequence capped by a dense **Later Stone Age** shell **midden** and underlain by a culturally sterile storm beach formed during a period of high

sea level. Singer and Wymer (1982) divided the 30 m-deep sequence into 38 layers of which 13–38 contain evidence of the MSA. Singer and Wymer grouped these layers into cultural phases designated, from oldest to youngest, as MSA I, MSA II, Howieson's Poort, MSA III, and MSA IV. Deacon revised the stratigraphy, dividing the cultural deposits into members named, from lowest to highest, Light-Brown Sands (LBS), Sands-Ash-Shell (SAS), Rockfall (RF), and Upper Member; a disconformity and occupation hiatus separates the LBS from the SAS member. Temporal span and how dated? The storm beach at the base of the section likely formed in **Oxygen Isotope Stage 5e** (i.e., c.125–115 ka) or a previous interval of high sea level. The MSA faunal remains have absorbed a substantial amount of uranium, producing disparate age estimates for the linear and early-uptake dating models. Linear uptake age estimates from **electron spin resonance spectroscopy dating** suggest ages of around 93.5 ± 10.4 or 88.3 ± 7.8 ka for the base of the SAS member, which agree with **amino acid racemization** dating estimates and **uranium-series dating** estimates for the end of **speleothem** growth beneath the SAS. ESR dates indicate ages of 60–80 ka for overlying samples in the SAS and 40–60 ka for the Howieson's Poort-bearing strata (Grün et al. 1990). Jacobs et al. (2008) reported optically stimulated **luminescence dating** ages for the pre-Howieson's Poort of 72.1 ± 3.4 and 71.6 ± 2.9 ka, for the Howieson's Poort-bearing strata between 63.4 ± 2.6 and 65.5 ± 2.3 ka and an age for the post-Howieson's Poort MSA levels of 57.9 ± 2.3 ka. Hominins found at site There are hominins from the MSA levels but none from the Howieson's Poort strata. The vast majority of the specimens derive from the SAS Member (MSA II) with a few found in the LBS member and two in the post-Howieson's Poort MSA levels (MSA III). The MSA hominin collection comprises 10 isolated teeth, five partial mandibles, a frontal, a zygomatic, a left temporal bone, 13 vault fragments, two fragmentary maxillae, a proximal left radius, a fragmentary right ulna, a fragmentary atlas, a lumbar vertebra, a small fragment of an innominate, a left metatarsal I, a large left metatarsal II, and a right metatarsal V. The hominins are remarkable for several reasons. They exhibit a striking variability in overall size, suggesting either that a higher level of **sexual dimorphism** existed than is seen in

recent modern humans or that the collection samples more than one morphologically distinctive population. Many support the claim that these fossils represent the earliest anatomically modern humans from southern Africa, but the degree to which the specimens are “anatomically modern” has been the subject of vigorous debate. Many of the hominin specimens show evidence consistent with having been defleshed and burned. Archeological evidence found at site Singer and Wymer (1982) organized the Klasies River strata into (from oldest to youngest) MSA I, MSA II, Howieson’s Poort, MSA III, and MSA IV. The Howieson’s Poort differs dramatically in frequencies and types of artifacts and in the greater proportion of exotic raw materials (e.g., **silcrete**) used. Shellfish as well as mammal and tortoise bone occur throughout the sequence. The MSA I occupies the LBS and the bottom of the SAS Member, the MSA II occurs in the rest of the SAS and RF member, and the Howieson’s Poort and MSA III–IV the Upper Member. Most of the MSA hominins from the site derive from the SAS member, but a few come from the LBS as well as the Upper Member deposits above the Howieson’s Poort. Stone raw materials are predominantly locally available **quartzites**, with a shift to finer-grained rocks such as **hornfels** and **chalcedony** in the Howieson’s Poort levels. Hearths, shell middens, and a highly fragmented fossil fauna with abundant cut and percussion marks attest to the use of the site as living area. Among the fauna are a number of burned and cutmarked hominin elements associated with other food remains from levels dating to *c.* 100–110 ka, suggesting cannibalism. Analysis of the faunal remains from the MSA of Klasies and other sites in southern Africa have fueled lively debates over the hunting abilities of MSA versus LSA people, as well as the relative roles played by taphonomy and population density in shaping the faunal record. Klasies River Mouth *See* Klasies River.

Kleine Feldhofer Grotte (Ge. *kleine*=small, *Feldhofer*=the name of a nearby farm, and *grotte*=cave) (Location 51°14’36”N, 6°57’4”E, Germany; etym. named after a local farm) History and general description Limestone cave now destroyed by mining. The original hominin associated skeleton (**Neanderthal 1**; an adult **calotte** plus 15 post-cranial bones) was part of a collection of fossils discovered by miners in 1856. The hominins in the collection were identified by a local school teacher, C. Fuhlrott, who brought it to the attention of H. Schaaffhausen and the two of them collaborated to report the find to the local natural history society; the Neanderthal 1 associated skeleton was made the holotype of *Homo neanderthalensis* **King, 1864**. No faunal or archeological evidence from the Kleine Feldhofer Grotte was reported and there seemed to be no prospect that such evidence, and thus information about the context and dating, could ever be obtained. However, as a result of careful archival research, Ralf Schmitz and Jürgen Thissen (Schmitz et al. 2002) were able to identify what remained of the sediments from the Kleine Feldhofer Grotte at the base of the south wall of the Neander valley. Excavations of these sediments in 1997 resulted in the recovery of fauna, artifacts, and fragments of hominin bone and the researchers reported that “a small piece of human bone (NN 13) was found to fit exactly onto the lateral side of the left lateral **femoral condyle** of Neanderthal 1” (*ibid*, p. 13342). In 2000 more fauna, more archeological evidence, and hominin skeletal fragments were recovered and “two cranial fragments...were found to fit onto the original Neanderthal 1 calotte” (*ibid*, p. 13343). The balance of the remains recovered by Schmitz and his colleagues has been attributed to two additional individuals (Neanderthal 2 and 3). Researchers have recovered short fragments of mitochondrial DNA from the humerus of the Neanderthal 1 type specimen (Krings et al. 1997, 1999) from what might be

the right tibial shaft of the same specimen (NN 4), and from the shaft of a right humerus (NN 1) of a second individual (Schmitz et al. 2002). Temporal span and how dated? Direct radiocarbon dating based on Neanderthal 1 and 2 suggest an age of *c.*40 ka. Hominins found at site Neanderthal 1 (1865/1997/2000), Neanderthal 2 (2000), and Neanderthal 3 (2000). Archeological evidence found at site Micoquian artifacts typical of late Middle Paleolithic as well as Upper Paleolithic artifacts from the Gravettian. Key references: Geology, dating, and paleoenvironment Schmitz et al. 2002; Hominins Fuhlrott and Schaaffhausen 1857, Schaaffhausen 1888, Krings et al. 1997, 1999, Schmitz et al. 2002; Archeology Schmitz and Thissen 2000a, 2000b. Location of the hominin fossils found at site Rheinisches Landesmuseum, Bonn, Germany.

KMH Acronym for Kebara Mousterian hominids and the prefix used by Baruch Arensburg for hominin fossils from Kebara associated with the Mousterian occupation levels in order that they are distinguished from the hominin fossils excavated in the 1930s from the Natufian levels.

KMH1 Site Kebara. Locality Middle Paleolithic layer VII. Surface/in situ *In situ*. Date of discovery 1965. Finders Hebrew University of Jerusalem team led by Moshe Stekelis. Unit N/A. Horizon Mousterian. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age The Mousterian levels at Kebara have been dated by thermoluminescence dating to 61–59 ka (Valladas et al. 1987) and by electron spin resonance spectroscopy dating to 64–60 ka (Schwarcz et al. 1989). Developmental age Infant *c.*7–9 months. Presumed sex Unknown. Brief anatomical description Fragments of the skull and postcranial skeleton and a complete set of deciduous teeth. Announcement Schick and Stekelis 1977. Initial description Smith and Arensburg 1977. Photographs/line drawings and metrical data Smith and Arensburg 1977. Detailed anatomical description Smith and Arensburg 1977. Initial taxonomic allocation *Homo neanderthalensis*. Taxonomic revisions None. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Signifi-

cance This is one of the more complete *H. neanderthalensis* juvenile fossils. Location of original Department of Anatomy and Anthropology, Tel Aviv University, Israel.

KMH2 Site Kebara. Locality N/A. Surface/in situ *In situ*. Date of discovery 1983. Finders The excavation team led by Ofer Bar-Yosef, Baruch Arensburg, and Bernard Vandermeersch. Unit N/A. Horizon Mousterian. Bed/member N/A. Formation N/A. Group N/A. Nearest overlying dated horizon N/A. Nearest underlying dated horizon N/A. Geological age The Mousterian levels at Kebara have been dated by thermoluminescence dating to 61–59 ka (Valladas et al. 1987) and by electron spin resonance spectroscopy dating to 64–60 ka (Schwarcz et al. 1989). Developmental age Adult. Presumed sex Male. Brief anatomical description Mandible but no cranium and the postcranial skeleton is missing most of left leg and all of the right leg. Announcement Arensburg et al. 1985. Initial description Arensburg et al. 1985. Photographs/line drawings and metrical data Bar-Yosef and Vandermeersch 1991, Bar-Yosef et al. 1986, 1992. Detailed anatomical description Bar-Yosef and Vandermeersch 1991. Initial taxonomic allocation The affinities of this individual with the Tabun, Amud, and Shanidar remains were noted early, aligning this fossil with other near-eastern *Homo neanderthalensis* rather than with the more modern human-looking hominins from Skhul and Qafzeh. Taxonomic revisions N/A. Current conventional taxonomic allocation *H. neanderthalensis*. Informal taxonomic category Pre-modern *Homo*. Significance This skeleton preserved a nearly complete Neanderthal pelvis, which helped end a debate about whether Neanderthals had different obstetric constraints than do modern humans (Rak and Arensburg 1987, Rak 1990). It also preserved the first Neanderthal hyoid, which was interpreted by the excavators to indicate that Neanderthals were potentially capable of speech (Arensburg et al. 1988, 1989, 1990, Tillier et al. 1991), although others have disagreed (Lieberman 1993). The preservation of the mandible, hyoid, and cervical vertebrae but the lack of a cranium led Bar-Yosef and colleagues (1992) to suggest that the skull was intentionally removed sometime after the ligaments that attached it to the spine had decomposed. Location of original Department of Anatomy and Anthropology, Tel Aviv University, Israel.

knapping (ME *knappen*=apparently it refers to the sound made when flakes are struck from a core) The act of intentionally fracturing stone by percussion for the production of **flakes**.

KNM Acronym for Kenya National Museum (now the **National Museums of Kenya**) and the prefix for fossils collected from sites in Kenya that are catalogued and stored in the National Museums of Kenya. The subsequent initials identify the site of origin of the fossil (e.g., **KNM-WT 15000** is an associated skeleton from West Turkana and **KNM-ER 1470** is a cranium from **Koobi Fora**, the site previously known as **East Rudolf**). The number that follows is the field number of the fossil that also functions as the museum accession number. *See also* **National Museums of Kenya**.

KNM-BC Prefix for fossils accessioned at the Kenya National Museum (now the **National Museums of Kenya**) that derive from sites in the Baringo region, Kenya, that are in the Chemeron Formation (e.g., **KNM-BC 1**). *See also* **Chemeron Formation**; **National Museums of Kenya**.
